Conventional external beam radiation therapy is the most commonly used treatment modality for patients. Various schedules have been applied with comparable results. Protocols consist of 5 to 10 applications of 3 to 4 Gy (total dose 30 Gy). Others have provided higher daily doses (5 Gy) during a 3-day induction phase followed by daily fractions of 3 Gy over 5 days for consolidation.¹⁹ In the palliative situation, single fractions of 8 Gy may be preferable. Long-course radiotherapy is associated with better local control and similar functional outcome and should be used in patients with a relatively favorable anticipated survival.^{35,36} Response to treatment depends on tumor histology. As one would anticipate, patients with relative radiosensitive tumors (breast cancer, lymphoma) have a higher chance of regaining or preserving motor function than patients with less radiosensitive tumors (non-small-cell lung cancer, melanoma, renal cell carcinoma).¹⁹ Dose escalation does not appear to improve outcome.³⁷ Recently, there has been an increase in the use of stereotactic radiosurgical techniques for spine metastases. A distinct advantage over conventional radiotherapy is the ability to deliver a higher radiation dose without exceeding the tolerance of the spinal cord. Various techniques and dosing schedules are available: linear-accelerator-based stereotactic radiosurgery (SRS), proton beam radiosurgery, or image-guided radiosurgery. SRS is typically administered as an 8 to 24 Gy single fraction. Stereotactic radiation therapy (SRT) is given in three to five fractions of 4 to 9 Gy. To date, radiosurgery has largely been used as salvage therapy for tumor progression in patients who have already been treated with conventional radiotherapy or as an adjuvant therapy following surgery. A role for spinal radiosurgery as a primary modality is seen in patients who are unable to undergo surgery or those with tumors poorly responsive to conventional radiotherapy. Local control rates of 85% to 90% and durable responses even against radioresistant tumors have been reported.^{38–40} In 2009, the Spine Oncology Study Group issued a “strong” recommendation to consider radiosurgery over conventional radiotherapy for patients with solid-tumor spinal metastases.⁴¹ In a phase 1/2 trial, SRT as primary or salvage treatment for mechanically stable spinal metastasis led to reductions in patient-reported pain and opioid requirement, satisfactory progression-free survival (72.4% at 2 years), and no late spinal cord toxicities.⁴² However, when spinal tumors abut the cord or if there is MSCC, SRS or SRT may not be feasible. Proper prospective evaluation of efficacy, morbidity, and cost-effectiveness as a function of tumor stage is pending and, considering the complexity of the patient population, may only become available for highly selected patient populations.

Strontium-89 is used as palliative treatment for widely metastatic bone metastases from prostate cancer. It provides pain control but cannot reverse the neurologic syndrome from epidural cord compression.

The role of surgical decompression in patients with MSCC remains a controversial subject. For the majority of patients, a benefit from surgical intervention has not been convincingly

shown.^{43,44} However, in carefully selected patients, tumor resection results in improved functional outcome compared with irradiation. In a prospective randomized trial, the ability to walk was preserved for a longer period of time after surgery compared with radiation therapy (122 days versus 13 days). Patients were eligible only if they did not have certain radiosensitive tumors (lymphomas, leukemia, multiple myeloma, and germ cell tumors) or concomitant neurologic problems not directly related to MSCC (e.g., brain metastases), the duration of paraplegia was <48 hours, MSCC occurred at one level, their general medical status rendered them acceptable surgical candidates, and their life expectancy exceeded 3 months.⁴⁵ Other commonly accepted indications for surgery are the lack of a recent history of cancer, involvement of a previously irradiated segment, progressive painful radiculopathy despite irradiation, cord compression resulting from pathologic fracture, and spinal instability.^{6,26,30} Younger patients are more likely to undergo surgical debulking.⁷ Posterior exposure with laminectomy at the level of cord compression has been a common approach. The metastatic focus, usually located within the vertebral body, cannot be completely visualized and thus at best is only partially removed. Laminectomy may increase the degree of instability in kyphotic deformities resulting from pathologic fracture. Thus, an anterior approach for surgical decompression is favored in selected patients. This procedure, reserved for patients with the possibility of long-term survival, includes resection of the affected vertebral body and implantation of stabilizing instrumentation. Frequently, two surgical sessions are required.^{26,46} Surgical morbidity is considerable. A posterolateral transpedicular approach with stabilizing instrumentation is a feasible alternative.²⁶

Treatment guidelines are similar in the pediatric population. Surgical intervention is recommended for patients with rapid neurologic deterioration or a severe transverse myelopathy at initial presentation.²¹

Systemic chemotherapy is an appropriate treatment only for patients with MSCC caused by highly chemosensitive tumors such as non-Hodgkin lymphoma or germ cell tumors. Radiation or surgical intervention may not be necessary.^{16,47,48}

It is unclear if asymptomatic patients benefit from treatment of incidentally detected epidural metastases. The decision depends

on tumor type and the patient's condition. Observation and serial MRI scans may be appropriate until pain ensues.

Bisphosphonates are now widely used, particularly in the treatment of breast cancer and multiple myeloma. Monthly provision of intravenous zoledronic acid or pamidronate in combination with other treatment modalities for the underlying cancer significantly reduces skeletal-related events (SRE; pathologic fracture, MSCC, palliative radiation to bone, or surgery to bone).^{24,49-52} The monoclonal antireceptor activator of nuclear factor kappa-B ligand (RANKL) antibody denosumab was found to be noninferior to zoledronic acid in preventing or delaying first on-study SRE in patients with advanced cancer metastatic to bone or myeloma and superior in patients with prostate or breast cancer metastatic to bone.⁵³⁻⁵⁵ The selective androgen biosynthesis inhibitor abiraterone acetate in combination with prednisone prevents SREs in patients with metastatic castration-resistant prostate cancer.⁵⁶

PROGNOSIS

Naturally, the prognosis for the patient with epidural metastasis and cord compression depends on the type and extent of the underlying malignancy. Untreated, patients with MSCC succumb within a month of diagnosis. The median overall survival of patients with MSCC ranges from 3 to 16 months and most patients die of systemic tumor progression.^{1,6-8,12,46,57} Patients with therapy-sensitive tumors such as lymphoma or myeloma live longer (lymphoma, 6 to 14 months) than patients with solid tumors.^{6,7,12,58} The most important determinant of functional outcome is the severity of neurologic damage at the time treatment is initiated. A total of 80% of patients treated at a time when a significant neurologic deficit is absent, and 50% of those with mild transverse myelopathy, but only 5% of patients who are paraplegic when definitive treatment is initiated remain ambulatory or regain the ability to walk after treatment.^{1,8,11,12,14} Late return of function within 6 to 20 months of treatment has been observed in long-term survivors of MSCC in non-Hodgkin lymphoma.^{14,16} The faster the neurologic deficit evolves, the lower the chance for recovery of motor function after treatment.⁵⁸

122 Metabolic Emergencies

Antonio Tito Fojo

INTRODUCTION

While increased awareness and improved prophylaxis have helped preempt some metabolic emergencies, their occurrence continues to present challenges to the practicing oncologist. Prompt recognition and the rapid institution of adequate therapy are essential to a successful outcome.

TUMOR LYSIS SYNDROME AND HYPERURICEMIA

General

Tumor cell death with the release of intracellular contents can lead to a constellation of metabolic abnormalities that comprise the tumor lysis syndrome (TLS). While it can occur spontaneously in rapidly proliferating tumors, it occurs most frequently following administration of cytotoxic chemotherapy to patients with hematologic malignancies, with a large percentage of proliferating, drug-sensitive cells (Tables 122.1 and 122.2).^{1,2} In these patients, TLS occurs a few hours to a few days after the initiation of therapy. Cell death leads to the release of potassium, phosphate, uric acid, and other purine metabolites overwhelming the kidney's capacity for clearance with resultant hyperkalemia, hyperphosphatemia and secondary hypocalcemia, and hyperuricemia (Table 122.3). Unchecked, TLS can progress to acute renal failure and metabolic acidosis. While established TLS is associated with a high morbidity and mortality, judicious prophylaxis can avoid complications. The higher mortality reported among patients with solid tumors is likely a consequence of less prophylaxis and reduced awareness.

The highest incidence of TLS occurs in patients with rapidly growing, chemosensitive myelo-lymphoproliferative malignancies with high white blood cell counts (acute leukemias) or large bulky adenopathy (high-grade non-Hodgkin lymphomas [NHL], especially Burkitt lymphoma).³⁻⁶ In high-grade NHL, an incidence of TLS as high as 42% has been reported, clinically significant in only 6% of patients.⁷ The latter agrees with a Pan-European retrospective chart review that identified TLS in 3.4%, 5.2%, and 6.1% of patients with acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), and NHL, respectively. In an era antedating modern interventions, this review found an overall mortality of 0.9% for all patients and 17.5% for patients who developed TLS.⁸ By comparison, TLS occurs infrequently in solid tumors, most likely due to the lower growth fractions, and slower response to treatment—occurring with tumors that are *highly or moderately* sensitive to chemotherapy, or if bulky, metastatic disease is present.⁹ TLS has also been reported following ionizing radiation including total-body irradiation in the transplant setting, embolization, radiofrequency ablation, monoclonal antibody therapy, glucocorticoids, interferon, and in the setting of hematopoietic stem cell transplantation. As new therapies emerge, TLS may occur in unanticipated settings, as seen in indolent chronic lymphocytic leukemia treated with flavopiridol.¹⁰ Table 122.2 summarizes the

Cairo and Bishop Classification System for TLS. Table 122.3 summarizes recent guidance from a tumor lysis expert panel.¹¹

Hyperuricemia can occur in TLS as noted previously, or more frequently as an isolated finding in patients with cancer. For example, in the Pan-European retrospective chart review previously noted, among 755 patients with ALL, AML, or NHL hyperuricemia without TLS was identified in 13.6% of cases, and with TLS in an additional 5.3%.⁸

Pathogenesis

Cell lysis with the release of contents at a rate exceeding the kidney's clearance capacity is the most important etiologic factor in TLS (see Table 122.3 and Fig. 122.1). Rapidly dividing cells have high nucleic acid turnover, and some cancer cells, particularly lymphoid cells, contain higher levels of phosphate than their normal counterparts.

Hyperkalemia poses the greatest immediate threat. Although release of potassium from dying cells is the principal cause, falling adenosine triphosphate (ATP) levels before cell lysis may lead to potassium leakage, explaining why a rise in serum potassium is often the first sign of TLS.

Hyperphosphatemia, like hyperkalemia, follows cell lysis. The initial adaptation involves increased urinary excretion and decreased tubular reabsorption of phosphate. However, as transport becomes saturated, phosphorus levels rise, the calcium phosphate multiple exceeds 70, and calcium phosphate precipitates in tissues resulting in hypocalcemia. Hypocalcemia leads to increased levels of parathyroid hormone, with decreased proximal tubule phosphate reabsorption, accentuating hyperphosphaturia and the risk of calcium phosphate crystals in renal tubules (nephrocalcinosis) with tubular obstruction.

While hyperuricemia alone may not be an acute threat, it is the most common finding and contributes to renal failure, a complication that in the setting of tumor lysis is usually multifactorial. Within the cell, there is continuous turnover and salvage of bases (Fig. 122.2). In humans, the end product of purine metabolism is uric acid. Adenine is catabolized to hypoxanthine, and this is converted by xanthine oxidase to xanthine and in turn to uric acid. Guanine forms xanthine that is converted to uric acid by xanthine oxidase. In most mammals, *urate oxidase* catalyzes the oxidation of uric acid to allantoin, a more soluble catabolite. However, a nonsense mutation in the coding region acquired during evolution precludes urate oxidase expression in humans, making uric acid, not allantoin, the final purine metabolite.¹²

Hyperuricemia occurs primarily as a result of accelerated cellular breakdown. Acute uric acid nephropathy occurs when urate and uric acid crystals obstruct renal tubules. Urate is filtered at high concentrations from the plasma and is further concentrated along the course of the tubular system. As the pH becomes more acidic, uric acid can precipitate, obstructing tubules, collecting ducts, and even pelves and ureters. Crystal deposition increases tubular and intrarenal pressure with extrinsic compression of the vasa recta, an increase in renal vascular resistance, and a fall in

renal blood flow. The elevated tubular pressure and decreased renal blood flow reduce glomerular filtration and can lead to acute renal failure.

Therapy

In the modern era, laboratory abnormalities alert physicians and guide preventive management (see Tables 122.1 and 122.3). In adults, preventive measures include foremost hydration, allopurinol, and oral phosphate binders, beginning preferably 24 hours before chemotherapy administration.

Aggressive hydration, the most important intervention, should begin immediately, administering at least 3,000 mL/m² per day, when possible delaying tumor therapy so hydration can be administered. Urine alkalinization remains controversial as it favors precipitation of calcium/phosphate complexes in renal tubules—calcium phosphate, unlike uric acid, becomes less soluble at an alkaline pH. Furthermore, metabolic alkalemia can worsen the neurologic manifestations of hypocalcemia. Administration of 100 mEq sodium bicarbonate will maintain urine pH above 7.5, a pH that is needed not because of uric acid, which has a pKa of 5.4 (so that above a pH of 6.4 >90% is sodium urate), but because of xanthine which as a pKa of about 7.4.

TABLE 122.2

Laboratory TLS	Clinical TLS
Abnormality in two or more of the following, occurring within 3 d before or 7 d after chemotherapy: <ul style="list-style-type: none"> ■ Uric acid >8 mg/dL or 25% increase ■ Potassium >6 meq/L or 25% increase ■ Phosphate >4.5 mg/dL or 25% increase ■ Calcium <7 mg/dL or 25% decrease 	Laboratory TLS plus one or more of the following: <ul style="list-style-type: none"> ■ Increased serum creatinine (1.5 × upper limit of normal) ■ Cardiac arrhythmia or sudden death ■ Seizure

TLS, tumor lysis syndrome.

Adapted from Cairo MS, Bishop M. Tumour lysis syndrome: new therapeutic strategies and classification. *Br J Haematol* 2004;127:3–11.

Hyperkalemia should be treated aggressively. Cation exchange resins should be used, recognizing their value will be delayed. Calcium gluconate antagonizes cardiac effects of hyperkalemia and can be especially helpful if there is concomitant hypocalcemia. Sodium bicarbonate corrects acidemia and shifts potassium back into cells; administering hypertonic dextrose and insulin can augment this. Loop diuretics can eliminate excess potassium in patients without renal failure; hemodialysis is indicated in renal impairment.

Hyperphosphatemia and its resultant hypocalcemia require oral phosphate binders except to manage hyperkalemia avoid calcium administration, because it can promote metastatic calcifications.

Given its central role in acute renal failure, hyperuricemia should be managed aggressively. Allopurinol, an analog of the purine base hypoxanthine, lowers uric acid by inhibiting xanthine oxidase, the enzyme responsible for converting hypoxanthine to xanthine and xanthine to uric acid (see Fig. 122.2). Its active metabolite, oxypurinol, also inhibits xanthine oxidase. Because both allopurinol and oxypurinol inhibit uric acid synthesis, but have no effect on preexisting uric acid, uric acid levels usually do not fall until after 48 to 72 hours of treatment. Furthermore, inhibition of xanthine oxidase leads to an increase in plasma hypoxanthine and xanthine levels, with increased renal excretion of both metabolic products. Like uric acid, xanthine (pKa = 7.4) but not hypoxanthine (pKa = 1.98) may precipitate contributing to acute renal failure. Oral allopurinol has a bioavailability of 50%; alternately, intravenous allopurinol (Aloprim, Bioniche Pharma, Belleville, Ontario, Canada) may be administered. Allopurinol should be discontinued if allergic reactions such as skin rashes and urticaria occur (incidence increased in patients receiving amoxicillin, ampicillin, or thiazides). Finally, the doses of allopurinol should be adjusted for creatinine clearance as follows:

Creatinine clearance	Allopurinol dose
≥20 mL/min	300 mg/d
10–20 mL/min	200 mg/d
3–10 mL/min	100 mg/d
<3 mL/min	100 mg/36–48 h

An alternate approach to the treatment of hyperuricemia involves the use of rasburicase (Fasturtec, Sanofi Synth, Paris, France; Elitek, Sanofi US, Bridgewater, NJ), a recombinant urate oxidase developed to replace uricase, a nonrecombinant urate oxidase. Because urate oxidase degrades uric acid rather than prevent its synthesis, as does allopurinol, rapid reduction in uric acid occurs following its administration without the accumulation of

precursors. Studies in adults and children have shown uric acid levels fall to 0.5 to 1 mg/dL within 4 hours of rasburicase injection with low levels maintained throughout treatment. Despite normalization of uric acid levels with rasburicase, a small percentage have required dialysis—a not unexpected observation, given the multifactorial nature of renal failure in TLS and the fact rasburicase affects only one component, albeit an important one.

Table 122.4 contrasts allopurinol and rasburicase, and notes that rasburicase is more expensive.¹³ The manufacturer recommends a rasburicase dose of 0.2 mg/kg for up to 5 days (<http://products.sanofi.us/elitek/elitek.html>). However, except in rare patients with very high serum levels of uric acid, much less is sufficient. A 5-day course of rasburicase is about 15,000 times more expensive than a 5-day course of allopurinol and 15 to 30 times more than intravenous allopurinol, so cost must be factored into decision making. With a 2013 price of ≈\$521/mg (Bluebook Average Wholesale Price is \$2,345 for three vials containing 1.5 mg each) the 5-day tab for a 70-kg patient receiving the manufacturer's recommended dose of 0.2 mg/kg for 5 days exceeds \$36,470. At this price, rasburicase can be justified only if it will prevent acute renal failure, and the existing data is not compelling. While some studies suggest rasburicase can reduce the need for dialysis, no differences or only clinically insignificant differences in serum creatinine have been reported in other studies, and at the present time the data do not definitively prove that less dialysis is required in patients treated with rasburicase.^{14–16} It *appears* rasburicase therapy is beneficial in children with hematologic malignancies; however, randomized controlled trials in adults have been less convincing. Nevertheless, rasburicase is approved by the US Food and Drug Administration for use in adults based on a randomized phase 3 trial.¹⁴ Because outcomes other than laboratory parameters were not different, the authors could only conclude “the incidence of laboratory TLS, which can be regarded as an indicator of the risk of clinical TLS, was significantly lower with rasburicase than with allopurinol” and “the rapid reduction in uric acid to less than 1.0 mg/dL with rasburicase simplifies uric acid control by reducing the need for

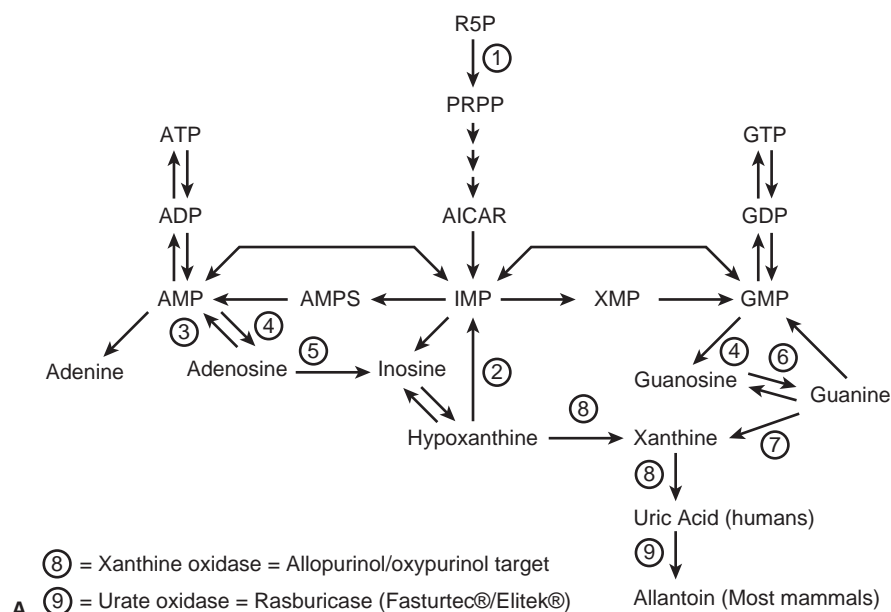

Figure 122.2 Purine metabolism/catabolism. **(A)** The figure shows the pathways of purine metabolism/catabolism in mammals with an emphasis on pathways involved in purine catabolism and generation of uric acid. The numbers enclosed in circles identify the enzymes involved in catalyzing the reaction. These are (1) PRPP synthetase; (2) hypoxanthine phosphoribosyltransferase; (3) adenosine kinase; (4) 5' nucleotidase; (5) adenosine deaminase; (6) purine nucleoside phosphorylase; (7) guanase; (8) xanthine oxidase, that also catalyzes the conversion of allopurinol to oxypurinol; and (9) urate oxidase or uricase, an enzyme that is present in mammals with the exception of humans and many primates. R5P, ribose 5' phosphate; PRPP, phosphoribosyl pyrophosphate; AICAR, aminoimidazole carboxamide ribonucleotide; IMP, inosine monophosphate; XMP, xanthosine monophosphate; GMP, guanosine monophosphate; GDP, guanosine diphosphate; GTP, guanosine triphosphate; AMPS, adenylosuccinate; AMP, adenosine monophosphate; ADP, adenosine diphosphate; ATP, adenosine triphosphate. **(B)** Structure and dissociation constants of key metabolites in purine metabolic/catabolic pathway.

TABLE 122.4

Allopurinol and Rasburicase: A Comparison

Allopurinol	Rasburicase
Oral, easy to use	Intravenous administration
Slow onset of action: No effect on preexisting uric acid levels	Rapid onset of action: Lowers preexisting uric acid levels without accumulation of precursors; may allow start of chemotherapy without delay
Ineffective in some patients	Lowers uric acid in all patients
1% incidence of allergic reactions ¹⁴	4% to 5% incidence of immunoallergic reactions including anaphylaxis ¹⁴
Can interfere with metabolism of oral but not intravenous 6-mercaptopurine¹³	No effect on drug metabolism
No added risk with G6PD deficiency	Can lead to hemolysis in patients with G6PD deficiency such as those of African or Mediterranean ancestry
Comparable efficacy in preventing acute renal failure and need for dialysis ^{14,16}	Lower incidence of laboratory TLS but not clinical TLS
Inexpensive	Very expensive

TLS, tumor lysis syndrome.

urinary alkalization in patients who are often critically ill with compromised organ function.¹⁴ An earlier Pan-European multicenter economic evaluation of rasburicase in prevention and treatment of hyperuricemia and TLS in patients with hematologic malignancies concluded rasburicase is economically attractive in the *treatment of hyperuricemia* both in adults and children while in the *prevention of hyperuricemia*, it “has an attractive economic profile in children and is cost-effective in adults with ALL and NHL . . . whereas in adult AML patients, the short average life expectancy and the lower baseline risk of hyperuricemia and TLS limits the cost-effectiveness of rasburicase.”⁸

In both children and adults, it appears the manufacturer’s recommended dose of 0.2 mg/kg/day for up to 5 days is excessive.^{17–20} Evidence indicates a single 3-mg dose is effective in the prophylaxis and treatment of hyperuricemia in adults with uric acid levels up to 12 mg/dL, with uric acid levels continuing to decline beyond 24 hours in most patients without additional treatment.¹⁹ For a 70-kg patient, a 3-mg dose—approximately one-fifth the recommended dose of 0.2 mg/kg—is convenient as vials contain 1.5 mg rasburicase, making it more affordable. Note that as the half-life of rasburicase in serum is approximately 18 to 21 hours, about one-half of the administered dose is still present 24 hours after administration. Given this, a reasonable strategy to consider might be the following: (1) continue to rely on the triad of aggressive hydration, management of electrolyte disturbances, and institution of allopurinol beginning immediately upon presentation; (2) evaluate patients for their TLS risk (see Table 122.1) and *administer a single 3-mg dose of rasburicase at presentation to patients with “high risk disease”*; and (3) follow the levels of uric acid and administer additional rasburicase doses only to patients with uric acid levels above an arbitrary number such as 5 mg/dL 24 hours after a rasburicase dose. Remember a few additional uric acid measurements are far less expensive than a dose of rasburicase. (*Important: Because serum samples contain rasburicase, immediately cool samples obtained for uric acid to 0°C to 4°C, so as to prevent ex vivo enzymatic uric acid degradation that will falsely lower levels. Label test tubes as requiring chilling to avoid removal from ice upon arrival in the laboratory.*)

Finally, if despite aggressive management acute renal failure develops, immediate hemodialysis is recommended. Indeed, in patients presenting with TLS, hemodialysis should be started before cytotoxic therapy is administered. Conventional hemodialysis is more effective in eliminating uric acid and phosphate than peritoneal dialysis.

CANCER AND HYPONATREMIA

General

Water and sodium homeostasis is frequently disordered in patients with cancer. Optimal homeostasis requires a delicate balance between renal free water clearance and renal sodium metabolism. Hyponatremia, commonly defined as serum sodium <130 mEq/L, occurs with a reported incidence of 3.7% in patients with cancer.²¹ Clinical manifestations of hyponatremia range from none to impaired consciousness progressing to coma and generalized hypotonia, or seizure activity all secondary to cerebral edema. Less dramatic symptoms, including anorexia, nausea, and asthenia, are often difficult to ascribe to a single cause in patients with cancer.

The differential of hyponatremia is extensive and includes many conditions patients with cancer experience including inappropriate secretion of arginine vasopressin (AVP = antidiuretic hormone = ADH)²² and sodium depletion secondary to reduced intake and gastrointestinal or renal losses each accounting for about one-third of cases (Table 122.5).²³ Other etiologies more likely to occur in patients with cancer than the general patient population include ectopic atrial natriuretic peptide (ANP) production, hyponatremia associated with third spacing of fluids (ascites),

TABLE 122.5

Classification and Differential Diagnosis of Hyponatremia

HYPOTONIC HYPONATREMIA

Hypovolemic hyponatremia

Loss of solutes (sodium or potassium) with secondary water retention. Solute losses may be renal or extrarenal in origin.

1. Gastrointestinal disease
2. Exercise-associated hyponatremia
3. Diuretic therapy
4. Cerebral salt wasting
5. Mineralocorticoid deficiency

Euvolemic hyponatremia

Relative or absolute excess of body water: (a) reduction in electrolyte-free water excretion by kidneys due to AVP effects at the V2R (most common), (b) secondary to overdrinking (rare), (c) non-AVP mechanisms (very rare).

1. Syndrome of inappropriate antidiuretic hormone secretion
2. Primary polydipsia
3. Nephrogenic syndrome of inappropriate antidiuresis
4. Glucocorticoid deficiency
5. Hypothyroidism
6. Exercise-associated hyponatremia
7. Low solute intake

Hypervolemic hyponatremia

Renal sodium/water retention manifest as edema, principally due to AVP effects at the V2R.

1. Heart failure
2. Cirrhosis
3. Acute kidney injury, chronic kidney disease, and nephrotic syndrome

PSEUDOHYPONATREMIA

Artificial decrease in serum Na⁺ because excess lipids/proteins occupy a relatively larger proportion of plasma volume. Usually directly measured plasma osmolality will be normal.

1. Elevated lipids
2. Elevated proteins (multiple myeloma and hyperproteinemias)

ISOTONIC OR HYPERTONIC HYPONATREMIA

Hyponatremia with normal or increased osmolality occurring when solutes other than sodium present in the plasma. Initial hyperosmolality causes osmotic shift of water from intracellular to extracellular fluid compartment that, in turn, produces a dilutional decrease in the serum Na⁺.

1. Hyperglycemia^a is the most common example of this phenomenon. Depending on the severity of hyperglycemia and the duration and magnitude of the accompanying glucose-induced osmotic diuresis, such patients may actually be hypertonic despite hyponatremia.
2. Mannitol.^b
3. Radiographic contrast agents.^b
4. Glycine from surgical irrigant solutions.^b

AVP, arginine vasopressin.

^a Assess plasma osmolality directly or correct measured serum Na⁺ for the glucose elevation.

^b Plasma osmolality must be ascertained by direct measurement.

Adapted from Verbalis JG, Goldsmith SR, Greenberg A, et al. Diagnosis, evaluation, and treatment of hyponatremia: expert panel recommendations. *Am J Med* 2013;126:S1–42.

and “pseudohyponatremia” as might occur in a patient with multiple myeloma and hyperproteinemia—although one can argue the latter is in fact true hyponatremia with the reduced sodium an adaptation at electrical neutrality imposed by the increase in positively charged myeloma proteins.²⁴

Pathogenesis

Only cell membrane impermeable solutes that are “relatively” restricted to either the extracellular or intracellular compartments can effectively function as solutes and create osmotic gradients across cell membranes. Sodium and its accompanying anions are the major cell membrane impermeable plasma solutes, so that hyponatremia is in effect a surrogate for hypoosmolality and these terms are usually synonymous. Under normal circumstances, plasma *osmolality* is closely regulated in the range of 280 to 295 mOsm/kg through (1) thirst perception, (2) control of free water clearance in the kidney by ADH also known as AVP, and (3) renal sodium excretion regulated by ANP and the renin angiotensin system. Understanding this helps one understand the causes of hyponatremia.

In patients with cancer, hyponatremia secondary to inappropriate secretion of AVP (or ADH; syndrome of inappropriate antidiuretic hormone [SIADH] or syndrome of inappropriate antidiuresis) occurs as a paraneoplastic syndrome, or as a complication of therapy.²² SIADH is defined as a hypo-osmolar or dilutional hyponatremia with excessive natriuresis. Hyponatremia occurs because AVP secretion continues even after plasma osmolality falls below the threshold for AVP release. Key and ancillary features are summarized in Table 122.6.^{22,23} The inappropriate secretion of AVP can originate from its normal source, the hypothalamus, as a consequence of dysregulation, or can be ectopic in origin, arising from cancer cells themselves. In cases of ectopic production, AVP is detectable in plasma and correlates with detectable AVP mRNA or immunoreactive peptides in tumor cells. While inappropriate AVP secretion can occur with any cancer, it is most frequently

reported with small-cell lung cancer, head and neck carcinomas, hematologic malignancies, and non-small-cell lung cancer.²⁵ Drugs reported to cause SIADH include cyclophosphamide and its isomeric analogue, ifosfamide; the vinca alkaloids including vincristine, vinblastine, and vinorelbine; the proteasome inhibitor bortezomib; as well as carboplatin and cisplatin, although the latter more frequently cause renal salt wasting.

Patients with small-cell lung cancer, hyponatremia, and without measurable AVP have also been reported.^{25,26} In a fraction of these patients, ectopic production of ANP mRNA and a peptide similar to the bioactive 28-amino acid ANP form present in plasma has been shown in tumors and leads to hyponatremia. Normally, ANP is produced, stored, and released by atrial myocytes and binds to a specific set of receptors increasing renal sodium excretion.

Besides SIADH and syndrome of inappropriate atrial natriuretic peptide (SIANP) production, there is increasing awareness of an alternate mechanism of salt loss referred to as the cerebral salt wasting syndrome (CSWS). Two major criteria must be met for a diagnosis of CSWS: (1) a cerebral lesion and (2) high urinary excretion of Na^+ and Cl^- , in a patient with contraction of the extracellular fluid volume. While the frequency of CSWS is less, it is important to make the correct diagnosis as management is different.

Therapy

The first step is to identify the cause and decide if sodium depletion secondary to either reduced intake, gastrointestinal losses, or renal losses is present. If these are excluded, physicians often proceed with a presumptive diagnosis of SIADH and attempt to restore serum sodium and osmolality to normal. If the hyponatremia is thought to be drug-induced, the offending agent(s) should be discontinued. The rapidity of correction is guided by the severity of the clinical presentation and the pace with which the hyponatremia developed. If the evidence suggests hyponatremia developed slowly, it is likely that some equilibration has occurred and correction *can and should* proceed over several days. Patients in whom hyponatremia develops rapidly are more likely to present with severe clinical symptoms, but can tolerate more rapid correction. Fortunately, most cases present with mild hyponatremia and can be managed with judicious water restriction and intravenous or even oral salt administration. Management options are summarized in Table 122.7. If saline and furosemide prove inadequate so that the hyponatremia fails to improve or worsens after 72 to 96 hours of fluid restriction, plasma levels of AVP and ANP should be measured to discriminate between SIADH [syndrome of inappropriate arginine vasopressin (SIADH)] and SIANP, especially in patients with SCLC. Unlike patients with SIADH and hyponatremia, patients whose tumors produce ANP experience a persistent decline in serum sodium following fluid restriction, especially if sodium intake is not concomitantly increased. Aquaretic agents, AVP-receptor antagonists, have demonstrated efficacy and safety in clinical trials and represent additional options for managing hyponatremia.^{27,28}

TABLE 122.6

Criteria for Diagnosing Syndrome of Inappropriate Antidiuretic Hormone Secretion

Key features:

1. Decreased effective osmolality of the extracellular fluid (<275 mOsm/kg of water)
2. Inappropriate urinary concentration: Urine osmolality >100 mOsm/kg H_2O with normal renal function
3. Clinical *euvolemia* as defined by the absence of signs of hypovolemia (orthostasis, tachycardia, decreased skin turgor, dry mucous membranes) or hypervolemia (subcutaneous edema, ascites)
4. Urine sodium >20–30 mmol/L in the face of normal salt and water intake
5. Normal thyroid and adrenal function
6. Normal renal function and no recent diuretic use

Ancillary features:

1. Plasma uric acid <4 mg/dL
2. Blood urea nitrogen <10 mg/dL (0.357 mmols/L)
3. Fractional sodium excretion >1%
4. Fractional urea excretion >55%
5. Hyponatremia corrected by fluid restriction but not by normal saline
6. Elevated plasma arginine vasopressin levels despite hypotonicity and euvolemia

Adapted from Ellison DH, Berl T. Clinical practice. The syndrome of inappropriate antidiuresis. *N Engl J Med* 2007;356:2064–2072; and Verbalis JG, Goldsmith SR, Greenberg A, et al. Diagnosis, evaluation, and treatment of hyponatremia: expert panel recommendations. *Am J Med* 2013;126:S1–42.

LACTIC ACIDOSIS AND CANCER

General

Among patients with cancer, spontaneous lactic acidosis can occur with hematologic and lymphoid malignancies as well as solid tumors having been described in patients with breast, colon, ovarian, and small-cell lung cancer, among others. In some patients with TLS, a metabolic acidosis not accounted by the degree of renal insufficiency can be caused by lactic acidosis. Although most patients with lactic acidosis present or evolve to a more severe acidosis, lactic acidosis is defined as a pH ≤ 7.35 , with plasma lactate concentration ≥ 5 meq/L.²⁹ Not surprisingly, the occurrence of metabolic acidosis in patients with cancer portends a poor prognosis.

TABLE 122.7

Management of Hyponatremia**High Risk of ODS**

- Serum Na⁺ concentration ≤ 105 mmol/L
- Alcoholism^a
- Advanced liver disease^a
- Hypokalemia^a
- Malnutrition^a

Initial Treatment of Hyponatremia

Asymptomatic or serum sodium ≤ 125 mmol/L and developed over weeks

- Chronic hyponatremia: Neurologic sequelae more likely if correction too rapid
- Increase serum Na⁺ a maximum of 0.5–2 mmol/L/hr
- High risk of ODS: Correct serum Na⁺ by 4–6 mmol/L/d not >8 mmol/L/24 h
- Normal risk of ODS: Correct serum Na⁺ 4–8 mmol/L/d, not >10 –12 mmol/L/24 h
- Intravenous normal saline ± 20 to 40 mg furosemide when patient is euvolemic

Symptomatic or serum sodium ≤ 115 mmol/L and developed acutely

- Increase serum sodium 2 mmol/L/hr; 4–6 mmol/L increase in serum Na⁺ sufficient to reverse most serious manifestations
- Severe symptoms: 100 mL of 3% NaCl over 10 minutes times three as needed
- Mild to moderate symptoms with low risk of herniation: 1 to 2 mL/Kg/hour 3% NaCl then 100 to 250 mL/hour normal saline
- 20 to 40 mg oral or intravenous furosemide when patient is euvolemic

Treatment of Syndrome of Inappropriate Antidiuretic Hormone Secretion

Vaptans^{27,28}

Cautions for Using Vaptans to Treat Hyponatremia

- Exclude hypovolemic hyponatremia; approved only for hypervolemic and euvolemic hyponatremia
- Do not use in conjunction with other treatments for hyponatremia or immediately after cessation of other treatments for hyponatremia, particularly 3% NaCl
- Monitor serum Na⁺ every 6–8 h for the first 24–48 h
- Maintain ad libitum fluid intake during the first 24–48 h of treatment; hyponatremia can correct too quickly with coincidental fluid restriction
- Symptomatic benefit to patients not established
- Do not use a vaptan for severe, symptomatic hyponatremia
- There are insufficient data using vaptans in severe asymptomatic hyponatremia
- Monitor volume status and serum Na⁺ frequently. Discontinue if hypovolemia, hypotension or rapid rate of rise of serum Na⁺.

Conivaptan Hydrochloride

- Combined vasopressin V1aR and V2R AVP-receptor.
- Loading dose of 20 mg IV followed by continuous infusion of 20 mg/d over 24 h, for 2–4 d. Following the initial day of treatment, dosage may be increased to 40 mg/d continuous infusion.

Tolvaptan

- Selective vasopressin V2-receptor antagonist.
- Starting dose is 15 mg once daily. Dosage may be increased at intervals ≥ 24 h to 30 mg once daily, and to a maximum of 60 mg once daily as needed to raise serum Na⁺. Monitor serum Na⁺ and volume status.

Demeclocycline

- 300–600 mg twice daily
- Continued several days to achieve maximal diuretic effects; wait 3–4 d before increasing dose
- Monitor renal function carefully

Treatment of Cerebral Salt Wasting Syndrome

1. Aggressive fluid and electrolyte replacement
2. Mineralocorticoid supplementation (fludrocortisone 100–400 mg/d)

ODS, osmotic demyelination syndrome; AVP, arginine vasopressin.

^aThe precise serum K⁺ concentration nor the degree of alcoholism, malnutrition, or liver disease that renders the brain vulnerable to ODS have not been defined.

Pathogenesis

Lactic acid production normally occurs under conditions of hypoxia in all tissues, and following release into the circulation, 90% of lactic acid is metabolized in the liver, where it is converted to pyruvate, with the remaining 10% metabolized or excreted by the kidney. Unlike normal cells, tumor cells rely on anaerobic glycolysis disproportionately, even in the presence of oxygen, producing large quantities of lactate that can lead to an imbalance between lactate production and its utilization by the liver. The essential role of the liver in lactic acid metabolism explains why patients with compromised liver function are more likely to develop severe lactic acidosis. In patients with cancer, compromise of liver function can occur when extensive hepatic metastases replace a substantial portion of the liver parenchyma. In these patients, once established, lactic acidosis can progress inexorably.

Among patients with leukemias and lymphomas lactic acidosis usually occurs in adults and has an extremely poor prognosis.²⁹ Liver involvement is frequently present, and in a substantial proportion of patients contributes to hypoglycemia. Indeed, the high frequency of liver involvement in adults with lymphoma and leukemia who develop lactic acidosis supports the possibility reduced hepatic lactate utilization is necessary in the pathogenesis of lactic acidosis. Some have suggested the loss of mitochondrial membrane potential ($\Delta\psi_m$) during programmed cell death or apoptosis results in compensatory glycolysis with accumulation of lactic acid and acidosis.³⁰

Therapy

Lactic acidosis usually develops in patients with extensive disease and frequently progresses rapidly. Even with maximal supportive therapy, mortality rates of 60% to 90% are common.³¹ The developing acidosis can lead to cardiac arrhythmias and hypotension with potential for cardiovascular collapse. Consequently, an aggressive therapeutic approach is indicated including the following: (1) aggressively support blood pressure with fluids and vasopressors to preclude generalized hypoperfusion that will lead to further lactic acid accumulation; (2) use of sodium bicarbonate, though controversial, as no controlled study has shown improvement in outcome but can be supported with acidosis severe enough to impact hemodynamic function and the response to catecholamines; (3) hemodialysis and hemofiltration with a bicarbonate-based replacement fluid; and (4) correction of the underlying causes is essential, but often very difficult if not impossible if the lactic acidosis is a complication of the patient's cancer.

HYPERCALCEMIA AND CANCER

General

Hypercalcemia is the most common paraneoplastic syndrome, occurring in 10% to 30% of patients with advanced cancer.³² While hypercalcemia has been reported with most tumors, humoral hypercalcemia, discussed subsequently, is most frequently encountered in patients with carcinomas of the breast, lung, kidney, and head and neck, whereas hypercalcemia with skeletal metastases is seen most often in patients with multiple myeloma.

Symptoms of hypercalcemia include nausea, vomiting, constipation, polyuria, and disorientation. Clinical evidence of volume contraction may be apparent. Early and widespread use of bisphosphonates has decreased the frequency and severity of hypercalcemia in patients with cancer.

Pathogenesis

Hypercalcemia can occur as result of focal bone destruction (osteolytic) or more frequently as a humoral paraneoplastic syndrome. Focal bone destruction can be mediated by local (paracrine) fac-

tors secreted by tumor cells infiltrating bone including cytokines and growth factors that stimulate osteoclasts directly or indirectly via osteoblast-mediated upregulation of osteoclast-activating factors. Alternately, hypercalcemia can occur as a paraneoplastic syndrome caused by tumor-produced factors that affect bone resorption and/or tubular calcium reabsorption. The systemic factor most commonly secreted by tumor cells, parathyroid hormone-related protein (PTHrP), mediates a humoral form of malignant hypercalcemia, often referred to as humoral hypercalcemia of malignancy. Circulating PTHrP is found in approximately 80% of hypercalcemic patients with cancer. Although PTHrP shares only limited homology with parathyroid hormone, the common amino terminus binds the same cell surface receptor in bone and kidney and stimulates increases in bone resorption and renal tubular calcium reabsorption leading to hypercalcemia. In addition, PTHrP can synergize local (paracrine) factors including interleukin-1, interleukin-6 and tumor necrosis factor- α further contributing to hypercalcemia.^{32,33} Finally, some lymphomas secrete the active form of vitamin D, 1,25 dihydroxyvitamin D—enhancing osteoclastic bone resorption and intestinal calcium absorption.

Hypercalcemia induces an osmotic diuresis, while inhibiting ADH. The resultant polyuria together with nausea and vomiting lead to progressive dehydration, reduced glomerular filtration, and increased calcium resorption further worsening the hypercalcemia.

Therapy

Therapeutic interventions depend on the presentation. Asymptomatic patients with a serum calcium level of ≤ 3.25 mmol/L can be managed conservatively, whereas symptomatic patients or those with a serum calcium level >3.25 mmol/L require immediate aggressive measures.

Although hydration results at most in only a mild (0.5 mmol/L [~ 2 mg/dL]) decrease in serum calcium levels, it is a simple, rapid, and effective intervention that can also preclude continued renal calcium reabsorption. After adequate hydration, 20 to 40 mg of intravenous furosemide can enhance calcium excretion.

Together with hydration, bisphosphonates are the cornerstone of therapy for malignancy-associated hypercalcemia. Bisphosphonates are based on a phosphorous-carbon-phosphorous backbone, similar to pyrophosphate. The carbon replacing the central oxygen renders the molecules resistant to hydrolysis, but allows the retention of pyrophosphate-like inhibition of bone resorption. Their mechanism of action is complex. Bisphosphonates inhibit both normal and pathologic bone resorption via direct and indirect effects on osteoclasts. The affinity of bisphosphonates for hydroxyapatite leads to their concentration in bone at the interface and they are internalized by osteoclasts at the time of bone resorption. Evidence indicates non-nitrogen-containing bisphosphonates such as clodronate resemble pyrophosphate and are metabolized intracellularly to nonhydrolyzable analogues of ATP that inhibit ATP-dependent intracellular enzymes and are thus cytotoxic. Nitrogen-containing bisphosphonates (aminobisphosphonates), including pamidronate, ibandronate, and zoledronate, impede protein prenylation and bone resorption by osteoclasts by inhibiting the mevalonate pathway (farnesyl diphosphate synthase) disrupting the signaling functions of key regulatory proteins.^{34,35} As a group, the bisphosphonates are well tolerated with a small incidence of fever, which is the most frequently reported adverse event. Transient hypocalcemia and hypophosphatemia, and a reversible increase in serum creatinine can also occur. Because of poor oral absorption and gastrointestinal discomfort, most are administered intravenously. Several bisphosphonates have been used in the treatment of hypercalcemia of malignancy including the following. (1) Clodronate, a second-generation bisphosphonate of intermediate potency, is usually given orally and achieves normocalcemia in 80% of cases. One-fifth of those treated have an increase in creatinine.³⁶ In the palliative setting, clodronate can be given subcutaneously with mild local reaction in one-third as the principal side effect.³⁷ (2) Pamidronate, a nitrogen-containing bisphosphonate, achieves normocalcemia in as many as 90% of patients, for a longer period

of time than clodronate.^{36,38} (3) Zoledronate, a third-generation bisphosphonate containing a heterocyclic nitrogen, is considered the current best choice, with normalization of serum calcium in 4 to 10 days that lasts 4 to 6 weeks in 90% of patients.³⁹ A Cochrane Database Review reported no significant adverse effects associated with bisphosphonate administration and found no evidence of superiority of any specific aminobisphosphonate or nonaminobisphosphonate for any outcome, although zoledronate appeared superior to placebo and etidronate in improving overall survival.^{39,40}

Bisphosphonates are most effective in the therapy of hypercalcemia associated with multiple myeloma, but are also efficacious in solid tumors with skeletal metastases. They are somewhat less effective in the treatment of patients with humoral-mediated hypercalcemia because they have no effect on tubular calcium reabsorption mediated by humoral factors, including PTHrP.⁴¹ Other agents including gallium nitrate,⁴² plicamycin (mithramycin), and calcitonin can be tried in hypercalcemia refractory to bisphosphonates. Plicamycin and calcitonin can effect rapid declines of serum calcium but require frequent administration.

Osteoprotegerin (OPG) is a naturally occurring soluble receptor that inhibits bone resorption by inhibiting osteoclast differentiation. OPG is part of a cytokine system that belongs to the tumor necrosis factor superfamily.⁴³ The components include the ligand RANKL (receptor activator of nuclear factor- κ B ligand), its specific receptor RANK (receptor activator of nuclear factor- κ B) and OPG, a soluble “decoy” receptor. By binding to RANK, RANKL enhances bone resorption by (1) increasing osteoclast formation from hematopoietic precursors, (2) increasing osteoclast activity, and (3) inhibiting osteoclast apoptosis. The activity of RANKL, also known as osteoclast differentiation factor (ODF) or OPG ligand, is counterbalanced physiologically by circulating OPG, with the net effect dependent on the local ratio of osteoclast differentiation factor to OPG. By acting as a “decoy,” intravenous administration of OPG has potent hypocalcemic effects in murine models of humoral hypercalcemia.

Denosumab, a fully human monoclonal antibody with a high affinity and specificity for RANKL, is approved by the US Food and Drug Administration “for prevention of skeletal-related events in patients with bone metastases from solid tumors . . . but is not indicated for the prevention of skeletal-related events in patients with multiple myeloma.” Two phase 3 trials randomized patients with breast cancer or castration-resistant prostate cancer to receive either 120 mg denosumab subcutaneously every 4 weeks or intravenous zoledronate administered at a dose of 4 mg every 4 weeks.^{44,45} Denosumab was superior both in delaying the time to the first on-study “skeletal-related events” (fracture, radiation to bone, surgery to bone, or spinal cord compression) and delaying the time to the first-and-subsequent skeletal-related events. In patients with castration-resistant prostate cancer overall adverse event rates were similar, with hypocalcemia in 13% and 6% of denosumab- and zoledronate-treated patients, respectively, and osteonecrosis of the jaw in 2.3% of patients receiving denosumab and 1.3% of patients treated with zoledronate ($p = 0.09$). While denosumab may garner US Food and Drug Administration approval for hypercalcemia associated with malignancy, it is not currently approved for this indication and data indicate its approval will have at best limited impact. A study of patients with advanced cancer and persistent hypercalcemia after incomplete response or relapse after recent bisphosphonate treatment found that while denosumab effectively lowered serum calcium in 80% of patients, the response was maintained a median of 26 days, compared within a median of 18 days after receiving the last dose of intravenous bisphosphonate.

CANCER-RELATED HEMOLYTIC UREMIC SYNDROME

General

The hemolytic uremic syndrome (HUS) is a microvascular disorder characterized histopathologically by disseminated microthrombi occluding the microvasculature. HUS is often associated

with the presence of large von Willebrand factor multimers capable of agglutinating circulating platelets. The hallmark of a Coombs-negative hemolytic anemia with an elevated schistocyte count results from fragmentation of erythrocytes as they pass through clogged arterioles. The disseminated microthrombi lead to ischemic organ damage, most commonly in kidneys and brain, with renal insufficiency, and a range of neurologic symptoms. Although thrombotic thrombocytopenic purpura and HUS represent a spectrum with considerable overlap, renal insufficiency invariably occurs in HUS but is often milder in thrombotic thrombocytopenic purpura, where neurologic symptoms often predominate.

Pathogenesis

In patients with cancer, HUS has been reported: (1) as a manifestation of the cancer itself, (2) as a complication of chemotherapy, (3) in the setting of bone marrow transplantation, and (4) more recently as a problem in patients receiving antibodies and immunotoxins. In untreated patients, HUS has been described primarily with disseminated cancer, although occasionally as a manifestation of occult or early cancers.^{47–49} While it has been reported more frequently with adenocarcinomas of the breast, lung, pancreas, prostate, and stomach, it has also been reported in patients with lymphomas as well as other malignancies.⁴⁷ In treated patients, a diverse group of chemotherapeutic agents have been implicated in the etiology of HUS. A 1986 review of chemotherapy-related HUS implicated mitomycin-C and 5-fluorouracil as the most frequent culprits.⁴⁹ Subsequent reports of gemcitabine-associated HUS reflect the widespread use of this agent.⁵⁰ Other agents that have been implicated in the etiology of this syndrome include bleomycin, cisplatin, cytosine arabinoside, daunomycin, deoxycytosine, estramustine, and methyl-CCNU. The incidence in patients undergoing bone marrow transplant is uncertain, given the difficulty in establishing a diagnosis.⁵¹

The clinical manifestations of fulminant HUS include the classic pentad of microangiopathic hemolytic anemia, thrombocytopenia, fever, rapidly progressive renal failure, and neurological deficits. Acute respiratory distress syndrome can also develop in some patients. In this setting, a high mortality rate has been reported, because treatment is made even more difficult in a patient with a severe underlying disease. In some patients, a subacute presentation with microangiopathic changes, mild thrombocytopenia, and gradual deterioration of renal function has been described. The main differential is disseminated intravascular coagulopathy. In patients undergoing allogeneic stem cell transplantation, transplant-associated microangiopathy defined as hemolysis and RBC fragmentation, can be found in 25% to 38% of patients. Associated renal dysfunction and neurologic manifestations in patients with more severe forms of this syndrome demonstrate a spectrum of severity that may represent endothelial damage driven by donor-host interactions.⁵²

Therapy

A definitive treatment approach for cancer-associated HUS remains to be established.^{53–56} When a given therapy is implicated as causative, this should be discontinued. Blood pressure should be controlled. The value of steroids is uncertain precluding their routine use. Hemodialysis is indicated in patients with renal failure. Although the efficacies of therapeutic plasma exchange using fresh frozen plasma as the substitution fluid and of immunoadsorption chromatography are arguable,⁵⁶ either or both should be initiated promptly at diagnosis in all patients. These therapies may need to be continued for months. Cryosupernatant plasma has been reported to be at least as effective as fresh frozen plasma. Greater success can be expected in patients with smaller tumor burdens, or those in whom anticancer therapy is effective, and in cases where vigilance has led to an early diagnosis. Some have also suggested that treatment may be more efficacious when HUS occurs as a manifestation of the underlying cancer than as a complication of therapy.

123 Metastatic Cancer to the Brain

John H. Suh, Samuel T. Chao, David M. Peereboom, and Gene H. Barnett

INTRODUCTION

Brain metastases represent the most common neurologic complication of cancer and affect many patients with cancer. Historically, the outcome for most patients was quite poor. Advances in neuroimaging, neurosurgery, radiation oncology, medical oncology, and supportive care have allowed for earlier detection, better local treatment modalities, and strategies to mitigate potential complications, which have improved survival and quality of life for these patients. As a result, the management of brain metastases has become complex and controversial given the array of treatment options that are currently available.

Epidemiology

The true incidence of brain metastases, which develops in nearly 30% of patients with cancer,¹ is not known although autopsy estimates are as high as 170,000 cases annually in the United States.² Brain metastases can be diagnosed at the same time or within 1 month of primary diagnosis, which occurs in about one-third of cases³ (synchronous) or after the primary tumor has been diagnosed (metachronous). An estimated 30% to 40% of patients present with a solitary lesion, which is defined as a single brain metastasis without any evidence of extracranial disease and controlled primary.⁴ Cancers of the lung and breast, which represent 50% and 15-20% of cases, respectively, are the most common primary tumors that spread to the brain.

Clinical Presentation

The clinical presentation can vary widely and may include headache, motor weakness, sensory disturbance, nausea and/or vomiting, cranial nerve abnormalities, change in mental status, seizures, ataxia, speech difficulties, and coordination abnormalities. Historic data from the 1970s to early 1990s showed that 10% of patients diagnosed by computed tomography (CT) or magnetic resonance imaging (MRI) were asymptomatic.⁵ Because screening scans are more frequently performed and imaging modalities are more sensitive, most likely an increasing percentage of today's patients present with asymptomatic disease.

Recently, a great deal of attention has been focused on the potential neurocognitive effects of whole-brain radiation therapy (WBRT), which had not historically been examined given the focus on survival rather than quality of life and given the poor outcomes of these patients. The majority of patients have neurocognitive deficits prior to the initiation of WBRT⁶⁻⁸ with a comprehensive phase 3 trial reporting that >90% of patients have some decline in neurocognitive function (NCF) prior to WBRT.⁷ NCF is typically tested with a battery of tests, as listed in Table 123.1. Tumor regression after WBRT appears to correlate with improved NCF.⁹

Imaging and Diagnosis

Imaging is very important in the diagnosis of brain metastases. Although CT scans may be useful in diagnosis, the imaging modality of choice is an MRI as it is more sensitive than CT for determining the number, distribution, and size of lesions.¹⁰ The detection of brain metastases may increase after the use of triple dose contrast.¹¹ Typically, brain metastases are solid or ring enhancing lesion(s), pseudospherical in shape, multiple in number, occur in the grey-white junction,¹² and occur most frequently in the cerebral hemispheres (80%) followed by the cerebellum (15%) and brain stem (<5%). Hemorrhagic lesions are seen more commonly with germ cell tumors, melanomas, thyroid carcinoma, choriocarcinoma, and renal cell carcinoma. In addition, the leptomeninges can also be involved. The differential diagnosis includes nonmalignant causes such as abscess, infection, demyelination and hemorrhage, and primary brain tumors. If uncertainty exists regarding diagnosis, biopsy or surgery should be performed to confirm diagnosis. For patients with known cancer, restaging scans, which typically include CT scan with and without contrast of the chest, abdomen, and pelvis, should be performed to assess primary and extracranial disease status. The use of fluorodeoxyglucose positron emission tomography alone as the only imaging modality of the brain is not recommended given the high background metabolic use of glucose by the brain.¹³ After surgery, postoperative MRIs should be done within 48 hours to differentiate tumor recurrence versus blood. For patients undergoing stereotactic radiosurgery (SRS), the MRI changes can be variable with approximately one-third of lesions experiencing a transient increase in tumor volume.¹⁴ Using diffusion tensor imaging, regional variation in white matter changes can be seen after WBRT, particularly in the inferior cingulum, corpus callosum, and fornix.¹⁵

Recently, the Response Assessment Working Group, an independent, international, collaborative effort, provided suggestions on the design of trials in patients with brain metastases with emphasis on radiographic response.¹⁶ In addition, the Response Assessment Working Group provided guidelines on neurocognitive, neurologic, and quality-of-life outcomes for patients with brain metastases.¹⁷ The criteria for response rates for patients with brain metastases have been variable between Response Evaluation Criteria in Solid Tumors,^{18,19} World Health Organization (WHO),²⁰ and those used for high-grade gliomas.^{21,22}

Prognosis

As the overall survival for patients with brain metastases remains poor, the use of prognostic scales helps to guide therapies. One of the earliest and most useful prognostic scales was based on 1,200 patients from three consecutive Radiation Therapy Oncology Group (RTOG) phase 3 brain metastases trials from 1979 to 1993.²³ Using recursive partitioning analysis (RPA), three well-defined

TABLE 123.1

Neurocognitive Battery of Tests Used in Many Modern Cooperative Group, Consortia, and Industry-Led Trials^a

Assessment	Domain(s) Tested	
Hopkins verbal learning test-revised	Learning and memory	Test administrator needed. Patient is read a list of words and then asked to verbally repeat the list and identify the words from a word list.
Trail making test, part A and B	Processing speed and executive function	Trained administrator needed. Both parts of the trail making test consist of 25 circles consisting of numbers or letters distributed on a sheet of paper. Patients are asked to draw lines to connect the circles in an ascending pattern.
Multilingual aphasia examination and controlled oral word association	Verbal fluency and executive function	Trained administrator needed. Patients are asked to produce words related to specific letter cues.

^aTime to complete the entire battery is typically 25 to 30 minutes. Trained administrators (e.g., research coordinator or other study staff) can give the tests. A study neuropsychologist should be involved in the study design and data analysis; however, an onsite neuropsychologist is not needed for test administration. From Lin NU, Wefel JS, Lee EQ, et al. Challenges relating to solid tumour brain metastases in clinical trials, part 2: Neurocognitive, neurological, and quality-of-life outcomes. A report from the RANO group. *Lancet Oncol* 2013;14:407–416, with permission.

prognostic groups (RPA class I, II, and III) were identified based on age (<65 or 65 and older), Karnofsky performance status (KPS) of ≥ 70 or <70, absence or presence of extracranial metastases, and primary tumor status (Fig. 123.1A).

To develop a less subjective and more quantifiable prognostic system, the graded prognostic assessment (GPA) was developed by analyzing data from five RTOG studies.²⁴ The GPA, which is stratified into four prognostic groups, is the sum of scores (0, 0.5, or 1.0) based on age, KPS, presence of extracranial metastases, and number of brain metastases (Fig. 123.1B). Given the heterogeneity of outcomes for patients based on tumor type, an updated diagnosis-specific (DS) GPA was developed by combining the databases from 11 institutions, which was the basis for a summary report on 3,940 patients²⁵ (Fig. 123.1C). Because patients with breast cancer have the best overall survival based on DS-GPA, further stratification incorporates biomarkers such as estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor 2 (HER2) status.²⁶ With advances in the understanding of tumor heterogeneity mediated by biomarkers (e.g., B-raf mutations in melanoma; epidermal growth factor receptor mutations in non-small-cell lung cancer [NSCLC]), molecular features will become more important in assessing the prognosis of patients with brain metastases.

An internally validated prognostic nomogram for survival estimates was developed for 2,367 patients based on seven RTOG randomized trials.²⁷ The best-fitting model was the Cox proportional hazards survival model, which included primary site and histology, primary disease status, extracranial spread, age, KPS, and number of lesions. The 12-month survival for each RPA class or DS-GPA group varied.

Symptom Management

Corticosteroids

As brain metastases can cause peritumoral edema, corticosteroids are frequently used to help temporarily control brain edema. Dexamethasone, which has low mineralocorticoid effect, is typically used given its long half-life. Based on a prospective randomized trial of patients who were not in danger of cerebral herniation, higher dose (16 mg/day) demonstrated no advantage compared to lower dose (4 mg or 8 mg/day) dexamethasone.²⁸ Patients receiving higher doses of dexamethasone had more frequent side effects. Common acute side effects may include insomnia, increased appetite, gastritis, fluid retention, mood swings, acne, and elevation of blood sugars. Long-term side effects may include weight gain, facial plethora, pedal edema, immunosuppression, proximal muscle myopathy, cataract formation, aseptic necrosis of the femoral head, and osteoporosis.

Because most brain metastasis trials have not assessed steroid use as endpoints, much controversy exists regarding specific indications and dosing.²⁹ For patients who are neurologically asymptomatic, routine use of corticosteroids is not necessary.^{30,31} For patients with more severe symptoms from increased intracranial pressure, doses of 16 mg/day or higher should be considered.³² If possible, steroids should be tapered within 1 week of initiation and discontinued within 2 weeks.³¹ When tapering dexamethasone, it is important to recognize withdrawal symptoms such as headaches, lethargy, weakness, dizziness, anorexia, diffuse arthralgias, and myalgias. To better understand the therapeutic ratio of corticosteroids, future studies should require better control and record keeping of steroid dose for analysis of response to therapy.³³

Anticonvulsants

Although seizures are the presenting symptom in 10% of cases and can occur in up to 25% of patients with brain metastases,³⁴ the role of antiepileptic drugs (AED) in patients with brain metastases has very limited class I evidence.³⁵ One study of 100 patients with newly diagnosed brain tumors (60 with brain metastases) and no history of prior seizures randomized patients to AEDs versus no AEDs.³⁶ The primary end point was seizure occurrence at 3 months post-randomization. The trial was terminated early as the seizure rate was only 10%, which was lower than the anticipated rate of 20%.

Given the lack of class I evidence, guidelines on the use of anticonvulsants for patients with metastatic brain tumors have been established.^{37,38} For patients without seizures, prophylactic use of AEDs is not recommended. Patients who present with seizures or who develop seizures during therapy should receive AEDs, preferably with agents that do not interact with hepatic cytochrome P450 (e.g., levetiracetam). For patients on dexamethasone, phenytoin levels can be affected by its use. In addition, phenytoin can affect clearance of chemotherapy agents and also can cause Stevens Johnson syndrome, which may be precipitated if radiation is used.³⁹ The use of anticonvulsants after surgery is controversial given results of a recent study.⁴⁰

Venous Thromboembolism

Because patients with brain tumors and thromboembolism are believed to be at higher risk for intracranial hemorrhage with anticoagulation, guidelines were established by the American Society of Clinical Oncology for prophylaxis and treatment of venous thromboembolism in patients with cancer.⁴¹ Low-molecular weight heparin is recommended for prophylaxis of hospitalized and higher-risk ambulatory patients given the minimal monitoring of coagulation and rare chance for major bleeding episode.⁴²

RPA Class	Characteristics	Median Survival (mo)
I	KPS \geq 70, age < 65, primary controlled, no extracranial metastases	7.1
II	All others	4.2
III	KPS < 70	2.3

	0	0.5	1
Age	>60	50–59	<50
KPS	<70	70–80	90–100
# of brain metastases	>3	2–3	1
Extracranial metastases	Present	–	None

C

Figure 123.1 (A) Recursive partitioning analysis class based on analysis of 1,200 patients treated on three consecutive Radiation Therapy Oncology Group trials conducted between 1979 and 1993, testing several different fractionation schemes and radiation sensitizers. Modified from Gaspar L, Scott C, Rotman M, et al. Recursive partitioning analysis (RPA) of prognostic factors in three radiation therapy oncology group (RTOG) brain metastases trials. *Int J Radiat Oncol Biol Phys* 1997;37:745–751, with permission.) (B) Graded prognostic assessment (GPA) based on analysis of 1,960 patients from five Radiation Therapy Oncology Group studies. (From Sperduto PW, Berkey B, Gaspar LE, et al. A new prognostic index and comparison to three other indices for patients with brain metastases: An analysis of 1,960 patients in the RTOG database. *Int J Radiat Oncol Biol Phys* 2008;70:510–514, with permission.) (C) Updated diagnosis-specific graded prognostic assessment based on combining the databases from 11 institutions of 3,940 patients. Karnofsky performance status (KPS), extracranial metastases (ECM), BM (brain metastases). Basal: triple negative; LumA: ER/PR positive, HER2 negative; LumB: triple positive; HER2: ER/PR negative, HER2 positive. ECM, extracranial metastases; ER, estrogen receptor; HER2, human epidermal growth factor receptor 2. (From Sperduto PW, Kased N, Roberge D, et al. Summary report on the graded prognostic assessment (GPA): An accurate and facile diagnosis-specific tool to estimate survival, guide treatment and stratify clinical trials for patients with brain metastases. *J Clin Oncol* 2012;30:419–425.)

Protamine can be used to reverse low-molecular weight heparin in an emergency. For patients with brain tumors and venous thromboembolism, anticoagulation is indicated unless the patient has had an intracerebral bleed or other contraindication for anticoagulation.⁴¹ The insertion of an inferior vena cava filter is an alternative but is associated with a higher risk of thrombosis distal to the filter.⁴³

Treatment Options

The optimal management of brain metastases is very controversial given the many factors that influence outcomes, the many modalities available, and the strong opinions that proponents of various treatment modalities have regarding the benefits and risks.⁴⁴ Even when “experts” are asked to provide guidance on treatment options, the management recommendations can vary widely.^{45,46} The National Comprehensive Cancer Network guidelines for the treatment of brain metastases are not specific as they allow for physician discretion.⁴⁷ The guidelines for WBRT, surgery, and radiosurgery for brain metastases by the American Association of Neurological Surgeons and Congress of Neurological Surgeons are more prescriptive, but also allow for flexibility.⁴⁸⁻⁵⁰

Whole-Brain Radiation Therapy

WBRT has been the standard treatment for patients with brain metastases since the initial reports from the 1950s.⁵¹ Because WBRT is widely available, is easy to deliver safely and accurately, is effective in providing palliation for the majority of patients, and does not require sophisticated technologies, it has long been considered the gold standard for treatment of brain metastases and represents the most common treatment modality worldwide. Symptomatic improvement has been poorly assessed and is variable. As the response to WBRT is best among patients with small-cell lung cancer, lymphoma, and germ cell tumors, these tumor types are generally excluded from clinical trials due to the relative radiosensitivity of these histologies.

The RTOG has completed numerous phase 3 trials evaluating various fractionation and dose schemes.⁵²⁻⁵⁵ These trials have shown that the majority of patients have partial or complete response of their neurologic symptoms, which range from 40% to 70%, and median survival that averages 3 to 5 months. Extended or hypofractionated WBRT has not shown benefit in terms of survival. As result, the most commonly used fractionation schemes in the United States are 30 Gy in 10 fractions or 37.5 Gy in 15 fractions. For patients with poor prognosis, shortened fractionation schemes of 20 Gy in 5 fractions can be used. Based on an international practice survey of 445 individuals, Tsao et al.⁵⁶ reported that 20 Gy in 5 fractions rather than 30 Gy in 10 fractions was preferred fractionation scheme in Canada and Australia/New Zealand. This practice survey also revealed that 88% chose comfort measures for patients previously treated with WBRT and now presented 6 months later with two to four brain metastases all <4 cm in size with poor performance. Seventy-eight percent would use WBRT alone for two to four brain metastases for patients with uncontrolled extracranial disease and KPS of 70. The Medical Research Council has an ongoing trial (QUARTZ) that randomizes patients with inoperable brain metastases from NSCLC to supportive care with dexamethasone versus WBRT and dexamethasone.

The imaging response rates or stabilization of tumors after WBRT are quite variable and can range from 0% to 71%.^{57,58} Nieder et al.^{59,60} studied the CT responses in 108 patients with 336 measurable lesions following WBRT (30 Gy in 10 fractions) and found the overall response rate at up to 3 months was 59% (lesion complete response rate of 24%, partial response rate of 35%).⁵⁹ The complete response rates varied by histology and were 37% for small cell carcinoma, 35% for breast cancer, 25% for squamous cell carcinoma, 14% for nonbreast adenocarcinoma, 0% for renal cell carcinoma, and 0% for melanoma. Smaller tumor volumes and absence of

necrosis influenced complete response rates. Higher response rate was obtained with 40 Gy at 2 Gy per fraction with or without a partial boost to 50 or 60 Gy compared with 30 Gy at 3 Gy per fraction.⁶⁰

The most common side effects that occur during or shortly following WBRT include hair loss, mild skin erythema, and fatigue. Other side effects may include headache, nausea, vomiting, loss of appetite, change of taste, serous otitis, and somnolence. Secondary to the effect of opposed tangential radiation beams on skin sparing, hair loss is variable and may be permanent in the top and back of the scalp. Skin reactions typically resolve after several weeks, and fatigue usually improves after 2 to 3 months and may respond to methylphenidate. The long-term and frequency of side effects from WBRT have not been well documented as they were discounted given the short survival of these patients. Long-term side effects may include somnolence, fatigue, hearing loss, memory loss, and, in rare cases, dementia.

Two approaches to minimize the neurocognitive effects of WBRT include innovations in radiation delivery and use of medications. RTOG 0933 was a phase 2 trial evaluating hippocampal avoidance-WBRT (HA-WBRT) for 100 evaluable patients with brain metastases.⁶¹ As the hippocampus dentate gyrus is thought to house neural stem cells responsible for memory, HA-WBRT using intensity-modulated radiation therapy minimizes dose to this stem cell compartment (<10 Gy). Results from this study demonstrated a 7% decline in delayed recall versus 30% from historical study ($p = 0.0003$). RTOG 0614 was a phase 3 trial that randomized 554 patients to WBRT (3,750 cGy in 15 fractions) with or without memantine, an N-methyl-D-aspartate receptor antagonist used for patients with mild to moderate Alzheimer disease.⁶² The memantine arm had significantly longer time to cognitive decline ($p = 0.02$), lower median decline on Hopkins Verbal Learning Test-Revised (0 in memantine arm versus -2 in placebo arm at 24 weeks; $p = 0.059$), and fewer patients with decline in Controlled Oral Word Association at 16 weeks ($p = 0.004$) or Trail Making Test Part A at 24 weeks ($p = 0.014$). No difference in overall survival and progression-free survival between the two arms was seen. Based on the results of these trials, a phase 3 study with memantine and HA-WBRT is planned.

Prophylactic Cranial Irradiation

Because patients with small-cell lung cancer (SCLC) have a high propensity to develop brain metastases, prophylactic cranial irradiation (PCI) is commonly used to prevent dissemination to the brain especially for patients who achieve a complete response to induction chemotherapy. The Prophylactic Cranial Irradiation Overview Collaborative Group reported the outcomes in seven previously published PCI trials for patients with complete response to systemic therapy and demonstrated a statistically significant survival advantage favoring the patients treated with PCI and significant reduction in the incidence of new brain metastases from 58.6% to 33.3% at 3 years.⁶³ Another meta-analysis of PCI efficacy reviewed 12 randomized trials and included 5 studies that evaluated the role of PCI in patients with SCLC who had a complete response after induction chemotherapy.⁶⁴ A significant decrease in the incidence of brain metastases was noted when all studies were considered and improvement in survival when PCI was given only to patients who experienced a complete systemic response. A phase 3 international, intergroup study of patients with limited-stage SCLC in complete remission after chemotherapy and thoracic radiotherapy randomized patients to 25 Gy in 10 fractions, 36 Gy in 18 fractions, or 36 Gy in 24 fractions of PCI with the standard dose (25 Gy in 10 fractions) being the recommended fractionation for PCI given the significantly higher risk for mortality seen in the higher dose arms.⁶⁵ For extensive-stage patients, 286 patients were randomized to WBRT or observation.⁶⁶ The primary end point was development of symptomatic brain metastases, which was decreased with PCI. In addition, PCI increased overall survival at 1 year from 13.3% to 27.1% ($p = 0.003$) and 1-year

disease-free survival from 14.6% in the observation group to 40.4% in the treatment group ($p < 0.001$).

The cognitive effects of PCI in patients with SCLC were prospectively studied in 300 patients with SCLC controlled systemically who either received PCI or were observed.⁶⁷ Neurocognitive assessment from baseline and 2 years after PCI revealed no significant difference in cognitive status between the observation and PCI-treated cohorts. Another study demonstrated similar results in 136 patients seen at 1 year posttreatment.⁶⁸

RTOG 0214 randomized patients with stage III NSCLC without disease progression after treatment with surgery and/or radiation therapy with or without chemotherapy to PCI (30 Gy in 15 fractions) or observation.⁶⁹ The primary end point of the study was overall survival. Unfortunately, the study closed early secondary to slow accrual. The 1-year overall survival and disease-free survival were not significantly different. The 1-year rates of development of brain metastases were significantly less for PCI at 7.7% versus 18.0% for observation ($p = 0.004$). Recently, the impact of PCI on self-reported cognitive functioning and Hopkins Verbal Learning Test were analyzed based on the results of RTOG 0214 and RTOG 0212.⁷⁰ At 6 and 12 months, a significant decline in self-reported cognitive functioning and Hopkins Verbal Learning Test was noted after PCI.

Radiation Sensitizers and Modifiers

Given the poor outcomes with WBRT alone, radiation sensitizers have been explored to improve the therapeutic ratio between tumor and normal tissues. Mehta et al.⁶ reported on survival and neurologic outcomes in a randomized trial of WBRT (30 Gy in 10 fractions) with or without daily injections of motexafin gadolinium, a redox modulator.⁶ Based on the results of subset analysis for NSCLC, a confirmatory trial was performed that showed no significant difference in time to neurologic progression.⁷¹ Suh et al.⁷² reported on results of phase 3 randomized trial comparing WBRT (30 Gy in 10 fractions) and supplemental O₂ with WBRT following daily injections of RSR-13 (efaproxiral), an allosteric modifier of hemoglobin.⁷² The phase 3 trial showed no significant difference in overall survival between the arms, although the breast subset appeared to do better. Confirmatory phase 3 trial of 360 women with brain metastases from breast cancer showed no survival improvement with RSR-13 and WBRT.⁷³ A phase 3 trial from the RTOG evaluating thalidomide and WBRT demonstrated no survival benefit over WBRT alone.⁷⁴

Surgery

Surgery plays an important role for some patients with brain metastases as it can provide immediate and effective relief from symptomatic mass effect and can confirm or establish the diagnosis, which is important for those patients who have unknown primary. In addition, patients with larger tumors (diameter >2 cm) may also benefit from surgery more than other treatment modalities. Advances in imaging and image guidance have improved the rates for complete resection.⁷⁵ Some of these advances include accurate localization with MRI and CT with stereotaxis, intraoperative imaging with ultrasound, mapping of the important cortices to determine brain function, and fiber tract mapping to avoid damage to important neural pathways to maintain or improve quality of life.

The type of surgical resection also appears to influence the rate of local recurrence. A retrospective review from MD Anderson Cancer Center of 570 patients undergoing surgical resection alone demonstrated that piecemeal resection compared with en bloc resection significantly predicted for higher local recurrence compared to en bloc surgery (hazard ratio = 1.7; $p = 0.03$).⁷⁶ Larger tumor volume exceeding 9.71 cm³ compared with smaller tumors also predicted for higher local recurrence (hazard ratio = 1.7; $p = 0.02$). Histologic subtype did not predict for local recurrence. The rate of leptomeningeal dissemination also appears to be higher after

piecemeal rather than en bloc resection of metastases, although larger tumors cannot always be removed without some internal decompression.^{77,78} A predisposition for leptomeningeal spread is also seen for surgical resection of metastases of the posterior fossa.⁷⁹ For patients with multiple brain metastases, no strong comparative data exists regarding the role of surgery for these patients,⁴⁹ but a retrospective report from Bindal et al.⁸⁰ showed that survival for patients with multiple metastases where all were surgically removed was equivalent to that of surgery for a single removed lesion and superior to those where some lesions were not removed.

Whole-Brain Radiation Therapy with or without Surgery

The first phase 3 study from the University of Kentucky randomized 48 patients with a single brain metastasis to surgical resection and WBRT versus needle biopsy and WBRT (36 Gy in 12 fractions).⁸¹ The addition of surgery to WBRT significantly improved survival (40 weeks versus 15 weeks, $p < 0.01$), local control (80% versus 48%, $p < 0.02$), and functional independence (38 weeks versus 8 weeks, $p < 0.005$) compared to biopsy and WBRT. Younger age, no extracranial disease, surgical resection, and longer interval from primary diagnosis to diagnosis of brain metastasis were associated with longer survival. The majority of these patients had NSCLC.

The second phase 3 study from Noordijk et al.⁸² randomized 63 patients with CT-confirmed brain metastasis to surgical resection and WBRT versus WBRT (40 Gy in 20 fractions). Surgery and WBRT improved median survival (10 months versus 6 months; $p = 0.04$) and functional independence (7.5 months versus 3.5 months; $p = 0.06$) over WBRT alone. Patients with active extracranial disease had no survival benefit with surgery (5 months in each arm). Patients without active extracranial disease had significantly improved median survival in the surgery arm (12 months versus 7 months).

Another phase 3 trial from Mintz et al.⁸³ showed no benefit for surgical resection and WBRT (30 Gy in 10 fractions) compared to WBRT alone in 84 randomized patients in terms of survival, 30-day mortality, morbidity, or causes of death. The presence of extracranial metastases was an important predictor of mortality (relative risk = 2.3). Unlike the other two randomized trials, a greater percentage of patients had active systemic disease, had lower baseline KPS, and had several gastrointestinal primary tumors in each group.

Surgery with or without Whole-Brain Radiation Therapy

The role of WBRT following surgical resection was addressed in a phase 3 randomized study of 95 patients who had single metastasis to the brain.⁸⁴ After gross total resection, patients were randomized to observation versus a protracted course of WBRT (50.4 Gy in 28 fractions). The primary end point was tumor recurrence in the brain with secondary end points of survival, cause of death, and functional independence. The addition of WBRT to surgery decreased the chance for neurologic death (14% versus 44%, $p = 0.003$), decreased local recurrence (10% versus 46%, $p < 0.01$), and decreased tumor recurrence anywhere in the brain (18% versus 70%, $p < 0.001$). The majority of patients (61%) received WBRT at time of recurrence, which resulted in a large crossover of the observation arm to WBRT. Survival was not different, although the study's end point was local control and was not powered to demonstrate a survival advantage.⁸⁵

Kocher et al.⁸⁶ reported the results of a phase 3 European Organisation for Research and Treatment of Cancer study of 359 patients comparing SRS (199 patients) or surgery (160 patients) with or without WBRT.⁸⁶ The primary end point for this study was time to deterioration of WHO performance status >2. Survival and time to WHO performance status deterioration >2 were not different between the two arms. At 2 years after surgery, WBRT

significantly decreased the risk of local and new brain relapse from 59% to 27% ($p < 0.001$) and 42% to 23% ($p < 0.008$), respectively.

Due to the previously discussed concerns of the impact of WBRT on NCF, the use of SRS to the tumor bed has recently gained favor despite lack of class I evidence and is discussed later in this chapter.

Stereotactic Radiosurgery

Unlike WBRT, SRS delivers high dose(s) of ionizing radiation to focal target(s) while minimizing the dose to surrounding brain tissue. Although the concept of SRS dates back to the 1950s, this treatment option did not gain acceptance for many years.⁸⁷ Brain metastases have features that make them ideal targets for SRS, which include pseudospherical shape, location in the gray-white junction, and maximum diameter of <4 cm. In addition, the vast majority of brain metastases have distinct pathologic and radiographic margins, which allows for clear delineation of the target.⁸⁸ All of these characteristics allow for accurate target delineation, planning, and treatment delivery through the use of multiple intersecting radiation beams, which produce steep dose gradients (“dose falloff”). The linear accelerator, cobalt-60–based units (Gamma Knife; Elekta AB, Stockholm, Sweden), and proton beam unit represent the different types of devices used for SRS. Table 123.2 lists the advantages for SRS and surgery.

Since the 1990s, numerous institutional and multi-institutional studies have been published on the results of SRS as a primary, adjuvant, and salvage treatment for brain metastases. When prescribing doses of 15 to 24 Gy, the local control rates range from 70% to 95%.^{89–92} Freedom from local progression depends on dose, volume, histology, and pattern of MRI or CT enhancement at the time of radiosurgery.^{93,94} In addition, SRS is effective for all types of primary tumor including radioresistant histologies such as melanoma and renal cell carcinoma.^{95,96} The ideal candidate for SRS is subject of debate, but generally consists of patients with controlled or absence of extracranial metastases and excellent KPS. Historically, the number (one to four) of brain metastases was considered a general contraindication, although recent publications refute this.^{97–99}

To study the relationship between maximum tolerated radiosurgery dose and maximum diameter of the tumor, RTOG 9005 was a phase 1/2 trial for patients with recurrent primary and metastatic brain tumors.¹⁰⁰ The maximum tolerated doses for >2 cm to 3 cm and >3 cm to 4 cm were 18 Gy and 15 Gy, respectively; maximum tolerated dose was not reached for tumors ≤ 2 cm given the reluctance to dose escalate beyond 24 Gy. Because the risk of radiation injury increases with increasing tumor volume and diameter,

doses for brain metastases are inversely proportional to the maximum tumor diameter or volume. As a result, the local control rates for smaller targets are generally higher than larger targets, especially when WBRT is not part of the management strategy.¹⁰¹ As the dose falloff is not as sharp for larger targets, which resulted in higher dose to normal brain tissues, radiosurgery targets are usually limited to maximum diameter of 4 cm. Recently, staged radiosurgery with repeat dose 3–4 weeks after initial treatment has been explored prospectively for larger lesions.¹⁰²

Because the head frame is minimally invasive, there has been growing interest in frameless radiosurgery to allow for fractionation (two to five fractions). This may be helpful for larger tumors and those close to critical structures such as the optic apparatus. The results with frameless radiosurgery appear equivalent to frame-based radiosurgery, although the total number of treated patients is still limited.^{103–107} For radioresistant tumors, fractionated SRS may be less effective than single-fraction SRS.¹⁰⁸

Unlike WBRT, SRS increases the risk for radiation necrosis, which can lead to significant side effects such as steroid dependency. As radiation necrosis can closely mimic tumor recurrence, the diagnosis and treatment of radiation necrosis can be very difficult.¹⁰⁹ A recent questionnaire regarding practice patterns for diagnosis and treatment of intracranial radiation necrosis after SRS revealed variation in the management of steroid refractory radiation necrosis.¹¹⁰ Figure 123.2 shows a sequence of images from diagnosis, after SRS, images confirming radiation necrosis, and resolution of radiation necrosis after treatment. Figure 123.3 shows an algorithm that we use to diagnose and treat radiation necrosis. In terms of imaging, cerebral blood volume can have high sensitivity and specificity.¹¹¹ Based on a double-blind, placebo-controlled phase 3 trial, the use of bevacizumab is the therapy with the best supported evidence for patients who are refractory to steroids.¹¹² One novel approach for treatment of steroid refractory radiation necrosis that is being explored is focused laser interstitial thermal therapy.¹¹³

Stereotactic Radiosurgery Versus Surgery

Several attempts at phase 3 trials comparing surgery to SRS have been done with little success. In the 1990s, the Joint Center for Radiation Therapy in Boston attempted to enroll patients onto a phase 3 trial comparing surgery to SRS and enrolled only six patients after 3 years due to patient or physician preference.¹¹⁴ A prospective randomized trial from Germany compared SRS alone versus surgery and WBRT for patients with a single metastasis.¹¹⁵ Unfortunately, this study closed early due to poor accrual with 33 patients in the surgery and WBRT arm, and 31 patients in the SRS alone arm. Overall survival, neurologic death, and local recurrence were equivalent. Shorter hospitalizations, less steroid treatment, and lower central nervous system (CNS) grade 1 and 2 toxicities were noted in the patients treated with SRS. Patients treated with SRS alone developed more distant recurrences ($p = 0.04$); however, this difference was lost after adjusting for salvage SRS. Another prospective randomized trial of surgery versus radiosurgery for patients with a single brain metastasis who were considered eligible for either treatment was performed at MD Anderson Cancer Center.¹¹⁶ A total of 59 patients were entered into the randomized arm (30 underwent surgery and 29 SRS), and 155 patients were entered into the nonrandomized arm (89 chose surgery and 66 chose SRS). Although the results demonstrated higher local recurrence with SRS alone, the statistical analyses used in this study are controversial. However, as radiosurgery was usually effective, SRS remains their primary management approach with surgery as salvage.¹¹⁷

Whole-Brain Radiotherapy with or without Stereotactic Radiosurgery

The first randomized trial of WBRT (30 Gy in 12 fractions) with or without SRS boost (16 Gy) enrolled functionally independent patients with two to four brain metastases measuring ≤ 2.5 cm in

TABLE 123.2

Comparison of the Advantages for Surgery and Stereotactic Radiosurgery

Surgery	Stereotactic Radiosurgery
Treatment of larger lesion(s) (>4 cm diameter)	Treatment of small deep lesion(s) or eloquent areas
Immediate removal of mass effect and edema	Minimally invasive
Histologic confirmation	No general anesthesia use
Rapid taper of steroids for symptomatic lesions	Outpatient procedure
Removal of cancer	Treatment of multiple lesions at same session
Minimal risk for radiation necrosis	Short recovery time (<1 wk)
Less intensive follow-up	Potentially avoid whole-brain radiation therapy
Less long-term dependency on steroids	Rapid initiation of systemic therapies
	Fewer immediate complications

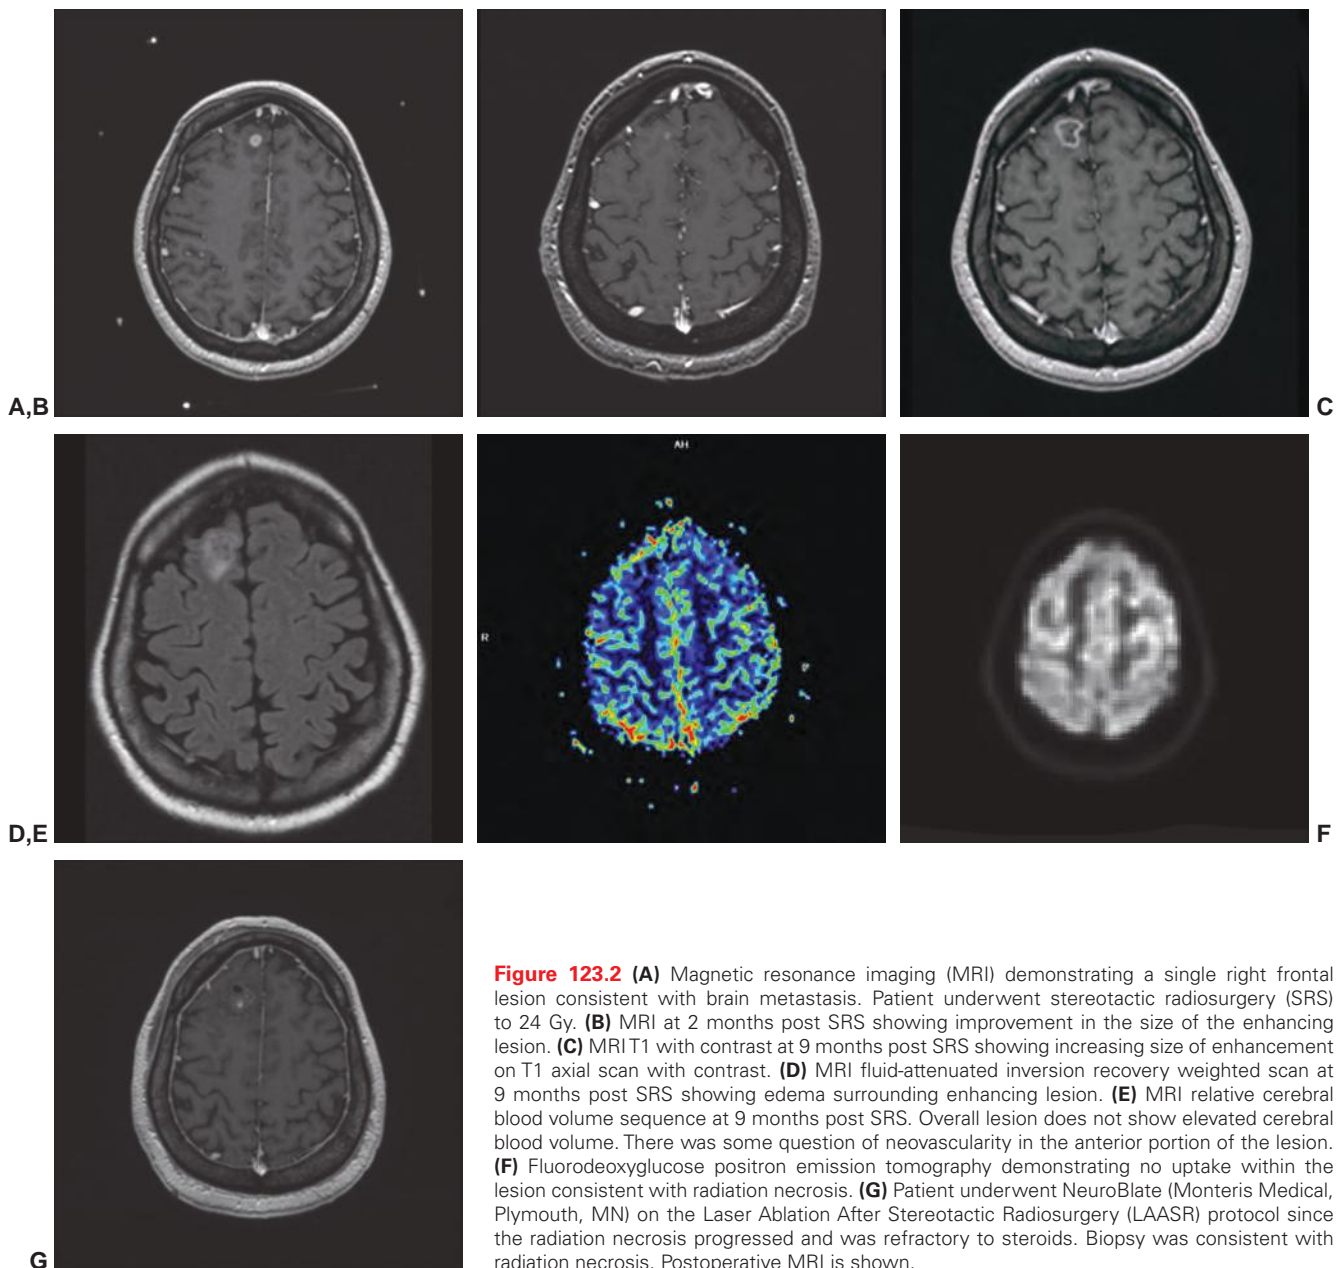

Figure 123.2 (A) Magnetic resonance imaging (MRI) demonstrating a single right frontal lesion consistent with brain metastasis. Patient underwent stereotactic radiosurgery (SRS) to 24 Gy. (B) MRI at 2 months post SRS showing improvement in the size of the enhancing lesion. (C) MRI T1 with contrast at 9 months post SRS showing increasing size of enhancement on T1 axial scan with contrast. (D) MRI fluid-attenuated inversion recovery weighted scan at 9 months post SRS showing edema surrounding enhancing lesion. (E) MRI relative cerebral blood volume sequence at 9 months post SRS. Overall lesion does not show elevated cerebral blood volume. There was some question of neovascularity in the anterior portion of the lesion. (F) Fluorodeoxyglucose positron emission tomography demonstrating no uptake within the lesion consistent with radiation necrosis. (G) Patient underwent NeuroBlate (Monteris Medical, Plymouth, MN) on the Laser Ablation After Stereotactic Radiosurgery (LAASR) protocol since the radiation necrosis progressed and was refractory to steroids. Biopsy was consistent with radiation necrosis. Postoperative MRI is shown.

diameter and >5 mm from the optic chiasm.⁵⁷ This trial enrolled only 27 patients secondary to early stopping rules. The two arms were well balanced with respect to known prognostic factors such as age, KPS, and extracranial disease status. The local control was 92% in the WBRT+SRS arm versus 0% in the WBRT arm ($p = 0.002$). Median survival was not significantly different in the two arms (7.5 months for WBRT versus 11 months for WBRT plus radiosurgery; $p = 0.22$).

The next trial, RTOG 9508, was a phase 3 trial of 333 patients with one to three newly diagnosed brain metastases who were randomized to WBRT (37.5 Gy in 15 fractions) with or without SRS boost using maximum doses from the RTOG 9005 trial.⁵⁸ Patients with brainstem or metastases located within 1 cm of the optic apparatus, RPA class III patients, and patients who had received systemic treatment within 1 month of enrollment were excluded. Median survival was significantly improved for patients with a single brain metastasis undergoing WBRT + SRS (6.5 months versus 4.9 months; $p = 0.039$) but not for patients with two or three lesions (5.8 months versus 6.7 months; $p = 0.98$). Patients in the SRS arm were more

likely to have stable or improved KPS through 6 months (43% versus 27%; $p = 0.03$) and better local control (82% versus 71%; $p = 0.01$). Neurologic death rate was similar in the two arms (approximately 34%). No survival advantage was noted based on type of radiosurgery unit used (linear accelerator versus Gamma Knife).

Since subset analysis from RTOG 9508 demonstrated benefit for patients with NSCLC, RTOG 0320 was a phase 3 trial of WBRT + SRS, WBRT + SRS + erlotinib, and WBRT + SRS + temozolomide.¹¹⁸ Primary end point was overall survival. Given poor accrual (126 of 381 patients), this study closed early and showed no significant survival advantage with the addition of erlotinib or temozolomide. The results suggested the best outcomes were achieved in the WBRT and SRS arm.

Stereotactic Radiosurgery with or without Whole-Brain Radiation Therapy

Arguably the greatest area of debate in the management of brain metastases is the routine use of WBRT.^{44,119} Sneed et al.¹²⁰ found

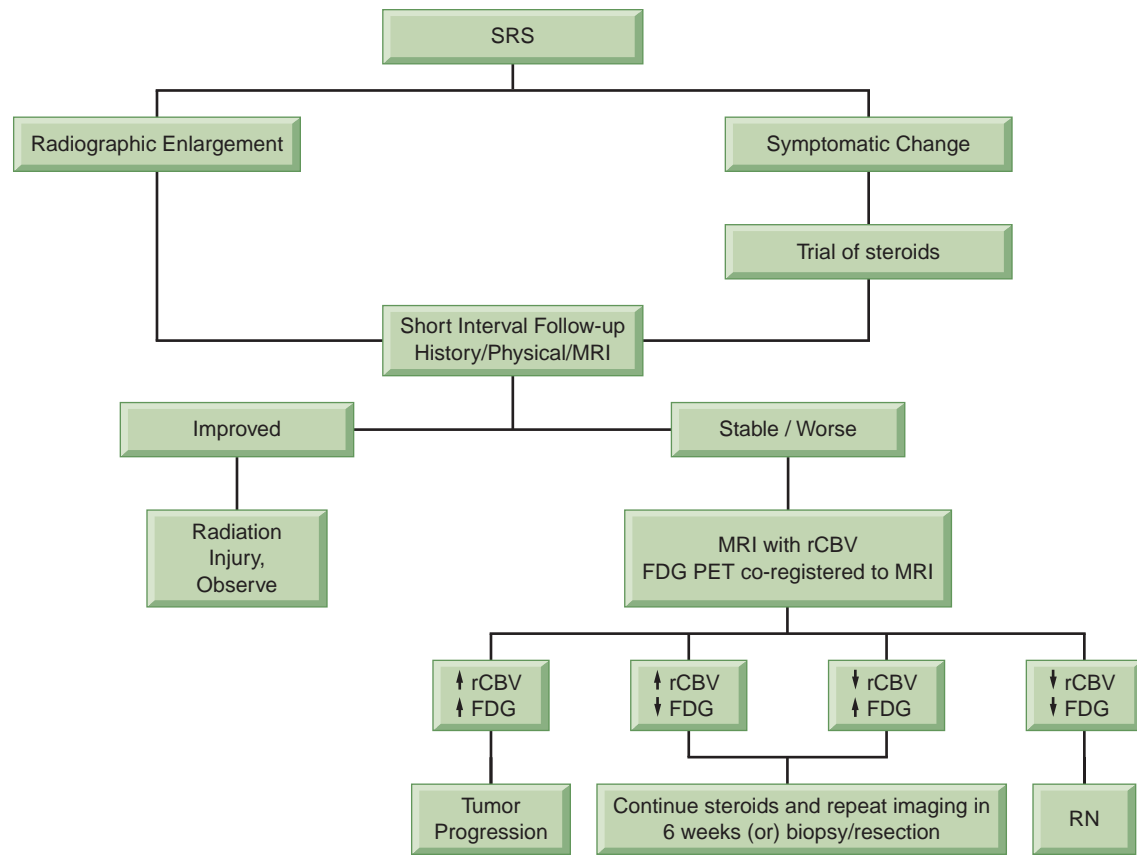

Figure 123.3 Algorithm for diagnosing and managing radiation necrosis at the Cleveland Clinic. SRS, stereotactic radiosurgery; MRI, magnetic resonance imaging; rCBV, regional cerebral blood volume; FDG, fluorodeoxyglucose; PET, positron emission tomography; RN, radiation necrosis. (From Chao ST, Ahluwalia MS, Barnett GH, et al. Challenges with the diagnosis and treatment of cerebral radiation necrosis. *Int J Radiat Oncol Biol Phys* 2013;87:449–457, with permission.)

that omission of WBRT in patients who received initial radiosurgery for up to four brain metastases did not compromise intracranial control, provided salvage therapy information was included in the actuarial outcome analysis, an analysis that is not usually reported. In a multi-institutional analysis, survival was substantially greater in patients who received SRS, with or without WBRT, compared to patients in the RTOG WBRT trials, for each of the three RPA classes.¹²¹

The Japanese Radiation Oncology Study Group conducted a randomized phase 3 trial of 132 patients with one to four brain metastases, each <3 cm in diameter.¹²² Patients were randomized to WBRT and SRS or SRS alone. The primary end point was overall survival. The median and 1-year actuarial survival rate were 7.5 months and 38.5% in the WBRT + SRS group and 8 months and 28.4% for SRS alone ($p = 0.42$), respectively. The 12-month brain tumor recurrence rate was significantly lower in the WBRT plus SRS group (46.8%) than the SRS alone group (76.4%) ($p < 0.001$). Salvage brain treatment was also less frequent in the WBRT plus SRS group compared to SRS alone. No significant differences in systemic and neurologic functional preservation, cause of neurologic death, and side effects of radiation between the two arms were demonstrated. When mini-mental state examination was examined in this study, the average duration until deterioration was 16.5 months in the WBRT and SRS group versus 7.6 months in the SRS alone group ($p = 0.05$), suggesting that control of the brain tumor was the most important factor for stabilizing NCF.¹²³

Chang et al.¹²⁴ published results of a randomized trial from the MD Anderson Cancer Center to examine NCF as the primary endpoint (Hopkins Verbal Learning Test-Revised) in patients who underwent SRS treatment with or without WBRT (30 Gy in

12 fractions). After accrual of 58 patients, the trial was stopped prematurely based on the early stopping rules because analysis determined that patients treated with SRS plus WBRT were at a greater risk of a significant decline in learning and memory function by 4 months, as shown by Hopkins Verbal Learning Test-Revised, compared with the group that received SRS alone. CNS recurrences were, however, significantly higher in the group receiving SRS alone; 73% of patients in the SRS + WBRT group were free from CNS recurrence at 1 year, compared with 27% of patients who received SRS alone ($p = 0.0003$), although the mortality was higher in the arm that received WBRT.

Kocher et al.⁸⁶ reported the results of a phase 3 European Organisation for Research and Treatment of Cancer study of 359 patients comparing SRS (199 patients) or surgery (160 patients) with or without WBRT. The primary end point for this study was time to deterioration of WHO performance status >2 . Survival and time to WHO performance status deterioration >2 were not different between the two arms. At 2 years after SRS, WBRT significantly decreased the risk of local and new brain relapse from 31% to 19% ($p = 0.04$) and 48% to 33% ($p = 0.008$), respectively. For all patients, the risk of neurologic death was more frequent in the observation versus the WBRT arm (44% versus 28%; $p < 0.002$).

The recently closed phase 3 intergroup trial led by the North Central Cancer Treatment Group (N0574) randomizing patients with one to three brain metastases to SRS alone or SRS and WBRT will provide additional information about the effect of SRS and WBRT on NCF. Table 123.3 summarizes the randomized trials of surgery or radiosurgery for patients with brain metastases.

Lal et al.¹²⁵ compared SRS alone versus SRS + WBRT for patients with three or fewer brain metastases, using actual life years saved (LYS), quality-adjusted life years, and incremental

cost effectiveness ratio. Compared to SRS with WBRT, SRS alone has a higher average cost (\$74,000 versus \$119,000, respectively). However, SRS alone has a higher average effectiveness of 1.64 LYS compared with combined SRS and WBRT (0.60 LYS). The authors conclude that SRS alone without WBRT is more cost-effective, even with salvage treatment delivered down the line.

Stereotactic Radiosurgery to Resection Cavity

Because patients undergoing surgical resection alone are at high risk for local recurrence, the use of radiosurgery rather than WBRT has been explored given the potential side effects of WBRT and the convenience of SRS.^{126,127} Choi et al.¹²⁸ reported that the 12-month cumulative incidence rates of LF with and without a 2-mm margin around the defined tumor bed were 3% and 16%, respectively ($p = 0.042$). For most patients, the greatest resection cavity volume change occurred immediately after surgery (postoperative days 0 to 3) with no significant volume change occurring up to 33 days after surgery.¹²⁹ Although the risk for leptomeningeal spread after SRS is low, patients with breast cancer histology has been found to have a higher rate of leptomeningeal spread.¹³⁰ The North Central Cancer Treatment Group, in collaboration with RTOG, has an ongoing phase 3 trial (RTOG 1270/N107C) of postsurgical SRS compared with WBRT for resected brain metastases for patients with four or fewer brain metastases. The resection cavity

must measure < 5 cm in maximal extent on the postoperative MRI (or CT) brain scan obtained ≤ 35 days prior to preregistration. The primary objective is whether there is improved overall survival in patients who receive SRS to the surgical bed compared to patients who receive WBRT. In addition, neurocognitive progression at 6 months postrandomization is being assessed.

Intraoperative Radiation Therapy and Brachytherapy to the Resection Cavity

Intraoperative radiation therapy has been investigated to decrease local recurrence after resection of brain metastases.^{131,132} Brachytherapy has also been investigated using high-activity iodine injected into double lumen balloon that is placed in the surgical cavity.¹³³ As both intraoperative radiation therapy and brachytherapy increases operating room time and may also increase complications such as radiation necrosis, neither technique has been widely adopted.

Salvage Therapy

A number of therapeutic options may be considered for salvage therapy. Given the various options that are available, the relative frequency of various combinations of first and second therapies are unavailable. If WBRT is given upfront and the patient later develops recurrence of brain metastases, the patient can be

safely salvaged with SRS. A retrospective study from Chao et al.¹³⁴ reviewed 111 patients treated from 1996 to 2004 who received SRS following failure from WBRT. Local control was 73% at a median time of 15.4 months. Median overall survival time was influenced by time from WBRT to recurrence. Repeat WBRT is not usually done as salvage for patients with better prognosis given concerns about the long-term effects of radiation. For patients with limited prognosis, lower doses and smaller fraction sizes, such as 20 to 25 Gy in 10 fractions or 30 Gy in 30 fractions (1 Gy twice a day), may be considered with outcomes are similar to that obtained following initial WBRT for RPA class II or III patients,^{135–137} with symptomatic improvement in most patients. Surgery is not often repeated, although reoperation can be considered for selected patients. Bindal et al.¹³⁸ reported median survival following reoperation of 11.5 months, no operative mortality or morbidity, and neurologic improvement in most patients (75%).

Chemotherapy

Although historically chemotherapy has not had a prominent role in the management of brain metastases, several advances have been made. One of the major challenges to success of chemotherapy has been that of drug delivery due to the presence of the blood–brain barrier (BBB).¹³⁹ This barrier is comprised of the tight junctions between endothelial cells that line cerebral capillaries. In general, two broad classes of drugs have the potential to cross the BBB. Lipid soluble molecules are able to traverse the endothelial cell membranes and cytosol to reach the brain tumor cell by passive diffusion.¹⁴⁰ Examples of such agents include carmustine or lomustine. Small molecules can pass through the tight junctions. In general, these molecules must be less than approximately 500 kDa.¹⁴⁰ Examples of such molecules are temozolomide and many “small molecule” targeted agents such as lapatinib and erlotinib.^{141–144} In addition, several drugs, such as bevacizumab, act on the abluminal side of the capillaries, obviating the need to cross the BBB in order to have activity.^{145,146}

Several other factors can limit access of drug to the brain tumor. Protein binding of molecules within the vascular space (e.g., imatinib) leaves only a small percentage of a compound as free drug to reach the tumor.¹⁴⁷ The BBB contains several drug efflux pumps, which reverse the movement of molecules across the barrier.¹⁴⁸ The Pgp drug transporter is probably the most prevalent of these pumps.¹³⁹ Finally, interstitial pressure within the tumor can create a mechanical barrier to convection of molecules toward the tumor.¹⁴⁹

While all interventions seek to improve survival, delay progression, and preserve or improve a patient's function and quality of life, several goals are unique to the use of chemotherapy for patients with brain metastases. These goals include the enhancement of efficacy of radiation therapy (radiosensitization), the delay for the need of radiation therapy, the simultaneous control of systemic disease, and the ability to address the entire brain parenchyma in patients who may already have received WBRT. One final goal is to treat the leptomeninges in the setting where intrathecal chemotherapy is likely to be ineffective (e.g., bulky leptomeningeal disease given the limited penetration of intrathecal chemotherapy into leptomeningeal deposits) or unsafe due to unpredictable cerebrospinal fluid (CSF) distribution (e.g., impaired CSF flow related to obstructive hydrocephalus). For example, high-dose intravenous methotrexate for the treatment of breast cancer brain and/or leptomeningeal disease can reach the CSF in cytotoxic concentrations.¹⁵⁰

The selection of patients appropriate to receive chemotherapy for brain metastases includes a number of considerations, especially in this setting where the goal is largely palliative. As with most interventions in oncology, the patient's performance status has a major impact on the likelihood that a patient might benefit from chemotherapy. The status of the patient's systemic disease matters—a patient whose systemic disease is uncontrolled is unlikely to benefit from a chemotherapy regimen intended for the

CNS. As an increasing number of agents becomes available for the treatment of a patient's systemic disease, the patient may have been heavily pretreated by the time CNS metastatic disease occurs. Thus end organ functional reserve, such as that of the bone marrow, must be evaluated carefully to ensure the safe administration of chemotherapy to such patients. The molecular phenotype of the patient's tumor must be considered as it can have a significant impact on prognosis and selection of treatment.²⁶ Importantly, the phenotype of the metastasis may differ from that of the primary tumor, an example of which is the loss/lack of HER2 receptor in a patient whose original tumor was HER2 positive.¹⁵¹ In such a patient, the use of lapatinib would be inappropriate. Therefore, in the occasional patient who has undergone a resection or biopsy of a brain metastasis, one should obtain molecular marker tests in the resected lesion if the results would alter the selection of chemotherapeutic agents.

Despite multiple trials that have evaluated the concurrent use of chemotherapy with WBRT, none have documented a meaningful clinical benefit such as a delay in neurologic decline when compared to WBRT alone. Current trials are incorporating such end points. Currently, however, chemotherapy does not have a standard role as a radiosensitizer. Because CNS imaging of asymptomatic patients with cancer has become more prevalent, the paradigm of preirradiation chemotherapy has become a more active area of investigation. The efficacy of chemotherapy against CNS metastases approximates that against systemic cancer when given in the preirradiation setting.^{152,153} The potential advantages of preirradiation chemotherapy include the possibility of delaying the need for radiation therapy, the theoretical possibility of improved drug delivery to unirradiated tumor, the delay of neurocognitive toxicity of radiation therapy in the high-risk patient, and the possibility of simultaneous treatment of systemic disease. Several recent trials have documented the efficacy of preirradiation chemotherapy.¹⁵¹ This paradigm remains a promising area of research. For patients with progressive brain metastases after radiation therapy, chemotherapy can be used based on non-randomized trials.^{154,155} Prevention strategies are beginning to emerge in clinical trials. Primary prevention refers to the use of chemotherapy with the goal of preventing the emergence of brain metastases in patients at high risk for CNS metastases (e.g., triple negative [ER negative/PR negative/HER2 negative] breast cancer). Secondary prevention refers to the use of chemotherapy to delay or prevent the outgrowth of new metastases following the primary treatment of brain metastases with surgical resection or SRS. This paradigm offers an alternative to WBRT for those patients and providers who wish to delay WBRT. A number of clinical trials will explore the utility of prevention strategies. Although chemotherapy does not yet constitute standard treatment for patients with brain metastases, several strategies are under active investigation and should be supported by enrollment of patients onto clinical trials. A particularly promising area of investigation involves the use of novel targeted agents.^{156,157} Table 123.4 lists the possible settings for the use of chemotherapy in brain metastases.

TABLE 123.4

Possible Settings for the Use of Chemotherapy in Brain Metastases

Concurrent with whole-brain radiotherapy
Before the use of radiation therapy
Recurrent or progressive disease after radiation therapy

Secondary prevention

LEPTOMENINGEAL METASTASES

Leptomeningeal metastases (LM) or neoplastic meningitis represents a devastating, serious complication of the CNS in patients with advanced solid or hematologic malignancies. Because LM is often underdiagnosed, early management can be challenging. As a result, treatment is mostly palliative, although early detection and treatment can result in stabilization and prevention of neurologic deterioration, which may improve quality of life. As LM from solid tumors is often associated with an advanced stage of systemic disease, the prognosis is poor with median survival of 2 to 3 months and 1-year survival of 15%.¹⁵⁸ For patients with leukemic and lymphomatous meningitis, the outcomes are better.

Epidemiology

Although the incidence (0.8% to 8%) of LM varies depending on the type of primary cancer and stage of disease, approximately 5% to 15% of patients with cancer are diagnosed with this complication. For patients with solid tumors, LM is estimated to occur in 5% to 18% of patients.¹⁵⁹ For patients with hematologic cancers such as leukemia and lymphoma, the incidence is 5% to 15% compared to 1% to 2% for patients with primary brain tumors, who appear to have the lowest incidence.¹⁶⁰ In autopsy series, the estimated rate of LM has been reported as high as 19%.¹⁶¹

Clinical Presentation

LM can easily be overlooked given the subtle signs and symptoms. As cranial nerves, spine, nerve roots, and brain may be affected, a number of symptoms and signs may occur such as headache, altered mental status, nausea/vomiting, seizures, difficulty swallowing, visual loss, facial numbness, focal weakness, and abnormalities of bowel and bladder function. Greater than 50% of patients have spinal cord dysfunction as the primary presenting symptom followed by cranial neuropathies, hemispheric defects and nonfocal presentations.¹⁶² For patients with hydrocephalus due to obstruction of the cerebral aqueduct or the arachnoid granulations, placement of an external ventricular drain and/or ventriculoperitoneal shunt may be used.¹⁶³

Diagnosis

Because the diagnosis of LM is difficult, a thorough neurologic history and physical examination, contrast-enhanced MRI of the brain, and examination of the CSF are important in establishing the diagnosis of LM.¹⁶⁴ In addition to history and physical examination, a sign and symptom-directed contrast-enhanced MRI of the spine should be completed. Radiographic presentations may include hydrocephalus without an identifiable intracranial lesion, partial or full obstruction of CSF flow, and leptomeningeal enhancement. Approximately 50% of patients with LM and spinal symptoms have abnormal imaging studies using gadolinium-enhanced MRI.¹⁶⁵ In addition, imaging may be the only positive diagnostic modality in 40% of cases.¹⁶⁵

Examination of the CSF, which is usually performed via high-volume lumbar puncture, represents the sole diagnostic criteria for LM in approximately one-half of cases. The CSF is examined for opening pressure, appearance, glucose, protein, white and red blood cell counts with differential, and the presence of any abnormal cells by cytology or flow cytometry.^{166,167} Unfortunately, cytologic evaluation of the CSF is an insensitive test with 40% to 50% of patients having negative CSF cytology.¹⁶⁸ Given the rapid degradation of malignant cells, CSF samples should be processed quickly.¹⁶⁰ In addition, adequate amounts of CSF (at least 10 mL, 1 to 2 mL, and 1 to 3 mL) should be sent for cytologic examination, flow cytometry, and routine studies, respectively.¹⁶⁰ For patients with leukemia or lymphoma, flow cytometry allows the earlier detection of LM before the onset of clinical symptoms and CSF pleocytosis and has superior

sensitivity compared to standard cytology.^{167,169} If the initial examination of the CSF is negative, up to two repeat CSF examinations should be performed to increase diagnostic sensitivity. Some biochemical markers such as CA 27.29 for breast cancer and CA-125 for ovarian cancer can be useful to help make diagnosis of LMD.

Radiation Therapy

Radiation therapy provides effective palliation in many cases of LM, particularly in areas of bulk disease, obstruction of CSF flow, and symptomatic sites and regions. It is also useful for patients with cranial neuropathies and cauda equina syndrome.¹⁷⁰ Craniospinal irradiation (CSI) is generally not recommended given the potential toxicities of CSI and previous radiation treatment that may have encompassed the brain or spine. In addition, the volume of bone marrow irradiated with CSI may preclude the use of future bone marrow suppressing chemotherapy. As a result, the use of involved field radiation therapy possibly followed by intrathecal chemotherapy is generally recommended given the complementary nature of both treatments.

Intra-Cerebrospinal Fluid Chemotherapy

Given the BBB, the best approach to administer chemotherapy within the leptomeningeal space without bulky disease is through an intraventricular access device such as an implanted subcutaneous reservoir and ventricular catheter (Ommaya reservoir) with intrathecal delivery via lumbar puncture as an alternative. As intra-CSF chemotherapy with agents such as cytarabine and methotrexate has limited systemic toxicity and allows for more uniform distribution and therapeutic levels of drug in the subarachnoid space, it is used for the treatment and prevention of LM from both solid and hematologic tumors.¹⁷⁰ A limitation of this approach is impaired or obstructed CSF flow from bulky meningeal disease. Bulky meningeal disease, which impairs or obstructs CSF flow, may be reversed with local irradiation. Generally, radiation therapy is delivered prior to intra-CSF therapy. Based on limited and older data, radiation therapy and intra-CSF therapies are not delivered concurrently secondary to concerns of increased neurotoxicity.¹⁷¹

Commonly used intrathecal chemotherapy agents include methotrexate, cytarabine, liposomal form of cytarabine, and thiotepea. Complications associated with intra-CSF chemotherapy include treatment-related meningitis that most frequently presents as a chemical arachnoiditis. Fewer than 10% of patients experience bacterial meningitis, usually with Gram-positive organisms. Myelosuppression can occur with high-dose methotrexate and thiotepea. Migration or malposition of the catheter and catheter obstruction can also occur including a 1% risk of postoperative hemorrhage. A small percentage of patients may experience chemotherapy-related leukoencephalopathy, which appears to occur most commonly in patients who receive intrathecal methotrexate following cranial irradiation.

Systemic Chemotherapy and Other Agents

Unlike most water-soluble drugs, high-dose systemic administration of methotrexate results in therapeutic drug levels in the CSF. As a result, high-dose methotrexate is active in neoplastic meningitis in lymphoma and in some solid tumors. High-dose intravenous methotrexate administration is active even when there is obstruction of CSF flow, which can sometimes compromise the subarachnoid administration of drugs. High-dose methotrexate administration requires detailed inpatient monitoring of fluid status and renal function, urine alkalization, and leucovorin rescue, which makes this approach not appropriate or practical for all patients.¹⁷² Other agents that have been investigated include rituximab for lymphomatous meningitis, topotecan for lung cancer, trastuzumab for breast cancer, and etoposide for SCLC in germ cell tumors.¹⁷³

124 Metastatic Cancer to the Lung

Jessica S. Donington and Christopher W. Towe

INTRODUCTION

Ultimately, uncontrolled metastatic disease is the most frequent cause of cancer-related death. Whereas widespread disease is often not amenable to localized therapy, metastatic spread that is limited to the lungs can be successfully treated with localized therapy. Surgical resection of metastatic pulmonary disease gained popularity in the 1960s and 1970s as a result of a series of patients who underwent repeated pulmonary resection for metastatic osteogenic sarcoma and demonstrated a 5-year survival rate >30% relative to 17% in historical controls.¹ Since that time, hundreds of studies have documented improved outcomes among many tumor types. Unfortunately, most studies of pulmonary metastasectomy are small, single-institution retrospective reviews, and large prospective data sets are not available to guide clinical decisions regarding which patients will benefit from resection. Furthermore, the increased efficacy of “targeted” molecular therapies in select histologies requires a continuous evolution of decision making because surgery may no longer be the “only” beneficial treatment option. This chapter discusses the evaluation and management of patients with pulmonary metastases. General issues addressed include the role of diagnostic imaging, surgical approach (video-assisted thoracoscopic surgery [VATS] versus thoracotomy), extent of resection (wedge versus anatomic resection), role of lymph node dissection, and expanding role of image-guided ablative therapies. The chapter will conclude with a review of evidence for metastasectomy by primary tumor type and will include a discussion of tumor-specific multimodality therapy.

PRESENTATION AND DIAGNOSIS OF PULMONARY METASTASES

The majority of pulmonary metastases are asymptomatic and detected radiographically. Approximately 20% of patients with pulmonary metastases are symptomatic, with cough and hemoptysis being the most common. The presence of symptoms usually suggests proximity of tumor to larger airways. True endobronchial metastases are rare, but they can occur in patients with metastases from colorectal, breast, renal, melanoma, and thyroid cancer. Patients may also present with chest pain (a possible sign of chest wall invasion) or constitutional symptoms. Workup should include careful history and physical exam as well as cross-sectional imaging.

Cross-sectional imaging is essential in the evaluation of a patient with pulmonary metastases. The most commonly used method is computed tomography (CT) scanning. Chest CT is accurate, widely available, and is generally associated with a low dose of radiation exposure. CT imaging technology has evolved significantly since its introduction, and modern thin-section low-dose CT is highly effective in imaging pulmonary metastases.^{2,3} Fluorodeoxyglucose-positron emission tomography enables identification of extrathoracic tumor sites and simultaneously characterizes pulmonary foci of disease on a metabolic basis. This can be especially important in patients who have a short disease-free

interval and have questionable extrathoracic sites of disease. Magnetic resonance imaging is not good at imaging the lung tissue and is generally not a useful modality for routine imaging pulmonary metastases compared with conventional CT. It is useful for demonstrating tumor invasion of the great vessels, heart, chest wall, or nervous structures including, the spine or brachial plexus, and in ruling out synchronous liver metastases.

The classic radiographic appearance of pulmonary metastases is a smooth, well-circumscribed, peripheral nodule, a “gumball” or “cannonball” (Fig. 124.1). Metastases also frequently appear in multiple sites throughout the lungs simultaneously. Despite radiographic appearance, it is important to differentiate suspected metastatic lesions from other pulmonary pathology. Multiple simultaneous lesions may need to be differentiated from infectious processes, while single lesions need to be differentiated from a primary lung cancer. The likelihood of pulmonary metastases relative to new primary malignancy is related to the tissue type of the patient’s antecedent cancer, risk factors for lung cancers, as well as the interval between the previous malignancy and presentation. In patients with history of sarcoma or melanoma, a new pulmonary nodule is 10-fold more likely to be a metastases than a new primary lung cancer. If the initial tumor was of genitourinary or colorectal origin, there is equal chance that the tumor is metastasis versus new primary, and if the tumor is of head and neck origin, the newly identified tumor is twice as likely to be a new primary lung cancer.⁴ These assumptions reflect relative differences between genetic aberrations and other risk factors (such as tobacco smoking) between lung cancer and the tumors in question. Nowhere is this truer than in patients with history of previous non-small-cell lung cancer (NSCLC). In the first 4 years following curative resection of early stage NSCLC, the risk for recurrence is 6% to 10% per person-year, but recurrence risk then drops to 2% per year, while the risk for a second primary NSCLC ranges from 3% to 6% per person-year and does not diminish over time.⁵ In patients with a history of previous lung cancer, new primary lung cancers are more likely after 4 years and usually have a classic radiographic appearance of early tumors, such as a mixed solid and ground-glass nodule. Primary lung cancer risk prediction models, such as the Bach model⁶ and model based on the European Prospective Investigation into Cancer and Nutrition data,⁷ which takes into account an individual’s age, sex, asbestos exposure history, and smoking history (duration, number of cigarettes per day, and time since quitting smoking), can also be used to estimate the probability that a lung nodule is a primary lung cancer as opposed to a metastases.

Ultimately determining whether a new pulmonary nodule in a patient with history of cancer is a metastasis requires histopathologic confirmation. In specific circumstances where surgical removal will not be pursued, nonoperative biopsy is preferable. Techniques such as image-guided percutaneous biopsy, fluoroscopic-guided transbronchial biopsy, endobronchial ultrasound, or navigational bronchoscopy are all reasonable approaches and should be individualized to the location of the nodule, institutional expertise, and patient-specific concerns. Differentiating site of origin can be confounded by the histologic similarity between primary lung

Figure 124.1 (A–D) Computed tomography image of pulmonary metastases demonstrates a classic radiographic appearance: circular, well circumscribed, multiple, and peripheral.

cancer and metastatic lesions, most commonly differentiating between primary squamous cell cancers from lung and metastatic head and neck tumors. Molecular analyses may be useful in these circumstances.⁸ In patients who cannot be diagnosed by nonoperative means, surgical exploration and biopsy, preferably by VATS or by thoracotomy, is reasonable.

SURGICAL METASTASECTOMY

Criteria for Surgical Resection

Analysis from numerous retrospective studies has led to the following generally accepted criteria for selection of patients for surgical pulmonary metastasectomy: 1) definitive control of the primary tumor has occurred (or is possible), 2) absence of (or ability to control) extrathoracic metastatic disease, 3) the lung metastases are amenable to complete resection, 4) the patient can tolerate the planned procedure, and 5) there is no better treatment alternative.⁹ Using these criteria, however, long-term survival after metastasectomy remains uncommon, reflecting the fact that in only a subset of patients does the resected disease represent the entirety of their metastatic burden. Ultimately, the greatest management difficulty is differentiating patients that might benefit from surgical extirpation from those whose disease has already, or will soon, spread beyond the means of surgical control. Studies have used retrospective analyses to help clinicians predict which patients will have good outcome after surgery. By far, the largest such analysis of outcomes after metastasectomy comes from the International Registry of Lung Metastasis (IRLM), which was published in 1997.¹⁰ That project retrospectively analyzed over 5,000 cases of surgical metastasectomy for curative intent for a variety of histologies from 18 institutions around the world. Actuarial overall survival was significantly higher among patients who underwent complete (R0) surgical resection, with 5-, 10-, and 15-year survival of 36%, 26%, and 22%, respectively, compared to 13% at 5 years and 7% at 10 years among patients with incomplete resections. While not as striking as the impact of complete resection, other factors that

had a positive effect on long-term survival in the IRLM analysis were disease-free interval >36 months (5-year survival 45% versus 31% <36 months) and single metastasis (5-year survival 43% versus 34% for two or three and 27% for four or more lesions). Based on their analysis, the outcomes could be differentiated into four groups based on the following risk factors: (1) whether their disease was resectable, (2) single or multiple metastases, and (3) if the disease-free interval was >36 months. Patients with favorable risk in all three criteria could anticipate 50% survival at 5 years compared to <15% for those with unfavorable criteria for each risk factor (Fig. 124.2).

The need to perform a second metastasectomy in the IRLM analysis was associated with remarkably good 5-year survival (44%), which suggested that patients who recur and are still physiologically able should be offered re-resection. Other studies of outcomes after metastasectomy have corroborated the IRLM results and continue to demonstrate the prognostic importance of complete resection, prolonged disease-free interval, and fewer numbers of metastases. Other prognostic factors that have since been proposed include the presence of lymph node metastasis, response to chemotherapy, and size of lesions.

These risk factors alone, however, are not sufficient to solely determine whether a patient should undergo surgery. The decision to operate must be individualized because the risk/benefit relationship is so closely tied to a patient's specific histology, tumor location, and physiologic state. Furthermore, the role of metastasectomy must be tailored to current nonsurgical treatment options, which continue to advance and may offer similar benefit to resection. Breast and renal cell carcinoma exemplify this phenomenon. Several large but older retrospective studies have demonstrated a benefit from pulmonary metastasectomy in these histologies, but patients with pulmonary metastasis from these tumors now have prolonged response to newer systemic therapies and only selected cases are reserved for surgery. As targeted and molecular therapies continue to improve the treatment of solid tumors, the selection criteria for pulmonary metastasectomy will change. The decision to proceed to surgical removal of pulmonary metastases must therefore be part of a multimodality discussion between patients, surgeons, medical oncologists, and radiation oncologists.

Figure 124.2 Kaplan-Meier survival curves from International Registry of Lung Metastases retrospective review of 5,206 cases of lung metastasectomy. Patient outcomes could be stratified using risk factors of (1) whether their disease was resectable, (2) single or multiple metastases, and (3) if the disease-free interval was >36 months. (Reprinted with permission from Pastorino U, Buysse M, Friedel G, et al. Long-term results of lung metastasectomy: prognostic analyses based on 5206 cases. The International Registry of Lung Metastases. *J Thorac Cardiovasc Surg* 1997;113:37–49.)

Large randomized trials are thought to provide the best evidence to direct efficacious treatment. A large trial of pulmonary metastasectomy for colorectal cancer is under way in Europe and will likely have a significant impact on clinical decision making.¹¹ Unfortunately, randomized data matures slowly and can be nearly impossible for all clinical scenarios, so the decision to operate often relies upon results of large retrospective series and databases. However, ongoing advances in the treatment of metastatic disease should temper the use of this retrospective data to direct clinical practice.

Open Versus Minimally Invasive Surgery

The surgical approach to metastasectomy is controversial with retrospective studies supporting both open and VATS approaches. The tension between these approaches is based on decreased pain, shorter hospital stay, and increased tolerability in patients with poor pulmonary function associated with VATS¹² relative to improved detection of small metastases afforded by manual palpation of the lung, which is not possible with a minimally invasive approach. As thoroscopic techniques gain popularity for a wide range of thoracic procedures, surgeons have been keen to apply this technique to metastasectomy. Some historical studies suggested that the lack of manual palpation of the lung leads to small metastatic lesions being missed, and is therefore increasing the risk for incomplete resection. Convincing evidence in favor of an open approach and manual palpation of the lungs came from a series from the Memorial Sloan Kettering Cancer Center in 1996.¹³ In this prospective evaluation, 18 patients underwent a VATS resection immediately followed by thoracotomy. Ten patients (56%) had additional malignant lesions found at thoracotomy that were not identified on preoperative imaging or during thoracoscopy. The major findings of the trial were as follows: (1) CT scan of chest underestimated the number of lung metastases (and therefore would be unable to be found thoroscopically) and (2) thoracotomy after VATS identified nodules missed during VATS. Although this study is criticized for not using “high-definition” imaging and modern thoroscopic techniques, other studies have subsequently corroborated these

results with a similar percentage of “missed” nodules.^{14–16} The rebuttal from VATS supporters is that patients who undergo VATS have similar long-term outcomes relative to thoracotomy.

Modern high-resolution CT scan affords precise diagnostic imaging of patients with pulmonary disease. However, numerous modern series continue to suggest that CT underestimates the number of pulmonary metastases identified during thoracotomy. In a recent study from the John Wayne Cancer Institute in California, additional lesions were identified in 26% of patients undergoing thoracotomy that were not identified by preoperative CT chest scan.¹⁷ In this series, “missed” nodules were more common if multiple nodules were identified preoperatively, and if the preoperative identified nodules were <1.5 cm. Similar results were reported by Cerfolio et al.¹⁶ in a prospective cohort of 152 patients, in which 51 patients (34%) had pulmonary nodules detected at surgery that were not imaged preoperatively and over half were malignant.

An additional concern with minimally invasive approaches is the increased difficulty with intraoperative localization of nodules identified by CT. In a study from Denmark, 37 patients underwent sequential thoracoscopy and thoracotomy for resection of pulmonary metastases. CT scan identified 55 lesions preoperatively, but only 51 were identified using VATS. An additional 29 lesions were found during subsequent thoracotomy, 7 of which (24%) were malignant.¹⁴

Despite evidence that nodules may be missed by VATS resection, multiple retrospective series have demonstrated that both short^{18,19} and long-term survival are similar between patients undergoing the open and VATS approaches.^{20–24} A study that compared VATS to thoracotomy for treatment of sarcoma metastases demonstrated nearly identical 3-year survival without ipsilateral recurrence (44.4% versus 45%).¹⁹ Proponents of the minimally invasive approach argue that ultimately, tumor biology is the factor that most profoundly affects survival after metastasectomy and that patients should be offered the least invasive procedure.

No large or randomized studies exist, or are likely to be performed, to determine which surgical technique is better. Currently, the majority of thoracic surgeons favor the use of thoracotomy for treatment of pulmonary metastases, but minimally invasive techniques are frequently being used with therapeutic intent. This is based on findings from a 2008 survey of the European Society of Thoracic Surgeons (ESTS). A total of 65% of respondents felt that “palpation is considered necessary,” relative to 29% who use thoracoscopy with therapeutic intent.²⁵ There has been a dramatic increase in use of VATS since the 1997 IRLM series, in which only 2% of cases were performed thoroscopically.¹⁰ An algorithm proposed from Cerfolio et al.¹⁶ to determine which surgical approach to use offers some insight as to the relative strengths and limitations of each technique offer (Table 124.1).

Approach to Open Metastasectomy

The controversy over surgical approach goes beyond the open versus minimally invasive debate. There is also controversy as to which open approach is ideal. In the setting of unilateral nodules, most advocate use of thoracotomy, but the decision is less clear in the setting of bilateral disease. Some advocate a single surgical procedure with a median sternotomy or clamshell for patients with bilateral metastases. Ideologically, it is appealing to limit the patient to one anesthetic and one recovery, but “one-stage” approaches have their drawbacks. Sternotomy affords poor exposure and restricts manual palpation of the posterior aspect of the lower lobes, especially on the left side. The clam shell incision offers improved access to both lung fields, but is associated with increased pain and postoperative recovery. In the 2008 ESTS practitioner survey, only 26.9% of respondents preferred a one-stage sternotomy approach to bilateral disease and only 7.6% preferred the clamshell approach.²⁵ The most popular approach to bilateral pulmonary metastasectomy is sequential thoracotomy, with contralateral disease being approached by a subsequent thoracotomy after a 3- to 6-week interval.^{25,26}

TABLE 124.1

Factors Supporting Use of Minimally Invasive or Open Approach to Pulmonary Metastasectomy

	Favors VATS	Favor Thoracotomy with Manual Palpation
Number of nodules	<3	≥3
Size of largest nodule	<5 cm	>5 cm
Size of smallest nodule	>1.5 cm	<1.5 cm
Location	Peripheral	Central
Histology	Colorectal cancer	Melanoma
Pulmonary function	Marginal	Normal
Previous chest radiation	Never	Yes
Lobar location	Upper or middle	Lower

VATS, video-assisted thoracoscopic surgery.

Role of Lymph Node Dissection

Another controversial aspect of pulmonary metastasectomy involves the decision to perform lymph node dissection or sampling at the time of surgery. The use of systematic lymph node evaluation during metastasectomy varies by institution; no consensus exists. The evidence for lymph node evaluation is supported by a study from Pfannschmidt and colleagues,²⁷ where 245 patients with metastases from colorectal carcinoma, renal cell carcinoma, and sarcoma underwent routine mediastinal lymphadenectomy. Approximately one-third of patients had lymph node involvement, half were limited to pulmonary and hilar metastases, and the other half had mediastinal nodal disease. Patients with more than one pulmonary metastasis or metachronous disease were more likely to have thoracic lymph node metastases, as were patients with renal cell cancer (42%) and colorectal carcinoma (31%) relative to sarcoma (20.3%). Patients without lymph node involvement demonstrated improved median survival (63.9 months) relative to patients with pulmonary nodal involvement (32.7 months) or mediastinal nodal involvement (20.6 months). Subsequent studies support the premise that intrathoracic nodal disease in conjunction with pulmonary metastasis is a poor prognostic indicator. This message was particularly striking in a Japanese cohort of patients undergoing resection of colorectal metastases; patients without intrathoracic lymph node disease had a 5-year survival of 53.6% compared to 6.2% at 4 years among patients with lymph node involvement (Fig. 124.3).²⁸

While the increased prognostic information received from lymphadenectomy appears to support its routine use, many surgeons believe that the primary role for lymphadenectomy is to determine the need for additional oncologic treatment; there are no widely accepted strategies for implementation. The lack of consensus is evident in the ESTS survey, where only 19% of respondents reported routinely performing complete lymphadenectomy, 55% perform lymph node sampling, and 32% do no nodal sampling.²⁵

Extent of Resection

In general, the goal of metastasectomy is complete removal of all gross tumor. Oncologic resection is defined further by the “completeness” of resection: An R2 resection involves a partial resection with gross residual disease, an R1 resection is removal of gross

disease but residual microscopic disease, and an R0 resection is a complete resection with no microscopic evidence of disease. In general, an R0 resection is essential for successful metastasectomy, because debulking of disease carries no clinical benefit. A second, but equally important, goal is maintenance of adequate pulmonary function and with that comes the consideration for extent of surgical metastasectomy. As approximately 50% of patients will present with recurrent disease after initial metastasectomy, an important objective of pulmonary metastasectomy is to remove as little functional lung tissue as possible in order to preserve function for the patient's physiologic needs and for possible subsequent resection(s).¹⁰ Nonanatomic wedge resections are ideal for removal of peripheral nodules and are generally associated with improved postoperative lung function relative to a larger anatomic resection (segmentectomy, lobectomy, or pneumonectomy). Lobar and segmental anatomic resections can be safely performed with mortality of <1%, but are usually associated with removal of more functional lung parenchyma than a wedge resection. Although lobectomy has been associated with lower rates of local recurrence in the treatment of primary NSCLC,²⁹ no such data exists for patients receiving resections for metastatic disease. On the contrary, because patients with pulmonary metastases frequently undergo multiple procedures (and additional other therapies), lung conservation is particularly essential.

Studies of lung function after surgical metastasectomy suggest that these resections are associated with a 10% to 15% decrease in pulmonary function on average. Pulmonary function was significantly reduced among patients receiving bilateral operations and postoperative chemotherapy.³⁰ For the purposes of metastasectomy, multiple wedge resections are frequently performed and patients can experience a cumulative decrease in lung function that is similar to a lobectomy.³¹ The use of VATS/thoracoscopy has been associated with less significant decrease in pulmonary function and fewer complications in patients with marginal lung function.^{32,33}

In patients with multiple lesions in a single lobe, central lesions, or involvement of airway or vascular structures, lobectomy may be the only therapeutic option, and therefore appropriate in patients with acceptable physiologic reserve. Pneumonectomy is rarely indicated for the treatment of metastatic disease, and many believe that the morbidity of a pneumonectomy is a relative contraindication to metastasectomy.²⁵ There are, however, select reports of long-term survival and acceptable morbidity in small case series.³⁴ Pneumonectomy should therefore be reserved for patients with ideal circumstances: long disease-free interval, single central lesion, and excellent performance status.

Figure 124.3 Kaplan-Meier survival curves of patients with and without lymph node involvement after pulmonary metastasectomy. (Reprinted with permission from Saito Y, Omiya H, Kohno K, et al. Pulmonary metastasectomy for 165 patients with colorectal carcinoma: A prognostic assessment. *J Thorac Cardiovasc Surg* 2002;124:1007–1013.)

ABLATIVE THERAPIES

Image-guided ablative therapies are being used with great frequency in the lungs and are a popular alternative to surgical metastasectomy. Stereotactic body radiotherapy (SBRT) or stereotactic ablative body radiotherapy is highly precise and dose-intensive form of external beam radiation therapy that has been used to treat metastases in the thorax. Percutaneous technologies include radiofrequency ablation (RFA), microwave ablation, or cryoablation, which uses heat or cold to create cellular destruction with necrosis. Patterns of the use of ablative therapies vary significantly according to practitioner and institutional expertise, but have been applied most consistently in patients whose performance status prevents thoracic surgery, or in whom complete surgical resection is not possible. Studies in those populations have been promising, and accordingly the use of ablative techniques to treat metastatic pulmonary lesions has increased. While, the “gold standard” treatment of pulmonary metastases remains surgical, the growing success of ablative techniques has led to more widespread use of these techniques. Rather than compare the techniques to determine which is superior for all cases, prudent complementary use of all available technologies is appropriate. For example, a patient who has undergone multiple previous thoracotomies for resection of metastases and has decreased lung function may benefit from an ablative technique to reduce toxicities associated with reoperative surgical resection. The specific strengths and weaknesses of each technique underscore the need for a multidisciplinary approach to patients with pulmonary metastases.

Radiofrequency Ablation

RFA is the most widely used and reported of the percutaneous image-guided technologies. It uses current transmitted through CT-guided, percutaneous probes to heat tissues to temperatures $>60^{\circ}\text{C}$, resulting in coagulative necrosis. The pattern of tissue injury is related to the tissue's specific electrical impedance and is modulated by the cooling effect of adjacent tissues such as airways and large blood vessels. In the lung, air-filled pulmonary parenchyma can act as a thermal insulator that protects nearby tissue. RFA is most efficacious for tumors <3.5 cm in diameter, with larger tumors requiring multiple applications. RFA is also less efficacious in areas adjacent to large blood vessels and is not recommended adjacent to central airways; therefore, application is typically limited to the middle and outer third of the lungs. Pneumothorax is the most frequent complication of percutaneous pulmonary RFA and is reported in up to 30% to 50%, less than a

third of which require a chest tube for management.^{35–37} Although radiographic evidence of fibrosis and/or cavitation is common after RFA, serious, symptomatic complications (including bronchopleural fistulae formation, hemoptysis, hemorrhage, infection, and pleurisy) are rare. Cutaneous metastases (tumor seeding) at the electrode insertion site have been documented, but are also uncommon.

Percutaneous ablative treatments of pulmonary metastases are gaining in popularity because of evidence of therapeutic similarity to surgical resection. In 2010, a prospective trial of percutaneous RFA of lung metastases demonstrated impressive long-term results among a group of patients with mixed tumor histology.³⁸ Of 148 patients treated, 26% had complete radiographic response, 20% had partial response, 39% had stable disease, and 16% showed disease progression. The median overall survival was 51 months, and in multivariate analysis, disease-free interval and response to treatment were independent predictors of overall survival. Other small studies have also shown good results of RFA ablation in pulmonary metastases of esophageal, colorectal, breast, and renal cancer^{39–41} (Table 124.2).

Stereotactic Body Radiation Therapy

SBRT is another ablative technique being used to treat metastatic lung lesions. Unlike conventional fractionated radiation therapy, SBRT uses highly focused and intensive radiation to deliver ablative doses of radiation to specific areas with less radiation injury to adjacent tissues. The techniques originated for use in the brain. Significant technologic advances were necessary to adaptation to the lung, especially due to the need to compensate for the normal physiologic movement associated with breathing in order to prevent radiation injury to normal tissue without compromising tumor control. Theoretically, the high-dose and tightly focused nature of SBRT provides an ablative response in the target area, which is of particular concern for treatment of pulmonary metastases. In a trial from Kyoto University in Japan, a higher dose of radiation was necessary to treat metastatic pulmonary lesions due to higher rates of local failure (relative to primary NSCLC).⁴²

Much of the experience with the use of SBRT for lung tumors was derived from the treatment of medically inoperable NSCLC. Studies in this population have demonstrated successful treatment of early stage NSCLC among patients unfit for surgery with few complications.⁴³ Although radiation injury to normal tissue can lead to significant toxicities, patients being evaluated for SBRT for lung metastases have few medical contraindications, and even patients with severe emphysema and chronic obstructive pulmonary

disease have tolerated the procedure with few respiratory side effects.⁴⁴ In fact, most studies of SBRT have demonstrated no grade 3 or higher toxicities.⁴⁵ Treatment of centrally located NSCLC, however, has been associated with increased toxicity⁴⁶ and has resulted in the use of altered fractionation schedules for tumors within 2 cm of the central airways.

Based on the success of SBRT in patients with NSCLC, it is now being used to treat foci metastatic disease in the lungs and throughout the body. While not considered the standard of care, it is being used with increased frequency and offers good local control and short-term overall survival. In a recent prospective trial of 32 patients with 47 lung metastases (~30% colorectal cancer), local control rates at 1, 2, and 3 years were 97%, 92%, and 85%, respectively. The median overall survival was 39.6 months. The 1-, 2-, and 3-year overall survival rates were 83%, 76%, and 63%, respectively.⁴⁷ Other studies have not documented such favorable results with 3-year survival among mixed group of patients only 16%.⁴⁸ Because of its recent introduction, few SBRT studies have mature long-term outcomes for treatment of metastases. A study of SBRT in treatment of various metastases (32% breast) in mixed sites (41% pulmonary) among 121 patients, showed a 6-year overall survival of 20% in the entire study group, and 47% 6-year overall survival among patients with breast cancer⁴⁹ (Table 124.3).

TREATMENT CONCERNS AND OUTCOMES FOR INDIVIDUAL HISTOLOGIES

Soft Tissue and Osteogenic Sarcoma

Soft tissue and osteogenic sarcomas are relatively rare malignancies, but they have high rates of pulmonary metastases. Failure to control pulmonary metastatic disease is the most frequent cause of death in these patients. This combined with the young age of patients with sarcoma has resulted in this being the histology in which surgical metastasectomy has been widely studied. Although no formal randomized trials exist, the large numbers of retrospective studies strongly suggest benefit for resection of metastatic disease in these patients. Furthermore, with the lack of efficacious chemotherapeutic options, metastasectomy will likely retain an important role in the treatment of patients with sarcoma for the foreseeable future.

Osteosarcoma is a histologic subtype with high predilection for pulmonary metastases. In 2003, the Cooperative Osteosarcoma Study Group found that, of 202 patients who had metastases at

diagnosis, 81% had lung metastases and in 62% the lung was the only site of metastases.⁵⁰ Studies have also shown that >50% of cancers recur only in the lung.⁵¹ Patients with osteosarcoma are generally young and healthy and as such are usually excellent candidates for pulmonary resection. Several reports have shown prolonged survival after surgical treatment of pulmonary metastases of osteosarcoma with 5-year overall survivals ranging from 30% to 40%⁵² (Table 124.4). While reports have varied, prognostic factors associated with good outcome are prolonged disease-free interval, complete surgical resection, and response to adjuvant therapy.^{53,54} Unfortunately, studies of metastasectomy in the pediatric population have documented that new lung metastases frequently recur after resection,⁵⁵ and therefore patients should be followed closely postoperatively. Although benign nodules can occur after the initial metastasectomy, recurrent disease ipsilateral to the initial resection is almost always metastatic recurrence, and aggressive surgical management is warranted.⁵⁶ Soft tissue sarcomas are a heterogeneous group of tumors with a predilection for metastatic spread to the lungs. Based on multiple retrospective studies, 5-year overall survival of 30% to 40% can be achieved following pulmonary metastasectomy (see Table 124.4). Studies attempting to identify prognostic factors associated with a favorable response to surgery have conflicting results. Generally, solitary pulmonary lesion, prolonged disease-free interval (>2.5 years), low histologic grade, and the ability to perform an R0 resection have been shown to confer a good prognosis.⁵⁷ Patients who meet all of these criteria may expect to have $\geq 70\%$ 5-year survival.

Although adjuvant chemotherapy protocols are not usually associated with significant benefit for treatment of soft tissue sarcoma, some sarcoma subtypes are chemosensitive and emerging therapies should be considered. Despite generally poor responses to chemotherapy, progression after receiving adjuvant chemotherapy is a marker for poor prognosis following metastasectomy. An MD Anderson Cancer Center study from 2011 showed that 5-year overall survival after metastasectomy in patients whose disease progressed after chemotherapy was substantially worse compared with patients without measurable progression (0% versus 32%).⁵⁸ The patients with soft tissue sarcoma and reasonable performance status whose disease recurs in the lung should be strongly considered for surgical metastasectomy because of the paucity of effective chemotherapy options.

Melanoma

Disseminated melanoma carries a dismal prognosis, typically with a median survival ≤ 6 months. While many chemotherapy

combinations have been attempted, few are successful. Biologic treatments, such as IL-2 and interferon- α , are efficacious but are associated with a survival benefit in only a minority of patients and significant systemic toxicities. Patients with disseminated melanoma often present with disease in multiple sites, and <10% have lung metastases alone.⁵⁹ Fluorodeoxyglucose-positron emission tomography is a useful tool for preoperative evaluation of patients and can accurately identify patients with extrathoracic metastasis, thereby avoiding unnecessary thoracic surgery.⁶⁰ In patients with isolated pulmonary disease, surgery is a reasonable option.⁵⁹ Among appropriately selected patients, resection of pulmonary metastases can result in median survival as high as 20 to 40 months (see Table 124.4). In a large Australian study of 292 patients undergoing pulmonary metastasectomy for melanoma, the progression-free and overall survival were 10 months and 23 months, respectively, with overall 3- and 5- year survival rates of 41% and 34%, respectively.⁶¹ Factors associated with poor overall survival following metastasectomy for melanomas are lesions >2 cm, multiple lesions, disease-free interval <36 months, and involved surgical margins.^{59,61} In a review of metastatic melanoma cases from the IRLM, patients with the most favorable prognostic factors had >25% survival at 10 years.⁶² Patients frequently recur after pulmonary metastasectomy but can achieve long-term survival despite need for re-resection with 19% surviving 5 years after the second resection in the IRLM database.⁶²

Renal Cell Carcinoma

Metastases from renal cell carcinoma are frequently present at the time of diagnosis or can develop after nephrectomy. In autopsy series, metastases to the lung occur in approximately 75% of patients, and the lung is the most common metastatic site.⁶³ Historically, few chemotherapy options were available, but in the modern era, the majority of patients with systemic disease are treated with targeted therapy.⁶⁴ Prior to these targeted therapies, surgical metastasectomy had been used with impressive results for patients with isolated pulmonary disease and may still have a role in selected patients after demonstrating a response to systemic therapy. Most studies of metastasectomy were performed prior to the introduction of targeted therapies and therefore offer limited insight in the modern management of these patients. Those “pretargeted therapy” studies demonstrated several factors that were associated with favorable prognosis: R0 resection, size of metastasis <3 cm, lack of pleural infiltration, fewer than three lesions, and negative mediastinal lymph nodes⁶⁵ (see Table 124.4). One study examined metastasectomy after targeted therapy in patients with advanced renal cell carcinoma. It showed that metastasectomy was feasible, safe, and could be associated with long-term survival, but was unfortunately in a small and heterogeneous patient cohort.⁶⁶ Current recommendations, therefore, are based on little evidence, but speak to prevailing theories: metastasectomy should be considered in patients with a small number of easily accessible pulmonary metastases who have demonstrated a long disease-free interval after nephrectomy or a partial response in metastases after systemic immunotherapy or targeted chemotherapy.⁶⁴

Breast Cancer

Although metastases from breast cancer frequently occur in the lungs, patients rarely present with isolated pulmonary disease. In a Mayo Clinic series of 13,502 patients with breast cancer, <1% developed isolated pulmonary metastases.⁶⁷ Despite the relative infrequency, metastasectomy for isolated pulmonary metastases has been described. Modern studies of metastasectomy demonstrate 5-year survival rates between 30% and 50%, with 5-year survival in excess of 80% in highly selected patients.^{68,69} Factors associated with prolonged survival include long disease-free interval (>36 months), R0 resection, hormone receptor positivity, and

fewer than four metastases⁶⁷⁻⁷¹ (see Table 124.4). The importance of hormone receptor status on survival after metastasectomy reiterates the need for individualized therapy in breast cancer therapy, and to that end, pulmonary metastasectomy is often used to obtain tissue to further guide treatment due to changes in molecular profile, which has been shown to occur in approximately a quarter of cases.⁶⁷ Thoracic surgery intervention can also be indicated for patients with breast cancer who develop extensive chest wall involvement, which can also present with direct pulmonary invasion. In these patients, chest wall resection and reconstruction can be considered and has been associated with improved quality of life and, in rare circumstances, prolonged survival.^{72,73}

Germ Cell Tumors (Testicular Cancer)

Survival following pulmonary metastasectomy is highest for germ cell tumors compared to other histologies. This is due primarily to the efficacy of chemotherapy and the important role surgery plays in the multimodality approach to these tumors. Testicular nonseminomatous germ cell tumors are the most common neoplasm in males younger than 40 years, and many present with supradiaphragmatic metastases. Disease can spread both hematogenously to the lungs (the most common site) and by lymphatic spread to mediastinal lymph nodes. Metastasis to these sites equates to stage III disease and is typically treated with cisplatin-based chemotherapy and surgical resection with excellent results.⁷⁴ Complete resection of residual postchemotherapy disease plays a critical part in achieving long-term cure and is another example of the role that surgery can take in a multimodal approach to pulmonary metastases (see Table 124.4). A large review of results in the cisplatin era documented overall median survival after thoracic metastasectomy of 23.4 years, 79% survival at 5 years, and 73% survival at 10 years.⁷⁵ The pathology from resection is important to determine the response to therapy and need for subsequent treatment in these patients. The majority will have complete necrosis or only residual teratoma in the resected specimen, each of which portends improved survival compared to those with persistent malignant disease.⁷⁵⁻⁷⁷ The presence of persistent malignant disease is an indication for additional chemotherapy. Other predictors of poor survival after surgery include older age at diagnosis, elevated preoperative serum tumor markers, and incomplete resections.^{75,76,78}

Colorectal Cancer

Lung metastases develop in 5% to 15% of patients with colorectal cancer, and pulmonary metastasectomy has become an integral part in the multimodality treatment of these patients. Colorectal cancer treatment is a rapidly evolving field, and the benefit of metastasectomy in the era of targeted therapy is accepted yet somewhat unproven. To address this question, a randomized trial of metastasectomy for colorectal carcinoma is currently under way in Europe. This trial compares “active monitoring” to “active monitoring plus pulmonary metastasectomy” and evaluates overall survival, relapse-free survival, lung function, and patient-reported quality of life.¹¹ Until these data are available, there is a considerable volume retrospective data that supports a role for metastasectomy in selected patients. In a recent meta-analysis of lung metastasectomy for colorectal carcinoma, four parameters were associated with poor survival after metastasectomy: short disease-free interval, multiple metastases, positive hilar and/or mediastinal lymph nodes, and elevated prethoracotomy carcinoembryonic antigen level⁷⁹ (see Table 124.4). In this analysis, the presence of liver metastases was not associated with poor prognosis. In fact, combined resection of colorectal hepatic and pulmonary metastases has been shown to offer improved outcomes relative to chemotherapy alone, with overall survival in metastasectomy patients more than double that of chemotherapy patients in matched-pair

analysis (65 months versus 30 months).⁸⁰ After initial resection, some patients will develop recurrent pulmonary metastases. Predictors of lung recurrence include more than three metastases at the first metastasectomy, and interval between primary surgery and first metastasectomy.⁸¹ Second surgery can be beneficial in patients who “re-recure” in the lung, as suggested by a trial that showed improved overall survival among patients receiving a second resection relative to patients who refused surgery and were treated with chemotherapy alone (58 months versus 24 months).⁸²

CONCLUSION

The management of patients with pulmonary metastases remains in a state of evolution. Since the initial revelation that long-term survival after metastasectomy was possible, clinicians now have a variety of treatment modalities to offer patients with metastatic solid tumors to the lungs. While the criteria for patient selection to undergo surgical metastasectomy have been stable for several

decades, the landscape in which patients are being treated has evolved. As targeted chemotherapies emerge, procuring tissue for genetic and chemosensitivity analyses will likely be an evolving aspect of surgical metastasectomy. After one decides that resection is indicated, it is necessary to consider which approach is appropriate, balancing the risk for missing unrecognized metastases with VATS versus the increased operative complications and recovery associated with thoracotomy. Even as randomized trials slowly define the role of surgical metastasectomy, clinicians should be mindful that the benefit of surgery should always be weighed against less invasive methods of controlling metastases with the goal of offering high-quality long-term survival. Although surgery remains the “gold standard” approach because it is associated with well-documented long-term results, ablative therapies offer impressive results (especially among patients not amenable to surgical resection). More frequently today, a multimodality approach to pulmonary metastases is being used and includes consideration for the patient’s specific physiologic status, tumor burden, and histology.

125 Metastatic Cancer to the Liver

Clifford S. Cho, Samuel J. Lubner, and Brian D. Kavanagh

INTRODUCTION

Hepatic metastasis is a unique oncologic event for three reasons. First, the nature of portal venous drainage makes the liver a common hematogenous destination of alimentary tract malignancies. Indeed, the most common metastatic tumors in the liver are derived from primary cancers of the alimentary tract and pancreas. Second, unlike other anatomic locations susceptible to hematogenous seeding (e.g., brain, lungs, bone), the liver is often the sole site of metastatic disease. Third, several aspects of hepatic anatomy and physiology make it particularly accessible to oncologic therapy. As a consequence, the phenomenon of hepatic metastasis deserves special focused attention. In this chapter, we will discuss disease biology and treatment options as they relate to the two types of hepatic metastasis (colorectal adenocarcinoma and neuroendocrine carcinoma) that are most commonly treated with liver-directed therapy, and will briefly discuss a few less-commonly treated forms of hepatic metastasis.

Relevant Hepatic Physiology

The venous drainage of the alimentary tract, pancreas, and spleen comprise the portal venous circulation. Blood flow returning from these sites converges into the portal vein. At the microscopic level, portal venous blood enters into the hepatic sinusoids, where it interfaces with hepatocytes. Once the contents from the portal venous circulation are metabolized and filtered, blood is directed into the hepatic venous system, which then re-enters the nonportal systemic venous circulation at the level of the inferior vena cava. A unique anatomic property of the liver is its dual blood supply. Hepatocytes derive the majority of their blood supply from the portal venous circulation; in contrast, the cholangiocytes that comprise the biliary ductal system derive most of their blood supply from the hepatic arterial circulation. Importantly, it is believed that primary and metastatic tumors within the liver generally derive the large majority of their blood supply from the hepatic arterial circulation. This important physiologic contrast in circulatory perfusion between normal hepatocytes and abnormal cancer cells provides an opportunity for therapeutic intervention; as will be discussed in the following, many liver-directed therapies rely on the delivery of embolic particles, chemotherapy, or radiation into the hepatic arterial circulation, where they will target mostly neoplastic cells while largely sparing normal hepatocytes. The highly metabolic properties of hepatocytes also facilitate liver-directed therapy. Chemotherapeutic agents that undergo first-pass hepatic metabolism can be delivered at unusually high concentrations into the hepatic arterial circulation, with the expectation that hepatocellular metabolism will result in negligible levels of systemic exposure and toxicity.

A unique physiologic characteristic of the liver is its ability to hypertrophy in response to various insults. Indeed, resection of up to 80% of the liver can be safely tolerated in patients with normal hepatic function. As long as the vascular perfusion and biliary and venous drainage of the remnant liver are preserved, it

will be capable of rapid hypertrophy that will restore full hepatic functional capacity within weeks. In a similar way, hepatocellular ischemia resulting from deprivation of portal venous inflow to one portion of the liver (e.g., due to venous thrombosis or tumoral invasion) induces a compensatory hypertrophic response in other portions of the liver; as a result, the ischemic atrophy of the affected liver is functionally offset by reactive hypertrophy of the non-ischemic liver. Liver-directed therapies take advantage of both of these physiologic phenomena. The ability of the liver to hypertrophy in response to resection allows surgeons to use aggressive operative procedures to resect even large and multifocal hepatic metastases, as long as a well-functioning liver remnant is preserved. Moreover, in some patients who are not candidates for aggressive surgical resection due to an excessively small future liver remnant (FLR), intentional portal vein embolization of the portions of the liver affected by tumor is commonly employed as a means of inducing sufficient hypertrophy of the anticipated FLR to permit safe surgical resection.

Hepatic Anatomic Nomenclature

A comprehensive understanding of the treatment modalities available in hepatic oncology requires some familiarity with hepatic anatomic nomenclature.¹ The liver is composed of eight segments, four sections, and two hemilivers. The right and left hemilivers are divided by the principal scissura, or Cantlie line, which runs between the inferior vena cava and the gallbladder fossa. The liver is also bisected by the middle hepatic vein, which runs through the principal scissura. The left hemiliver is divided into two sections separated by the umbilical fissure, a natural cleft that houses the left portal vein and remnant of the umbilical vein. The left lateral section, comprised of segments II and III, is situated to the left of the umbilical fissure, and the left medial section, comprised of segment IV, is situated between the umbilical fissure and the principal scissura. The venous drainage of the left hemiliver is via the left hepatic vein, which courses between segments II and III, and the middle hepatic vein. The right hemiliver is separated into a right anterior section and a right posterior section; the anatomic plane between the right anterior and posterior sections is defined by the course of the right hepatic vein. The right anterior section is comprised of segments V and VIII, and the right posterior section is comprised of segments VI and VII. Segment I, or the caudate lobe, is a centrally located structure that lies between the portal vein and inferior vena cava. Operative procedures are named according to the anatomic structures that are being removed. For example, resection of the left hemiliver (i.e., removal of segments II to IV) is referred to as a left hemihepatectomy; a right hemihepatectomy refers to removal of segments V to VIII. Resection of segments II and III is referred to as a left lateral sectionectomy; resection of segments VI and VII is referred to as a right posterior sectionectomy. Resection of segments IV to VIII is a right trisectionectomy. Resection of the caudate lobe is referred to as a segmentectomy I.

Hepatic Imaging

Nearly every aspect of the clinical management of hepatic metastases is dependent on and made possible by high-quality radiographic imaging. At a minimum, the evaluation of patients with hepatic metastases requires high-resolution contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI). Ultrasonography and positron emission tomography (PET) are used more selectively, and somatostatin receptor scintigraphy is occasionally employed during the evaluation of neuroendocrine carcinoma.

CT imaging should include so-called triple-phase imaging (consisting of a noncontrast phase, an arterial phase, and a venous phase) to provide maximal characterization of tumors based on their uptake and excretion of intravenous contrast. For example, neuroendocrine carcinoma metastases often appear very intense on arterial-phase imaging, whereas colorectal adenocarcinoma metastases typically have lower attenuation characteristics that are best appreciated on delayed venous phases, when the rest of the hepatic parenchyma has taken up contrast. Current multidetector helical CT scanners provide thin-slice (1 to 2 mm) images that can be reconstructed in coronal and sagittal projections to facilitate accurate tumor localization.

Because of the availability of numerous imaging sequences including T1- versus T2-weighted imaging and diffusion-weighted imaging, and the availability of numerous contrast agents, MRI is particularly useful for characterization of lesions that elude precise characterization by CT. Newer hepatocyte-specific contrast agents like gadoxetate disodium (Eovist, Bayer HealthCare Pharmaceuticals Inc., Whippany, NJ) and gadobenate dimeglumine (Multihance, Bracco Diagnostics, Inc., Munroe Township, NJ), which are taken up by hepatocytes and partially excreted through the biliary system, appear to enhance the sensitivity of MRI in the detection of metastatic lesions.^{2,3}

Because of its comparatively weaker sensitivity and specificity, the utility of ultrasonography is largely confined to intraprocedural guidance during tumor ablation, or during intraoperative examination of the liver. Although not yet universally available in the United States, contrast agents for use in ultrasonography may strengthen the sensitivity and specificity of this modality in the detection and characterization of liver metastases.

When used after administration of radiolabeled ¹⁸F-fluorodeoxyglucose, PET may be a means of identifying hypermetabolism within liver lesions. Because of its poor anatomic resolution, PET is typically used in conjunction with CT imaging. Several analyses have found that routine use of PET can provide additional information that alters treatment planning in up to a third of patients with hepatic colorectal adenocarcinoma metastases, particularly by detecting extrahepatic disease.^{4,5} Two important caveats are that PET is insensitive for the detection of tumor foci that are <1 cm in diameter, and its sensitivity in the detection of colorectal adenocarcinoma is blunted when patients are receiving chemotherapy. Somatostatin receptor scintigraphy can be useful in identifying foci of neuroendocrine carcinoma; however, it does not appear to enhance the level of diagnostic information that can be rendered with CT and MRI alone.⁶

Hepatic Resection

The determination of resectability of hepatic metastases centers around the concept of the FLR, which is defined as the portion of the liver that will remain following hepatic resection. As stated previously, the FLR is generally capable of rapid postoperative hypertrophy; however, the FLR must be capable of a minimum level of function in order to avoid fatal postoperative hepatic failure. In order for hepatic resection to be performed safely, four criteria regarding the FLR must be met: (1) the FLR must be well-vascularized (i.e., the portal venous and hepatic arterial inflow into

the FLR must be retained), (2) the FLR must have adequate biliary drainage (i.e., the hepatic duct[s] emanating from the FLR must not be damaged), (3) the FLR must have adequate venous drainage (i.e., the hepatic vein[s] decompressing the FLR must remain intact), and (4) the FLR must be of an adequate size. Using cross-sectional CT or MRI, the volume of the FLR and the volume of the entire liver can be calculated. In this way, the ratio of the FLR volume to the total estimated liver volume (or, alternatively, to the total ideal liver volume based on patient size) can be calculated.⁷ The minimal FLR to total liver volume ratio necessary to sustain sufficient postresection liver function and hypertrophy depends on the condition of the underlying liver. In patients with normal liver function, the ratio can be as small as 20%. In patients with severe underlying liver dysfunction (e.g., resulting from cirrhosis), the minimal ratio may be 40% to 50%. As will be outlined subsequently, iatrogenic impairment of hepatic function resulting from prolonged chemotherapy may require a minimal FLR of 30% to 40%. In cases of advanced disease with large or multifocal tumors, adjustments to operative planning may become necessary in order to preserve a sufficient FLR. These so-called parenchymal-sparing approaches to hepatic metastasectomy may invoke the use of adjuncts like thermal ablation or portal vein embolization, as will be discussed in the following.

Although the safety of hepatic surgery has greatly improved in recent decades (with operative mortality risk following major hepatic resections approximating 1% to 3% in large volume centers), it remains a considerable undertaking. The major perioperative risks for hepatic resection are hemorrhage, bile leak, and postoperative hepatic failure. The predominant source of intraoperative hemorrhage results from venous "backbleeding" from the inferior vena cava and hepatic veins; consequently, great effort is expended to minimize central venous pressure to as low as 0 to 3 mm Hg during hepatic parenchymal transection. Patients with underlying comorbidities that render them unable to tolerate the hemodynamics of low central venous pressure are clearly at higher risk of operative blood loss. Hemorrhage during hepatic parenchymal transection can also result from injury to portal venous and hepatic arterial inflow vessels; this risk can be mitigated by transient occlusion of the hepatic inflow at the porta hepatis (the so-called Pringle maneuver). In the absence of significant underlying hepatic functional derangement, the liver can tolerate relatively prolonged periods of hepatic inflow occlusion during hepatic transection, particularly when it is performed during intermittent periods (10 to 20 minutes) interrupted by brief pauses (5 minutes) to restore hepatic perfusion. A number of methods for parenchymal transection have been developed and compared, including direct manual ligation of biliary and vascular structures, thermal energy devices, and cutting staplers, but no single approach has been consistently proven to decrease hemorrhage. In experienced hands, the majority of major hepatic resections can be performed without the need for intraoperative or postoperative blood transfusion. Bile leakage from the cut surface of the liver occurs in <5% to 10% of cases, and, when necessary, can typically be managed with percutaneous drainage. Interestingly, there is evidence that the increasing complexity of hepatic resections that has evolved over time may be associated with an increasing prevalence of bile leakage.⁸ The most devastating complication that can occur after hepatic surgery is postoperative hepatic failure. If the remnant liver is incapable of sustaining hepatic function, postoperative demise from hepatic insufficiency typically cannot be averted. For this reason, great attention is devoted to the FLR preoperatively, intraoperatively, and postoperatively. Meticulous care is taken to avoid unnecessary intraoperative dissection of and injury to the vascular and biliary inflow and outflow of the FLR. Minimally invasive approaches to hepatic resection are being adopted with gradually increasing frequency, although to a lesser extent compared with other arenas of surgery. In well-selected cases and in experienced centers, minimally invasive hepatic surgery is a safe alternative to traditional open methods.

Thermal Ablation

An important adjunct or alternative to operative resection is thermal tumor ablation using radiofrequency ablation (RFA) or microwave ablation (MWA). RFA and MWA have largely replaced the older modality of cryoablation and can be applied percutaneously or directly into the liver. Thermal ablation is often used in conjunction with or instead of operative resection. RFA and MWA involve the direct insertion of ablation probes into the region of a tumor, followed by the application of several cycles of hyperthermic energy to induce a zone of cell death that fully encompasses the tumor. For deep-seated tumors that would require resection of a large volume of liver (e.g., deep, centrally located tumors that would require a formal hemihepatectomy), ablation can be useful as a parenchymal-sparing approach to hepatic metastasectomy. As such, the combined use of ablation with surgical resection enables some patients with traditionally unresectable disease to undergo complete tumor eradication. The conduct of thermal ablation requires radiographic guidance, usually with the use of real-time ultrasonography, in order to direct accurate placement of probes into and around the tumor. Ablation can be administered at the time of open or laparoscopic operation, or in a percutaneous fashion.

Stereotactic Body Radiation Therapy

Stereotactic body radiation therapy (SBRT) is a noninvasive technique of providing local therapy for liver malignancies with ablative intent. The historical development of SBRT has been well chronicled.^{9,10} In essence, SBRT is an extracranial application of methodologies developed for intracranial stereotactic radiosurgery of benign and malignant brain lesions. As it is defined by the American Society for Radiation Oncology, here the adjective *stereotactic* implies that the target lesion is localized relative to a fixed three-dimensional spatial coordinate system.¹¹ Multiple non-opposed radiation beams or arcs converge upon the tumor target, thus avoiding a high dose to normal tissues in the entrance and exit paths of the beams while depositing an ablative dose within the target volume. The entire course of therapy is abbreviated into five or fewer treatments, or fractions.

The ideal SBRT treatment delivery plan achieves a high level of dose conformality, implying that the volume receiving the prescription dose closely approximates the intended target volume, thus minimizing the volume of normal tissue exposed to a high dose. Unlike the case in some applications of conventionally fractionated radiation therapy, wherein dose homogeneity within the target volume is clinically valuable for cosmetic or other end points,¹² for SBRT it is usually advantageous to allow for a dose hotspot to be present within the target volume, both for the purpose of increasing the intensity of therapeutic effect and also steepening the gradient of dose falloff into surrounding normal tissues. This latter goal is often best achieved by closely conforming the beam's eye view of the tumor closely to the cross-sectional projection of the tumor, sometimes with even a "negative margin" where the beam is slightly smaller than the tumor projection, thus exploiting the fact that the steepest gradient of dose falloff outside the beam is generally at the midpoint of the lateral penumbra.¹³

SBRT has a range indication as either primary treatment of an early stage cancer or radical therapy of oligometastatic disease. Liver SBRT in particular was initially studied in prospective dose escalation studies utilizing a so-called critical volume method that is conceptually similar to the FLR notion mentioned previously with respect to hepatectomy. Initially applied when considering radiation effects on the spinal cord,¹⁴ in principle the critical volume method works backward from the premise that for any given organ, a certain amount of functional tissue must remain after a course of radiation therapy to avoid severe late sequelae. In the case of liver SBRT, the proposed initial good faith estimate was that at least 700 ml of normal liver must receive a dose <15 Gy in

a three-treatment regimen, a threshold below which organ functionality was expected to be preserved. With this type of constraint in place, it was possible to escalate the prescription dose to individual lesions to 60 Gy in three fractions in the initial University of Colorado study,¹⁵ and in five fractions in the University of Texas-Southwestern study,¹⁶ thus achieving actuarial rates of local control of 93% to 100% at 18 to 24 months.

A structured review of normal liver tolerance after SBRT or conventionally fractionated radiotherapy is available in the QUANTitative Normal Tissue Effects in the Clinic project report.¹⁷ It should be appreciated, though, that the rate of radiation-induced liver disease after SBRT is extremely low in the absence of preexisting liver disease, primarily because the mean normal liver dose is kept low. In clinical practice, the more concerning dose-limiting structure for liver SBRT is typically the gastrointestinal tract in cases where the treated lesion approaches within <1 cm or so of the medial surface. To minimize the risk of severe mucosal injury, conservative constraints that have been recommended by a leading expert include a maximum point dose to the upper intestine in the range of 24 to 30 Gy in three fractions and slightly higher for a five-fraction regimen.¹⁸ The Mayo Clinic group has reported outcomes from a series of patients treated with SBRT to the liver and other abdominal targets that suggests a higher risk of bowel toxicity in patients receiving abdominal SBRT and a vascular endothelial growth factor inhibitor,¹⁹ though this finding has not yet been observed by other groups.

Portal Vein Embolization

Some patients with multifocal metastases are not candidates for complete tumor eradication if the size of their anticipated FLR is insufficient to sustain hepatic function. For these patients, consideration can be given to preoperative chemotherapy or to operative adjuncts to maximize the size of the FLR. Downsizing of tumors through the use of preoperative systemic chemotherapy may enable a parenchymal-sparing approach to resection and/or ablation that permits a FLR of sufficient volume. Alternatively, portal vein embolization (PVE) can be used as a means of inducing FLR hypertrophy.^{20,21} In this approach, embolization of portal venous inflow to the portion of the liver to be resected is performed prior to operative intervention to induce rapid and significant hypertrophy of the nonembolized hepatic segments. For example, some patients may have multifocal or large tumors that can only be completely removed with a right trisectionectomy. If the FLR (segments I to III) is too small to permit safe resection, PVE of segments IV to VIII is undertaken. If hepatic function is normal, this will usually result in a rapid hypertrophy of segments I to III that peaks in 4 weeks. Thus, if repeat imaging and volumetric analysis performed 1 month following PVE identifies sufficient post-PVE hypertrophy, operative therapy can be undertaken immediately thereafter. In circumstances of impaired liver function (e.g., patients with significant chemotherapy-associated hepatotoxicity), the hypertrophic response to PVE can be attenuated. Indeed, absence of post-PVE hypertrophy (<5% increase in FLR volume) is strongly predictive of postresection liver failure. As such, PVE can occasionally be employed as a "stress test" to predict the likelihood that partial hepatectomy could be safely tolerated. Although it had previously been thought that systemic chemotherapy would significantly impair the hepatic hypertrophic response to PVE, recent analyses suggest that chemotherapy may be safely used in patients with aggressive disease during the period between PVE and resection.²²

Two-Stage Hepatectomy

A common treatment algorithm employed for patients with advanced, multifocal disease is the two-stage hepatectomy.²³ In this approach, two separate operative procedures are used to effect

complete clearance of hepatic tumors. In the first stage, operative resection and/or ablation is used to clear the anticipated FLR (most commonly the left hemiliver or left lateral section). This is often undertaken in a minimally invasive manner so as to facilitate recovery and progression to subsequent therapy. Very shortly after this procedure, contralateral PVE is performed to induce hypertrophy of the newly cleared portion of the liver. If post-PVE imaging verifies satisfactory hypertrophy of the FLR, completion hepatectomy is then performed to clear all remaining sites of disease.

Transarterial Therapy

Transarterial therapies take advantage of the aforementioned unique physiologic characteristic of hepatic metastases. Unlike normal hepatocytes, which derive approximately 75% of their blood supply from the portal venous circulation, hepatic metastases derive 80% to 90% of their blood supply from the hepatic arterial circulation. As a result, a number of therapeutic interventions targeting hepatic metastases have been designed to be delivered intra-arterially (via the hepatic arterial system). Hepatic arterial infusion (HAI) chemotherapy involves the delivery of chemotherapeutic agents directly into the hepatic arterial system. HAI typically employs chemotherapeutic agents that undergo high first-pass hepatic metabolism. Once metabolized by hepatocytes, negligible quantities of chemotherapy are then exposed to the rest of the body; in this way, HAI enables the administration of vastly higher concentrations of chemotherapy to hepatic metastases than can be delivered systemically. Transarterial embolization (TAE) involves the selective administration of polyvinyl alcohol or microspheres into the small arterial vessels that perfuse hepatic tumors. Once delivered, these agents induce thrombosis in small-diameter arteries that results in selective ischemia of tumors but not of the surrounding hepatic parenchyma. Transarterial chemoembolization (TACE) is a combination of these two approaches, in which high doses of chemotherapy are selectively delivered into the arteries that perfuse tumor, after which the arteries are embolized.

Selective Internal Radiation Therapy

Selective internal radiation therapy (SIRT) is a targeted approach that delivers glass or resin microspheres labeled with ⁹⁰Yttrium, primarily a beta particle emitter, into the arteries that perfuse metastatic or primary liver tumors. The rationale for the potential selectivity of the technique is that postinfusion histologic analysis demonstrates that the spheres are preferentially distributed into vessels around the periphery of the tumor, with relative sparing of the normal liver.²⁴ It is difficult to compare SBRT and SIRT directly; in general, SBRT can likely provide a more intense dose of radiation to individual discrete lesions, whereas SIRT can be used for somewhat larger and more diffuse hepatic involvement. The initial assessment of the appropriateness of SIRT for a given patient involves a consideration of not only performance status and goals of treatment but also an evaluation of the expected distribution of particles within the patient's liver and identification of any potential concerns regarding a pulmonary shunt or anatomic variant that would cause an excess amount of particles to be distributed into nontarget regions.²⁵

The pre-SIRT evaluation may be achieved using planar or single photon emission CT scintigraphy of technetium-99m macroaggregated albumin. The scans will provide information useful for determining the appropriate amount of radioactivity to be infused based on the expected ratio of tumor to normal liver distribution as well as the dose-limiting constraint of pulmonary radiation dose in cases with a demonstrable pulmonary shunt. The incidence of radiation-induced liver toxicity after SIRT is typically low,²⁶ but gastrointestinal toxicities can also occur from exposure to adjacent tissue or nontargeted sphere deposition.²⁷ The rate of individual tumor control is not commonly reported after SIRT, but intrahepatic control is lower than after SBRT, possibly because the disease burden

treated with SIRT is typically higher. For example, in one series the median liver tumor volume treated was over 300 ml; the progression-free survival was 3.2 months, and half the patients experienced a component of intrahepatic failure.²⁸ 6 month intrahepatic control rate was. The therapy is often used as sole treatment for liver lesions but can also be positioned as a bridge to transplantation or downstaging method prior to other interventions.²⁹

Palliative Whole Liver Radiation Therapy

Less biologically potent than SIRT is the use of palliative whole liver external beam radiation therapy. This form of treatment becomes more appropriate as the goals of treatment move farther away from radical, potentially curative ablation of oligometastatic disease toward symptom relief in patients with limited life expectancy. A high burden of liver disease can sometimes cause nausea, anorexia, and pain presumed to result from stretching of the liver capsule, among other symptoms. A number of prospective studies have addressed this condition, and an American Society for Radiation Oncology–commissioned review of the topic has been published.³⁰ The major prospective clinical studies of note are the Radiation Therapy Oncology Group studies performed in the late 1970s and early 1980s. The initial Radiation Therapy Oncology Group pilot study enrolled over 100 patients and involved whole liver external beam radiation therapy regimens in the range of 21 to 30 Gy in 7 to 19 fractions.³¹ Patient-reported symptom reduction was observed in most patients: 55% had at least partial relief of abdominal pain, 49% experienced reduced nausea and vomiting, and 28% had less anorexia. There was no clear advantage to a dose above 21 Gy in seven fractions. In a subsequent Radiation Therapy Oncology Group study, this regimen was used again (21 Gy in seven fractions) and was confirmed to achieve pain relief in approximately 80% of patients within 2 to 6 weeks following treatment.³² The pain relief was complete in 54% of patients; toxicity was limited to mild transient nausea in 22% of patients, and 28% of patients enjoyed improved performance status. More recently, the Princess Margaret Hospital group has reported encouraging similar overall results for palliative liver radiotherapy using an even simpler and shorter schedule involving a single fraction of 8 Gy to the whole liver.³³

HEPATIC COLORECTAL ADENOCARCINOMA METASTASES

Introduction

Like other adenocarcinomas of the alimentary tract (e.g., gastric adenocarcinoma, pancreatic adenocarcinoma), colorectal adenocarcinoma has a proclivity for hepatic metastasis. However, very much unlike other alimentary tract adenocarcinomas, the liver is often the *only* site of metastatic spread for colorectal adenocarcinoma. This nuance of cancer biology makes liver-directed therapy an attractive approach in the management of metastatic colorectal adenocarcinoma. Another impetus for aggressive liver-directed therapy is the broad availability of effective systemic chemotherapy. Indeed, over the past several decades, continual advances in chemotherapy have incrementally but substantively raised the median overall survival for patients with metastatic colorectal adenocarcinoma from 6 months in the era of 5-fluorouracil (5-FU) monotherapy to over 2 years in the contemporary era of combinatorial FOLFOX or FOLFIRI chemotherapy administered in conjunction with so-called targeted biologic agents.

Hepatic Resection

The goal of hepatic metastasectomy for colorectal adenocarcinoma is complete tumoral extirpation with negative resection

margins. It is evident that a subset of patients who undergo resection of their hepatic colorectal metastases will be cured. Longitudinal analyses indicate that the cure rate is approximately 20% of all patients; these studies also demonstrate that recurrences can occur late, such that the declaration of cure cannot be made until 10 years after surgical resection.³⁴ Despite decades of accumulating experience with surgical therapy, there are no prospective randomized data to verify that hepatic metastasectomy improves survival for patients with hepatic colorectal adenocarcinoma metastases beyond that which could be expected with systemic chemotherapy alone. However, as shown in Table 125.1, single-institution series have demonstrated steady improvements in actuarial survival estimates that now approximate 5-year overall survival rates of 50% after hepatic metastasectomy.^{35–39} As systemic chemotherapy has become more effective, surgical therapy has been implemented more aggressively, being offered to patients who previously might have been deemed poor candidates for operative intervention. Indeed, tumor characteristics that were once considered contraindications to surgical intervention (e.g., bilobar tumor involvement, more than four tumors) are now commonplace among patients undergoing hepatic metastasectomy. As the indications for operative therapy broaden, and as surgical resection is offered to more and more patients with highly aggressive manifestations of metastatic disease, it is unlikely that the chance of actual cure will rise. However, in light of the ever-improving capacity of systemic chemotherapy to prolong survival for patients with advanced disease, it is also likely that aggressive hepatic metastasectomy, when used rationally and in the context of multimodality, multidisciplinary care, may prolong survival.

Extrahepatic Disease

One special circumstance of liberalizing indications for hepatic metastasectomy that deserves mention is that of extrahepatic metastases. The presence of additional foci of metastatic disease outside of the liver (e.g., pulmonary, peritoneal, retroperitoneal) was once universally considered to be an absolute contraindication to hepatic resection. However, there is now accumulating experience with combined hepatic and extrahepatic metastasectomy. Although this experience is derived from highly unique and selected cases, in the context of this careful patient selection, it is apparent that patients undergoing resection of hepatic and pulmonary metastases can experience a median overall survival of 3 to 4 years (recurrence-free survival of approximately 2 years), and patients undergoing resection of hepatic and peritoneal metastases can experience a median overall survival of 2 to 3 years

(recurrence-free survival of approximately 2 years). Interestingly, comparatively worse survival outcomes have been described for patients presenting with hepatic pedicle or retroperitoneal lymph node metastases.^{40,41}

Thermal Ablation

Thermal ablation using MWA or RFA has the advantage of allowing greater parenchymal sparing than hepatic resection, particularly for deep-seated, centrally located tumors. As such, ablation is often used instead of or in conjunction with resection. Ablation can be performed intraoperatively during open or laparoscopic procedures, or percutaneously in a nonoperative setting. The less invasive nature of ablation can be attractive for patients who are suboptimal candidates for major operative intervention. Ablation is particularly appealing for cases of colorectal adenocarcinoma metastases that have recurred following previous resection, as it avoids the heightened risks of repeat hepatic resection. A review of single and multi-institutional experiences with thermal ablation for hepatic colorectal adenocarcinoma metastases indicates a risk of local recurrence (i.e., incomplete ablation; Table 125.2).^{42–47} In experienced hands, the risk of local recurrence can be <10%. The biggest risk factor for local recurrence is tumor size; for small tumors (<1 to 2 cm), the likelihood of incomplete ablation with modern MWA and RFA is quite small. The overall survival estimates observed in these series is significantly lower than those associated with hepatic resection; however, this is likely reflective of the significant selection bias that is inherent in any decision to undertake ablation over operative resection.

Adjuvant and Perioperative Chemotherapy

Adjuvant chemotherapy has been shown to decrease the risk of recurrence and improve survival for patients with stage III colorectal adenocarcinoma; moreover, systemic chemotherapy clearly prolongs survival for patients with unresectable metastatic colorectal adenocarcinoma. For these reasons, operative resection and systemic chemotherapy are typically used in close conjunction with one another, even for patients with readily resectable hepatic metastases. A fair amount of effort has been expended in an effort to measure the benefit of this multimodal approach to patients with resectable hepatic colorectal adenocarcinoma metastases. The largest multicenter prospective randomized trials evaluating the influence of adjuvant systemic chemotherapy are summarized in Table 125.3.^{48–52} Two prospective randomized clinical trials

comparing surgical resection alone to surgical resection followed by postoperative 5-FU and leucovorin identified a suggestion of improvement in progression-free survival among patients randomized to receive chemotherapy, but no improvement was seen in overall survival.^{48,49} Although some have argued that the combination of 5-FU and leucovorin is largely of historical interest because of the advent of more effective regimens of chemotherapy, a randomized

trial comparing adjuvant 5-FU/leucovorin to FOLFIRI showed no differences in survival.⁵⁰ Indeed, the more recent European Organisation for Research and Treatment of Cancer 40983 randomized trial comparing patients treated with surgical resection alone versus surgical resection with perioperative FOLFOX4 chemotherapy also only suggested an improvement in progression-free survival on subset analysis.^{51,52} It is worth recognizing that patients

who eventually develop recurrent metastatic disease after resection are likely to receive systemic chemotherapy, regardless of the nature of perioperative or postoperative treatment. Thus, it is quite possible that the reason these trials did not show differences in overall survival was because systemic chemotherapy was able to “salvage” patients who developed disease recurrence.

Neoadjuvant Chemotherapy

Regardless of these uncertainties, most patients with hepatic colorectal adenocarcinoma metastases are treated in a multimodal manner. Indeed, for patients with radiographic evidence of resectable disease (and whose underlying medical condition permits operative therapy), the decision is generally not whether to give chemotherapy, but when. It is likely that optimal therapy of hepatic colorectal adenocarcinoma metastases involves the multimodal use of systemic chemotherapy and operative tumor resection (or ablation). However, controversy persists regarding the ideal sequencing of treatment for patients with resectable tumors. The routine use of neoadjuvant chemotherapy (administered prior to operative therapy) offers several theoretical advantages: (1) it allows one to measure the chemosensitivity of tumors by observing radiographic evidence of tumoral regression; (2) in circumstances of rapid disease progression, as is the case with synchronous metastases, it allows for a period of safe observation in which other occult foci of metastases may become evident; and (3) it helps to ensure that patients will receive a vital component of multimodality therapy (chemotherapy), even if they develop major postoperative complications that prevent them from completing additional therapy. As the response rate of hepatic colorectal metastases to contemporary chemotherapy has improved to well over 50%, the rationale for using neoadjuvant therapy for drug selection or as a means of monitoring for prognostically adverse disease progression has diminished.^{53–55}

Conversion to Resectability

A major advancement in the treatment of metastatic colorectal adenocarcinoma has been in the array of technologies that can occasionally enable patients with initially unresectable disease to eventually undergo complete tumor extirpation. In circumstances where the FLR is insufficient in size, PVE and two-stage hepatectomy are commonly employed. A typical case example is illustrated in Figure 125.1.

On occasion, the extent of tumor burden is so great that PVE and two-stage approaches are not enough to achieve resectability. Fortunately, the steady improvements in response rates to chemotherapy have led to the use of systemic chemotherapy as a means of converting some patients with unresectable disease to resectability.⁵⁶ In one illustrative experience of 1,104 patients with unresectable hepatic colorectal adenocarcinoma metastases treated over an 11-year period at the Hôpital Paul Brousse, 138 patients (12.5%) demonstrated sufficient disease regression after an average of 10 cycles of chemotherapy to permit an attempt at resection; potentially curative hepatic metastasectomy was possible in 93% of the 138 patients, resulting in actuarial 5-year survival estimates of 33%.⁵⁷ It is important to recognize that this aggressive utilization of surgical resection for patients with advanced disease is unlikely to be curative; over the course of follow-up in this series, 80% of patients eventually developed disease recurrence, and overall survival in this select cohort of patients was significantly poorer than in patients who initially presented with resectable disease. However, it is likely that the outcomes observed following such aggressive surgical interventions might not have occurred following chemotherapy alone. A recent analysis from the MD Andersen Cancer Center compared patients with extensive tumor burden who exhibited a radiographic response to systemic chemotherapy. After controlling for a number of relevant patient and tumor characteristics, they

observed a striking difference in survival between patients who underwent hepatic metastasectomy at some point in their treatment versus patients who did not.⁵⁸ Although this study cannot account for all of the selection biases inherent in a retrospective comparison of surgical and nonsurgical patients, the magnitude of difference suggests that operative metastasectomy may likely impart an independent influence on survival duration.

Biological Agents

The armamentarium of systemic treatment options has been greatly expanded by the introduction of so-called biologic agents, which are targeted inhibitors or antibodies that interfere with the function of specific proteins and receptors involved in carcinogenic signaling pathways. Biologic agents such as bevacizumab, which targets the angiogenic vascular endothelial growth factor,^{59–61} and cetuximab, which targets the mitogenic epithelial growth factor,^{62,63} have been shown to improve response rates and progression-free survival when used in conjunction with traditional chemotherapy. One concern related to the use of bevacizumab is its potential negative influence on wound healing and bleeding. Although the extent to which preoperative administration of bevacizumab affects perioperative complication rates remains uncertain, a preferred approach has been to delay operative intervention until 4 to 8 weeks after the last administration of bevacizumab; when used in this manner, no significant changes in wound-related complications have been observed.^{64,65} An important variable to consider when using cetuximab is the tumoral mutational status of the KRAS oncogene; retrospective and prospective analyses have verified that the benefit associated with the use of cetuximab is confined to the KRAS wild-type population.^{66,67}

Chemotherapy-Associated Hepatotoxicity

An important argument against neoadjuvant chemotherapy is the risk of chemotherapy-associated hepatotoxicity. As the efficacy of chemotherapeutic agents against colorectal adenocarcinoma has increased, so too has their side effect profile of hepatotoxicity.^{68–70} Agents like 5-FU and irinotecan have been associated with a risk of hepatic steatosis, which can evolve into steatohepatitis. Livers afflicted by steatosis appear rounded and pink, and those with steatohepatitis demonstrate fibrotic changes that, over time, can progress to frank cirrhosis; both are associated with higher risks of intraoperative hemorrhage and impaired hepatic regeneration. Oxaliplatin is primarily toxic to endothelial or vascular tissues in the liver, and has been associated with sinusoidal vasodilation and obstruction that appears as a patchy bluish discoloration of the liver; heavy oxaliplatin use has been associated with higher risks of intraoperative hemorrhage. Several retrospective studies have reported higher rates of perioperative morbidity and prolonged hospitalizations in patients undergoing hepatic metastasectomy after prolonged courses of chemotherapy,^{71,72} and the aforementioned European Organisation for Research and Treatment of Cancer 40983 prospective trial identified a significantly higher rate of postoperative complications in the perioperative chemotherapy arm versus the operation alone arm (25% versus 16%, $p = 0.04$).⁵¹ As outlined previously, the ability of neoadjuvant or adjuvant chemotherapy to improve overall survival for patients undergoing hepatic metastasectomy remains unclear; whether and how the timing of chemotherapy vis-à-vis resection affects survival is unknown. Because prolonged administration of chemotherapy can induce enough liver damage to challenge the safety of surgical intervention, some clinicians have argued against the routine administration of neoadjuvant chemotherapy for patients with resectable hepatic metastases. At the very least, care should be taken to limit the duration of preoperative chemotherapy so as to minimize the risk of chemotherapy-associated hepatotoxicity; based on retrospective analyses, it appears that the risk of perioperative complications

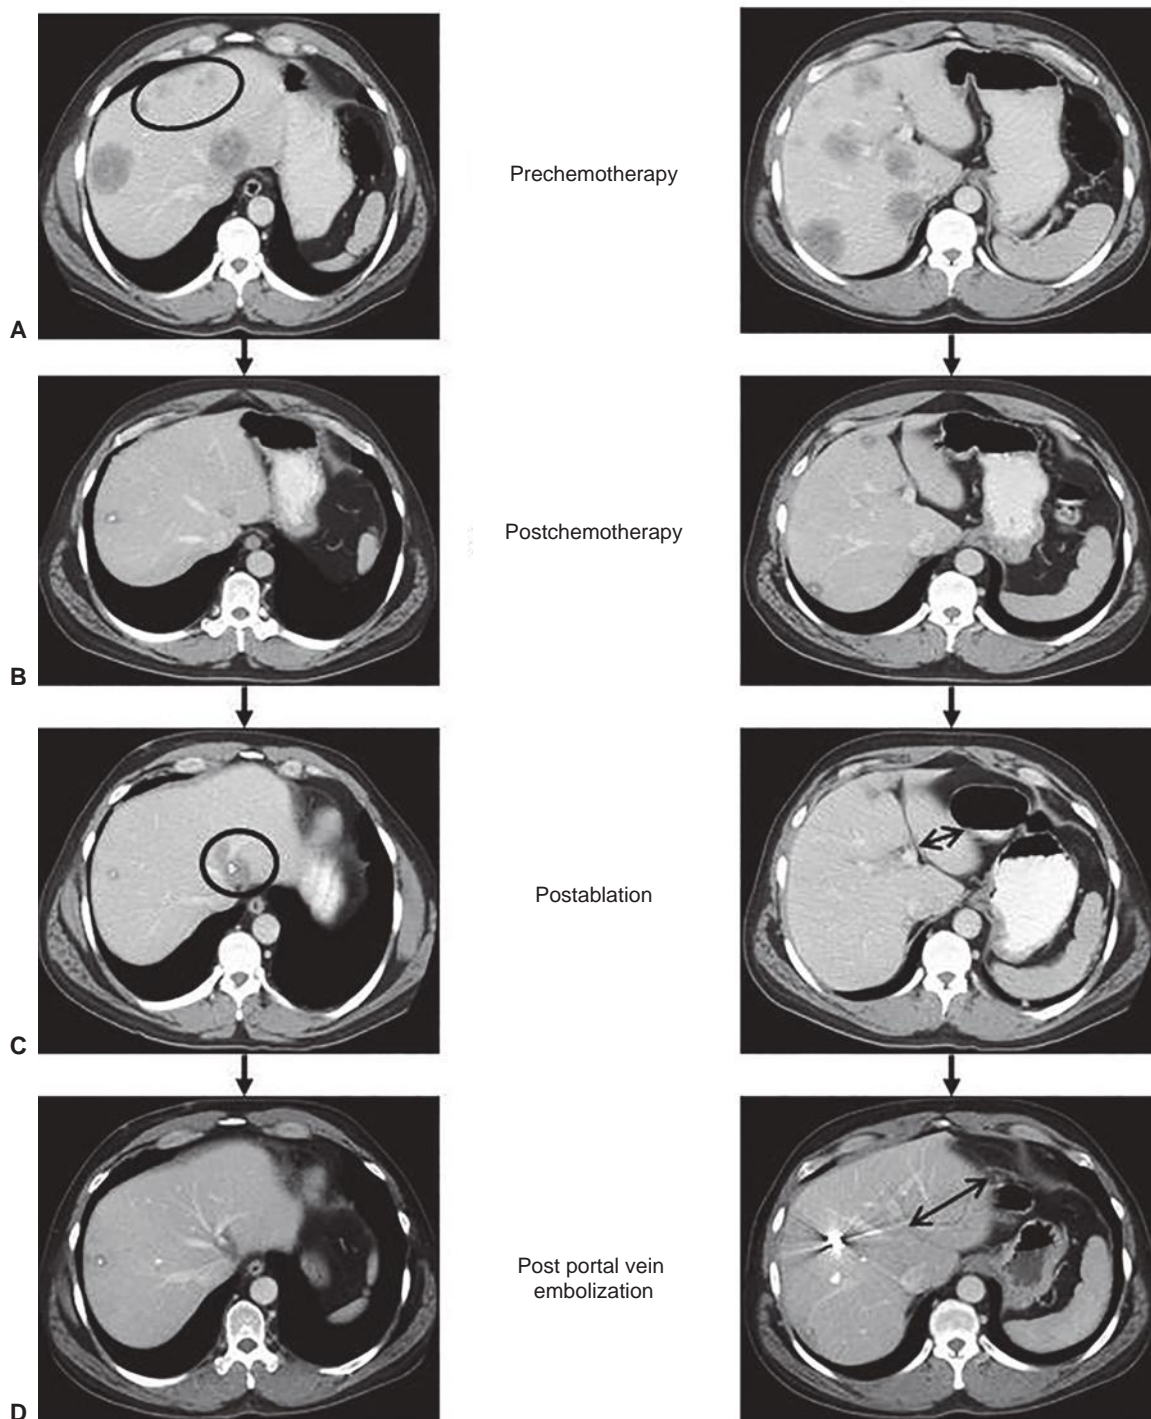

Figure 125.1 Two-stage hepatectomy. A man in his 50s presented with colon adenocarcinoma and radiographic evidence of synchronous, multifocal, bilateral hepatic metastases (**A**). Repeat imaging obtained after six cycles of systemic FOLFOX chemotherapy demonstrated marked regression of his metastases (**B**). Some of the lesions seen on initial imaging (circled in **A**) were no longer evident following chemotherapy. He underwent colectomy and microwave ablation of his solitary segment II metastasis, after which repeat imaging (**C**) and hepatic volumetrics (not shown) verified the presence of a small future liver remnant (segments II/III shown between arrows in **C**). Right portal vein embolization was performed, after which postembolization imaging suggested hypertrophy of the future liver remnant (segments II/III shown between arrows in **D**). Following verification of satisfactory hypertrophy by postembolization volumetrics (not shown), the patient underwent an extended right hemihepatectomy but subsequently developed intrahepatic and extrahepatic metastases after an interval of 18 months.

increases after six or more cycles of preoperative chemotherapy. Identification of chemotherapy-associated hepatotoxicity can be challenging, as routine laboratory assessment of hepatic function is typically not sensitive enough to identify these changes. Thrombocytopenia can be suggestive of hypersplenism resulting from hepatic fibrosis–induced portal hypertension. Radiographic evidence

of steatosis (as estimated by a decrease in hepatic parenchymal attenuation on CT imaging or signal dropout on in- and out-of-phase MRI sequences) or fibrosis (as indicated by alterations in hepatic segmental atrophy or hypertrophy or irregularities in parenchymal contour) can also be suggestive of hepatotoxicity.⁷³ Because of the inconsistency with which these preoperative diagnostics identify

significant hepatotoxicity, some have argued for the routine use of percutaneous liver biopsy (to evaluate for steatosis, fibrosis, or sinusoidal obstruction) in patients who have received intensive systemic chemotherapy.⁷⁴

Hepatic Artery Infusional Chemotherapy

As stated previously, hepatic metastases preferentially derive their perfusion from the hepatic arterial circulation. Floxuridine (FUDR) is a derivative of 5-FU that is rapidly metabolized by the liver. HAI of FUDR has therefore been developed as a means of delivering extremely high doses of chemotherapy to hepatic tumors with negligible systemic exposure. Clinical trials have demonstrated impressive benefits with the use of adjuvant and neoadjuvant HAI chemotherapy.⁷⁵⁻⁷⁷ However, many of these trials were undertaken prior to the availability of more modern chemotherapeutic agents; as a result, the contemporary role and benefit of HAI chemotherapy is not clear. Use of HAI FUDR has been associated with favorable response rates when used in patients who have been refractory to contemporary chemotherapy, suggesting that there is likely to be a role for this modality of treatment.^{77,78} However, its use requires familiarity with proper techniques for infusion pump placement and care. In addition, patients receiving HAI chemotherapy must be closely monitored for signs of biliary sclerosis. Like metastases, cholangiocytes of the biliary tree also derive their blood supply from the hepatic arterial system; as a result, prolonged arterial infusion of chemotherapy can result in biliary strictures. Administration of dexamethasone in conjunction with FUDR has been found to mitigate this risk.

The “Disappearing Metastasis”

Because of the risk of chemotherapy-associated hepatotoxicity, patients with advanced disease undergoing preoperative systemic chemotherapy must undergo serial imaging surveillance so that operative intervention can be undertaken before the onset of liver damage. On occasion, follow-up imaging will identify a complete radiographic disappearance of tumor(s). Appropriate management of the “disappearing metastasis” remains controversial. It is evident that a majority of these tumors have simply become radiographically occult, but will eventually reappear and progress after discontinuation of chemotherapy.⁷⁹ Interestingly, longitudinal analyses suggest that a subset of as many as one-fifth of highly selected patients may have durable remission of “disappeared metastases.”^{80,81} However, it is also noteworthy that most of these patients will eventually show signs of disease progression elsewhere, attesting to the significant risk of eventual relapse among patients with aggressively advanced hepatic colorectal metastases.

Prognostic Factors

A number of investigations have sought to identify the patient and disease variables that influence outcomes after hepatic metastasectomy. A prognostication system that has been shown to be of some utility is the Memorial Sloan Kettering Cancer Center Clinical Risk Score, which is a simple 0 to 5 scoring system incorporating the presence (or absence) of five prognostic variables related to both the primary and metastatic disease ([1] node-positive primary cancer, [2] disease-free interval [between the time of primary and metastatic cancer diagnosis] <12 months, [3] carcinoembryonic antigen >200 ng/mL, [4] maximal hepatic tumor size >5 cm, and [5] multifocal [>1] hepatic tumors). Developed prior to the introduction of contemporary chemotherapeutic regimens, the Clinical Risk Score has been shown to be useful for stratifying patients in terms of their risk of developing recurrent disease.⁸² However, recent analyses have suggested that, in the modern era of highly effective systemic therapy, the dominant variables influencing

outcomes after hepatic metastasectomy may be tumor responsiveness to chemotherapy and technical resectability.⁸³ This suggests that modern chemotherapy has largely overcome the impact of such traditional prognostic factors as nodal positivity and disease-free interval, largely reducing the decision of whether to undertake surgical intervention to a technical determination of resectability.

The goal of operative therapy is a margin-negative resection. However, the optimal distance of margin clearance remains unclear. As hepatic resections become more aggressive in their efforts to clear multifocal tumors while preserving a maximal amount of hepatic parenchyma, the ability to consistently obtain widely negative resection margins has become more difficult. Interestingly, recent analyses suggest that the critical goal is simply the presence of a microscopically negative margin, with relatively little prognostic impact being associated with the actual distance of margin clearance.⁸⁴⁻⁸⁶

Stereotactic Body Radiation Therapy

It is difficult to compare SBRT clinical outcomes with those observed after resection primarily because the SBRT series generally include patients who have been heavily pretreated with systemic therapy for metastatic disease and are, therefore, further along in the disease history. In most of the early liver SBRT pilot trials, an assortment of primary histologic types of cancers were included, though the most common is generally colorectal cancer by virtue of its frequency among cancer types. In 2006, Hoyer and colleagues⁸⁷ reported a phase 2 study of SBRT for patients with limited metastatic colorectal cancer. While the trial included patients with metastatic disease in a variety of sites, the majority (44/64 patients) had liver metastases, alone or in combination with other sites.⁸⁷ The 45-Gy dose was prescribed to the isocenter and not to the periphery of the tumor, and thus the actual dose received by the periphery of the tumor was likely close to 30 Gy in three fractions. The treatment was administered without the use of daily CT-based image guidance. Over half the patients had received prior chemotherapy, and roughly one-third had had prior surgery or RFA. The 2-year actuarial lesion local control rate was 86%, and the 1-year survival was 67%. One patient died due to hepatic failure possibly related to treatment, and another had surgery for colonic perforation. The toxicity observed was otherwise generally mild.

In 2011, Chang and colleagues⁸⁸ reported a pooled experience of liver SBRT restricted to colorectal cancer metastases from three major institutions collected prospectively on prospective clinical trials at each institution. Sixty-five patients with 102 lesions treated from August 2003 to May 2009 were analyzed. The patients were heavily pretreated: 47 (72%) patients had had one chemotherapy regimen prior to SBRT and 27 (42%) patients had had two or more regimens. Daily image guidance was used in all cases; only two patients experienced any late grade 3 toxicity, and none had any grade 4 or 5 toxicity. Local control of individual lesions was correlated with total dose and either of two composite equivalent dose indices taking into consideration the number of fractions and fraction size. When the data were fit to a logistic tumor control probability curve, the dose required to expect $\geq 90\%$ local control was on the order of 48 Gy or higher in three fractions. On multivariate analysis, active extrahepatic disease was associated with worse overall survival, and the attainment of durable local control was also closely correlated with longer survival. The results support the contention that even for heavily pretreated patients, clearing or cytoreducing the burden of tumor in the liver is associated with longer survival.

Evaluating local control after SBRT requires an understanding that there will be changes on CT scans whereby transiently for a few months after treatment, a hypodense region will be seen that correlates to the volume of liver that received a dose above the threshold to cause local veno-occlusive change, and this region is typically larger than the treated tumor.⁸⁹ PET scanning likely

offers a more reliable means of evaluating whether active tumor remains after treatment. Transient moderate increases in individual lesion maximum standardized uptake value (SUV_{max}) may be observed after SBRT, but generally the SUV_{max} declines steadily in a manner that can be modeled as exponential decay with a half-life of approximately 2 months, eventually reaching the typical normal liver tissue SUV_{max} of approximately 3.⁹⁰ It has been proposed that an SUV_{max} of 6 could serve as a cutoff to score post-SBRT local recurrence after SBRT.

HEPATIC NEUROENDOCRINE CARCINOMA METASTASES

Introduction

Like colorectal adenocarcinoma, neuroendocrine carcinoma arising from the gastrointestinal tract and pancreas commonly metastasizes to the liver via the portal venous circulation. As a result, therapies to target hepatic metastases have been developed and pursued aggressively. Unlike colorectal adenocarcinoma, comparatively little progress has been made in the development of systemic chemotherapy for neuroendocrine carcinoma. The motivation and rationale for aggressive liver-directed therapy for patients with hepatic neuroendocrine carcinoma center on the generally indolent and often highly symptomatic nature of its disease course. Well-differentiated forms of neuroendocrine carcinoma often grow and progress slowly, with median survival of patients with even widely metastatic disease being measured in years. In addition, the hormones that are often elaborated by neuroendocrine neoplasms escape hepatic metabolism when they arise from tumors located in the liver; as a result, patients with hepatic metastases can suffer from occasionally bizarre syndromes of hormonal overproduction that can quickly become refractory to pharmacologic suppression. The effort to prolong survival and/or improve quality of life has led to a variety of treatment options for patients with hepatic neuroendocrine carcinoma metastases.

An important difference between hepatic metastases from colorectal adenocarcinoma and neuroendocrine carcinoma is that neuroendocrine metastases tend to be more diffuse and multifocal in their dissemination. Indeed, it is not uncommon to find innumerable, miliary liver lesions in patients with metastatic neuroendocrine carcinoma. Not surprisingly, the likelihood of performing a complete resection, and the durability of hepatic recurrence-free survival, are much lower for hepatic neuroendocrine metastases. This important difference informs decision making when considering the various treatment options available for this disease.

Hepatic Resection

Hepatic neuroendocrine carcinoma metastasectomy follows the same principles of anatomy, physiology, and surgery that influence hepatic metastasectomy for colorectal adenocarcinoma. As such, assessment of FLR and the use of adjuncts like ablation and PVE are very relevant to the care of hepatic neuroendocrine metastases. Because of the paucity of systemic chemotherapy options for patients with metastatic neuroendocrine carcinoma, neoadjuvant and adjuvant chemotherapy and chemotherapy-associated hepatotoxicity are not particularly relevant.

Analyses of outcomes after hepatic metastasectomy are limited to retrospective series of carefully selected patients.⁹¹⁻⁹⁴ An overview of such analyses (Table 125.4) suggests that most patients can expect to survive for years following surgical therapy. However, it is also evident that the likelihood of cure is vanishingly small; in most series with reasonable durations of follow-up, the vast majority of patients experience disease recurrence, most often in the liver remnant.

One very important difference in the approach to hepatic resection for neuroendocrine carcinoma is the concept of operative cytoreduction. Whereas the goal of surgical treatment for hepatic colorectal metastases is invariably a complete resection, subtotal resection (also referred to as “debulking”) is occasionally advocated in the management of hepatic neuroendocrine metastases. The circumstance in which this is most appropriately pursued is in the palliation of patients with refractory symptoms of hormonal overproduction. Operative cytoreduction of a majority of hepatic disease burden has been associated with a magnitude and duration of symptomatic improvement that compares very favorably with nonoperative modalities of treatment. When cytoreduction is undertaken for this reason, therapy is typically directed at eliminating the largest tumors and resecting the maximal amount of total disease burden possible. However, there are no clear data to support the specific manner (e.g., the target tumor size or percentage of tumor bulk elimination) in which cytoreduction should be best performed. Some centers have argued that operative cytoreduction also prolongs survival for patients with metastatic neuroendocrine carcinoma.⁹³ However, it is important to recognize that patients with even significant hepatic tumor burden often survive for years without any form of tumor-directed therapy. Therefore, in the absence of randomized controlled data, the extent to which operative cytoreduction (resulting in gross residual disease) prolongs survival remains unclear. On the other hand, in light of the often diffuse manner in which neuroendocrine carcinoma metastasizes to the liver, and the near inevitability of hepatic recurrence following surgical resection, one can make the argument that all hepatic resections for metastatic neuroendocrine carcinoma are inherently cytoreductive.

TABLE 125.4

Selected Published Series of Outcomes After Hepatic Resection of Neuroendocrine Carcinoma Metastases

Author	Era	N	Median FU	Operative Mortality	Five-y OS	Ten-y OS	Median OS	Five-y RFS	10-y RFS	Median RFS	Symptom Control	Five-y SFS	Median SFS

FU, follow-up; OS, overall survival; RFS, relapse-free survival; SFS, symptom-free survival; NS, not stated.

^a Five-year progression-free survival.

Systemic Chemotherapy

Until recently, systemic therapy for patients with metastatic neuroendocrine carcinoma was restricted to somatostatin analogs and cytotoxic chemotherapy.⁹⁵ Treatment with somatostatin analogs like octreotide has been shown to delay disease progression when compared with placebo controls. Somatostatin analog therapy can also ameliorate hormonal symptoms in 60% to 90% of patients; however, this effect is typically short-lived, as symptoms typically recur in a refractory fashion about 1 year after initiation of therapy. Combinatorial approaches to cytotoxic chemotherapy using 5-FU, streptozocin, and doxorubicin or cisplatin and etoposide have been associated with response rates of approximately 40% for patients with poorly differentiated carcinoma. Unfortunately, these regimens are also associated with significant treatment-related toxicity.

Targeted therapies with biologic agents that have been used against other malignancies have recently shown promising efficacy and tolerability when used to treat pancreatic neuroendocrine carcinoma. Treatment with sunitinib, a tyrosine kinase inhibitor that targets vascular endothelial growth factor receptors and platelet-derived growth factor receptors, has been shown to prolong median progression-free survival (11.4 months versus 5.5 months) with a significantly higher objective response rate (9% versus 0%) when compared with placebo in the treatment of well-differentiated pancreatic neuroendocrine carcinoma.⁹⁶ Treatment with everolimus, an inhibitor of the protein mammalian target of rapamycin, resulted in a similar prolongation of progression-free survival (11 months versus 5.4 months) and improvement in objective response rates (5% versus 2%) compared with placebo in patients with well-differentiated pancreatic neuroendocrine carcinoma.⁹⁷ Further investigations will determine the efficacy of these novel agents in the treatment of hepatic neuroendocrine metastases.

Transarterial Therapy

Neuroendocrine carcinoma tumors are highly vascular, and the avidity with which hepatic metastases derive their blood supply from the hepatic arterial circulation has led to a great deal of interest in transarterial therapies. TAE and TACE have both been used to treat advanced cases of hepatic neuroendocrine carcinoma metastases. Despite the theoretical advantage of TACE, comparative studies have not identified a clear advantage of TACE over TAE, with both modalities of therapy improving hormonally referable symptoms in one-third to three-quarters of patients and inducing radiographically objective tumor regression in the majority of patients.⁹⁸ Accumulating experience suggests that ⁹⁰Yttrium-based SIRT compares favorably with TAE and TACE.⁹⁹ Of note, hormonal symptoms can occasionally be paradoxically exacerbating immediately following transarterial therapy; periprocedural administration of octreotide and histamine blockers may alleviate this transient effect.

Prognostic Factors

It is evident that the most informative prognostic variable for neuroendocrine carcinoma is the degree of histologic differentiation. Neuroendocrine carcinoma is characterized into three levels of histologic differentiation based on mitotic activity as assessed by mitotic figures or by Ki-67 immunohistochemical proliferative index. Classification of well-differentiated, moderately differentiated, and poorly differentiated disease permits stratification of oncologic outcomes. The prognosis of poorly differentiated neuroendocrine carcinoma is extremely poor, such that patients whose neuroendocrine metastases are preoperatively determined to be poorly differentiated are typically not subjected to aggressive surgical therapies.⁹²

Selective Internal Radiation Therapy

In the consensus report of the 2011 National Cancer Institute Neuroendocrine Tumor clinical trials planning meeting, the limitations on data concerning liver-directed therapy were acknowledged.¹⁰⁰ Specifically, it was noted that patients who undergo either hepatic resection or orthotopic liver transplantation are typically well selected; at the same time, it was acknowledged that randomized controlled trials studying patient outcomes with these treatment modalities would likely be difficult to execute.

A pooled multi-institutional retrospective review of patients who received SIRT for neuroendocrine tumor liver metastases was reported in 2008.¹⁰¹ A total of 148 patients who underwent 185 separate procedures were analyzed. The median age was 58 years (range, 26 to 95), and the median activity delivered was 1.14 GBq (0.33 to 3.30 GBq). The risk of Common Toxicity Criteria for Adverse Events grade 3 or higher fatigue or nausea was 6.5% and 3.2%, respectively. The 3-month imaging-based response was stable in complete in 3%, partial in 60%, stable in 23%, progressive disease in 5%, and unavailable in the others. No radiation-related liver failure occurred, and the median survival was 70 months.

In a 42-patient prospective study, King and colleagues¹⁰² treated patients with neuroendocrine tumor liver metastases who had failed standard-of-care therapies, defined as progression on octreotide and after resection, ablation, or embolotherapy. SIRT was performed with either ⁹⁰Yttrium resin or glass microspheres. Prior treatments included medication (60%), surgery or ablation (55%), and bland or chemoembolization (14%). The overall response rate was approximately 50% for either type of microsphere (resin or glass). Median survival was roughly 2 years for the entire group.

NONCOLORECTAL NONNEUROENDOCRINE HEPATIC METASTASES

Introduction

As stated, liver-directed therapy is often undertaken for colorectal adenocarcinoma and neuroendocrine carcinoma because of nuances related to disease biology and available chemotherapy. The tendency of metastatic colorectal adenocarcinoma and neuroendocrine carcinoma to be confined to the liver, the availability of effective systemic chemotherapy (for colorectal adenocarcinoma), and the relative indolence of disease progression (for neuroendocrine carcinoma) all enable the aggressive implementation of surgical and nonsurgical liver-directed treatments. For noncolorectal and nonneuroendocrine malignancies that do not share these biologic and therapeutic characteristics, the decision to utilize liver-directed therapy is made on a more individualized, case-by-case basis. As a result, it is difficult to provide generalized treatment recommendations for these types of metastatic disease. However, there has been enough experience with some malignancies such as ocular melanoma, breast carcinoma, and sarcoma to share a few observations.

Ocular (Uveal) Melanoma

Like colorectal adenocarcinoma and neuroendocrine carcinoma, ocular melanoma has a biologic tendency to metastasize to the liver. Because of its tendency to metastasize in a miliary, diffuse manner, meaningful surgical intervention is rarely an option. However, because the liver is the predominant site of metastatic disease in 70% to 90% of cases, transarterial therapy like TACE, SIRT, and HAI chemotherapy have been used in carefully selected patients, with over half of patients exhibiting tumoral regression or transient disease stabilization.¹⁰³

Breast Carcinoma

Liver-directed therapy is occasionally contemplated for unusual cases of oligometastatic breast carcinoma in which the metastases are confined to the liver. The preferred therapy for metastatic breast carcinoma is systemic chemotherapy and hormonal therapy. However, in carefully selected patients, hepatic metastasectomy has been associated with median overall survival estimates of 3 to 4 years, with median disease-free survival estimates of nearly 2 years.¹⁰⁴ In the absence of randomized controlled trials, the extent to which these outcomes represent actual improvements beyond those that might have been expected with systemic chemotherapy alone remains uncertain.

Sarcoma

Intraabdominal and retroperitoneal sarcomas occasionally metastasize to the liver. There are relatively few effective systemic chemotherapy options for patients with metastatic sarcoma, and liver-directed therapy is generally undertaken in highly selected cases that exhibit relatively favorable disease biology. One important exception to this is gastrointestinal stromal tumors, which are likely to respond to systemic administration of the tyrosine kinase inhibitors imatinib and sunitinib. Not surprisingly, hepatic metastasectomy can be undertaken more aggressively in patients with metastatic gastrointestinal stromal tumors when used in conjunction with tyrosine kinase inhibition. When used in this manner, hepatic metastasectomy has been associated with median overall survival estimates exceeding 5 years.^{104,105}

126 Metastatic Cancer to the Bone

Edward Chow, Joel A. Finkelstein, Arjun Sahgal, and Robert E. Coleman

INTRODUCTION

Bone metastases are most frequent in breast and prostate carcinomas, and affect two-thirds to three-quarters of patients with advanced disease from these tumors. In addition, lung, thyroid, and renal carcinoma metastasize to bone in approximately 30% to 40% of cases.¹ Mean survival ranges from a low of 6 months for those with lung carcinoma, to several years for those with bone metastases from prostate, thyroid, or breast carcinoma.¹ If patients have skeletal metastases only, their average survival is even longer.

PRESENTATION

The morbidity associated with metastatic bone disease, often referred to as skeletal-related events (SRE), includes pain that may require opiates, the need for radiotherapy and/or surgery, hypercalcemia, pathologic fractures, and spinal cord compression. The most common symptom is pain. Pain initially may be either a well-localized focus of pain or a diffuse ache, typically worse at night and often not relieved by lying flat. Pain from extremity lesions tends to be well defined, in contrast to spine and pelvic sites, which produce vague, diffuse symptoms. Eventually the pain worsens with weight-bearing activity. Initially, pain results from the physical presence of tumor in the bone; with the release of inflammatory mediators, neuropeptides, and cytokines; as well as elevation of the intraosseous pressure from tumor mass effect, causing irritation of intraosseous and periosteal nerve endings.² Functional pain is caused by the mechanical weakness of the bone, which can no longer support the normal stresses of daily activities. Mechanical pain is more typically associated with the focal bone loss within lytic lesions; however, radiographically blastic lesions may also weaken the bone through associated areas of osteolysis that are sufficient to compromise structural integrity. The development of functional pain may be a marker for bone at risk for fracture. Pathologic fractures may be the first sign of metastatic bone disease. In breast carcinoma, as many as 35% of patients with bone disease experience a fracture.³ Breast, lung, renal, and thyroid cancers have been the most common cancers with pathologic fracture, but even in endocrine-resistant prostate cancer where osteoblastic metastases are typical, annual fracture rates in excess of 20% may be seen.¹

PATHOPHYSIOLOGY

Historically, Batson¹ described the high-flow, low-pressure, valveless plexus of veins that connects the visceral organs to the spine and pelvis. Recent research has focused on the multistep cellular process of metastases. First, the cancer cell must disengage from its primary site. The loss of expression of E-cadherin, a cell-surface adhesion molecule, has been demonstrated in breast, prostate, colorectal, and pancreatic carcinoma as an early step in cellular disengagement. After invasion of the vascular or lymphatic system,

the cancer cell must survive the immune system and then arrest at its final destination. At the distant site, the malignant cell must adhere to the basement membrane, invade the surrounding tissue, induce angiogenesis, and develop into a secondary mass.

However, in addition to these generic steps involved in metastases, tumor cells in the bone marrow require interaction with normal bone cells to establish a metastatic lesion in bone. The growth factor and cytokine expression of the tumor cells leads to an interaction with osteoclasts and osteoblasts, the balance of which determines the nature of the lesion and its corresponding radiographic appearance. Osteoclastic activity has been shown to be increased by tumor expression of interleukins 6 and 11, and parathyroid hormone-related protein.⁴ Bone resorption leads to the release of bone-derived growth factors, notably transforming growth factor-beta, that in turn may react with receptors on the tumor cells. This sets up the so-called vicious cycle whereby the stimulation of bone cell activity produces a favorable microenvironment for the neighboring tumor cells and facilitates the metastatic process. The new bone formation associated with osteoblastic lesions has been associated with endothelin-1 and insulin-like growth factor stimulation of osteoblasts, but typically even in osteoblastic lesions there is also an associated increase in osteoclastic bone resorption.⁵

DIAGNOSTIC EVALUATION

Radiographs and bone scans are the first lines of imaging to document the presence or absence of an osseous lesion, and to identify whether these are solitary or multiple lesions. In the spine, plain films classically show absence of a pedicle with the “winking owl sign” (Fig. 126.1).

A computed tomography (CT) scan is the best to define the size of an osseous lesion and to evaluate the extent of cortical involvement. In the spine, CT scan is most useful to evaluate aspects of bony stability as measured by pedicle and/or posterior body wall integrity. These factors are important in establishing risk of burst fracture and for planning and assessing the safety of vertebroplasty as a treatment alternative.⁶ CT-guided biopsy can be used for obtaining tissue samples. Magnetic resonance imaging is valuable for evaluating marrow disease and is most sensitive in identifying metastatic deposits in the spine and pelvis. In patients with neurologic compromise, magnetic resonance imaging is best for assessing epidural disease and extent of vertebral involvement (solitary versus multifocal).

THERAPEUTIC MODALITIES

Optimal management requires a multidisciplinary team. Medical treatment, radiation therapy, surgery, and bone-targeted treatment with the bisphosphonates and denosumab are combined depending on the biology of the disease, extent of the skeletal involvement, and the life expectancy of the patient.

Figure 126.1 Anteroposterior radiograph of thoracolumbar spine. Right-sided T10 pedicle is absent, giving appearance of a winking owl (see arrow).

Systemic Therapy

Systemic therapy for bone metastases can be targeted against the tumor cell itself to reduce tumor burden or, alternatively, directed toward blocking the effect of tumor-derived growth factors and cytokines on host cells. Chemotherapy, biologically targeted agents, and endocrine treatments have direct antitumor effects, whereas agents such as the bisphosphonates and denosumab are effective by preventing host cells (primarily osteoclasts) from reacting to tumor products. Systemic therapy, therefore, has either direct or indirect actions. In general, the choice of systemic treatment for metastatic bone disease is based on the same criteria as those used for other metastatic manifestations of the malignancy.⁷

For breast cancer, endocrine therapy is the treatment of choice for the initial treatment of metastatic disease unless the disease is known to be estrogen receptor–negative or there is extensive and/or aggressive visceral disease. Objectively responding patients usually gain relief of symptoms (including bone pain) and might become able to resume their previous activities. Although in general the median duration of response to endocrine therapy is around 15 months, prolonged responses to first-line hormone treatments lasting several years are not uncommon in patients with bone metastases.

There have been many recent developments in cytotoxic and biologic treatments of relevance to the patient with metastatic bone disease from breast cancer. Response in bone to chemotherapy is nearly always only partial, with a median duration of response of 9 to 12 months. Chemotherapy can be more hazardous for patients with extensive bone disease, because of both poor bone marrow tolerance after replacement of functioning marrow by tumor and the effects of previous irradiation. Primary prophylaxis with hematopoietic growth factors may be required to enable chemotherapy to be administered safely.

In prostate cancer, at least 80% of prostate tumors exhibit some degree of hormone responsiveness with a median duration of response of around 2 years. Until recently, treatment to extend

survival for castration-resistant prostate cancer (CRPC) was limited to docetaxel. Patients with CRPC tend to be elderly and often of too poor a performance status to receive aggressive systemic therapy. However, the recent introduction of the endocrine agents, such as abiraterone and enzalutamide, and the bone-seeking, alpha particle–emitting radioisotope alpharadin into clinical practice provides well-tolerated additional therapeutic options.

Skeletal morbidity is a major problem in multiple myeloma despite a high rate of response to chemotherapy. Despite the subjective improvement that is seen, bone healing is rare, with lytic lesions persisting despite control of the disease for months or years. Newer agents provide many more options and have transformed the clinical course of multiple myeloma in recent years into that of a chronic disease. Bone involvement in germ cell tumors and lymphoma conveys a worse prognosis, but despite this, cure with chemotherapy is frequent. For relatively chemotherapy-resistant solid tumors such as non–small-cell lung cancer or melanoma, the benefits of current chemotherapy regimens are limited and many patients with skeletal metastases from these tumors derive most benefit from local radiotherapy and bone-targeted agents. However, more effective treatments are emerging, notably the angiogenesis inhibitors in renal cell cancer, and the emergence of a range of targeted treatments for patients with specific mutations (e.g., b-raf in melanoma, epidermal growth factor receptor and alk in lung cancer) that are providing exciting new options for subsets of patients with solid tumors that also involve the skeleton.

Bisphosphonates for Metastatic Bone Disease

Over the past 15 years, bisphosphonates have become established as a valuable additional approach to the range of current treatments. Bisphosphonates are analogues of pyrophosphate, characterized by a phosphorus-carbon-phosphorus-containing central structure that binds to bone and a variable side chain that determines the relative potency, side effects, and the precise mechanism of action.⁸ Bisphosphonates bind avidly to exposed bone mineral, and during bone resorption, bisphosphonates are internalized by the osteoclast and subsequently cause apoptotic cell death.

After intravenous administration of a bisphosphonate, the kidney excretes approximately 25% to 40% of the injected dose, and the remainder is taken up by bone where it is retained for months or even years. All bisphosphonates suffer from poor bioavailability when given by mouth and must be taken on an empty stomach, as they bind to calcium in the diet. It is generally accepted that osteoclast activation is the key step in the establishment and growth of bone metastases. Biochemical data indicate that bone resorption is of importance not only in classic “lytic” diseases such as myeloma and breast cancer, but also in prostate cancer.⁵ As a result, the osteoclast is a key therapeutic target for skeletal metastases irrespective of the tissue of origin.⁹ Although radiotherapy is the treatment of choice for localized bone pain, the bisphosphonates provide an additional treatment approach for the relief of bone pain across a range of tumor types.⁹

Oral Bisphosphonates

The absorption of bisphosphonates from the gut is poor, variable, and dramatically inhibited by food intake. Nevertheless, oral clodronate and ibandronate have been shown in randomized trials to have useful efficacy in breast cancer.^{9,10}

Intravenous Bisphosphonates

There is extensive experience with intravenous bisphosphonates in breast cancer, with zoledronic acid, pamidronate, and ibandronate all showing useful clinical activity.^{9,10} Comparative data are

few but, in a double-blind randomized trial of 1,130 patients with advanced breast cancer, an additional 20% reduction in the risk of SREs was seen with zoledronic acid compared with pamidronate ($p = 0.025$).¹¹ Ibandronate is licensed in Europe for the treatment of metastatic bone following a placebo-controlled trial of monthly infusions that showed a significant reduction in skeletal-related morbidity.¹²

Intravenous bisphosphonates have become routine clinical management for most patients with multiple myeloma, with zoledronic acid and pamidronate the agents of choice.^{11,13} Improved survival with the inclusion of zoledronic acid in first-line myeloma treatment, as well as fewer SREs, has been shown in a large randomized comparison of zoledronic acid to oral clodronate.¹⁴ In advanced CRPC, zoledronic acid was shown to reduce the overall risk of skeletal complications by 36%.¹⁵ Additionally, zoledronic acid significantly reduced the risk for SRE(s) by about 30% ($p = 0.003$) in the management of bone metastases from solid tumors other than breast or prostate cancer.¹⁶

DENOSUMAB

Denosumab is a fully human monoclonal antibody that binds and neutralizes RANKL with high affinity and specificity to inhibit osteoclast function and bone resorption. Following a single subcutaneous dose, denosumab caused rapid and sustained suppression of bone turnover in patients with multiple myeloma and patients with breast cancer.¹⁷ A subsequent dose-finding phase 2 study defined a subcutaneous 120 mg dose every 4 weeks for phase 3 development.¹⁸ A broad development program in >5,700 patients with metastatic disease has shown superiority of denosumab over zoledronic acid in the time to first SRE in trials encompassing a broad range of solid tumors.^{19–21} The hazard rates for first SRE were 0.82 (95% confidence interval [CI] = 0.71 to 0.95),¹⁹ 0.82 (95% CI = 0.71 to 0.95),²⁰ and 0.84 (95% CI = 0.71 to 0.98),²¹ in the trials performed in breast cancer, CRPC, and other solid tumors and myeloma groups, respectively. However, no differences in overall survival or investigator-reported disease progression were found between the two treatment groups in any of the studies.

The safety profiles of denosumab and zoledronic acid are different. Denosumab does not adversely affect renal function, eliminating the need for routine monitoring of renal function. Acute-phase reactions are also less common with denosumab, but hypocalcemia is more frequent.^{19–21} As a result, vitamin D deficiency should be corrected and all patients should be encouraged to take calcium and vitamin D supplements throughout the course of their treatment. As with intravenous bisphosphonates, the most important adverse event associated with denosumab in the oncology setting is osteonecrosis of the jaw. This occurs with similar frequency in patients treated with denosumab or zoledronic acid, affecting 0.5% to 1% of patients per year on treatment.²²

Optimum Use of Bone Targeted Agents in Metastatic Bone Disease

Despite the obvious clinical benefits of bisphosphonates and denosumab, it is clear that only a proportion of events are prevented, while some patients do not experience a skeletal event despite the presence of metastatic bone disease. It is currently impossible to predict whether an individual patient needs or will benefit from a bisphosphonate. Because of the logistics and cost of delivering monthly treatments to all patients with metastatic bone disease, certain empiric recommendations on who should receive treatment are needed. These should take into account the underlying disease type and extent, the life expectancy of the patient, the probability of the patient experiencing an SRE, and the ease with which the patient can attend for treatment (or be

treated by a domiciliary service).²³ The development of an SRE is not a sign of treatment failure or a signal to stop treatment; evidence is now available to confirm that bone-targeted treatments delay second and subsequent complications, not just the first event.

The recent guidelines on the management of metastatic bone disease in breast cancer from the American Society of Clinical Oncology did not recommend one bone-modifying agent (zoledronic acid, pamidronate, denosumab) over another.²⁴ Although denosumab has some efficacy and convenience advantages, it is much more expensive than zoledronic acid and pamidronate, which are now available as generic formulations. Denosumab or zoledronic acid is appropriate for patients with endocrine-resistant metastatic bone disease from prostate cancer,²⁵ whereas zoledronic acid or pamidronate are recommended for multiple myeloma.²⁶ Patients with other tumors and symptomatic metastasis to bone should certainly be considered for treatment with denosumab or zoledronic acid if bone is the dominant site of metastasis, and also if bone is one of multiple involved sites when the prognosis is reasonable (life expectancy >6 months).⁹ Bone resorption markers such as N-telopeptide of type 1 collagen may be useful to identify patients at high risk of skeletal complications.⁵ Additionally, normalization of bone resorption is associated with improved clinical outcomes including fewer SREs and prolonged survival.²⁷

NEW TARGETED THERAPIES IN THE TREATMENT OF METASTATIC BONE DISEASE

A number of targeted agents have entered clinical development. These include radium-223, inhibitors of cathepsin K, an osteoclast-derived enzyme that is essential for the resorption of bone, and Src kinase, a key molecule in osteoclastogenesis. Of all these, radium-223 shows the most promise. Radium-223 is a calcium mimetic that preferentially targets bone metastases and emits high-energy alpha particles resulting in highly localized cytotoxic effects with minimal myelosuppression. In a recent phase 3 study of radium-223 in 921 patients with CRPC and symptomatic bone metastases, radium-223 improved median overall survival by 3.6 months (hazard ratio = 0.70; 95% CI = 0.58 to 0.83; $p < 0.001$) and significantly delayed the time to first symptomatic skeletal event (hazard ratio = 0.66; 95% CI = 0.52 to 0.83; $p < 0.001$).²⁸

EXTERNAL BEAM RADIATION THERAPY

Radiotherapy is effective in relieving bone pain, preventing impending fractures, and promoting healing in pathologic fractures. Hematologic or gastrointestinal side effects are usually mild and transient. Numerous randomized trials have been conducted on dose-fractionation schedules of palliative radiotherapy. Despite that, there is still no uniform consensus on the optimal dose fractionation scheme. One of the first randomized studies on bone metastases was conducted by Radiation Therapy Oncology Group (74-02).²⁹ A total of 90% of patients experienced some relief of pain, and 54% achieved eventual complete pain relief. The trial concluded that the low-dose, short-course schedules were as effective as the high-dose protracted programs. However, this study was criticized for using physician-based pain assessment. A reanalysis of the same set of data, grouping solitary and multiple bone metastases, using the end point of pain relief and taking into account of analgesic intake and retreatment, concluded that the number of radiation fractions was statistically significant related to complete combined relief (absence of pain and use of narcotics). The conclusion was that protracted dose-fractionation schedules were more effective than short-course schedules.³⁰ This reanalysis was

contrary to the initial report, highlighting that the choice of end points are very important in defining the outcomes of clinical trials.³¹

Several large-scale prospective randomized trials were subsequently performed. The United Kingdom Bone Pain Trial Working Party randomized 765 patients with bone metastases to either an 8-Gy single fraction or a multifraction regimen (20 Gy in 5 fractions or 30 Gy in 10 fractions).³² There were no differences in the time to first improvement in pain, time to complete pain relief, or time to first increase in pain at any time up to 12 months from randomization. Retreatment was twice as common after 8 Gy than after multifraction radiotherapy. There were no significant differences in the incidence of nausea, vomiting, spinal cord compression, or pathologic fracture between the two groups. The study concluded that a single 8 Gy is as safe and effective as a multifraction regimen for the palliation of metastatic bone pain for at least 12 months. The Dutch Bone Metastases Study included 1,171 patients and found no difference in pain relief or the quality of life following a single 8-Gy or 24-Gy dose in six daily radiation treatments.³³ However, the retreatment rates were 25% in the single 8-Gy arm and 7% in the multiple-treatment arm, respectively. In the cost-utility analysis of this randomized trial, there was no difference in life expectancy or quality-adjusted life expectancy. The estimated cost of radiotherapy, including retreatments and nonmedical costs, was statistically significantly lower for the single-fraction schedule than for the multiple-fraction schedule.³⁴

One critical review included a systematic search for randomized trials of localized radiotherapy of bone metastases employing different dose fractionations.³⁵ The authors suggested that protracted fractionated radiotherapy, given over 2 to 4 weeks, results in more complete and durable pain relief. However, two earlier meta-analyses showed no significant difference in complete and overall pain relief between single-fraction and multifraction palliative radiotherapy for bone metastases.^{36,37} The meta-analysis reported that the complete response rates (absence of pain) were 33.4% and 32.3% after single-fraction and multifraction radiation treatments, respectively, while the overall response rates were 62.1% and 58.7%, respectively. Most patients will experience pain relief in the first 2 to 4 weeks after radiotherapy, be it single or multiple fractionations.³⁶ However, the retreatment and pathologic fracture rates were higher in single-fraction treatments.³⁷

Since the publication of the two meta-analyses, more randomized trials on bone metastases have been reported. The Radiation Therapy Oncology Group repeated the randomized study in patients with breast or prostate cancer who had one to three sites of painful bone metastases and moderate to severe pain with patient self-assessment.³⁸ There were 455 patients in the single 8-Gy arm and 443 in the 30-Gy in 10 fractions arm. Grade 2 to 4 acute toxicity was more frequent in the multiple arms (17%) than in the single arm (10%) ($p = 0.002$). Late toxicity was rare (4%) in both arms. The overall response rate was 66%. Complete and partial response rates were 15% and 50%, respectively, in the single-fraction arm compared with 18% and 48%, respectively, in the multiple-fractions arm ($p = 0.6$). Both regimens were equivalent in terms of pain and narcotic relief at 3 months. The single-fraction arm had a higher rate of retreatment (18% versus 9%; $p < 0.001$). Four Norwegian and six Swedish hospitals planned to recruit 1,000 patients with painful bone metastases. Patients were randomized to single 8 Gy or 30 Gy in 10 fractions.³⁹ The interim analysis indicated that, as in other recently published trials, the treatment groups had similar outcomes. Similar pain relief within the first 4 months was experienced in both groups and this was maintained throughout the 28-week follow-up. No differences were found for fatigue, global quality of life, and survival in both groups.

An updated meta-analysis reporting 25 randomized trials totaling 2,818 and 2,799 randomizations in single-fraction and multiple-fraction arms revealed the overall and complete response rates were 60% and 23%, respectively, in single-fraction

arm versus 61% and 24%, respectively, in multiple-fraction arms, again demonstrating equal efficacy.⁴⁰ However, there is some evidence that certain groups of patients would benefit from a protracted schedule. Roos et al.⁴¹ compared a single 8 Gy versus 20 Gy in five fractions for 272 patients with bone metastases causing pain with a neuropathic component. They concluded that a single dose was not as effective as multiple fractions for the treatment of neuropathic pain; however, it was also not significantly worse. They recommended that 20 Gy in five fractions be used as standard radiotherapy for patients with neuropathic pain. However, in patients with short survival, poor performance status, where the cost/inconvenience of multiple treatments was a factor, and in treatment centers with lengthy wait times, single fractions could be used instead.⁴¹

How, then, are radiation oncologists to prescribe treatment? The answer most likely resides within the clinical circumstances and individual wishes of each patient. There is no doubt that in patients with short life expectancy, protracted schedules are a burden. However, in patients with a longer expected survival, such as patients with breast cancer and patients with prostate cancer with bone metastases only, other parameters need to be taken into account. Because retreatment rates are known to be higher following a single versus multiple fractions, about 25% versus 10%, respectively, patients with good performance status may wish to share in the decision-making process.

What should be an optimal dose for single fraction treatment? A prospective randomized trial on 270 patients with painful bone metastases compared efficacy of 4-Gy or 8-Gy single doses.⁴² At 4 weeks, the actual response rates were 69% for 8 Gy and 44% for 4 Gy ($p < 0.001$), but there was no difference in complete response rates at 4 weeks or duration of response between the two arms. It is concluded that 8 Gy gives a higher probability of pain relief than 4 Gy, but that 4 Gy can be an effective alternative in situations of reduced tolerance. Another randomized trial of three single-dose radiation therapy regimens in the treatment of metastatic bone pain consisted of single 4 Gy, 6 Gy, or 8 Gy.⁴³ The authors confirmed that 8 Gy could be considered as probably "lowest" optimal single-fraction radiation treatment for painful bone metastases, although single 4 Gy should not be easily discarded because of its applicability in specific cases.

Wide-Field or Half-Body External Beam Radiation

Wide-field or half-body irradiation (HBI) differs from localized external beam radiation mainly in the volume of tissues and bone metastases covered as a single treatment field. It is more useful for patients with multiple painful bone metastases. HBI is usually delivered either to the upper half or to the lower half of the body. Single-fraction HBI has been shown in retrospective and prospective phase 1 and 2 studies to provide pain relief in 70% to 80% of patients.^{44,45} Pain relief is apparent within 24 to 48 hours, suggesting that cells of the inflammatory response pathway may be the initial target tissue, as tumor cell activities are unlikely to be halted so quickly. Toxicities include minor bone marrow suppression and gastrointestinal side effects such as nausea and vomiting in upper abdominal radiation and may be controlled with ondansetron or dexamethasone.

Pulmonary toxicity is minimal provided the lung dose is limited to 6 Gy.⁴⁶ Fractionated HBI was investigated in a randomized phase 2 study involving 29 patients, comparing a single fraction with fractionated HBI (25 to 30 Gy in multiple fractions). Pain relief was achieved in over 94% of patients. At 1 year, 70% in the fractionated and 15% in the single-fraction group had pain control, and repeat radiation was required in 71% and 13% for the single and fractionated group, respectively.⁴⁷ Poulter et al.⁴⁸ reported results of a randomized trial of 499 patients comparing local radiation alone versus local radiation plus a single fraction of HBI.

The study documented a lower incidence of new bone metastases (50% versus 68%) and fewer patients requiring further local radiotherapy at 1 year after HBI (60% versus 76%). The choice of dose-fractionation schedule for HBI was explored by Salazar et al.⁴⁹ among 156 randomized patients. Among the three trial arms of 15 Gy in five fractions over 5 days, 8 Gy in two fractions over one day, and 12 Gy in four fractions over 2 days, the 15-Gy regimen not only provided pain relief as much as the other regimens, but also a longer survival duration in prostate cancer patients.

Reirradiation

As effective systemic treatment and better supportive care result in improved survival, certain subsets of patients have longer life expectancies than before and outlive the duration of the benefits of initial palliative radiotherapy, requiring reirradiation of the previously treated sites.

Among the radiation trials comparing single- versus multiple-fractionation schemes, reirradiation rates varied from 11% to 42% following single-fraction and 0% to 24% following multiple-fraction schedules. There are at least three scenarios of “failure” where reirradiation may be considered. Response to reirradiation may be different for each of these scenarios: (1) No pain relief or pain progression after initial radiotherapy, (2) partial response with initial radiotherapy and the hope to achieve further pain reduction with more radiotherapy, and (3) partial or complete response with initial radiotherapy but subsequent recurrence of pain.

Mithal et al.⁵⁰ reported a retrospective analysis of 105 patients treated with palliative radiotherapy for painful bone metastases. A total of 280 individual treatment sites were identified, of which 57 were retreated once and 8 were retreated twice. The overall response rate to initial treatment was 84% for pain relief, and at first retreatment this was 87%. Seven of the eight (88%) patients retreated a second time also achieved pain relief. A total of 17 of 23 (74%) patients responded to second radiation that used a number of single-fraction regimens, which was not significantly inferior to 31 of 34 (91%) obtained with more protracted regimens. Jeremic et al.⁵¹ investigated the effectiveness of a single 4 Gy given for retreatment of bone metastasis after previous single-fraction radiotherapy. Of 135 patients retreated, 109 patients were retreated because of pain relapsing, whereas 26 patients were reirradiated after initial nonresponse. Of the 109 patients who were reirradiated for pain relapse, 80 (74%) patients responded (complete response = 31%; partial response = 42%). Among the 26 patients who did not respond initially, there were 12 (46%) responses. The authors concluded that the lack of response to initial single-fraction radiotherapy should not deter repeat irradiation. Toxicity in their series was low and gastrointestinal only. No acute toxicity grade 3 or higher was reported. Pathologic fractures were reported in 3 of 135 (2%) patients and spinal cord compression in 3 of 135 (2%) patients in their series. The same group reported the efficacy of the second single 4 Gy reirradiation for painful bone metastases following the previous two single fractions. The overall response rate of the 25 patients (19 responders and 6 nonresponders to the two prior single fractions) was 80%, with both complete response and partial response being 40%. No acute or late high-grade toxicity (≥ 3) was observed in their study. No pathologic fractures or spinal cord compression were seen in any of these patients during the follow-up.⁵²

The Dutch Bone Metastases Study Group presented the efficacy of reirradiation of painful bone metastases.⁵³ For patients not responding to the initial radiation who were reirradiated, 66% of patients who initially received a single 8-Gy fraction responded to the retreatment versus 33% of patients who received the initial multifraction regimens. Retreatments for patients with progression was successful in 70% single-fraction patients versus 57% multifraction patients. In general, retreatment was effective

in 63% of all retreated patients. A recent intergroup randomized trial on dose fractionations in repeat radiation for painful bone metastases in 850 patients concluded a single 8 Gy appears to be noninferior and less toxic than 20 Gy in multiple fractions with 2-month response rates in evaluable patients of 45% versus 51%, respectively ($p = 0.17$).⁵⁴

SYSTEMIC RADIONUCLIDES

Patients with bone metastases often have diffuse bony disease. Administration of a systemic radionuclide has the advantage of targeting all bony lesions simultaneously, and can be given as a single administration on an outpatient basis. Osteoblastic bone metastases can be detected by a technetium-99 methylenediphosphonate bone scan. Radionuclides react with bone mineral (hydroxyapatite), and the pattern of uptake mirrors that seen on the bone scan. Strontium-89 and samarium-153 are the agents most commonly used in clinical practice; phosphorus-32, rhenium-186, and tin-117 have also been used. These radionuclides emit beta particles with a mean range between 0.2 to 3 mm, thereby minimizing toxicity to surrounding tissue. Retention in the areas of bone metastases is greater than in the normal bone marrow, with a tumor-to-marrow ratio of 10:1. The average time to clinical response is 7 to 14 days, with a median duration of action of 18 weeks. Retreatments are possible, with an interval of 10 to 12 weeks for strontium-89 and 6 to 10 weeks for samarium-153, although a nonresponder is unlikely to respond to subsequent administration. The mechanism of pain reduction is unclear but may include radiation-induced apoptosis of lymphocyte-secreting cytokines and direct cell kill and reduction of mass effect.

Treatment-related toxicity consists mainly of reversible myelosuppression, especially thrombocytopenia. The nadir is 4 to 6 weeks after injection; recovery is completed by 6 to 10 weeks, with severity related to disease burden. Bone marrow toxicity is therefore of concern with the use of systemic chemotherapy. A small percentage of patients (10% to 20%) may experience a pain flare shortly after administration. Contraindications to the use of radionuclides include poor performance status, <2 months' projected survival, extensive soft tissue metastases, platelet count $<60 \times 10^9/L$, recent rapid fall in platelet count even if $>60 \times 10^9/L$, white count $<2.5 \times 10^9/L$, and disseminated intravascular coagulation within 1 month of myelosuppressive chemotherapy and within 2 months of hemibody radiotherapy. Impending or actual pathologic fracture and cord compression are also contraindications for use.

The evidence for use of radionuclides has been reported in several phase 2 and 3 trials. Overall pain reduction rates for the various radionuclides are comparable and similar to localized and hemibody external beam radiotherapy, with an overall response rate of 80% and complete response rate of 20%. The “Trans Canada” study reported on 126 patients with metastatic prostate cancer randomized to strontium-89 or placebo in addition to external beam radiotherapy.⁵⁵ Patients receiving strontium showed a significant improvement at 3 months in analgesic use and an improved quality of life. Reduced lifetime requirements for radiotherapy and reduction in development of new painful bone metastases were seen. Hematologic toxicity was acceptable. A lifetime management cost savings of \$5,800 in the group receiving strontium-89 was found.⁵⁶ A second multicenter trial in patients with prostate cancer compared strontium-89 with either local-field or wide-field radiotherapy and found no significant difference in analgesic efficacy, with a significant increase in time for further radiotherapy and development of new pain sites.⁵⁷ Samarium-153 is also licensed for use in the United States and has shown similar efficacy to strontium. Patients with a variety of primary malignancies had an 85% pain response rate, with patients with breast cancer achieving the best palliation. The recent introduction of radium-223 for advanced prostate cancer was discussed earlier.²⁸

Controlling Side Effects of Treatment

Radiation treatment planning is the most critical aspect of reducing radiation side effects. Management of the acute effects of radiotherapy requires attentive medical management that prevents expected side effects. Radiation side effects are specific to the area treated. Careful radiation treatment planning that avoids critical structures like mucosal surfaces can prevent most side effects. Patients should be reassured that the unavoidable side effects that they experience will resolve following the completion of radiotherapy. Skin reactions are usually minimal during radiotherapy for bone metastases and are limited only to the radiation portal. Nausea and vomiting, resulting from a radiation portal that includes the abdomen, will usually respond to antiemetic therapy, but ondansetron or dexamethasone also is commonly used, especially if patients have recently received emetogenic chemotherapy. Diarrhea, resulting from abdominopelvic radiation, will respond to antidiarrhea medications such as loperamide. Local irritation from mucositis of the oropharyngeal region may be relieved by soluble aspirin, analgesics, or benzydamine mouthwashes. Secondary infections, like *Candida*, should be treated.

The side effects of electron beam radiation are more limited because they only treat superficial structures like the ribs, skin lesions, and superficial lymph nodes. Underlying structures are spared with the selection of the proper electron beam energy. The most prominent side effect of electron beam radiation is an erythematous skin reaction. Other side effects listed here do not occur with electron beam radiation because the radiation beam does not penetrate to these structures. No side effects, other than a possible flare of pain in the first 2 weeks after administration, are observed with systemic radioisotope therapy because all the radiation is localized to the bone. This is an important consideration for patients who have significant symptoms of the disease or other treatments. Side effects from external beam radiation also are more severe when the radiation fields are large because more normal tissues are treated. Pain flare is common after palliative radiotherapy for osseous metastases.⁵⁸ Systemic radioisotopes can have significant advantage over large external beam radiation fields by reducing risk for side effects like nausea and diarrhea.

RADIOTHERAPY FOR COMPLICATIONS OF BONE METASTASES: LOCALIZED EXTERNAL BEAM RADIOTHERAPY FOR PATHOLOGIC FRACTURES

Pathologic and Impending Fractures

Pathologic fractures are handled with orthopedic stabilization whenever possible. Surgery rapidly controls pain and returns the patient to mobility. Elective orthopedic stabilization has reportedly resulted in good pain relief and sustained mobility in up to 90% of patients. Early identification of patients with a high risk of fracture is especially important. A fracture of the weight-bearing long bones can be a devastating event even in a healthy person. Prophylactic orthopedic fixation is often advised to avoid the trauma of a pathologic fracture. The operative procedure has fewer complications and less impact on functional outcome.

In the randomized Dutch Bone Metastasis Study, 14 fractures occurred in 102 patients with femoral metastases. The authors analyzed the pretreatment radiographs of femoral metastases and concluded that fracturing of the femur mostly depended on the amount of axial cortical involvement of the metastases. They recommend treating femoral metastases with an axial cortical involvement of ≤ 30 mm with a single 8-Gy dose for relief of pain.

If the axial cortical involvement is >30 mm, prophylactic surgery should be considered to minimize the risk of pathologic fracturing or, if the patient's condition is limited, irradiation to a higher total dose.⁵⁹

Although radiotherapy provides pain relief and tumor control, it does not restore bone stability. Postoperative radiotherapy is usually recommended after surgical stabilization of a pathologic fracture. Townsend et al.⁶⁰ reported normal use of extremity (with or without pain) in 53% for postoperative radiotherapy versus 11.5% for surgery alone. Second orthopedic procedures to the same site were more frequent in the group that received surgery alone.

Patients who are without visceral metastases and who have a relatively long survival (e.g., >3 months) are more likely to benefit from postoperative radiotherapy. Because the entire bone is at risk for microscopic involvement and the procedure involved in rod placement may seed the bone at other sites, the length of the entire rod used for bone stabilization should be included in the radiation field. When the radiation fields are more limited, instability of the rod, resulting in pain and need for reoperation, can result from recurrent osteolytic metastases outside the radiation portal. When a pathologic fracture has occurred, the primary goal is to provide pain relief. Secondary intentions are to achieve stability and restore function. Unless there are medical contraindications or extremely short life expectancy, surgery is usually recommended. Otherwise, radiotherapy alone may be considered.

Stereotactic Body Radiotherapy of Spinal Metastases

Technological advances in radiation oncology have resulted in the ability to apply stereotactic body radiotherapy (SBRT) to the spine, and the predominant indication has been spine metastases. The Canadian Association of Radiation Oncology defined SBRT as "the precise delivery of highly conformal and image-guided hypo-fractionated external beam radiotherapy, delivered in a single or few fraction(s), to an extra-cranial body target with doses at least biologically equivalent to a radical course when given over a conventionally fractionated (1.8-3.0 Gy/fraction) schedule."⁶¹ For spine metastases, this application represents a major shift in the therapeutic intent as doses such as 16 to 24 Gy in a single fraction, 24 Gy in two to three fractions, and 30 to 35 Gy in five fractions represent two to six times the biologically equivalent dose as those investigated in the conventional radiotherapy literature.⁶² With respect to the ideal candidate for spine SBRT, a detailed summary of inclusion and exclusion criteria have been summarized in the American Society for Radiation Oncology International Bone Metastases Guideline.⁶³

Although the spine SBRT evidence suggests high rates of local tumor control at $>80\%$ ² and pain control with complete pain relief at $\sim 50\%$,⁶⁴ the data are uncontrolled and a randomized controlled trial (Radiation Therapy Oncology Group O631) is accruing patients with the two arms being 8 Gy in one fraction delivered conventionally and 16 to 18 Gy in one fraction delivered with SBRT.

Beyond the high-dose aspect of SBRT, the aim is to target the gross tumor volume with or without an anatomic clinical target volume while sparing the spinal cord and surrounding normal tissues from the high tumor dose. This is achieved using sophisticated radiotherapy treatment planning and delivery units that allow for intensity-modulated radiotherapy, image guidance, and multiple beams of radiation centered on the target. This is a stark contrast to traditional practice where at least one or two healthy vertebrae beyond the disease is included in a simple one- or two-field treatment, which has the benefit of ensuring the entire target receives the prescribed dose. This fundamental contrast is illustrated in Figures 126.2 and 126.3. There has been progress as to optimal target volume to treat, as described by Cox et al.,⁶⁵ that essentially

Figure 126.2 A typical radiation field for a seventh thoracic vertebrae metastases where two vertebral bodies above and below the target are included in the radiotherapy field. This patient was treated with 8 Gy in a single fraction, and one can appreciate the entire vertebral column within the field being encompassed by the 8-Gy isodose line in yellow.

confirms the practice of taking at-risk spinal anatomy into the target volume. This is critical as it has been shown that the risk of local failure increases if we treat only what we see as gross tumor on imaging.⁶⁶

The treatment of spinal metastases with SBRT is not without risk given the high doses delivered within the bone, millimeters away from tissues such as the spinal cord, esophagus, and kidneys. With respect to acute toxicity, the risk of pain flare has been well documented following conventional radiation,⁵⁸ and only recently following spine SBRT. Chiang et al.⁶⁷ reported that the majority of patients experienced a pain flare at 68%, and that rescue dexamethasone was effective in reducing the pain response. More importantly, the risk of clinically significant late toxicities with conventional palliative radiotherapy regimens is negligible; however, spine SBRT has resulted in serious adverse events. The most devastating is radiation myelopathy, which can leave the palliative patient paralyzed and is unacceptable considering the goals of treatment for this population. Much progress has

been made, and there are now guidelines for the maximum spinal cord doses that are safe for both the unirradiated and reirradiated patient based on dose-volume histogram analysis of cases and controls.^{68,69} What has become more alarming is the risk of SBRT-induced vertebral compression fracture (VCF). A pooled analysis of 410 spinal segments treated with SBRT was recently reported, and the 1-year cumulative incidence of fracture (new or progression of an existing VCF) was 12.4%.⁷⁰ From this analysis, we learned that SBRT dose is an independent risk factor, and with ultra-high single fraction doses such as 24 Gy in one dose, the risk of VCF was prohibitive at 39%. When the dose per fraction was kept below 19 Gy, the risk was more reasonable at 10%. The investigators also applied the spine instability neoplastic score criteria to each treated segment and determined that misalignment (kyphotic deformity), preexisting VCF, and lytic tumor were significant risk factors on multivariate analysis. With respect to pathomechanism, it is postulated that radionecrosis is causal as explained by Al-Omair et al.,⁷¹ and a comprehensive

Figure 126.3 A spine stereotactic body radiotherapy treatment plan for a patient with a first lumbar vertebrae hepatocellular paraspinous metastasis that involves the ipsilateral pedicle and lamina. The location of this target is complicated as it is situated between the kidneys. Together with thecal sac sparing, the treatment planning is even more complex. This patient was treated with 24 Gy in three fractions and the high-dose isodose lines in green and orange conform tightly around the target while the thecal sac and kidneys are spared from the high dose. The lower 14-Gy isodose line skirts the left kidney while sparing the spinal cord, hence, reflecting the highly shaped nature of the dose distribution at both the high and lower dose levels. Despite a radioresistant hepatocellular histology, the patient had an excellent response 4 months following therapy with significant regression of the disease, as shown on the right-hand posttreatment axial image.

TABLE 126.1

Summary of Key Issues Comparing and Contrasting Conventional External Beam Radiotherapy with Spine Stereotactic Body Radiotherapy in the Treatment of Spinal Metastases

Conventional External Beam Radiotherapy	Stereotactic Body Radiotherapy
■ Low BED delivered to the tumor	■ Two to six times the BED delivered to the tumor
■ Technique requires at least one or two healthy vertebral bodies to be treated	■ Targeted treatment to only those areas of disease
■ Low risk of acute and long-term side effects due to low BED exposure to healthy tissues	■ Pain flare a high-risk acute event and devastating late toxicities have been reported
■ Risk of vertebral compression fracture ~5%	■ Prohibitive risk of vertebral compression fracture with ultra-high single fraction doses (24 Gy in one fraction)
■ Protracted regimes can include 5 to 20 fractions	■ Fewer treatments whereby definition SBRT involves one to five fractions
■ May be less efficacious in radioresistant histologies like sarcoma and renal cell carcinoma	■ Greater dose may lead to better outcomes for radioresistant tumors
■ Greater volume of normal tissue exposed to the prescribed tumor dose and potential for greater acute toxicities	■ Dose to the normal surrounding nontumor tissue much lower than that prescribed to the tumor, which may limit acute toxicities
■ Short treatment times of 5 to 10 min, which are ideal for the patient in pain	■ Prolonged treatment times where each treatment takes 45–60 min and requires strict immobilization
■ If local failure occurs then likely dose- or biology-related as opposed to geographic miss	■ Potential for geographic miss and if within the epidural space then tumor regrowth can lead to cord compression
■ Limited doses apply in the retreatment patient, which may preclude efficacy	■ High doses still possible in the retreatment patient and data suggest efficacy
■ Standard of care for patients with malignant epidural cord compression with level 1 evidence for efficacy	■ Contraindicated in the patient with symptomatic malignant epidural spinal cord compression
■ Indicated for the patient with multiple-level spinal metastatic disease	■ No more than three consecutive metastases recommended to be treated at once
■ Deliverable in any radiotherapy department and low cost	■ Requires sophisticated radiation equipment and quality assurance
■ Level 1 evidence and well-defined outcomes supporting common palliative treatment regimens	■ No level 1 evidence to indicate superiority over conventional radiotherapy

BED, biologically effective dose; SBRT, stereotactic body radiotherapy.

review is recommended for the interested reader that also discusses the surgical management of VCF.⁷² This toxicity is serious as approximately 50% of patients are then treated with some form of surgical salvage, although the predominant treatment has been a percutaneous cement augmentation procedure.^{70,73} It has also been shown that this complication occurs relatively soon after SBRT with a median time to fracture of 2.5 months,⁷⁰ which implies that patients should be followed relatively frequently within the first 6 months.

Spine SBRT is still considered an emerging therapeutic option for patients with spinal metastases. It is technically demanding, requires considerable skill, requires close and ongoing follow-up, and there is potential for serious late toxicities that are not otherwise a concern with conventional radiotherapy. Although there is a significant potential to improve long-term pain relief and local control as compared to conventional palliative radiotherapy (Table 126.1), the true value will only become apparent by randomized controlled trials.

Surgical Management of Bone Metastases

Prophylactic stabilization of the appendicular skeleton or decompression of the spine is preferable to a catastrophic unexpected

event. Prophylactic or preventative surgery is optimal as it gives clinicians time to optimize patients for surgery from a medical standpoint. The goal of surgery is to allow immediate weight bearing and return to function immediately.⁷⁴

MECHANICAL STABILITY AND FRACTURE RISK

Stability is an important concept to understand. In the spine, this is the ability of the supporting structures of the spine to allow for physiologic loading in order to prevent pain and deformity. Spinal instability may not necessarily result in a catastrophic collapse and paralysis; however with a pathologic burst fracture this can occur. More commonly, the affected spinal segment will develop a gradual loss of architecture resulting in activity related pain. In the appendicular skeleton, instability results in mechanical pain from cortical loss, creating symptoms with use of the extremity or with weight bearing. A pathologic fracture can result when loads applied are greater than the support provided by the normal bony trabeculae. An impending fracture is a bone at risk of fracture if not treated.

The biomechanical effects of osteolytic metastases are of two categories: stress risers and open-section defects.⁷⁵ Stress

TABLE 126.2

Mirels System			
Variable/score	1	2	3
Site	Upper limb	Lower limb	Peritrochanteric
Pain	Mild	Moderate	Functional
Radiographic appearance	Blastic	Mixed	Lytic
Size	Less than one-third of the cortex	One-third to two-thirds of the cortex	Greater than two-thirds of the cortex

risers are perforations that are smaller than the cross-sectional diameter of the bone that decrease torsional rigidity by 60%. Open-section defects decrease bone strength by almost 90%. Accurate prediction of which metastases are most likely to fracture is essential. Severity of pain and site and size of the metastatic lesion affect risk of fracture. The Mirels system has been used to help predict the risk of pathologic fractures in weight-bearing bones within 6 months (Table 126.2).⁷⁶ Risk of fracture increases above a score of 7. Lesions with scores <6 can be treated with radiation; scores >8 should be treated with prophylactic internal fixation.

Lower Extremity

Pathologic fractures of the femur have profound morbidity for the patient as well as considerable issues related to stabilization that would be preventable if treated prior to fracture. A femur at high risk of fracture included cortical bone destruction >50%, lesions >2.5 cm, pathologic avulsion fracture of the lesser trochanter, and persisting pain after radiation. In the absence of these signs, femoral metastases can be treated nonoperatively.⁷⁷⁻⁷⁹

The subtrochanteric segment of the femur extends from the lesser trochanter to the junction of the proximal and middle thirds of the diaphysis. This segment of the femur is subjected to very high axial loads of weight bearing and tremendous bending forces because of the eccentric load application to the femoral head. The medial cortex is loaded in compression and the lateral cortex in tension. Ward et al.⁸⁰ compared the results of 97 impending fractures of the femur with 85 complete fractures. In the impending group, there was less blood loss (438 ml versus 636 ml), shorter hospital stays (7 days versus 11 days), greater likelihood of discharge home as opposed to an extended-care facility (79% versus 56%), and a greater likelihood of resuming support-free ambulation (35% versus 12%).

For diaphyseal lesions of the femur, the loads are less and the threshold for surgical stabilization is higher. Each case needs to be individualized, taking into consideration the degree of functional impairment, pain, and radiosensitivity of the tumor. The same size lesion in the diaphysis is less of a risk for fracture than in the subtrochanteric region. Recent work at our center on remineralization of bone following radiation may allow us to avoid surgical intervention in the appropriate candidate.⁸¹

Operative Techniques

Proximal Femur. Impending or pathologic fractures of the femoral neck or head or intertrochanteric region are usually managed with hemiarthroplasty. If there is involvement of the acetabulum, total hip arthroplasty is indicated. Lesions in the intertrochanteric region can also be stabilized with a hip screw and side plate device with consideration for augmentation using polymethylmethacrylate (PMMA) cement. It is imperative to plan preoperatively with a full-length femur radiograph to ensure the plate is able to span the length of disease involvement. With associated diaphyseal or distal femur involvement, an intramedullary device is indicated in order to span the entire length of the femur. Second- and third-generation nails are most commonly used in order to allow fixation into the femoral head (Fig. 126.4).⁸²

Figure 126.4 (A) Plain anteroposterior radiograph of a lytic metastatic lesion with impending fracture of the peritrochanteric region of the femur. (B) Plain anteroposterior radiograph after treatment with reconstruction intramedullary nail providing fixation into the femoral head.

Femoral Diaphysis. Similar to proximal femoral lesions, intramedullary devices are used for fixation. In the case of an impending fracture, a distal vent should be used to allow efflux of marrow contents in order to reduce the risk of fat emboli.^{83,84}

Pelvis and Acetabulum. Reconstruction of the proximal part of the femur and the acetabulum is often technically demanding, and hardware failure is not uncommon. The implant is at risk of failure because the forces about the hip are extremely high for most normal activities. Forces on the proximal femur can be 3.5 times body weight during the midstance phase of gait and can increase to 7.7 times body weight during stair climbing.^{85,86} Acetabular insufficiency secondary to bone metastases is classified according to location and extent of bone loss. Where the acetabulum is structurally intact, a conventional total hip arthroplasty can be performed. PMMA is often used to provide added support in cases of perforations of the medial wall. When the medial wall has an unconstrained defect, techniques are required that transfer the stress of weight bearing away from the deficiency and onto the intact acetabular rim with use of a protrusion ring. With more extensive bone involvement including both the medial and lateral walls, reconstruction of the acetabular columns requires the use of implants such as Steinmann pins and PMMA to fix the protrusion ring into place.

Preoperative Embolization of Bone Metastases

Metastases from renal cell carcinoma are hypervascular as a result of neovascularization. Other primaries can also be associated with hypervascularity.⁸⁷ Historically, stabilization of spinal or appendicular lesions from renal cell carcinoma was associated with excessive bleeding requiring transfusion. Uncontrollable hemorrhage may even result in death. There is growing experience and evidence that preoperative embolization is a safe and reliable method of reducing intraoperative blood loss at the time of stabilization of bone metastases. The methods of embolization include the use of polyvinyl alcohol, coils, and gel foam. The procedure is performed in the angiography suite, and surgery should be performed within 48 to 96 hours of embolization or revascularization will occur.

Roscoe et al.⁸⁸ reported on the use of embolization for renal cell carcinoma metastases to the spine before stabilization. Comparing 8 patients who underwent perioperative embolization with 20 patients who did not, the blood loss during stabilization for former group averaged 940 ml compared with 1,975 ml in the nonembolized group. Similar results have been reported by other authors on the safe and effective role of perioperative embolization prior to spinal decompression and stabilization^{89,90} (Fig. 126.5).

Upper Extremity

In the upper extremity, the difference in management and patient outcome is less profound between an impending and pathologic fracture. Fractures of the humerus can be managed with plate fixation or with intramedullary devices. Atesok et al.⁹¹ have shown that an unreamed humeral nail provides immediate stability and pain relief with minimum morbidity and early return of function to the arm. Similar conclusions were made by Dijkstra et al.⁹² when comparing intramedullary nail with compression plating for humeral pathologic fractures.

Spine

The spine is the most common site of metastatic bone disease. Spinal complications are due to loss of mechanical stability creating

pain and spinal cord compression causing paralysis. Neurologic compression occurs due to direct tumor load in the epidural space or from a pathologic fracture causing bony compression or vertebral instability. The goals of spinal surgery in metastatic disease are to preserve or restore spinal stability for pain and to restore or protect neurologic function.

Because of immunosuppression, poor nutritional status, and medical comorbidities, surgery to the spine may be associated with significant complications. Considerations in decision making are life span of the patient, general medical condition, number of spinal levels involved, age, cancer type, and radiation status.⁹³ The significance of the primary cancer type on survival is well established. After detection by bone scan of spine involvement, Tatsui et al.⁹⁴ reported a 1-year survival of 0% and 22% for gastric and pulmonary cancers, respectively, and 78% and 83% for breast and prostate primaries, respectively. In a population-based study, Finkelstein et al.⁹⁵ used Cox multivariate regression to model survival as a function of potential predictor variables in a cohort of 987 patients. This study also quantified postoperative complication rates and identified significant risk factors that were associated with poor survival and outcome. There was an overall 1- and 3-month mortality rate of 9% and 29%, respectively. Increasing age and primary lung cancer were significant risk factors for death within 30 days of surgery. For overall survival, each year of advancing age had a 1% increased risk of dying. Lung primary had a 2.65 relative risk of mortality within 30 days.

The effect of a preoperative neurologic deficit on survivorship has been evaluated by a number of authors. In a multicenter study by Argenson et al.,⁹⁶ patients with a preoperative deficit had significantly lower mean survival at 1 and 3 years after surgery. We have shown that patients with preoperative neurologic deficits were 71% more likely to get a postoperative infection, likely from the administration of preoperative radiation. Other authors have likewise found increased infection rates and poorer outcomes following surgery in the presence of preoperative radiation.^{95,97-99} In 2003, Wai et al.⁹³ prospectively evaluated the efficacy of surgery in patients with metastatic spinal disease with respect to quality of life using a validated outcome measure specific for palliative patients. This study demonstrated the largest improvement to be in pain following surgery. There were significant improvements in six other domains and trends toward improvement in another one. There was no significant deterioration in any domain. The major benefit of surgery occurs within the first month and remained stable until death or at least 6 months (length of follow-up).

Principles of open surgical techniques and considerations are beyond the scope of this chapter. In general, tumor location within the vertebrae, spinal level, radiation status, neurologic deficit, and number of levels involved affect decision making. Surgery can be from an anterior or posterior approach. Rarely is decompression alone suitable for management of metastatic spinal cord compression. Laminectomy and radiation has been shown to be no better than radiation alone. Unless there is solely posterior epidural disease, posterolateral decompression is required with pedicle screw stabilization.

A more recent approach to management of metastatic spinal disease is percutaneous vertebroplasty (PV) and kyphoplasty. These are minimally invasive approaches and an alternative to open surgery for restoring stability to the spine.^{100,101} PV may be applied to a greater number of candidates with pain due to instability. These same patients may not be suitable for invasive spinal surgery because of medical comorbidities, multilevel disease, or having a profound neurologic deficit. PV is performed under intravenous sedation in the radiology suite or in the operating room. Real-time fluoroscopy is used to introduce bone cement (PMMA) into the vertebral body via a parapedicular or transpedicular approach. Commercially available PV kits contain bone cement, mixers, trocars, cannulas, and syringes. PMMA is injected in a

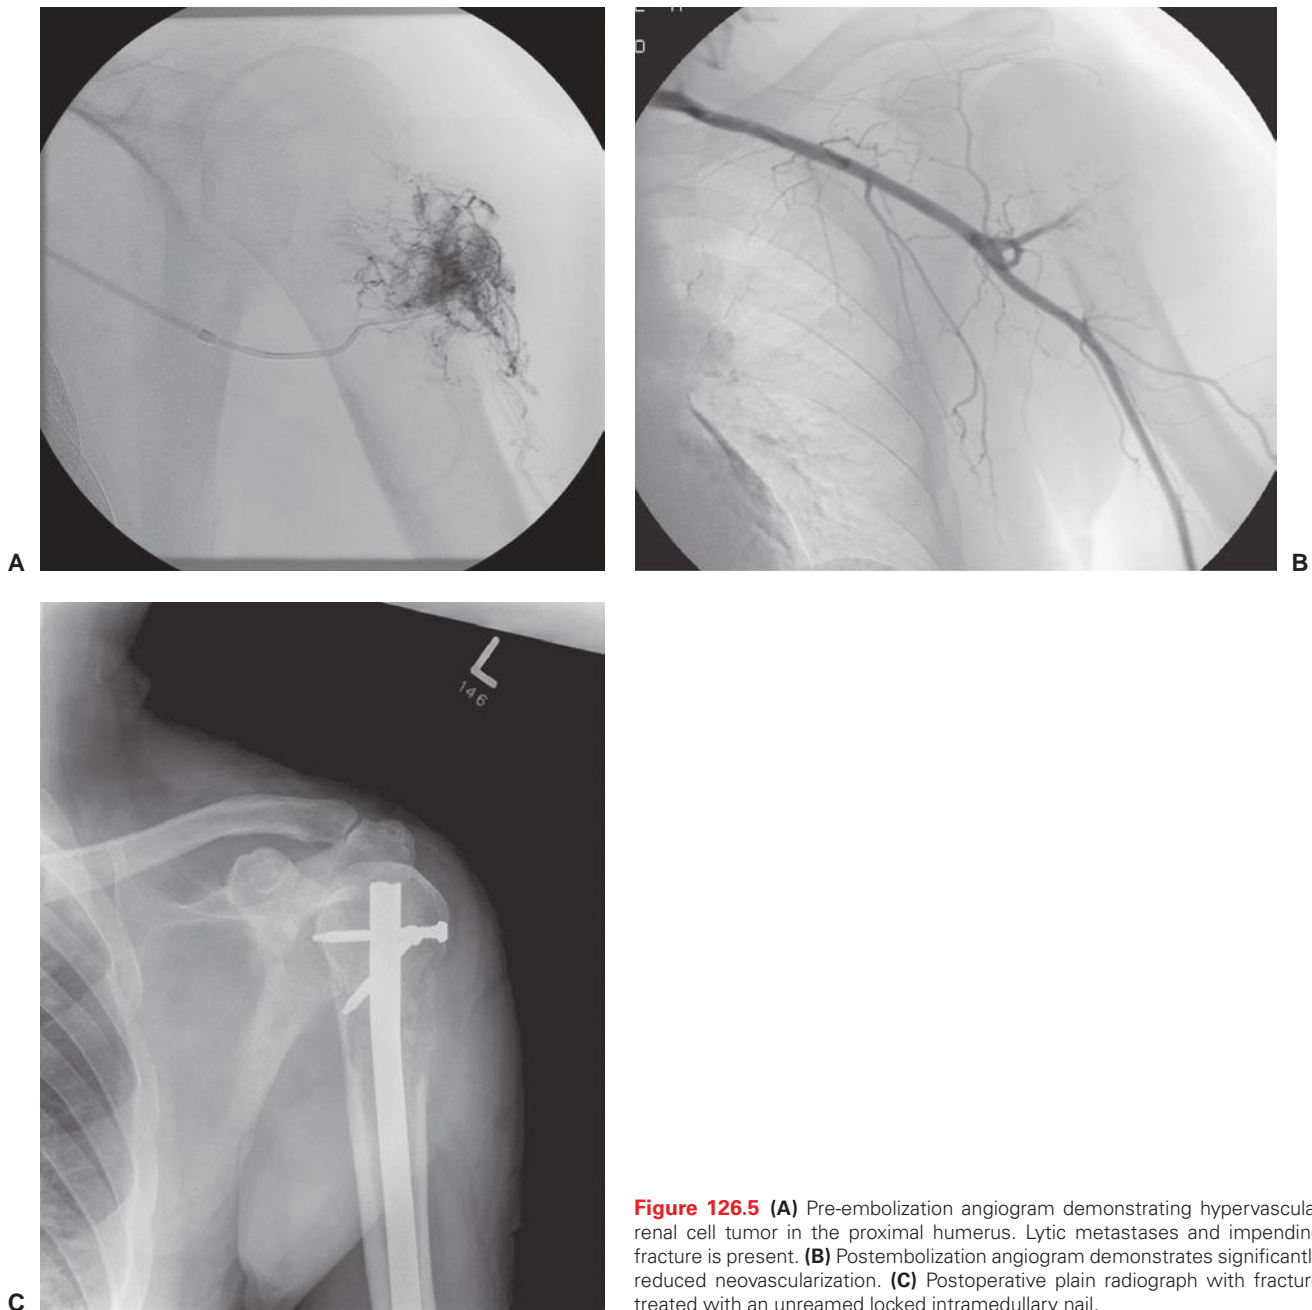

Figure 126.5 (A) Pre-embolization angiogram demonstrating hypervascular renal cell tumor in the proximal humerus. Lytic metastases and impending fracture is present. (B) Postembolization angiogram demonstrates significantly reduced neovascularization. (C) Postoperative plain radiograph with fracture treated with an unreamed locked intramedullary nail.

semiliquid state such that extravasation and intravertebral pressure is minimized.

Complication rates of PV have been reported to be around 10% in metastatic disease.¹⁰² These complications include cement entering the nerve root foramen or spinal canal, resulting in radiculopathy or spinal cord compression. Systemic complications include embolic events due to marrow fat, tumor fragments, or cement entering the circulation. The use of biplanar fluoroscopy and “live” imaging during injection, the addition of increased concentration of barium to facilitate visualization, intraosseous venogram, limiting the volume of fill, gentle and slow injection, and the use of viscous cement are technical details that have been described to minimize the complications of this procedure.¹⁰³ Despite these precautions, extrusion of cement has been commonly reported. The vast majority of

extrusions, however, are minor and do not result in neurologic sequelae.¹⁰⁴

Vertebroplasty and kyphoplasty more recently have been combined with decompression in an open technique (Fig. 126.6). PMMA is used to provide anterior column support following decompression and in some cases is able to replace the need for posterior instrumentation. In some candidates with or without previous radiation or in the high-risk/poor surgical candidate with multiple-level disease, unifocal decompression can be performed and stabilized in this technique. The concerns for hardware failure as previously noted are eliminated. This minimalistic approach is providing improved outcomes, allowing for greater numbers of patients to be operated on when previously the risks associated with multilevel fixations had unacceptable complication rates.

127 Malignant Pleural and Pericardial Effusions

Dao M. Nguyen and Eddie W. Manning, III

MALIGNANT PLEURAL EFFUSION

Malignancy is the second most common cause of exudative pleural effusions and the term malignant pleural effusion (MPE) signifies the identification of cancer cells in the pleural fluid or the pleura of the affected hemithorax.¹ In the absence of positive cytologic or histologic confirmation of malignancy, pleural effusion in association with cancers is termed paramalignant pleural effusion. Over 150,000 cases of MPE are diagnosed annually in the United States.¹ Exudative pleural effusion occurs in 90% of patients with malignant pleural mesothelioma (primary cancer of the pleura with an annual incidence of 3,000 new cases a year in the United States). The vast majority of MPE, however, is caused by metastasis to the pleura with lung and breast cancers accounting for about 50% of cases and lymphoma, gynecologic, and gastrointestinal malignancies responsible for most of the remaining cases while 10% of MPEs have no known primary.² MPE is the first presenting sign and symptom in about 10% of patients eventually proven to have metastatic cancers.²

The parietal pleura plays a more crucial role than does its visceral counterpart in the homeostasis of pleural fluid in which an equilibrium exists between the rate of fluid production and fluid absorption keeping the intrapleural fluid volume constant. Pleural effusion occurs when there is a disruption of pleural fluid homeostasis with either too much production or too little absorption or more frequently a combination of both. Metastasis of cancer cells to the visceral/parietal pleurae elicits local inflammation/fibrosis, increased permeability of capillaries in pleural surfaces, and physical obstruction of lymphatics that lead to both increased fluid exudation and impaired fluid absorption and the net effect of pleural effusion. Cancer cells may shed into the pleural fluid and be detectable by cytologic examination of the fluid. In many instances, in the absence of positive cytology for malignancy, MPEs are only diagnosed by pleural biopsy at the time of thoracoscopy.

Unilateral pleural effusions in patients with a history of malignancy raise the possibility of MPE. Its presence frequently indicates advanced disease, and the overall prognosis of patients with MPE depends largely on the underlying type of malignancy and the extent of primary disease. Effective chemotherapy exists for lymphoma, breast cancer, or colon cancer affording longer survival for patients with MPE secondary to these cancers than those with MPE from lung cancer. As life expectancy of patients with MPE is often markedly reduced (averaging about 6 to 9 months),³ the primary goal of its management should be palliation, with an emphasis on employing therapies to prevent reaccumulation of pleural fluid and dyspnea, and those that may be administered with minimal morbidity/mortality and the shortest hospitalization possible.

Clinical Presentation

Moderate to large MPEs are often symptomatic, with dyspnea being the predominant symptom. Chest discomfort can range from dull ache (characterized as heaviness or pressure) to sharp

pleuritic pain. Physical examination usually reveals decreased breath sounds with dullness to percussion and diminished tactile fremitus. Tracheal deviation and low cardiac output related to mediastinal compression occasionally may be seen with massive MPEs.

Diagnosis and Evaluation

Radiographic Examinations

As little as 200 ml of pleural fluid, resulting in blunting of the costophrenic angle, can be detected by standard chest radiographs. Upright and lateral decubitus chest radiographs are often performed initially and can demonstrate “free-flowing” pleural effusions. However, MPEs are best assessed radiographically with a computed tomography (CT) scan of the chest performed with administration of an intravenous contrast agent. Particularly in the setting of a newly diagnosed effusion, CT can define fluid loculations, mediastinal and/or hilar lymphadenopathy, pleural-based masses, and any associated parenchymal disease. Complete opacification of the hemithorax occurs in about 15% of MPEs. An opacified hemithorax with mediastinal shift toward the contralateral side indicates massive effusion and raises concern for a tension hydrothorax, which requires urgent percutaneous drainage of the effusion to relieve the intrathoracic pressure. Opacification of the hemithorax from a massive effusion without mediastinal shift is also possible, the etiology of which is the combination effects of pleural fluid accumulation and lung collapse secondary to proximal airway obstruction, or mediastinal fixation by malignant lymphadenopathy, or a diffuse malignant process involving the parietal pleura thus restricting mediastinal movement.

Invasive Diagnostic Maneuvers

After appropriate radiographic assessment of a newly presenting effusion, thoracentesis should be performed to obtain fluid for biochemical and cytologic analyses, to relieve symptoms, and to determine the extent of lung re-expansion following pleural fluid drainage. When a free-flowing effusion is found, thoracentesis can be safely performed at the level of the sixth or seventh intercostal space posteriorly. In the presence of a large pleural effusion occupying >50% of the pleural cavity, gradual drainage of the fluid, vis-à-vis smaller volumes incrementally over time, has traditionally been advocated to avoid re-expansion pulmonary edema (RPE) and subsequent respiratory insufficiency.⁴ However, the overall incidence of clinically significant RPE is low and thoracic surgeons routinely remove >1.5 L of pleural effusion without serious sequelae during thoroscopic procedures to treat various conditions. The widespread availability of small-bore catheters (8-Fr to 14-Fr “pigtail” catheters, which are named for the formation a curve tip after removal of the inner metal stylet once inserted to prevent dislodgement) and their ease of insertion under local anesthetic at the bedside have replaced the use of needle thoracentesis as the initial diagnostic/therapeutic maneuver in the

management of pleural effusion including MPE. Slow fluid drainage and gradual expansion of the lung following placement of a small-bore pigtail catheter over minutes are safe and not associated with RPE in our experience. If the pleural fluid collection is loculated, however, ultrasound or CT guidance may be necessary to direct drainage of accessible portions of the effusion. Intrapleural fibrinolytic therapy using recombinant tissue plasminogen activator may be required to facilitate drainage (chemical decortication) and expansion of the lung.

If the diagnosis of MPE has not been previously confirmed, pleural fluid should routinely undergo biochemical analysis, cell counts, cultures, and cytopathologic examination. Frequently, pleural fluid from an MPE is blood-tinged or grossly hemorrhagic because of disruption of capillaries or venules by direct tumor invasion or cytokine-mediated increased vascular permeability resulting in erythrocyte diapedesis. MPEs are typically hypercellular, populated with leukocytes (predominantly lymphocytes and monocytes), reactive mesothelial cells, and exfoliated tumor cells. Identification of malignant cells within the cellular component of the effusion fluid (either via cell smears or cytospin cell blocks) or from a pleural biopsy specimen is diagnostic of the malignant nature of the pleural effusion.

Initial cytology from the pleural fluid is positive in approximately 66% of patients with MPE. If initial cytology has negative results, repeat thoracentesis can be performed (no longer a common practice) or the patient may proceed directly to thoracoscopy if clinical conditions permitted for both diagnostic and therapeutic intents (a favored approach). Repeat thoracentesis can improve the yield of confirming the diagnosis of MPE in an additional 20% of cases.⁵ Thoracoscopy performed via direct pleuroscopy under local anesthesia with intravenous sedation or with video assistance under general anesthesia has a diagnostic yield of nearly 100% for malignant disease involving the pleura.⁶ Thoracoscopy has obviated the need for “blind” pleural biopsy as a diagnostic procedure for MPE.

Management and Treatment

Because advanced disease states often lead to the development of MPE, the overarching treatment goal should be palliation via selecting therapeutic options associated with the least morbidity and greatest preservation of quality of life for the patient. The initial steps in the management of malignant effusions should be focused on confirming a diagnosis of MPE, within reasonable measures, and relieving to the extent possible the degree of symptoms associated with the newly identified pleural effusion. If the patient is asymptomatic from a respiratory standpoint and the corresponding effusion is small in size in a patient eligible to continue further effective anticancer treatment, then it may be prudent to closely observe the patient for the onset of pulmonary symptoms, deferring drainage of the effusion to a later time point, and thus avoiding delay to further anticancer therapy. In patients with symptomatic or recurrent malignant effusion despite prior drainage procedures, therapeutic intervention is warranted and the optimal choice of palliative treatment is primarily dependent on the performance status of the patients as measured by Eastern Cooperative Oncology Group or Karnofsky scores, the life expectancy, patient's preference, and most importantly whether full lung re-expansion can occur after evacuation of the effusion to restore normal apposition of the visceral and parietal pleurae. The goal of therapy for MPE is complete evacuation of the pleural effusion and prevention of recurrence by means of inducing symphysis of the parietal and visceral pleurae (pleurodesis) using sterile talc. Therapeutic interventions for MPE include thoracentesis, tube thoracostomy (large-bore [28-Fr to 32-Fr] or small-bore [8-Fr to 14-Fr] pleural tubes) with or without transcatheter pleurodesis, indwelling tunneled pleural catheter (TPC), thoracoscopy and talc pleurodesis (lung expansion to fill >90% of pleural cavity), or placement

of tunneled catheter (trapped lung with residual pleural space) and rarely pleural decortication (mainly for malignant pleural mesothelioma).

Thoracentesis

Thoracentesis, in addition to being the initial diagnostic procedure for patients with pleural effusion including MPE, is an appropriate treatment for patients with very limited life expectancy or who cannot tolerate more invasive procedures. However, recurrent effusions occur in virtually every case of MPE following thoracentesis alone and hence this is not a definitive therapeutic option. In general, instillation of chemical pleurodesis agents into the chest without the placement of a pleural drainage catheter is ineffective because residual or reaccumulating pleural fluid will dilute the concentration of the sclerosing agent, thus diminishing its irritant effects on the pleura. Loculated effusions may also form after such treatment, making subsequent definitive therapy of the pleural effusion more complicated. In select patients, particularly those with chemotherapy-responsive malignancies such as breast cancer, presenting with MPE as the initial manifestation, thoracentesis alone followed by immediate systemic chemotherapy may successfully treat the pleural space as well, obviating the need for more invasive procedures. However, the majority of MPEs require additional intervention to prevent recurrence.

Complex multiloculated MPEs can pose a therapeutic challenge as they are frequently refractory to complete drainage by thoracentesis or chest tube drainage and thus unsuitable for percutaneous chemical pleurodesis. Some have reported that intrapleural instillation of fibrinolytics such as streptokinase, urokinase, or recombinant tissue plasminogen activator for loculated MPE can be effective in promoting lysis of fibrinous septations and facilitating complete pleural drainage and ultimately successful pleurodesis.⁷ This noninvasive approach should be reserved for those patients with poor performance status or who may not tolerate surgical procedures to take down pleural loculations.

Tube Thoracostomy Pleurodesis

Following thoracentesis and confirmation of lung re-expansion, the pleural space should be completely evacuated with a large-bore chest tube (28-Fr or 32-Fr) or pleural catheter (preferably 14-Fr pigtail catheter) to allow for full apposition of the visceral and parietal pleurae. Recurrent effusions occur in 60% to 100% of patients following chest tube drainage alone.⁸ Chemical pleurodesis is a preferred treatment for patients with MPE, and its efficacy is dependent on (1) complete drainage of the pleural space and full re-expansion of the lung to allow for apposition of the pleural surfaces, and (2) instillation of an effective sclerosing agent into the pleural space and retention of this agent in the chest for several hours to induce an intense intrapleural inflammatory response and symphysis of pleural surfaces and practically obliterate the pleural space. Once complete drainage is achieved (as confirmed by chest radiograph), the sclerosing agent (suspended or dissolved in 50 ml of normal saline) is instilled into the pleural space via the pleural catheter. The tube is then clamped for up to 4 hours to allow for retention of the sclerosant within the pleural space. Although many practitioners rotate the patient's positioning in bed (lateral decubitus, supine, and prone) to enhance distribution of the sclerosant inside the pleural cavity, there is a paucity of objective data to indicate such maneuvers are necessary for successful pleurodesis.⁹ Concurrent intrapleural administration of lidocaine 3 mg/kg (up to 250 mg total) and the sclerosant of choice is recommended, as significant pleuritic chest pain occurs in 7% to 40% of patients having chemical pleurodesis as shown with talc or doxycycline, respectively.¹⁰ Pain, discomfort, and anxiety associated with pleurodesis performed at bedside may also be alleviated with judicious use of intravenous sedatives and narcotics in a monitored setting. Subsequently, the tube is unclamped and the chest drain is connected to suction until the daily drainage is <150 ml, at

which point the chest tube can be removed from the patient. This method of treatment requires hospitalization. With regards to whether the size of chest tube used for pleurodesis effect outcome, recent studies involving small numbers of patients have indicated that pigtail catheter drainage and chemical pleurodesis may be as successful as the more traditional chest tube–pleurodesis approach and associated with less discomfort and acceptable results.¹¹

Video-Assisted Thoracoscopic Surgery

Thoracoscopic surgery for MPE is performed under either general anesthesia or intravenous sedation/local anesthetics without the need for single lung ventilation. The advantages of thoracoscopy include rapid and complete drainage of pleural fluid, breakdown of fibrinous septations, evaluation for lung entrapment, biopsy of abnormal parietal pleura, and enhanced distribution of chemical pleurodesis via talc insufflation. Video-assisted thoracoscopic surgery (VATS) can simply be performed using a single 1-cm thoracic port site with intermittent apneas for lung deflation using an operating thoracoscope, whereas both pleural biopsy and talc insufflation can be accomplished through the inline working channel of the thoracoscope. If trapped lung is detected, an indwelling tunneled catheter can be placed when the catheter enters the pleural cavity through the camera port. While VATS can be performed rapidly and safely with minimal morbidity for many patients with MPE and with acceptable performance status (Eastern Cooperative Oncology Group 0 to 2), its use is contraindicated in more debilitated patients as other less invasive options are available.

Pleurodesis Agents

Many chemicals have been used to induce pleural symphysis to treat exudative pleural effusions including MPE. Only a few sclerosants (i.e., doxycycline, bleomycin, and talc) have been extensively evaluated in both randomized and nonrandomized clinical studies for their efficacy as pleurodesis agents; these are further discussed in detail in the following text for academic interests. All sclerosants share a common mechanism of inducing pleurodesis by causing intense pleural inflammation and subsequent adhesive fibrosis of the parietal and visceral pleurae. Among these, only bleomycin is known to possess antitumor activity. Overall, talc is the most frequently used drug to date because it is a safe, effective, and least expensive sclerosing agent. Recent survey of >800 physicians who collectively performed >8,000 pleurodeses annually indicated that the majority preferred talc as the sclerosing agent of choice.¹²

Tetracycline and Doxycycline. Tetracycline has been extensively used as a sclerosant to treat pleural effusions of benign and malignant etiologies because of its efficacy, low cost, and safety. However, tetracycline is no longer commercially available for pleurodesis. The semisynthetic antibiotics, doxycycline and minocycline, are currently used in place of tetracycline in the United States. Response rates range from 67% to 88% following doxycycline pleurodesis.¹³ Side effects are similar to those observed with tetracycline, but most patients require repeated doxycycline instillations for successful pleurodesis. Only 15% of patients responded to a single treatment, and 9% required more than four instillations. Doxycycline is administered intrapleural as 500 mg in 100 ml of normal saline; also, doxycycline is light sensitive and care must be taken to avoid exposure of the drug to ambient light.

Bleomycin. Intrapleural administration of bleomycin (60 to 120 U) achieves pleurodesis in about 65% of patients with MPE (range, 62% to 81%).^{8,14} Intrapleural bleomycin is well tolerated and associated with few side effects. In one multicenter randomized trial, bleomycin was found superior to tetracycline for pleurodesis; 70% of patients treated with bleomycin had successful control of

their MPE compared with only 47% of patients treated with tetracycline.¹¹ Unfortunately, bleomycin can be considerably more expensive than its alternatives. Bleomycin has been compared with the less expensive talc in one prospective randomized study of 29 women with MPE secondary to breast cancer—all 10 patients (100%) treated with talc had complete control of their MPE compared with 10 of 15 patients (67%) receiving bleomycin.¹⁴

Talc. Asbestos-free, gas-sterilized, or heat-sterilized talc may be administered via chest tube as slurry (4 to 5 g in 50 or 100 ml of normal saline), or insufflated as aerosolized powder (4 to 6 g) during thoracoscopy or thoracotomy.¹⁵ Talc pleurodesis is highly effective with overall response rates ranging from 80% to 100%.^{16–18} Viallat and colleagues¹⁸ reported on thoracoscopic talc poudrage (dusting of powder) pleurodesis for MPE in 360 cases (88 patients with mesothelioma and 272 individuals with other malignancies). Approximately 3 to 4.5 g of heat-sterilized asbestos-free talc was insufflated via atomizer during thoracoscopy. Pleurodesis was successful in 90% of 327 evaluable patients at 1 month, and 82% of individuals had lifelong pleurodesis. Talc has been consistently shown to be superior to other commonly used sclerosing agents (tetracycline, doxycycline, or bleomycin).^{16–18} Many single-institution studies have similarly demonstrated the effectiveness of talc pleurodesis either by thoracoscopic insufflation of dry talc to the pleural cavity or by intrapleural instillation of talc slurry (TS) via chest tubes, but controversies still exist with respect to the cost-effectiveness and the clinical efficacy of each method. A random-assignment phase 3 intergroup clinical trial led by the Cancer and Leukemia Group B (9334) was initiated in 1993 to address this question.¹⁹ The primary end point was 30-day freedom from radiographic MPE recurrence in surviving patients whose lungs initially re-expanded >90%. A total of 501 patients were accrued to this study that compared the efficacy, cost-effectiveness, and quality of life of talc pleurodesis for MPE using either TS via chest tube or thoracoscopic talc insufflation (TTI). There was no difference between study arms in the percentage of patients with successful 30-day outcome (TS 71% versus TTI 78%; $p = 0.169$). However, a subgroup of patients with primary lung or breast cancer had higher success with TTI than with TS (82% versus 67%; $p = 0.022$). The 30-day survival rates were similar in both groups and respiratory complications were greater in the TTI group (13.5%) compared with TS group (5.6%; $p = 0.007$). Quality-of-life measurements demonstrated less fatigue with TTI than TS. Patient ratings for comfort and safety were also higher for TTI, but there were no differences on perceived value or convenience of the procedure. A prospective comparative analysis involving 109 patients with MPEs (77 secondary to breast or lung cancer) of talc poudrage by thoracoscopy (72 patients, 66%) versus TS pleurodesis via 20-Fr chest tube performed at the bedside (37 patients, 33%) demonstrated that 82% of patients having thoracoscopic talc poudrage had lifelong pleurodesis compared to 62% of patients having TS ($p = 0.023$). There was no procedure-related mortality, and both techniques had similar incidences of morbidities, mainly pleuritic pain and fever.²⁰ The authors concluded that thoracoscopic talc pleurodesis was significantly more effective than chest tube TS. Collective review by Tan and colleagues²¹ summarized the current practice of pleurodesis for MPE: talc is associated with less recurrence compared to other sclerosing agents; there is no difference in the effectiveness of tube pleurodesis via small- or large-bore pleural catheters; and TTI is associated with less recurrence than bedside TS pleurodesis via chest tube.²¹ The most commonly reported adverse effects of talc pleurodesis are fever (16%) and pain (7%), and less common complications include empyema (thus the common clinical practice of administering empiric broad-spectrum antibiotic prior to talc pleurodesis), pneumonitis (similar to acute respiratory distress syndrome), and respiratory failure.²² The deleterious pulmonary effects of talc appear related to the use of small rather than large particle-sized talc. Small particle-sized talc (<15 micron) is associated with increased pulmonary inflammation,

damage, and impaired gas exchange while large particle-sized talc (>15 micron) is not.²² Thus, modern formulations of medicinal grade sterile size-calibrated talc should be considered safe in the treatment of MPE.

Indwelling Tunneled Pleural Catheter

Another treatment option for MPE independent from chemical pleurodesis is the use of indwelling TPC. Two types of TPC are approved for clinical application, yet the one manufactured by Denver Biomedicals Inc., Golden, CO (PleurX), is the current industry standard for TPC. The other type of TPC is the Aspira pleural drainage system (Bard Access System, Salt Lake City, UT). Both catheters can be inserted percutaneously and tunneled subcutaneously under local anesthesia and mild intravenous sedation, which can be performed on an inpatient or outpatient basis. The external end of the PleurX catheter has a unidirectional valve to allow for egress of pleural fluid when desired but prevents the inflow of air into the pleural space. Vacuum bottles are connected to the catheter for intermittent drainage of the pleural effusion. The Aspira catheter is connected to a collection bag with a pump in-line. The patient squeezes the pump to initiate pleural fluid drainage to the bag, the flow of which is aided by gravity. The TPC is particularly indicated when the lung cannot re-expand fully to achieve pleural surface apposition despite complete drainage of an effusion, and in such cases pleurodesis is unlikely to be successful irrespective of the chosen sclerosant or approach to pleurodesis. The use of TPC to treat MPE has increased steadily in the last 15 years. Multiple large case series^{23–25} and a collective review²⁶ demonstrated 90% of patients experienced symptomatic relief and required no further intervention. Spontaneous durable pleurodesis occurs in about 45% (28% to 58%) of MPE treated with TPC regardless of the status of lung expansion, and the catheter can be removed without risk of recurrence (median 45 days after insertion).^{23–26} The authors have observed pleurodesis in patients with MPE with trapped lung and small residual pleural space (<30% of pleural space volume) who were selectively treated with TPC and eventually had the catheter removed. Complications of TPC include empyema (3.8%), catheter-related complications (3.7%), symptomatic loculations (8%), and cellulitis (3.4%). The successful use of TPC requires a committed third-party payer, patient cooperation, the existence of infrastructure support systems in the community to manage frequent fluid drainage as well as the availability of supplies and health-care providers. Our personal experience is that the majority of patients rely on visiting nurses to perform drainage and catheter maintenance at home, and the initial acceptance of this device decreases significantly over time.

The first prospective multi-institutional random-assignment clinical trial comparing the efficacy of the PleurX pleural catheter versus chest tube doxycycline pleurodesis (not the more superior sclerosing agent talc) for recurrent symptomatic MPE in 144 patients was conducted by Putnam and colleagues (randomization ratio of 2:1, 99 patients with indwelling catheter, 45 patients with doxycycline pleurodesis).²⁷ The two groups in the study were equivalent with respect to performance status or initial dyspnea scores. After treatment, both groups showed similar improvements of respiratory symptoms and had similar morbidity. Because the study treatments differed markedly between the two arms, the most meaningful measure of success is the long-term absence of recurrent pleural effusion. In this study, there was no difference in the numbers of late failure as defined by recurrence of MPE between treatment groups (13% for pleural catheter group and 21% for doxycycline group, $\chi^2 = 0.23$; $p = 0.631$). This study is the first to demonstrate that TPC is as safe and effective as chest tube doxycycline pleurodesis but requires less hospitalization (median 1 day versus 6.5 days for tube pleurodesis). A small phase 3 random-assignment clinical trial comparing TPC versus bedside talc pleurodesis (Cancer and Leukemia Group B 30102) for MPE ($n = 57$) demonstrated that TPC achieved superior palliation of unilateral MPE than tube talc pleurodesis, especially in patients

with trapped lung.²⁸ A patient-centered approach was taken whereby patients with MPE requiring intervention together with their physicians selected TPC versus talc pleurodesis (chest tube or thoracoscopy).²⁹ While safety profiles and symptom control were similar in both groups, TPC was associated with shorter hospital stay and less re-intervention.²⁹ Such observation was substantiated by the randomized controlled Therapeutic Intervention in Malignant Pleural Effusion Trial comparing TPC and chest tube talc pleurodesis.³⁰ Freeman and colleagues³¹ performed propensity-matched comparison of thoracoscopic talc pleurodesis or thoracoscopic placement of TPC for MPE. They noted equal efficacy of symptom control by both techniques, yet TPC afforded shorter hospitalization and faster initiation of systemic therapy. A single-institution retrospective analysis of the treatment outcomes of TPC versus thoracoscopic talc pleurodesis ($n = 109$, 59 had TPC and 50 had VATS talc pleurodesis) demonstrated that TPC was associated with shorter postprocedure hospital stay and lower rates of re-intervention for pleural effusion.³² Long-term TPC is therefore an effective and economical palliative measure for recurrent MPE refractory to pleurodesis or those associated with incomplete lung re-expansion and can decrease the overall in-hospital time for many patients with cancer. Puri and colleagues³³ provided a cost-effectiveness analysis of the treatment modalities of MPE (repeated thoracentesis, bedside tube talc pleurodesis, TPC, and VATS talc pleurodesis) using sophisticated modeling methodology. They demonstrated that TPC is the preferred treatment for patients with MPE with limited survival (<3 months), whereas bedside talc pleurodesis is the most cost-effective treatment for patients with MPE with more prolonged (12 months) survival. All these studies confirm the initial report by Putnam and colleagues²⁷ that TPC is a useful treatment modality for MPE. None of these studies, however, address the direct cost and quality-of-life assessment associated with postdischarge care of the indwelling catheter. Talc pleurodesis, while associated with longer hospital stay and slightly higher treatment-related morbidities, has a higher rate of durable pleurodesis (>80% for thoracoscopic talc pleurodesis versus about 50% for TPC) and requires no prolonged outpatient care.

Practical Treatment Algorithm for the Management of Malignant Pleural Effusion

Following the diagnosis of MPE, the clinician needs to determine the best treatment option of the patient. There is no “one-size-fits-all” therapy in the management of MPE. Each patient’s presentation and underlying malignancy is unique and requires a personalized approach. This starts with assessment of the patient’s performance status, estimated survival, expectations, availability of family and community support, as well as insurance status. Patients with marginal performance status should have pigtail catheter and bedside talc pleurodesis or PleurX catheter if there is failed initial talc pleurodesis or the presence of trapped lung. Patients with acceptable performance status, especially in the absence of cytologic diagnosis of MPE, should be offered VATS for pleural biopsy and confirmation of pleural metastasis and talc pleurodesis if lung expands or PleurX if lung is trapped. Patients without access to outpatient care should not have PleurX catheter placement unless such a device is absolutely indicated (recurrence MPE after talc pleurodesis/trapped lung) and should have talc pleurodesis preferably by thoracoscopic technique (Fig. 127.1).

MALIGNANT PERICARDIAL EFFUSION

Malignancy is one of the most common causes of pericardial effusion in the Western world.³⁴ Pericardial effusion in patients with current or past history of malignancy can be directly caused by the malignancy itself (contiguous extension or metastasis to the pericardium evidenced by identification of cancer cells in the pericardial fluid and/or in the pericardium) or due to inflammatory process such as benign idiopathic pericarditis or radiation-induced

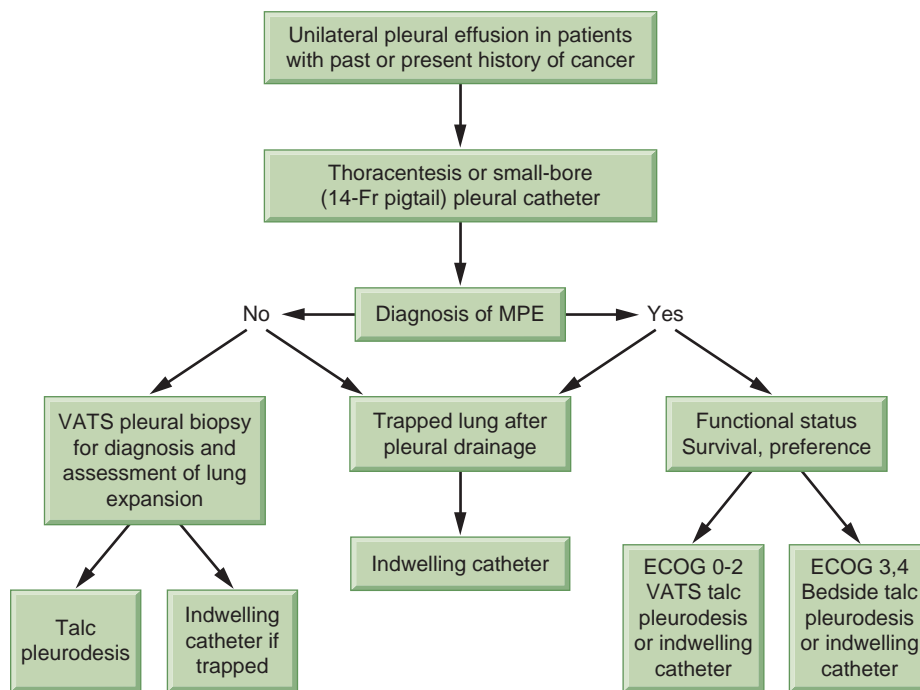

Figure 127.1 Treatment algorithm for malignant pleural effusion. MPE, malignant pleural effusion; VATS, video-assisted thoracoscopic surgery; ECOG, Eastern Cooperative Oncology Group.

pericarditis.³⁴ Primary cancers of the pericardium, such as mesothelioma, fibrosarcoma, and lymphangioma, are exceedingly rare. Patients with malignant pericardial disease may be asymptomatic or present with a number of manifestations, with pericardial effusion being the most common. Cardiac tamponade due to malignant pericardial effusion (MPCE) accounts for at least 50% of all reported cases of pericardial fluid that require intervention. Only 15% to 25% of patients with documented metastasis to the pericardium have pericardial effusion and only a small percentage of those patients will develop pericardial tamponade.³⁴ Similar to MPEs, MPCEs are frequently indicative of advanced incurable malignancy, and the overall median survival of patients with MPCE is often <6 months.

Clinical Presentation

In most cases, MPCE is observed in patients with an established diagnosis of cancer, typically at late stages of their disease. MPCE is rarely seen as the initial manifestation of extracardiac malignancy. Nonspecific symptoms are frequent with MPCE; as such, pericardial effusion may remain unsuspected in patients for whom nonspecific symptoms are otherwise attributed to overall disease progression. Whether cardiac tamponade presents as the initial manifestation of MPCE is highly variable and depends on the rate of fluid accumulation, volume of pericardial fluid, and the patient's underlying cardiac function. Classic signs and symptoms of cardiac tamponade include dyspnea, orthopnea, low cardiac output (peripheral vasoconstriction, cold clammy extremities, poor capillary refill, and diaphoresis), jugular venous distention, distant heart sounds, pulsus paradoxus, and narrowed pulse pressure. An electrocardiogram may show low-voltage complexes across all monitoring leads and electrical alternans.

Diagnostic Modalities

Radiographic and Echocardiographic Studies

Pericardial effusion should be suspected in the asymptomatic patient with cancer when an enlarged globular water-bottle pericardial silhouette is found on plain posteroanterior and lateral chest

radiographs or more commonly detected by thoracic CT scans. Once a pericardial effusion is suspected, echocardiography should be performed to confirm its presence, to assess the hemodynamic significance of pericardial effusion, and to determine the presence of pericardial or intracardiac masses. Right atrial and ventricular collapse are the classic echocardiographic signs of cardiac tamponade, with sensitivity ranging from 38% to 60% and specificity ranging from 50% to 100%.³⁵ Echocardiography-guided pericardiocentesis is a preferred initial approach to alleviate pericardial tamponade.

Cytopathology and Histopathology

The cytology of a pericardial effusion determines definitively its benign or malignant nature. Malignant cells are identified in pericardial fluid from 66% to 79% of MPCE, with the cytology correlating with histologic diagnosis of the underlying malignancy in 100% of these individuals.³⁶ In contrast, parietal pericardial biopsy is frequently nondiagnostic because the distribution of malignant involvement is not uniform.

Treatment

General goals of treatment for MPCE include relief of immediate symptoms, confirmation of the malignant nature of the fluid, and prevention of recurrence. Therapy for MPCE should be tailored to the performance status and prognosis of each patient. Although simple pericardiocentesis can be life-saving in cases of cardiac tamponade, more definitive treatment options for clinically significant MPCE are indicated to minimize the risk of recurrence. These include surgical procedures such as subxiphoid pericardiostomy (pericardial window), transthoracic pericardial window or pericardiectomy (either by VATS or thoracotomy), and medical interventions such as percutaneous tube pericardiostomy with or without intrapericardial instillation of sclerosing agents.

Pericardiocentesis

Pericardiocentesis is the intervention of choice for patients with hemodynamic instability due to pericardial effusion as removal of as little as 50 ml of pericardial fluid can significantly improve signs and symptoms of acute cardiac tamponade. In patients with cancer

with symptomatic pericardial effusion, pericardiocentesis may be performed to stabilize the patient prior to additional drainage procedures, such as percutaneous tube pericardiostomy or subxiphoid pericardial window. Echocardiography-guided pericardiocentesis is the preferred technique as it minimizes complications and improves the success of the pericardiocentesis by delineating the size and location of the effusion relative to cardiac structures. Overall rates of complication and success are approximately 2.4% and 100%, respectively, for echocardiography-guided pericardial drainage as compared with 4.8% and 90%, respectively, for unassisted pericardiocentesis.³⁷

Percutaneous Tube Pericardiostomy and Pericardial Sclerotherapy

Following pericardiocentesis, the rate of fluid reaccumulation has been reported to range from 44% to 70%.³⁸ To improve these results, a 9-Fr pigtail draining catheter is now routinely placed into the pericardial space using Seldinger technique, following successful needle pericardiocentesis, to enable more complete evacuation of the effusion and provide access for sclerotherapy. Tetracycline and doxycycline have been most extensively evaluated as pericardial sclerosing agents. Maher and colleagues³⁸ reported 93 patients with MPCE treated by percutaneous pericardial drainage followed by tetracycline or doxycycline sclerotherapy. Successful placement of the pericardiostomy tube was achieved in 85 patients (92%). Pericardial effusion was controlled in 75 patients (88%); 10 patients (12%) did not respond to sclerotherapy, 8 of whom subsequently underwent surgical pericardiostomy. Successful sclerotherapy often requires multiple instillations of tetracycline or doxycycline (range, 1 to 8; median, 3); 50 patients required three or more instillations to control their effusions. Treatment-related complications (in decreasing order of frequency) included pain, catheter occlusion, fever, and atrial arrhythmias. The favorable results of this minimally invasive treatment strategy are offset by the need for repeated instillations of the sclerosing agent in order to achieve pericardial symphysis. Liu and associates³⁹ conducted a prospective study to evaluate the efficacy and toxicity of bleomycin versus doxycycline as sclerosing agents in MPCE. Bleomycin was found to be as effective as doxycycline in achieving satisfactory control of MPCE but with much less retrosternal pain. As a result, these authors recommend that bleomycin be considered the first-line chemical sclerosing agent for MPCE. Phase 2 random-assignment clinical trial evaluating intrapericardial bleomycin sclerotherapy following pericardial drainage (tube pericardiostomy or subxiphoid pericardiostomy) in 79 patients with lung cancer with MPCE only demonstrated a very modest additional clinical benefit of reducing recurrence of pericardial effusion.⁴⁰ Pericardial sclerotherapy, while being reported in these small series, is not a commonly performed procedure.

Percutaneous Balloon-Tube Pericardiostomy

Percutaneous balloon-tube pericardiostomy is an extension of the more commonly performed percutaneous tube pericardiostomy. In balloon-tube pericardiostomy, pericardiocentesis is performed as previously described but 150 to 200 ml of fluid is intentionally left in the pericardial space. Subsequently, dilatation of the needle tract is performed under fluoroscopy using a balloon catheter creating a larger pericardial opening to the subcutaneous space and mimicking surgical pericardiostomy to reduce recurrence. Ziskind and colleagues⁴¹ reported that this technique was effective in relieving pericardial effusions in 46 of 50 patients (92%). Procedure-related complications included fever (six patients), pleural effusion requiring chest tube placement or thoracentesis (eight patients), small pneumothorax (two patients), and right ventricular injury requiring surgery (one patient) for an overall clinically significant complication rate of 18%. This is an effective minimally invasive

technique of pericardial drainage in experienced hands but it is not widely used.

Subxiphoid Pericardiostomy (Subxiphoid Pericardial Window)

Subxiphoid pericardiostomy is the most commonly performed surgical procedure for benign as well as MPCEs. This procedure can be performed under local anesthesia with intravenous sedation or general anesthesia. It can be performed as the initial procedure for MPCE in medically stable patients or following needle pericardiocentesis in unstable patients with signs and symptoms of significant cardiac tamponade. A comprehensive review of >800 patients with effusions of different etiologies who underwent subxiphoid pericardiostomy indicated an overall mortality rate of 0.62% (range, 0% to 2%), an overall morbidity rate of 1.87% (range, 0% to 7%), and a recurrence rate of 3.6% (range, 0% to 9.1%).⁴² These results compare favorably with percutaneous pericardiocentesis/pericardiostomy with or without sclerosis (1.03% mortality, 9.48% morbidity, and 13.8% recurrence [cumulative results from nine reported series including 427 patients]).⁴²

Partial Pericardiectomy or Pericardial Window via Thoracotomy

Pericardial window or pericardiectomy via thoracotomy is performed uncommonly today. Piehler et al.⁴³ reviewed surgical management of pericardial effusions in 145 patients and concluded that the extent of pericardial resection influenced incidence of recurrent effusions. However, comparative analysis indicated no difference in recurrence rates of patients treated by subxiphoid pericardiostomy compared with those undergoing transthoracic drainage.⁴⁴ The postoperative complications (pneumonia, pleural effusion, respiratory failure, cardiac arrhythmia, deep vein thrombosis, and pulmonary embolism) are much less frequent following subxiphoid pericardial drainage compared with transthoracic pericardial resection (10% versus 50%, respectively). Thus, transthoracic pericardial resection is rarely the initial recommended procedure for drainage of MPCE.

If a transthoracic approach is chosen, VATS should be used if transthoracic pericardial resection is needed for the treatment of recurrent MPCE following subxiphoid pericardiostomy, or for diagnosis and treatment of simultaneous pleural/parenchymal pathology. Compared with thoracotomy, VATS approaches, when feasible, are more suitable interventions in the debilitated patient with cancer. A potential limitation of VATS pericardiectomy for patients is the need for general anesthesia and single-lung ventilation.

Local or Systemic Therapies for Malignant Pericardial Effusion

Radiotherapy is generally reserved for MPCE associated with lymphoma or breast carcinoma. Vaitkus et al.⁴⁵ reported 54 patients treated with radiotherapy as the primary mode of therapy for MPCE. Of these patients, 39 (72%) underwent initial pericardiocentesis. The majority received neither systemic nor other direct pericardial intervention. Radiation therapy was successful in controlling MPCE in 36 patients (66.7%). The highest success rates were noted in patients with leukemia/lymphoma and patients with breast cancer (93% and 71%, respectively). Forty-five percent of patients with other solid tumors had adequate control of their effusions as well. Although noninvasive radiotherapy requires repeated visits or even prolonged hospitalization and may theoretically cause acute pericarditis or myocarditis, these potential complications may not be as pertinent in many patients with MPCE because of their limited survival. Patients with MPCE secondary to lymphoma or breast carcinoma may have effusions that respond to systemic chemotherapy. These authors also reported another

46 patients with breast (38 patients), lymphoma (2 patients), or other solid tumors (6 patients) treated with systemic chemotherapy. Of this group, 36 patients (78%) underwent initial therapeutic pericardiocentesis. Systemic chemotherapy prevented recurrence of effusion in 31 patients (67%); successful control of effusion was achieved in over two-thirds of these select individuals irrespective of whether pericardiocentesis preceded systemic therapy. Intrapericardial instillation of chemotherapeutic agents (teniposide, 5-fluorouracil, carboplatin, cisplatin) to achieve high local drug concentrations has been reported for MPCE⁴⁶ but is considered still too experimental to be discussed here.

Summary

MPCE is frequently an indication of advanced, incurable malignancy. Hence, the goals of intervention include relief of symptoms and prevention of recurrence if possible. The treatment of MPCE should proceed in a stepwise fashion. Surgical (subxiphoid pericardiostomy) or medical (ultrasound-guided percutaneous tube pericardiostomy and sclerotherapy) interventions have acceptable risks and provide excellent results. The choice of treatment for any particular patient should consider the individual's specific medical issues and overall life expectancy.

128 Malignant Ascites

Ajay V. Maker

INCIDENCE AND ETIOLOGY

Ascites is the accumulation of serous fluid in the abdominal cavity. Malignant ascites (MA) is a pathologic condition secondary to either primary peritoneal neoplasms or advanced-stage cancers resulting in either increased abdominal fluid production, inhibited reabsorption, or both, accounting for 10% of ascites cases.¹ Abdominal malignancies commonly associated with MA include ovarian, endometrial, appendiceal, colorectal, gastric, primary peritoneal, and pancreatic tumors, whereas breast, lung, and hematologic malignancies are the main nonabdominal tumors responsible. Ascites may be found in 52% of patients at the time of cancer diagnosis,² with up to one-third of these patients having nonmalignant etiologies for their accumulation of free peritoneal fluid (e.g., malnutrition, portal hypertension, cirrhosis, congestive heart failure, nephrosis, pancreatitis, infectious processes, or benign gynecologic conditions); however, the majority of patients with newly diagnosed ascites and cancer will be found to have MA.³ Approximately 15% of all patients with gastrointestinal cancers will develop ascites during the disease process, whereas up to 20% of all MA cases are from an unknown primary.^{4,5}

ANATOMY AND PATHOLOGY

Ascitic Fluid Homeostasis

Lining the abdominal cavity is the parietal peritoneum, a thin layer of mesothelium that contains multiple foramina. The amount of fluid and solutes that are secreted through this layer are tightly controlled, first by the capillary endothelium, then the capillary basement membrane, followed by the interstitial stroma between the capillaries and the peritoneum, and then the mesothelial basement membrane.^{6,7} The capillary endothelium contains anionic charges within an extracellular glycocalyx that discourages anionic proteins and albumin from extravasating. This maintains plasma oncotic pressure. The capillary basement membrane is also lined with negatively charged proteoglycans, acting as a selective barrier against transit of anionic proteins. The interstitial space is a negatively charged filter of connective tissue, fibroblasts, and hyaluronic acid that is lined by the mesothelial cell basement membrane, also coated with anionic glycosaminoglycans. The peritoneal mesothelial cells also maintain a glycocalyx of anionic charges, thereby forming a multilayered matrix that functions to inhibit transgression of intravascular proteins into the abdominal cavity.

The total peritoneal surface area is approximately 2 m², and fluid is continually secreted into the abdomen. At least two-thirds of peritoneal fluid reabsorbs into the open lymphatic channels of the diaphragm, leaving approximately 100 ml of fluid to lubricate and bathe the serosal surfaces.⁸ The free fluid enters through open ends of lymphatic channels, stomata, which connect the abdominal cavity with the submesothelial diaphragmatic lymphatics.^{6,7,9} Scintigraphic studies have traced the fluid from this point through mediastinal lymph channels into the right thoracic duct and ultimately the right subclavian vein.¹⁰

Pathophysiology of Malignant Ascites

MA results from an imbalance in fluid production and absorption by the peritoneal lining, with a net positive balance. The relationship is defined by Starling's law where the amount of fluid leaving the capillary is determined by the hydraulic pressure minus the plasma oncotic pressure multiplied by the product of the porosity of endothelium and its surface area.^{11,12} In equation form:

$$\begin{aligned} \text{Net filtration} &= \text{Capillary Porosity} \times \text{Surface area} \times \\ &\quad (\Delta\text{Hydraulic pressure} - \Delta\text{Oncotic pressure}) \\ &= \text{Capillary Porosity} \times \text{Surface area} [(\text{Capillary} \\ &\quad \text{hydraulic pressure} - \text{Interstitial hydraulic} \\ &\quad \text{pressure}) - S(\text{Capillary oncotic pressure} - \\ &\quad \text{Interstitial oncotic pressure})] \end{aligned}$$

where S is a permeability coefficient.

Therefore, increased net filtration can result from any of the following or a combination of (1) increased capillary permeability, (2) increased surface area, (3) increased hydraulic pressure differences, and (4) decreased oncotic pressure differences.

Increased Capillary Permeability

Murine models of carcinomatosis have revealed increased permeability of proteins compared to control animals, with peritoneal capillary permeability reaching three times normal within a week of intraperitoneal tumor instillation.¹³ This permeability is thought to be driven, in part, by tumor angiogenesis, as in the process of neovascularization the basement membrane and stroma are remodeled and there is a period of hyperpermeability during the migration and proliferation of new endothelial cells.¹⁴ Multiple growth factors are critical to the process of angiogenesis, including fibroblast and vascular endothelial growth factor (VEGF), and early murine models of MA found increased VEGF (termed vascular permeability factor at the time) in the ascitic fluid proportional to the amount of neovascularization.¹⁵ The MA could be inhibited by treating mice with anti-VEGF antibodies, which reaccumulated upon withdrawing the antibodies.¹⁶ These findings have been reflected in patients with MA where marked neovascularization of the parietal peritoneum was observed,¹⁷ and ascitic fluids were found to contain high levels of VEGF, especially in patients with gastric, colorectal, and ovarian cancers compared to ascites from patients with nonmalignant ascites due to cirrhosis.^{18–20} The effect of VEGF on vascular permeability is estimated to be 50,000 times more potent than histamine.²⁰

Another factor that may increase vascular permeability in these patients is the increased production and secretion of matrix metalloproteinases (MMP) by tumor cells. These enzymes, namely gelatinase and stromelysin-3, function to digest extracellular tissue scaffolds to allow tumor in-growth.^{21–23} Inhibition of these enzymes can reduce MA formation, and in a murine model of colon and ovarian MA, not only was ascites formation inhibited, but survival was increased.^{24,25} Therefore, carcinomatosis appears to increase capillary permeability through a process of growth factor-driven

angiogenesis and MMP production, and this may play a role in increasing intraperitoneal fluid and macromolecules.

Increased Surface Area

As the surface area of capillaries increases, so does the potential amount of cell permeate. Secondary to angiogenesis and growth factor-stimulated neovascularization, the size and amount of mesothelial blood vessels is increased in a murine model of MA.²⁶ Furthermore, in patients with carcinomatosis, studies measuring the sources of ascitic effluent by using plastic rings and absorptive paper on both tumor surfaces and tumor-free surfaces, found an abundance of effluent from nontumor-bearing omentum and small bowel, thus identifying additional surfaces not traditionally considered responsible for ascites formation.^{27,28}

Increased Hydraulic Pressure Differences

Increased portal pressures can increase the hydraulic pressure in the mesothelial capillaries. Though this does not seem to play a large role in the formation of MA, increases in portal venous pressure have been seen in patients with ovarian cancer with MA.²⁸ Furthermore, malignancies that cause liver dysfunction due to excessive hepatic tumor load or form on a background of cirrhosis (e.g., hepatocellular carcinoma) can tip the balance of hydrostatic pressures in the mesothelial capillaries to levels above the interstitium.

Decreased Oncotic Pressure Differences

Chronic or advanced malignancy can result in chronic protein malnutrition. This results in a catabolic state with reduced intravascular protein, thereby creating an oncotic pressure gradient that favors fluid extravasation from the vessels into the peritoneal cavity and lack of fluid reabsorption.²⁹ In addition, due to the increased capillary permeability in patients with carcinomatosis, proteins and other macromolecules enter the ascitic fluid and accumulate in the intraperitoneal cavity.^{20,30} A combination of these forces increases the extravascular oncotic pressure, driving fluid into the interstitium.

Increased Ascitic Fluid Production

Increased fluid production appears to contribute to the formation of MA secondary to increased microvascular permeability, increased surface area, increased hydraulic pressure, and decreased colloid oncotic pressure. Capillary permeability is increased due to cytokine release. Molecules such as VEGF, vascular permeability factor, interleukin-6, and tumor necrosis factor (TNF) are intimately involved.⁴ Enhanced vascular permeability leads to secretion of osmotic particles and fluid into the peritoneum, further increasing the intra-abdominal fluid volume. Endocrine homeostasis may also contribute. Intravascular volume is decreased with increasing ascites, which results in pressure-volume feedback loops that stimulate renin and aldosterone secretion. These hormones reduce urinary output and incidentally increase accumulation of ascites.^{4,31} Furthermore, due to decreased removal of fluid as a consequence of malignant obstruction of lymphatics, the circulating blood volume is further reduced and this similarly activates the renin-angiotensin-aldosterone system.

Reduction in Fluid Reabsorption

Venous and lymphatic obstruction by visible solid tumors or by microscopic tumor cells is one mechanism that results in impaired drainage of peritoneal fluid content.³² Fluid kinetic studies performed on patients undergoing peritoneal dialysis identified

that the normal rate of lymphatic uptake remains constant at 40 ml/h.³³ This rate would be necessary in the absence of increased production to maintain homeostasis. Murine models of carcinomatosis by intraperitoneal tumor cell injection resulted in diaphragmatic and retrosternal lymph occlusion by 5 days with ascites forming soon thereafter. Lymphoscintigraphy in human patients with MA also documented no radioactive sulfur colloid above the diaphragm in 85% of patients treated with tagged intraperitoneal colloid, implying that diaphragmatic lymphatics were obstructed by malignant invasion.^{13,34-36} Additionally, due to increased capillary permeability, proteins and other macromolecules enter the ascitic fluid and these can mechanically obstruct lymphatic drainage channels.²⁰ Therefore, the rate of lymphatic uptake may be decreased or inhibited in malignancy, contributing to increased intra-abdominal fluid.

DIAGNOSIS

Comprehensive history taking combined with physical exam will diagnose ascites in most patients. In patients with known malignancy, increasing abdominal girth, bloating, abdominal discomfort, or weight gain are concerning for carcinomatosis and MA. Imaging, usually computed tomography (CT) scan or ultrasound,³⁷ can confirm the presence of ascites (Fig. 128.1). The CT finding of peritoneal nodules, thickening, omental caking, solid organ metastases, or intraperitoneal nodules raise the suspicion that ascites is malignant as opposed to secondary to benign etiologies. In over 100 patients studied with MA or cirrhotic ascites, CT signs significantly associated with a malignant etiology were fluid in the omental bursa, higher ascitic density (11.5 HU versus 6.7 HU), thickening of the parietal peritoneum, and, in patients with at least a moderate amount of ascites, a tethered-bowel sign.³⁸ As most patients with abdominal pain or malignancy are undergoing cross-sectional imaging as part of the workup or for surveillance, attention to these radiographic signs are important as they can help direct treatment and streamline further workup.

The gold standard to diagnose MA is positive peritoneal cytology, which is present nearly 100% of the time in patients with carcinomatosis.³⁹ This can be obtained percutaneously and safely under image guidance. For advanced gastrointestinal and hepatopancreaticobiliary malignancies without metastases on cross-sectional imaging, diagnostic laparoscopy is often utilized for evaluation of occult carcinomatosis (see Fig. 128.1). If incidental low-volume ascites is found in these patients, then ascites can be aspirated and set for cytology, as can peritoneal washings. This is now a standard approach for advanced gastric cancer in some centers, including our own, as positive peritoneal cytology carries a prognosis similar to stage IV disease.

For those without carcinomatosis but still with MA, cytology is diagnostic in only 50% to 60% of patients.⁴⁰ For these patients, perhaps the most useful single test is the serum to ascites albumin gradient. Calculated as the difference between serum and ascites albumin concentrations, values <1.1 g/dl are suspicious for carcinomatosis as opposed to portal hypertension or other cardiopulmonary causes.⁴¹ The use of ascitic fluid protein and other chemistries to discriminate between malignant and nonmalignant causes is variable and not reliable. If negative for malignancy, cell counts with >250 neutrophils per mm³ are suggestive of infection and Gram stain should be performed. High levels of ascitic amylase may reflect pancreatic ascites or small bowel perforation.⁴² Ascitic fluid fibronectin levels have been reported to be 100% sensitive and specific for malignancy, but this is not a standard test currently, nor is sialic acid, telomerase, or human gonadotropin-beta, all of which have shown discriminatory promise.⁴³⁻⁴⁶

In the absence of a known primary tumor or imaging revealing evidence of malignancy, serum tumor markers can be helpful. Elevated carcinoembryonic antigen values are traditionally associated with colorectal cancer, but can also be elevated in breast,

Figure 128.1 (A) Exploratory laparoscopy in a patient with known poorly differentiated gastric cancer but no evidence of metastases on cross-sectional imaging revealed malignant ascites with positive peritoneal cytology. Resection was not performed and the patient was treated with palliative systemic chemotherapy. (B) A patient with progressive abdominal pain and an omental nodule on cross-sectional imaging underwent a diagnostic laparoscopy revealing extensive primary peritoneal mesothelioma and cytology positive malignant ascites. The patient was treated with cytoreduction and hyperthermic chemotherapy. (C) A patient with node-positive pancreatic adenocarcinoma underwent a successful R0 resection followed by adjuvant chemotherapy; however, the patient presented over a year later with increasing abdominal girth and anorexia. Cross-sectional imaging confirmed recurrence and malignant ascites.

lung, pancreas, gastric, or breast cancers. Hepatopancreaticobiliary tumors can often reveal elevated Ca19-9 levels. Increased Ca125 levels are most suspicious for ovarian carcinoma, though they can be elevated in pancreas, lung, and breast cancers. Alpha-fetoprotein is another helpful serum marker, which when elevated can be indicative of hepatocellular carcinoma.

MANAGEMENT

The management of MA has evolved from the contributions of many specialties, including surgical oncology, medical oncology, hepatology, palliative care, and interventional radiology. The goals of treatment are to provide symptomatic relief and to either maintain or improve the quality of life. Randomized controlled trials are lacking, and studies evaluating the efficacy of various treatments are difficult to extrapolate to the individual patient. Common end points have included comparisons in time between paracenteses. Therefore, there is no standard approach to these patients and multiple medical and surgical options exist. The mainstays of treatment have been based on non-malignant ascites and include diuretics and paracentesis.⁴ A survey of randomly sampled Canadian medical oncologists, gastroenterologists, palliative care physicians, and gynecologic oncologists revealed that 98% employed paracentesis with 89% efficacy, followed by diuretic use 61% of the time and rarely peritoneal shunting—both with unclear advantages.⁴⁷ Certainly, systemic antineoplastic therapy should be utilized whenever possible in a malignancy-specific fashion. In the last few years, new systemic agents as well as regional chemotherapy combined with surgical cytoreduction have offered alternative options for palliation. The various options for treatment are reviewed herein.

Removal of Fluid

Perhaps the most utilized treatment strategy in managing MA is by removal of fluid, either by diuresis, paracentesis, or shunting.

Diuretics

The use of diuretics in the management of MA is largely extrapolated from the treatment of cardiogenic or cirrhotic ascites, though it has been advocated as first-line treatment of MA.⁴⁸ Its role appears to be most useful when the etiology of ascites involves stimulation of the renin-aldosterone axis.^{8,49} As a result, diuretic use is most successful in selected patients with liver dysfunction or portal hypertension secondary to metastatic liver disease or extensive intrahepatic primary tumor burden, as opposed to patients with peritoneal disease or superficial disease of Glisson capsule.^{40,49} For this reason, patients with a serum to ascites albumin gradient <1.1 (see the section titled “Diagnosis”) have been found to be less responsive to diuretic use, as was identified in a prospective study of patients with MA of various primary tumor etiologies.⁴⁹ A review of five studies with >100 patients with MA from a variety of primary tumors found the use of diuretics to be successful in managing symptoms in up to 43% of patients.⁵⁰ The agent most commonly utilized is spironolactone with doses ranging from 150 to 450 mg/day.⁵¹ Loop diuretics (e.g., furosemide) can be added to spironolactone.⁴ Maximal expected ascitic reabsorption can reach 800 ml with optimized medication doses in selected patients, though it was noted by Pockros et al.⁴⁹ that no change in ascitic volume was achieved in patients with MA secondary to peritoneal carcinomatosis or chylous malignant ascites. Complications of diuretic use include dehydration, renal toxicity, and electrolyte imbalances that can result in cardiac arrhythmias. There is no level 1 data evaluating diuretic efficacy in MA and, as a result, its use is controversial and without clear guidelines.⁴⁷

Paracentesis

Paracentesis is the most commonly used treatment for patients with MA with up to 98% of physicians utilizing it for their patients.⁴⁷ Improvement in symptoms, although temporary, can be achieved in $\sim 90\%$ of these patients,²⁴ and its use in palliation is supported by the available literature.⁵² There are no randomized trials comparing paracentesis with the use of diuretics in the management of MA.

The volume of drainage per session is limited by the potential complications of hypovolemia and resulting hypotension or renal dysfunction, though hypovolemia and hypotension may be averted with concomitant 5% dextrose infusions or intravenous albumin.⁵³⁻⁵⁷ Randomized studies have demonstrated no difference in survival between patients treated with albumin compared to other plasma expanders, and for patients with MA no definitive trials on this subject have been performed.⁵⁸ Reports of 5 L per 1 to 2 hours were demonstrated to be safe without hypovolemia or renal dysfunction,⁵⁰ and volumes up to 20 L per session have been reported, though there is no consensus on the rate of withdrawal, ranging from 30 minutes to 24 hours.^{54,56,59-61} Forty-eight paracenteses in 44 patients with MA suggested that removal of a mean of 5.8 L (range, 0.8 L to 15 L) can provide palliation of symptoms.⁵⁵ Serial paracentesis can result in hypoalbuminemia, a complication possibly minimized with high-protein diets and small volume taps.^{62,63} Additional procedural risks of paracentesis include solid and hollow viscous organ injury or perforation, bleeding, fistula, peritonitis, and sepsis. In patients with carcinomatosis and/or prior surgery, there may be extensive scarring and fluid loculations, making ultrasound-guided paracentesis attractive with potentially less complications in this population. As the procedure is often required on multiple occasions,⁴⁷ efficacy decreases and complication risks compound. In a study of 67 patients with ovarian, breast, and colorectal cancer, 392 paracentesis, or approximately six aspirations per patient, were required for palliation with other studies reporting mean procedure-free intervals to be 10 to 11 days.^{50,64}

To overcome the risks, potential complications, and patient discomfort of serial paracentesis, indwelling peritoneal drainage catheters may be advocated. Furthermore, these catheters offer the option of self-drainage. The utility of catheter placement should be weighed against the patient's condition as survival from catheter placement ranges from 15 days to 18 months.⁶⁵ Typically, patients with a life expectancy of >2 to 3 months and requiring serial taps are considered for this procedure.⁶⁶ The most frequently used options include tunneled Tenckhoff catheters (Covidien, Mansfield, MA), untunneled or tunneled PleurX

catheters (Denver Biomedicals Inc., Golden, CO), cope-type loop catheters, and tunneled peritoneal Port-a-Caths (Smiths Medical, St. Paul, MN).⁶⁵ The greatest risk with indwelling catheters is peritonitis, which occurred in 4.4% of patients with tunneled Tenckhoffs⁶⁷ and 2.5% of tunneled PleurX catheters compared to reports of 21% to 34% for untunneled catheters.⁶⁸

Additional complications can occur in ~25% of patients with untunneled catheters including leakage from the insertion site, cellulitis, infections, occlusion, and fatal hypotension.^{4,47,64,65,67,69} Tunneled catheters appear to have a superior efficacy and patency rate of >95%.⁶⁹ Control of ascites ranges from 83% to 100% of cases with a mean patency duration of 52 days.⁴ It should be noted that though these catheters are widely used to treat MA with successful outcomes, it remains off-label use.

Shunting

Shunting involves removal of fluid from the peritoneal cavity and returning it to the venous circulation (superior vena cava) with the goal of maintaining electrolytes and proteins, as compared to drainage procedures. The most commonly employed options include the LeVeen catheter and the Denver shunt (Denver Biomaterials Inc., Denver, CO)⁷⁰ (Fig. 128.2). Peritoneovesicular shunts were attempted; however, peritonitis and occlusion limited their utility.⁷¹ There is no level 1 evidence comparing shunt efficacy in MA.⁵⁰ Contraindications to shunt placement include hemorrhagic ascites, loculations, heart disease, renal failure, jaundice, portal hypertension, pleural effusion, and clotting disorders.^{4,66} Theoretically, there is a risk of systemic seeding from positive peritoneal cytology, but this has not been found to be clinically significant.^{66,72} Though shunt placement would be advised only in select patients with prolonged life expectancy, survival has been found to be ~30 days in one study and ranged from 52 to 266 days in a comprehensive review, with perioperative mortality as high as 20%.^{66,72} A review of 27 studies evaluating LeVeen and Denver shunts found 78% control of ascites with 70% subclinical and ~3% clinical disseminated intravascular coagulation, a mean patency of

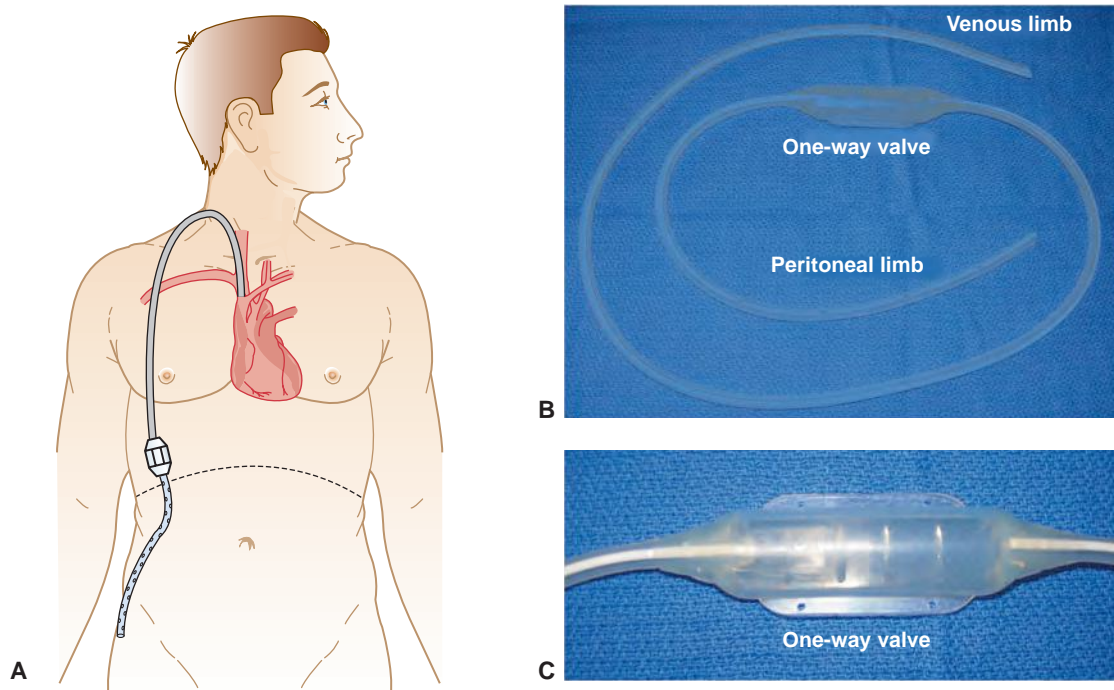

Figure 128.2 (A) Peritoneovenous shunt placement. (B, C) Denver shunt showing the compressible chamber and one-way valve. (A modified from Millard FC, Powis SJ. Management of intractable malignant ascites using the Denver peritoneovenous shunt. *J R Coll Surg Edinb* 1988;33:138, with permission.)

10 weeks, and lowest response rates in patients with gastrointestinal cancers (10% to 15%).⁵⁰ Therefore, their use in gastrointestinal malignancies is relatively contraindicated.^{24,66} Complication rates of 25% to 40% are reported with kinking or occlusion occurring in almost one-third of patients.^{24,73–75} In summary, in highly selected patients with prolonged life expectancy, surgical shunting may provide palliation with known procedure related morbidity and mortality.

Regional Treatments

Intracavitary Chemotherapy, Cytorreduction, and Hyperthermic Chemotherapy

The goal of intracavitary chemotherapy is to expose tumor cells to higher concentrations of toxic chemotherapy than would otherwise be possible via systemic administration. The theoretical mode of action involves direct cytostatic effects plus ensuing fibrosis and scar formation, inhibiting peritoneal secretion and limiting the free volume of the peritoneal cavity.^{8,66} Response rates in controlling MA have varied from 33% to 85% in different histologies and historically using different agents, including mechlorethamine, thiotepa, bleomycin, mitoxantrone, 5-fluorouracil, cisplatin, and mitomycin C.^{60,76–81} Ovarian cancer seems to be the most sensitive to local peritoneal chemotherapy, and success appears improved when limited to microscopic disease.⁴

Penetration of the selected chemotherapeutic agent into the tumor is critical, and optimal tumor bulk <1 mm is recommended^{82,83}; therefore, cytorreduction is often required prior to treatment to improve outcomes. This can be an extensive and morbid surgical procedure involving removal of all involved visceral and parietal peritoneal surfaces, and organ resection when stripping is not possible.^{84,85} This, combined with heating the chemotherapy, has led to studies evaluating the efficacy of intraperitoneal hyperthermic chemotherapy (HIPEC). Hyperthermia of selected chemotherapeutic agents can enhance cytotoxicity through improved tissue penetration and reduced drug resistance.⁸⁶ Agents studied in HIPEC include cisplatin, etoposide, mitomycin C, paclitaxel, taxol, gemcitabine, and 5-fluorouracil. In many tumor histologies studied, improved local control and overall survival can be achieved with this approach. Regarding MA specifically, in one study of 32 patients with gastrointestinal and ovarian cancers, MA was successfully treated in 11/12 patients, and in another report of 39/84 patients with ascites from gastrointestinal-only cancers, 79% of patients achieved control of their ascites.^{87,88} Rates of control of MA with HIPEC range from 75% to 100%.^{88–91} Studies in patients with ovarian malignancy, primary peritoneal mesothelioma, and pseudomyxoma peritonei in particular have demonstrated promising results, and continued study of additional tumor histologies is warranted.^{92,93}

Combining minimally invasive surgery with HIPEC may offer a less invasive approach to achieve similar goals, and in a study of five patients with MA from stage IV gastric cancer, HIPEC with mitomycin C and cisplatin achieved complete response of MA in all patients without morbidity or mortality.⁹⁴ In 52 patients with MA secondary to gastric cancer, colorectal cancer, ovarian cancer, breast cancer, peritoneal mesothelioma, and melanoma, laparoscopic HIPEC with cisplatin and doxorubicin or mitomycin C resulted in resolution of ascites in 49/52 patients.⁹⁵ In a review of eight studies with 183 patients, the procedure effectively controlled MA in 95% of cases.⁹⁶

This approach often foregoes the extensive cytorreduction of open procedures, and the optimal approach of HIPEC in these patients remains to be determined. Clearly, in highly selected patients with optimal tumor biology, with specific histopathologies, and using select cytotoxic agents, intracavitary chemotherapy plays a significant role in controlling MA, and future treatments will likely involve study of cytorreduction, HIPEC, and minimally invasive surgical techniques.

Immunotherapy: Cytokines, Infectious Agents, and Monoclonal Antibodies

The goal of immunotherapy in MA is to incite an antitumor response within the peritoneal cavity that will reduce tumor burden and decrease ascites formation. Various immunostimulatory agents, both specific and nonspecific, have been administered systemically and locally with varying responses. Cytokines studied have included TNF and interferon (IFN). TNF- α use was promising in preclinical models, but has not been well established in humans. One study demonstrated no objective response in controlling MA in 39 patients with ovarian cancer, while another demonstrated a 76% objective response rate in a phase I trial of 29 patients with MA of various histopathologies.^{97,98} IFN may increase natural killer cell activity in the peritoneal cavity, and both IFN- α 2b and IFN- β reduced MA in some patients when administered intraperitoneally.^{99–102}

Infectious agents have also shown an immunologic response resulting in improvement in MA. OK-432 is a penicillin-heat-treated powder of Su-strain *Streptococcus pyogenes* A3 that indirectly enhances cytotoxic T-cell activity.¹⁰³ Intraperitoneal OK-432 alone or when combined with other immunostimulatory cytokines has been shown to palliate MA, and in 400 patients with MA of various tumor histologies reduced effusions in 60% of cases.^{103–105} *Corynebacterium parvum* has also been administered in a small series of patients resulting in decreased malignant effusion formation.¹⁰⁶

Monoclonal antibodies, including the antimucin antibody 2G3, have been used in the past to increase the time needed between paracenteses.¹⁰⁷ By specifically targeting VEGF, a growth factor thought to promote ascites formation (see section titled “Incidence and Etiology”), anti-VEGF antibodies have been theorized to improve outcomes in patients with MA. PTK-787, an inhibitor of the VEGF receptor, significantly inhibited MA and the growth of intraperitoneal ovarian cancer cells in a murine model, and also enhanced control of MA in patients with ovarian cancer.^{99,108} Further research evaluating the utility of anti-VEGF therapy, such as with SU5416, an anti-VEGF receptor 2 small molecule inhibitor, is ongoing.¹⁰⁹ Bevacizumab, a humanized monoclonal antibody against VEGF-A that has been used systemically in various cancers, has been administered intraperitoneally in a small pilot study of nine patients. Presentation in abstract form revealed resolution of MA in all patients treated.¹¹⁰

Recently, a trifunctional monoclonal antibody, catumaxomab, has been engineered with two different antigen-binding sites and a functional Fc domain.¹¹¹ One binding site engages EpCAM, an epithelial cell adhesion molecule expressed in 70% to 100% of epithelial tumor cells found in MA from breast, ovarian, gastric, and colon cancers, and the other engages CD3.^{112–114} The Fc domain activates phagocytosis and cytotoxicity in various immune effector cells. The use of this antibody in various tumor histologies including ovarian and gastric cancers was found to be safe and resulted in control of MA.^{115–118} A recent phase 2/3 clinical trial randomized 258 patients with MA consisting of 129 ovarian and 129 nonovarian primaries into treatment with paracentesis alone or in combination with catumaxomab.¹¹⁹ Puncture-free survival was improved as was the time to next paracentesis, both by over 1 month. Importantly, signs and symptoms of ascites were improved. Clearly, immunotherapy may have a role in the future management of malignant ascites.

Steroids, Radioisotopes, and Octreotide

Intraperitoneal triamcinolone was used in a phase 2 study of 15 patients with MA of various histologies and improved symptoms and decreased the time between paracentesis by approximately 1 week.¹²⁰

Radioisotopes have been employed in patients with MA to administer local particulate radiation for decades with good effect. In 566 patients treated with intraperitoneal Au-198, ascites was

reduced in 47% of patients.¹²¹ Chromic phosphate colloid (32P), which penetrated tissues up to 8 mm compared to 3.8 mm for Au-198,¹²² also resulted in clinically significant response rates up to 80%.^{66,123,124} Dose escalation in both cases improved control but increased toxicity, including intestinal necrosis. Au-198 is now considered hazardous; however, 32P may still have a role in patients with no adhesions and minimal tumor bulk with only positive cytology.

Though small series of patients treated with octreotide appeared promising, in a pilot study of 33 patients with MA, octreotide did not prolong the time to next paracentesis.¹²⁵

Metalloproteinase Inhibitors

MMPs function to digest extracellular tissue scaffolds to allow tumor in-growth, thus inhibitors of these enzymes may play a role in tumor cell cytostasis and palliation of MA (see section titled "Incidence and Etiology"). Intraperitoneal administration of the MMP inhibitor batimastat after paracentesis in 23 patients with MA of various histologies resulted in no reaccumulation of ascites in 12 patients in a phase I study.²¹ However, preclinical models have shown variable improvement in MA with this agent, and further studies investigating marimastat and other subsequent-generation MMPs in MA may warranted before MMPs are clinically applicable.

129 Paraneoplastic Syndromes

Ramaswamy Govindan, Thomas E. Stinchcombe, and Daniel Morgensztern

INTRODUCTION

Paraneoplastic syndromes are disorders caused by systemic effects occurring remotely from the cancer primary site or metastasis. They are estimated to affect up to 8% of patients with cancer.¹ The most commonly involved systems in paraneoplastic syndromes are the neurologic, endocrine, hematologic, dermatologic, and rheumatologic. Small-cell lung cancer (SCLC) is the most commonly associated malignancy, with lymphoproliferative disorders, thymoma, and gynecologic and breast cancers accounting for the majority of the other causes. The two main mechanisms for paraneoplastic syndromes are ectopic production of humoral factors such as hormones, peptides, or cytokines, and immune cross-response between malignant and normal tissues.

Paraneoplastic syndromes may be the first manifestation of a malignancy, and their timely detection may allow the diagnosis of tumors at an early stage. Therefore, these malignancies that would likely be otherwise clinically occult may be detected at an earlier stage with increased probability of cure. The successful treatment of the underlying malignancy usually results in resolution of the paraneoplastic syndromes caused by ectopic hormone production. However, the tumor-directed treatment is less effective in the immune-mediated syndromes.

PARANEOPLASTIC NEUROLOGIC SYNDROMES

Paraneoplastic neurologic syndromes (PNS) are a rare complication of malignancies, and it is estimated that only 0.01% of all patients with cancer will develop PNS.^{1,2} Malignancies that produce neuroendocrine proteins such as SCLC, immunoglobulin (lymphoma or multiple myeloma), or involve immune organs such as thymoma are the most commonly associated with the development of PNS. It is estimated that approximately 5% of patients with SCLC and approximately 10% of patients with lymphoma or multiple myeloma will develop PNS.³ In the majority of cases, the neurologic symptoms are detected prior to the diagnosis of the malignancy. This clinical situation creates a diagnostic dilemma as the symptoms of the PNS, including cognitive changes, ataxia, weakness, or numbness, are often nonspecific and may be associated with other nonmalignant syndromes or etiologies.

The presenting symptoms provide insight into the area of the nervous system affected, the type of PNS, and the potential underlying malignancy. PNSs that affect the central nervous syndrome include limbic encephalitis (LE) and paraneoplastic cerebellar degeneration, whereas those affecting the neuromuscular junction include myasthenia gravis (MG) and Lambert-Eaton myasthenia syndrome (LEMS). Involvement of the peripheral nervous system can cause autonomic neuropathy and subacute sensory neuropathy. Approximately 70% of cases with limbic encephalitis and subacute sensory neuropathy are associated with a malignancy. However, only 40% to 50% of cases subacute cerebellar ataxia, LEMS, and MG are associated with a malignancy.³

PNSs occur when the immune system cross-reacts with antigens on the tumor cells and proteins expressed in the neurologic system.⁴ The two categories of antigens are intracellular antigens and extracellular antigens, with the pathophysiology differing according to the antigen.⁵ For syndromes where the antigen is an intracellular, the antibody stimulates antigen-specific T-cell lymphocytes, leading the immune system to attack the neurologic system.⁶ In syndromes where the antigen is extracellular, including myelin proteins, gangliosides, ion channels, or cell membrane proteins, the antibodies bind with the target and change the protein expression of the cell or damage the cell membrane by complement activation. The syndromes related to monoclonal antibodies against extracellular antigens respond better to therapy than syndromes associated with cell-mediated mechanisms.⁷ Because the tumor cells are not the source of antibody production, successful treatment of the malignancy may not reduce the symptoms associated the PNS and the neurologic damage sustained prior to diagnosis may be permanent. Another mechanism of action for the monoclonal antibodies is a direct interference with the extracellular protein or receptor. An example of this mechanism is LEMS in which the monoclonal antibody interferes acetylcholine binding and post-synaptic signal transduction at the neuromuscular junction, leading the symptoms of muscle weakness. The role of the monoclonal antibody and the pathophysiology in PNSs is unknown in many syndromes.

Diagnosis

The initial diagnostic workup depends on whether the patients have a known malignancy or not. For patients with a known malignancy the workup includes radiologic imaging to evaluate for brain metastases, leptomeningeal disease or spinal cord compression, and a review of previous radiation therapy or chemotherapy treatments that are associated with neurologic toxicity. Once other causes of the neurologic symptoms have been excluded, a workup for PNS is initiated, including additional imaging, cerebrospinal fluid (CSF) analysis, nerve conduction studies, and electroencephalography, or electromyography depending on the symptoms. Lumbar puncture can be performed to evaluate for leptomeningeal disease and inflammatory or infectious etiologies of the symptoms. In PNS, the CSF often reveals pleocytosis and elevated protein consistent with inflammation, elevated immunoglobins (Ig) G and oligoclonal bands.⁸ Oligoclonal bands may be the only CSF abnormality in 10% of the cases.⁸

The constellation of symptoms define a syndrome, and the syndromes are often defined as “classical,” which are the syndromes commonly associated with an underlying malignancy. An international panel of neurologists established criteria for “definite” and “possible” PNS (Table 129.1).⁹ Examples of classical syndromes include encephalomyelitis, LE, subacute cerebellar degeneration, opsoclonus-myoclonus syndrome (OMS), subacute sensory neuropathy chronic gastrointestinal (GI) pseudo-obstruction, LEMS, and dermatomyositis (DM).⁹ Some syndromes are associated with specific malignancies (Table 129.2).

TABLE 129.1

Diagnostic Criteria for Neurologic Paraneoplastic Syndromes

Definite	Possible
1. A classical syndrome and cancer that develops within 5 years of the diagnosis of the neurologic disorder	1. A classical syndrome, no onconeural antibodies, no evidence of cancer but a high risk of having an underlying cancer
2. A nonclassical syndrome that resolves or significantly improves after cancer treatment without concomitant immunotherapy (provided the syndrome is not susceptible to spontaneous remission)	2. A neurologic syndrome (classical or not) with partially characterized onconeural antibodies and no cancer
3. A nonclassical syndrome with onconeural antibodies (well characterized or not) and cancer that develops with 5 years of the diagnosis of the neurologic disorder	3. A nonclassical syndrome, no onconeural antibodies, and cancer present within 2 years of diagnosis
4. A neurologic syndrome (classical or not) with characterized onconeural antibodies (anti-HU, Yo, CV2, Ri, Ma2, or amphiphysin) and no cancer	

TABLE 129.2

Overview of Common Paraneoplastic Neurologic Syndromes

Syndrome Name	Common Clinical Symptoms	Associated Malignancies	Onconeural Antibodies	Potential Diagnostic Studies
Limbic encephalitis	Mood changes, hallucinations, memory loss, seizures, hypothalamic syndromes	1. SCLC (most common) 2. Testicular germ cell 3. Breast 4. Thymoma 5. Teratoma 6. Hodgkin lymphoma	1. Anti-Hu 2. Anti-Ma2 3. Anti-CRMP5 4. Anti-amphiphysin	1. EEG 2. MRI of the brain for hyperintensity in the temporal lobe 3. CSF analysis
Subacute cerebellar degeneration	Ataxia, diplopia, dysphagia, dysarthria, dizziness, nausea/vomiting	1. SCLC 2. Gynecologic 3. Hodgkin lymphoma 4. Breast	1. Anti-Yo 2. Anti-Hu 3. Anti-CRMP5 4. Anti-Ma 5. Anti-Tr 6. Anti-Ri 7. Anti-VGCC 8. Anti-MGluR1	1. MRI of brain for cerebellar atrophy
Lambert-Eaton myasthenia syndrome	Lower extremity proximal muscle weakness, fatigue, diaphragmatic weakness, bulbar symptoms, autonomic symptoms	1. SCLC 2. Prostate 3. Cervical 4. Lymphoma	Anti-VGC	EMG: low muscle action amplitude, decreased response with low-rate stimulation and increased response with high rate stimulation
Myasthenia gravis	Fatigable weakness of voluntary muscles (ocular-bulbar and limbs), diaphragmatic weakness	Thymoma	Anti-AchR	EMG: decreased response to repetitive nerve stimulation
Autonomic neuropathy	Panautonomic neuropathy involving sympathetic, parasympathetic, and enteric systems (symptoms include orthostatic hypotension, GI, or bladder dysfunction, dysphagia, altered pupillary light reflexes, arrhythmias)	1. SCLC 2. Thymoma	1. Anti-Hu 2. Anti-nAChR 3. Anti-CRMP5 4. Anti-amphiphysin	Symptom dependent

SCLC, small-cell lung cancer; EEG, electroencephalogram; MRI, magnetic resonance imaging; CSF, cerebrospinal fluid; EMG, electromyogram; GI, gastrointestinal.

Frequently, a panel of serum antibodies against neural proteins, referred to as onconeural antibodies, are checked as part of the initial workup, as a single syndrome may be associated with multiple antibodies.¹⁰ These antibodies are useful but have some well-recognized flaws. The association between onconeural antibodies and PNS is variable (Table 129.3).⁹ Onconeural antibodies found in both PNS and nonmalignant syndromes include antiacetylcholine receptor, antinicotinic, antivoltage-gated calcium channel (VGCC), and voltage-gated potassium channels (VGKC).^{1,4} Among the known VGCC subtypes including L, R, T, N, and P/Q,^{11,12} the latter two are expressed in SCLC and are common targets for antibodies in these patients.¹³ All these antibodies target extracellular antigens. Importantly, <50% of patients with a clinical syndrome of PNS will have the antibodies detected, and these antibodies can be detected in patients without PNS.^{1,10} Therefore, the absence of onconeural antibodies should not exclude the diagnosis of PNS, and the presence of onconeural antibodies alone should not be considered diagnostic. Of note, anti-Tr antibodies associated with cerebellar degeneration can be detected in the CSF but not in the serum.¹⁴ Another clinical dilemma is that onconeural antibody tests take time and symptomatic patients may require treatment before the results are available.

Patients may present with symptoms consistent with PNS without a known diagnosis of cancer, and a workup for an underlying malignancy is initiated. This should include a history to assess for symptoms and risk factors for an underlying malignancy, a physical exam, and a workup for occult malignancy. Frequently, the initial test is computed tomography scan of the chest, abdomen, and pelvis. Fluorodeoxyglucose positron emission tomography (FDG-PET) is increasingly popular. A small study compared computed tomography and FDG-PET, and the sensitivity for detection of tumor or tumor recurrence in patients with PNS was 30% and 90%, respectively ($p < 0.01$).¹⁵

Specific Syndromes

Numerous neurologic syndromes have reported to be associated with malignancy in case reports. However, several specific syndromes with a common constellation of symptoms have been reported consistently in the literature. This section will focus on the more common PNSs. PNSs that affect the central nervous system include LE, subacute cerebellar degeneration, and OMS. Symptoms associated with LE include short-term memory loss, confusion, psychiatric symptoms such as hallucinations and mood changes, and seizures. The symptoms will present over a period of several days to several months. Magnetic resonance imaging (MRI) reveals hyperintensity of the medial temporal lobe(s), and CSF analysis will reveal pleocytosis, elevated protein, elevated IgG, and oligoclonal bands.¹ LE is associated with onconeural antibodies against the VGKC.⁹ Subacute cerebellar degeneration typically presents with symptoms of ataxia, diplopia, dysphagia, and dysarthria. Typically, the first symptoms are isolated gait ataxia and subsequent development of truncal and hemispheric cerebellar dysfunction.⁹ The onset of symptoms is generally <12 weeks, and MRI of the brain does not reveal any significant cerebellar atrophy. The P/Q type anti-VGCC antibodies and other antibodies have been reported with this PNS.^{1,16} Concurrent cerebellar degeneration and LEMS has been reported as well in patients with SCLC.¹⁷ OMS is characterized subacute onset of opsoclonus, a disorder or saccadic eye movements, chaotic saccades in all directions, and arrhythmic-action myoclonus that predominately involves the trunk, limbs, and head.¹⁸ The pathophysiologic mechanism for this disorder is unclear but may be mediated by disruption of the Nova-1/ Nova-2 proteins of the glycine receptor.¹⁹ This disorder has been associated with SCLC in adults and neuroblastoma in children.¹⁹

Subacute sensory neuropathy and GI dysmotility are two PNSs that affect the peripheral nervous system. The common symptoms

TABLE 129.3

Onconeural Antibodies and Associated Syndromes and Malignancies

Onconeural Antibody	Paraneoplastic Syndrome	Malignancy	Antigen Location
Strong Association			
Anti-Hu (ANNA-1)	<ul style="list-style-type: none"> ■ Limbic encephalitis ■ Paraneoplastic cerebellar degeneration ■ Subacute sensory neuropathy ■ Chronic gastrointestinal pseudo-obstruction ■ Autonomic neuropathy 	SCLC, neuroblastoma, prostate cancer	Nucleus

Anti-mGluR1	Paraneoplastic cerebellar degeneration	Hodgkin disease	Cytoplasmic

SCLC, small-cell lung cancer.

of subacute sensory neuropathy are numbness and pain of the extremities, marked asymmetry of symptoms at onset, and loss of proprioception; the onset symptoms is often <12 weeks.^{1,9} In the later stages, patients can develop ataxia and multifocal involvement. On physical exam, there is loss of the deep tendon reflexes, and electrophysiologic studies reveal involvement of sensory fibers and absence of sensory nerve action potentials.

Patients with cancer often report GI symptoms, including anorexia, early satiety, nausea, emesis, abdominal pain, diarrhea, or constipation. Among the multiple causes for GI complaints in patients with cancer is a paraneoplastic dysmotility, which may affect either the entire GI tract or isolated segments, where they produce specific syndromes such as achalasia, gastroparesis, and intestinal dysmotility with constipation.²⁰ Paraneoplastic dysmotility should be suspected in patients with rapid symptom onset, significant weight loss, presence of concurrent autonomic or sensory neuropathy, and risk factors for malignancy such as smoking and strong family history. The onset of GI dysmotility usually precedes the diagnosis of cancer, and the most common associated malignancy is SCLC. The presumed pathophysiology is the presence of tumor antigens that elicit an immune response which cross-reacts with the enteric nervous system. The most common antibody associated with GI dysmotility is the antineuronal nuclear antibody-1, also known as anti-Hu, and approximately 30% of patient with this antibody have symptoms of GI dysmotility.^{20,21} Other antibodies associated with GI dysmotility include antineuronal nuclear antibody-2 (anti-Ri), VGCC types N and P/Q, VGKC, and Purkinje cell cytoplasmic (anti-Yo). In a retrospective evaluation of 12 patients diagnosed with malignant tumors and GI motor dysfunction, SCLC was the most common primary malignancy, accounting for 9 cases.²² The three other patients had lung adenocarcinoma, follicular lymphoma, and ovarian papillary serous adenocarcinoma. The most common presenting symptoms were weight loss, nausea, emesis, and early satiety, which were acute in onset and rapidly progressive in all patients. Although the symptoms preceded the diagnosis of SCLC by a mean interval of approximately 9 months, they developed after the diagnosis in patients with other tumors. Among the 11 patients with serum available, 10 had one or more markers of paraneoplastic immunity including antineuronal nuclear antibody-1, which was detected in all 8 patients with SCLC tested.

MG and LEMS are two PNSs that impact the function of the neuromuscular junction. MG is characterized by muscle weakness of the voluntary muscles that is worsened by exertion. Common symptoms are diplopia and ptosis related to eye muscle weakness. Other symptoms include dysarthria, problems with chewing and swallowing caused by oropharyngeal weakness, and limb girdle weakness, which is generally more pronounced in the proximal than distal muscle groups. Approximately 85% of patients have an onconeural antibody against the muscle acetylcholine receptor (antiacetylcholine receptor), and about 6% of patients will have an onconeural antibody against the muscle specific kinase known as "striational antibodies."²³ MG is associated with thymoma. MG occurs in 30% to 50% of patients with thymoma but only 15% of patients with MG will have thymoma. The presence of antistriational antibodies in a patient younger than 60 years is suspicious for a thymoma.²³ Patients with MG and thymoma may have a better prognosis due to early detection and/or more indolent disease.²⁴ Importantly, thymectomy will result in an improvement of the symptoms of in the MG, and all thymic tissue should be removed to reduce the rate of recurrence.²⁵

Approximately 50% to 60% of patients with LEMS have an underlying tumor, the most commonly SCLC.²⁶ Clinical symptoms include proximal muscle weakness, autonomic features such as dry mouth, constipation, erectile dysfunction, and less commonly orthostatic hypotension and micturition difficulties, and reduced tendon reflexes. Proximal muscle weakness is frequently the first symptom.²⁶ Distinguishing MG from LEMS on clinical symptoms can be difficult. In MG, the initial weakness frequently affects the

extraocular or bulbar muscles, whereas in LEMS the proximal muscle weakness is frequently the presenting symptom.²⁷ Patients with LEMS frequently present with leg weakness, whereas limb weakness restricted to the arms is more common in patients with MG. Onconeural antibodies against the P/Q-type VGCC on the presynaptic nerve terminal are characteristic of LEMS and the cause of the muscle weakness. Electromyography studies reveal a low amplitude compound muscle action potential, which becomes lower at low-stimulating frequencies.²⁶ In order to distinguish LEMS from MG, high-frequency or postexercise stimulation are the diagnostic tests. An increased compound muscle action potential of 60% is considered abnormal and is very sensitive and specific for LEMS.²⁸ Postexercise stimulation and high-frequency stimulation have a similar sensitivity, but high-frequency stimulation is painful and should be avoided if possible.²⁶

Treatment

Given the rarity of PNS, there are no "evidence-based" studies for optimal care. In general, care follows the principles of treating the underlying malignancy, immunosuppression, and symptom-directed supportive care. Many times, the care of a patient with a PNS requires the coordination of care with oncologists, neurologists, and specialists in palliative care. The appropriate care for the type and stage of underlying malignancy should be initiated. Immunosuppression used in the treatment of PNS including corticosteroids, alkylating agents such as cyclophosphamide, intravenous Ig (IVIG), rituximab, and plasmapheresis. The prednisone dose frequently employed is 1 mg/kg daily or high-dose intravenous methylprednisolone (1 gm/day for 5 days, followed by weekly therapy of the same dose for 6 to 12 weeks).¹⁰ The dose of oral cyclophosphamide frequently used is 2 mg/kg daily, and azathioprine dose frequently used is up to 2.5 mg/kg daily with adjustments related to toxicity such as myelosuppression.

IVIG is believed to modulate the immune system by interacting with the Fc receptor on immune cells, neutralizing the autoimmune antibody and/or increasing the clearance of the autoimmune antibody, and increasing the regulatory T-cells.²⁹ PNSs that frequently respond to IVIG include LEMS, MG, Guillain-Barre syndrome, stiff person syndrome, and anti-VGKC limbic encephalitis.²⁹ IVIG is frequently given 400 to 1,000 mg/day for a total of 2 to 3 g, and the most serious toxicity is nephrotoxicity.²⁹ Plasmapheresis removes the onconeural antibodies from circulation, and an improvement in symptoms can be observed within days. The effect generally only lasts several weeks, and the concurrent administration of immunosuppressive drugs is required.¹ Rituximab, an anti-B-cell monoclonal antibody, has been used as immunosuppression and case reports of efficacy exist in the treatment of OMS, stiff-person syndrome, paraneoplastic cerebellar degeneration, and LE.^{30,31} Rituximab has been mainly studied in patients with PNS who demonstrate the presence of an established onconeural antibody, and the rituximab did not result in consistent effect of serum or CSF antibody titers.³¹ The standard dose of rituximab of 375 mg/m² weekly for 4 weeks has been used.

Some PNS benefit from therapies focused on reducing symptoms. The best examples of this are LEMS and MG in which treatment was with the cholinesterase inhibitor pyridostigmine, which inhibits the degradation of acetylcholine at the neuromuscular juncture and may improve muscle strength.³² For patients with LEMS, guanidine inhibits the VGKC and enhances the release of acetylcholine. However, the toxicities of myelosuppression and renal insufficiency make the use of this agent problematic, especially if the patient requires cytotoxic chemotherapy.³³ Aminopyridines prolong nerve terminal depolarization, which increases calcium and consequently the release of acetylcholine. Whereas dalfampridine, the first available aminopyridine, is not routinely used due to toxicity concerns, 3,4-diaminopyridine is better tolerated and has been shown to improve motor and autonomic

symptoms.^{34,35} The common adverse effects include lightheadness, fatigue, epigastric distress, and difficulty sleeping. For patients with autonomic neuropathy and symptomatic hypotension, treatment options include increased water intake, fludrocortisone, midodrine, and caffeine.^{36,37} For patients with pseudo-obstruction, neostigmine has been investigated.³⁸

Prognosis

Given the rarity of and the multiple different malignancies associated with this PNS, it has been difficult to determine the impact of this PNS of prognosis. In the case of MG associated with thymoma, there is some evidence that patients may have a better prognosis due to more indolent disease and/or earlier detection, and for patients with SCLC with anti-Hu antibody-associated PNS, there is some evidence that they are more responsive to therapy.^{24,39} Conversely, patients with a PNS often have poor performance as a consequence of well-advanced malignancy, and many times there are justifiable concerns about the patient's ability to tolerate cytotoxic chemotherapy. If the poor performance status is related to the underlying PNS, cancer-specific therapy is often initiated in an attempt to improve the symptoms. Although the exact impact of a concurrent PNS on prognosis is difficult to assess, survival consistent with the prognosis of the underlying malignancy has been reported with treatment.

PARANEOPLASTIC ENDOCRINOLOGY SYNDROMES

Inappropriate Antidiuretic Hormone Secretion

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is a disorder of sodium and water balance characterized by a hypotonic euvolemic hyponatremia. The nonapeptide antidiuretic hormone (ADH) or arginine-vasopressin is synthesized in the hypothalamic magnocellular neurons of the supraoptic and paraventricular nuclei and stored in the posterior lobe of the pituitary gland. There are three known receptors for ADH at the cell membrane: V1a, V1b, and V2.^{40,41} V1a receptors are found in the vascular smooth muscle, uterus, platelets, and hepatocytes, where the main functions include vasoconstriction, uterine contraction, platelet aggregation, and glycogenolysis, respectively. V1b receptors are located in the corticotroph cells of the anterior pituitary gland where they are involved in the release of adrenocorticotrophin hormone (ACTH) and beta-endorphin. V2 receptors are located in the basolateral membrane of the renal-collecting duct principal cells, vascular smooth muscle, and vascular endothelium, where they are involved in the synthesis and insertion of aquaporin 2 (AQP-2) channels into the apical membrane, vasodilation, and release of von Willebrand and factor VIII. Binding of ADH to the V2 receptor in the basolateral membrane of the collecting duct cells leads to activation of adenylate cyclase, with increased production of cyclic adenosine monophosphate, which in turn leads to activation of protein kinase A. Protein kinase A phosphorylates vesicles containing preformed AQP-2 vesicles, which leads to their movement to the apical membrane, where AQP-2 is inserted and works as selective water-conducting channel according to the gradient from the tubular lumen to the medullary interstitium. V2 receptor activation also leads to the increased synthesis of AQP-2. The water enters the cells through AQP-2 channels in the apical membrane and exits through the constitutively active AQP-3 and AQP-4 in the basolateral membrane. The two main stimuli for the ADH secretion are the increased plasma osmolality and decreased intravascular volume, which are regulated by the hypothalamic central sensing system and baroreceptors, respectively. Both ADH and thirst maintain the serum osmolality within a narrow range

averaging approximately 285 mOsm/kg, with an increased osmolality above the threshold being the most important stimulus for the ADH secretion. A second stimulus is a decrease in the effective arterial volume caused by extracellular volume depletion or hypotension, which is detected by the volume-sensitive receptors on the left atrium and leads to a restoration of the effective blood volume through V2 receptors and the blood pressure through V1a receptors in the vascular smooth muscle.⁴² Stimulation of V1a receptors occur at higher plasma concentrations of ADH compared those needed for V2-dependent antidiuretic effects.

The main etiologies for SIADH can be broadly categorized into malignancies or drug-induced and pulmonary or central nervous system disorders. Both intrathoracic and extrathoracic malignancies have been associated with SIADH, with SCLC usually identified as the most common cause. List and colleagues⁴³ reported the presence of SIADH in 40 (11%) out of 350 patients with SCLC, without correlation to stage or site of metastases, and no influence, as an independent variable, on response to chemotherapy or survival. SIADH has been described in approximately 3% of patients with head and neck cancer,⁴⁴ most commonly in tumors of the oral cavity.⁴⁵ Other malignancies that have been rarely associated with SIADH include thymomas,^{46,47} lymphoma,^{48–50} pancreatic carcinomas,⁵¹ and prostate cancer.^{52–54}

Clinical Manifestations

The symptoms from SIADH depend on the degree and rapidity of the change in the serum sodium levels, with the rate of sodium fall considered to be a stronger predictor for morbidity and mortality compared its magnitude.^{55,56} Severe hyponatremia is arbitrarily defined as serum sodium concentration <115 mmol/L.⁵⁷ Due to hyposmolality, there is an entry of free water into the cells, with the brain being particularly affected as it has limited space for expansion inside the skull. Therefore, the most common symptoms from hyponatremia are neurologic and result from cerebral edema. The presence of brain edema triggers an adaptive response to restore the brain volume and limit the neurologic complications, with an initial decrease in brain electrolyte content followed by loss of organic solutes such as creatine and amino acids.⁵⁸ During acute hyponatremia, defined as the rapid decline of serum sodium over a period of <48 hours, the adaptive brain response is overwhelmed, with the development of severe brain edema and neurologic symptoms including nausea and vomiting and headaches, which may progress to seizures, respiratory arrest, and death. Patients with chronic hyponatremia are usually either asymptomatic or have milder symptoms compared to acute hyponatremia, including fatigue, confusion, falls, and attention deficit.⁵⁹

Diagnosis

The diagnostic criteria for SIADH may be subdivided into essential and supplementary features (Table 129.4).^{60–62} The diagnosis of SIADH is usually made after exclusion of other etiologies for hyponatremia through the use of the essential diagnostic criteria. The first step is to measure the plasma osmolality, with values <275 mOsm/kg of water ruling out the causes of hyponatremia with normal or increased plasma osmolality such as translocation by hyperglycemia or pseudohyponatremia caused by hyperlipidemia or hyperproteinemia. The next step is to evaluate the urinary osmolality, which should be >100 mOsm/kg of water during hypotonicity, to define the presence of inappropriate renal dilution and help to exclude the few causes of hyponatremia with decreased urinary osmolality such as beer potomania and polydipsia. Clinical euvolemia is defined as the absence of signs of volume depletion (dry mucous membranes, tachycardia, and orthostasis) caused by renal or extrarenal sodium loss or volume overload (edema and ascites) caused by renal failure, nephrotic syndrome, cirrhosis, and heart failure. The next step is to rule out hypothyroidism and glucocorticoid deficiency, the other two common etiologies that fall into the hypotonic euvolemic hyponatremia.

TABLE 129.4

Diagnostic Criteria for Inappropriate Antidiuretic Hormone Secretion

Essential features	<ol style="list-style-type: none"> 1. Effective osmolality <275 mOsm/kg of water 2. Urine osmolality >100 mg/kg of water during hypotonicity 3. Clinical euolemia 4. Urine sodium >40 mmol/L with normal dietary salt intake 5. Normal thyroid and adrenal function 6. No recent use of diuretics
Supplemental features	<ol style="list-style-type: none"> 1. Serum uric acid <4 mg/dl 2. BUN <10 mg/dl 3. Fractional sodium excretion >1% 4. Fractional excretion of urea >55% 5. Failure to correct the hyponatremia after infusion of 2 L of 0.9% saline 6. Correction of hyponatremia with fluid restriction 7. Abnormal result on the water test load 8. Elevated plasma ADH levels despite hypotonicity and clinical euolemia

BUN, blood urea nitrogen; ADH, antidiuretic hormone.

The supplementary features include reduced uric acid and blood urea nitrogen, increased fractional excretion of sodium and urea, correction of hyponatremia with fluid restriction but not after a 2 liter infusion of 0.9% saline, elevated plasma ADH levels despite hypotonicity and clinical euolemia and abnormal result on the test of water load, which is defined as inability to excrete at least 90% of a 20 mg/Kg water load in 4 hours or failure to achieve an urine osmolality <100 mOsmol per Kg of water. Decreased blood urea nitrogen and uric acid are both indicative of euolemia although not specific for SIADH, whereas increased values are suggestive of hypovolemia. Because some patients with nonparaneoplastic SIADH may have low or undetectable levels of ADH, the term syndrome of inappropriate diuresis has been proposed as a more accurate description of this condition.⁶⁵

Treatment

The treatment of paraneoplastic SIADH may be broadly subdivided into indirect and direct modalities. In addition to cancer-specific therapy that, if effective, may eventually improve the hyponatremia by reducing the production of ADH by the malignant cells, the initial treatment for nonsevere cases of hyponatremia caused by SIADH is fluid restriction to approximately 800 ml daily in an attempt to induce a negative balance as the urinary excretion plus insensible losses usually exceed 1 L per day.⁵⁵ This treatment modality, however, is associated with a slow improvement, has a very low compliance rate, particularly in outpatients, and is often insufficient to improve the hyponatremic symptoms. Therefore, pharmacologic interventions are usually indicated. Oral administration of urea at 30 g daily has been associated with improvement in hyponatremia associated with SIADH by causing osmotic diuresis and increased water excretion.⁶⁴⁻⁶⁶ The main drawback from urea is the poor palatability, with most patients unable to tolerate it despite being dissolved in strong flavored liquids. Loop diuretics such as furosemide and triamterene have been shown to be effective in patients with SIADH by causing increased excretion of free water.⁶⁷ Both demeclocycline and lithium decrease the responsiveness to ADH in the collecting tube, causing nephrogenic diabetes insipidus, with decreased urine concentration despite elevated ADH.⁶⁸⁻⁷¹ Demeclocycline is a tetracycline derivative

with unpredictable onset of action and may cause significant side effects including GI intolerance, photosensitivity, and azotemia. The typical doses are from 300 to 600 mg twice daily. Lithium improves hyponatremia through dysregulation of AQP-2⁷² but has been abandoned as a treatment for SIADH due to the association with interstitial nephritis and end-stage renal failure as well as decreased efficacy compared to demeclocycline.⁶⁹

Patients with symptomatic acute hyponatremia should be treated with continuous infusion of hypertonic saline (3% NaCl), as the euolemic hyponatremia is unlikely to respond to normal saline, with a maximal correction rate of 8 to 12 mmol/L during the first 24 hours.⁶² The initial infusion rate can be estimated by multiplying the patient's body weight in kilograms by the desired rate of increase of serum sodium in mmol/L per hour.⁷³ As an example, for a 70-kg patient, an infusion of 3% saline at 70 ml and 35 ml/hour will increase the serum sodium by approximately 1 mmol/L and 0.5 mmol/L per hour, respectively. Patients with known cardiovascular disease should receive 20 to 40 mg of intravenous furosemide to avoid volume overload. The main goal of therapy is to achieve a safe serum levels with symptomatic relief, rather than completely normal levels. Therefore, acute treatment can be discontinued once the symptoms are resolved, a safe serum sodium usually defined as ≥ 120 mmol/L, or the total magnitude of correction reached 18 mmol/L.

Vasopressine Receptor Antagonists

Vasopressine receptor antagonists (vaptans) are nonpeptide ADH (arginine-vasopressin) antagonists that penetrate deeper into the transmembrane region of V2 receptors compared to ADH, and competitively block the activation of the receptor by endogenous ADH.⁷⁴ With the inactivation of the receptor, the synthesis and transport of AQP-2 into the apical membrane of the collecting duct cells is inhibited, resulting in a decrease in the free water reabsorption and increased urine volume.⁷⁵ Although the increased diuresis produced by V2 receptor antagonists is quantitatively similar to loop diuretics, the latter produces essentially an aquaresis, which unlike the diuretics, is characterized by decreased urinary osmolality. Vaptans are indicated for patients with either euolemic or hypervolemic hyponatremia, and should not be used in hypovolemic hyponatremia. During treatment with vaptans, it is very important to monitor the sodium levels to exclude rapid correction rates; there is no need for fluid restriction. Among the four vaptans with reported data from randomized clinical trials, only conivaptan and tolvaptan are currently approved by the US Food and Drug Administration and are available for clinical use (Table 129.5). Conivaptan is the only drug that inhibits both V2 and V1a receptors, while the other vaptans are V2 receptor-specific.⁷⁶⁻⁷⁸ Another difference between conivaptan and the other vaptans is that although the former was originally developed

TABLE 129.5

Vaptans Tested in Clinical Trials

Name	Receptor Specificity	Administration Route	Dose
Tolvaptan	V2	Oral	15-60 mg once daily
Lixivaptan	V2	Oral	50-100 mg twice daily
Satavaptan	V2	Oral	5-50 mg once daily
Conivaptan	V1a/V2	Intravenous	20-40 mg once daily

as an oral preparation,^{79,80} it was subsequently approved by the US Food and Drug Administration and marketed as an intravenous drug.⁸¹ The recommended treatment includes a loading dose of 20 mg over 30 minutes followed by a maintenance dose of 20 to 40 mg daily through continuous infusion for up to 4 days. Due to infusion site complications, including erythema, phlebitis, and swelling, the infusion should be through a large vein with the site changed every 24 hours. There are several medications with potential for significant drug interactions including statins, calcium channel blockers, benzodiazepines, azole antifungals, and chemotherapy agents including vinca alkaloids, doxorubicin, and etoposide, with the latter particularly important given the frequency of SCLC as the SIADH etiology, for which etoposide is commonly the chemotherapy of choice in the first-line setting. Tolvaptan is an oral drug that is 29 times more selective for V2 receptors than V1a and does not have intrinsic agonist effects.^{82,83} Schrier and colleagues⁸⁴ reported the combined results of two multicenter randomized clinical trials, the Study of Ascending Levels of Tolvaptan in Hyponatremia (SALT) 1 and 2, where 448 patients were randomized to oral tolvaptan 15 mg daily or oral placebo. During the first 4 days of therapy, the dose of the study drug could be escalated to up to 60 mg daily according to the serum sodium concentrations. Eligible patients had hyponatremia due to cirrhosis, congestive heart failure, or SIADH. Tolvaptan was associated with a significant increase in the serum levels of sodium during the first 4 days ($p < 0.001$) and after 30 days of therapy ($p < 0.001$). The treatment was well tolerated with increased thirst, dry mouth, and urination as the main side effects. In a subset analysis of 110 patients with SIADH from the SALT trials, the results were similar to the overall population, with a significant improvement in the serum sodium concentration both in the first 4 days and on day 30.⁸⁵ The long-term administration of tolvaptan was evaluated by the open-label SALTWATER study, which was an extension of the SALT studies where 111 patients previously assigned to both placebo and tolvaptan arm received tolvaptan for an extended period of time.⁸⁶ Prolonged treatment was associated with maintenance of normal serum sodium levels and tolerable profile where the most common toxicities were similar to SALT studies, including dry mouth, thirst, polydipsia, and polyuria. The most likely role for vaptans in SIADH is in the treatment of mild to moderate hyponatremia and severe asymptomatic hyponatremia.⁸⁷ There is not enough data to support the use of vaptans in patients with symptomatic hyponatremia, who should be treated with hypertonic saline.

One of the main concerns during the treatment of chronic hyponatremia is the overzealous treatment, which may lead to osmotic demyelination.⁸⁸⁻⁹⁰ This complication, also known as osmotic demyelination syndrome (ODS), occurs when the hyponatremia is corrected too rapidly, outpacing the recapture of lost organic molecules by the brain. During the rapid increase in the serum osmolality, the brain cells try to reverse the loss of solutes by increasing the production of organic osmolytes and inorganic ions.⁹¹ This process, however, causes a significant metabolic strain on glial cells leading to adenosine triphosphate depletion. The shifting of water to outside the cells during the correction of hyponatremia results in shrinkage of the glial cells, cellular damage, and disruption of the blood-brain barrier, with the latter allowing inflammatory mediators to enter the central nervous system where they may cause damage to the oligodendrocytes and demyelination. Some central nervous system areas such as the pons appear to be more vulnerable than others. The main risk factors for the development of ODS are serum sodium ≤ 105 mmol/L, hypokalemia, alcoholism, malnutrition, and advanced liver disease. ODS usually follows a biphasic course with an initial symptomatic improvement with the correction of the hyponatremia, which is followed by new and progressive neurologic symptoms developing a few days later. The presentation symptoms range from confusion to progressive quadriplegia associated with dysphagia and dysarthria. ODS is best evaluated by MRI where hypodense nonenhancing lesions can

be seen on T1-weighted images and hyperdense lesions on T2-weighted images.^{92,93}

Ectopic Cushing Syndrome

Cushing syndrome is a constellation of symptoms caused by a sustained exposure to excessive concentrations of circulating glucocorticoids. The most common cause of Cushing syndrome is iatrogenic, due to exogenous administration of glucocorticoids. Endogenous Cushing syndrome may be subdivided into ACTH (or corticotropin) dependent and independent.⁹⁴ ACTH-dependent Cushing syndrome is far more common, accounting for approximately 80% to 85% of the cases and subdivided into Cushing disease, which is caused by pituitary adenomas and accounts for 80% of the ACTH-dependent endocrine causes, ectopic secretion of ACTH by nonpituitary tumors in approximately 20% of cases, and the rare ectopic secretion of corticotropin-releasing hormone (CRH). ACTH-independent Cushing syndrome is almost always caused by adrenal adenomas or carcinomas, with <1% of cases caused by macronodular adrenal hyperplasia, primary pigmented nodular adrenal disease, and McCune-Albright syndrome.

The most common tumors associated with ectopic ACTH production are the SCLC and bronchial carcinoids, with each accounting for approximately 22% of cases in the largest series.⁹⁵⁻⁹⁹ Other reported tumors include GI neuroendocrine tumors, thymic carcinoids, medullary thyroid carcinoma, and pheochromocytoma. Occult tumors have been reported in approximately 13% of cases, ranging from 6.7% to 18.9%. In a retrospective review of 545 patients with SCLC seen at the Toronto General Hospital between 1980 and 1990, there were 23 patients (4.5%) with Cushing syndrome caused by ectopic ACTH production. These patients had low response to chemotherapy, high rate of complications from the chemotherapy, and shorter survival.

The clinical features of Cushing syndrome are variable, with decreased libido, obesity or weight gain, facial plethora or rounding, menstrual changes, hypertension, and hirsutism as the most common manifestations.¹⁰⁰ The characteristic features of increased supraclavicular fat, proximal muscle weakness, and purple striae occur in a minority of patients. When compared to neuroendocrine tumors, SCLC has been shown to be associated with higher frequency of hyperpigmentation and ankle edema, but lower frequency of psychiatric findings.⁹⁸ Due to the high percentage of SCLC and other advanced malignancies, which are usually associated with weight loss, weight gain is less common in paraneoplastic than nonmalignant Cushing syndrome.

Diagnosis

Patient with characteristics of glucocorticoid excess should have a biochemical confirmed diagnosis of hypercortisolemic state prior to proceeding to the differential diagnosis of Cushing syndrome.

The initial screening tests for Cushing syndrome are the 24-hour urinary free cortisol, low-dose dexamethasone suppression, and the late-night salivary cortisol tests.¹⁰¹⁻¹⁰³ The measurement of urinary cortisol allows a direct assessment of the circulating free cortisol. In contrast, plasma cortisol levels measure the total cortisol levels, including both free and bound to cortisol-binding globulin or other serum proteins. When the excess of cortisol saturates the cortisol-binding proteins, it is excreted in the urine in a free or unbound form. Therefore, unlike serum cortisol, urinary levels measure only the biologically active form and are not affected by conditions and drugs that alter cortisol-binding globulin. Urinary free cortisol values higher than four-fold greater than the upper normal limit are rare in disorders other than Cushing syndrome. However, up to three 24 hour collections may be required to exclude intermittent hypercortisolism, and the test is not reliable in patients with creatinine clearance < 30 ml/min.

There are two low-dose dexamethasone suppression tests commonly used, based on the fact that in normal subjects, the

administration of supraphysiologic doses of glucocorticoids suppresses ACTH and cortisol secretion.¹⁰⁴ In patients with endogenous Cushing syndrome, however, the administration of low-dose dexamethasone does not suppress ACTH. The overnight test involves the administration of 1 mg of dexamethasone between 11 p.m. and 12 a.m. with measurement of fasting serum cortisol between 8 and 9 a.m. of the following day. In the 48-hour test, patients receive 0.5 mg of dexamethasone every 6 hours for eight doses, starting at 9 am on day 1, with serum cortisol measured at the start of the test and 6 hours after the last dose. Serum cortisol levels <1.8 mcg/dl have a sensitivity and specificity rates of >95% and 80%, respectively, in excluding Cushing disease. The late-night salivary cortisol test is based on the high correlation between free serum and salivary cortisol levels, independently of salivary flow rates.¹⁰⁵ Furthermore, unlike the serum counterpart, salivary cortisol is not significantly affected by changes in the serum-binding proteins. Due to its easy collection and prolonged stability at room temperature, the late-night salivary cortisol test appears particularly suitable for outpatient screening of Cushing disease. The saliva samples are collected during expected plasma cortisol nadir, between 11 p.m. and 12 a.m., via a cotton swab or by spitting into a tube, which can be sealed and transported at room temperature. Normal reference levels are dependent on the assays used, with cutoff values used in trials ranging from 3.6 to 15.2 mmol/L. Therefore, the values should be validated for each laboratory. The presence of normal salivary cortisol levels from samples obtained in two separate days makes Cushing syndrome very unlikely. The diagnosis of Cushing syndrome is confirmed when two tests are unequivocally abnormal, with additional evaluation required in case of slightly abnormal or discordant test results.

Once the diagnosis of Cushing disease is confirmed, the next step is to establish the cause among the three broad subgroups including the ACTH-independent adrenal etiologies, ACTH-dependent pituitary, and ectopic causes. The workup starts with the measurement of plasma ACTH, with levels <5 pg/mL and >20 pg/mL indicating ACTH independent and dependent, respectively.^{106–108} In cases with intermediate values, the CRH stimulation test may help to clarify the ACTH dependency.¹⁰⁹ In this test, 100 mcg of CRH is administered intravenously with measurements of ACTH before and after the infusion. Increase in ACTH suggests ACTH-dependent causes. ACTH responses, however, are more common in Cushing disease than ectopic ACTH secretion. As both pituitary and ectopic causes belong to the ACTH-dependent category, the next task is to rule out Cushing disease, usually by a brain MRI but occasionally with bilateral inferior petrosal sinus sampling, which is considered the gold standard for the differential diagnosis of ACTH-dependent Cushing syndrome.^{110–113} In this test, ACTH is collected simultaneously from both inferior petrosal sinuses, which drain directly from the pituitary circulation and blood. CRH stimulation is occasionally used to increase the test sensitivity. Petrosal sinus to serum ACTH ratios >2 in basal condition or 3 after CRH stimulation are consistent with Cushing disease. Despite the very high sensitivity and specificity for this test, its use is limited by the cost and expertise necessary to perform the inferior petrosal sinus collection. Patients with ACTH-dependent Cushing syndrome without evidence of a pituitary cause are likely to have ectopic ACTH production from neuroendocrine malignancies. Therefore, in patients without the established cancer diagnosis, the next step would be to search for the occult malignancy with computed tomography scans of the chest and abdomen. The use of further imaging tests will be guided by the findings from the initial workup.

Treatment

Complete remission of Cushing syndrome may be achieved in the majority of patients where the ectopic source of ACTH is identified and the tumor is treated with curative intent. Nevertheless, curative resection is often not possible and patients require therapies

aimed at decreasing the cortisol secretion by the adrenal glands. Although systemic therapy may improve the hypercortisolism, particularly in cases of SCLC, most patients require inhibitors of cortisol secretion. The most commonly used drugs are ketoconazole metyrapone and mitotane.¹¹⁴ Ketoconazole inhibits several steps in adrenal steroidogenesis, has a rapid onset of action, and is effective in approximately 50% of patients with ectopic ACTH secretion.^{115,116} The typical dose ranges from 400 to 1200 mg daily. Metyrapone inhibits 11-beta hydroxylase in the adrenal cortex, blocking the conversion of 11-deoxycortisol to cortisol. Mitotane is adrenolytic and inhibits several steroidogenic steps in the adrenal cortex. An alternative to medical therapy is bilateral adrenalectomy, which induces a rapid resolution of the Cushing symptoms and may be performed through laparoscopic surgery.¹¹⁷

Hypoglycemia

Hypoglycemia is most commonly caused by drugs, usually as a complication from treatment with insulin or oral hypoglycemic agents in patients with diabetes mellitus. Hypoglycemia in patients without diabetes mellitus undergoing treatment is rare and may be caused mainly by drugs, ethanol, liver disease, renal disease, congestive heart failure, endocrinopathies, malnutrition, sepsis, and malignancies.¹¹⁸ Hypoglycemia in patients with cancer may occur due to increased production of insulin by pancreatic insulinomas or ectopic insulin-producing tumors, destruction of the liver and adrenal glands by large metastases, or production of substances interfering with the glucose metabolism such as secretion of insulin-like growth factor (IGF)-I and partially processed precursors of IGF-II, which are collectively known as nonislet cell tumor-induced hypoglycemia (NICTH).¹¹⁹ Although virtually any type of cancer may cause NICTH, the most common etiologies are sarcomas, hepatocellular carcinoma, and GI carcinomas. The proposed mechanism for the development of NICTH is the increased production of pro-IGF-II that cannot be processed by the tumors, leading to release of the stable and metabolic active intermediate pro-IGF-IIe (68–88) (“big IGF-II”) into the circulation. The released big-IGF-II competes with the mature IGF-I and IGF-II for the IGF-binding proteins. Unlike mature IGF-II, big-IGF-II does not allow the formation of a ternary complex with acid-labile subunit, forming mostly a binary complex with IGF-binding protein. There also an increase in free IGF-I and IGF-II due to decreased binding to IGF-binding proteins. Due to the large size, the ternary complexes cannot pass the capillary membrane. However, both the binary complexes and free IGFs cross the capillary membranes, resulting in increased tissue levels of IGF-II and big-IGF-II, which causes hypoglycemia through binding to the insulin receptor B.

Diagnosis

Clinical hypoglycemia is defined as a plasma glucose concentration that is low enough to cause symptoms.¹²⁰ As it is unable to either store or generate glucose, the brain relies on a continuous external supply of glucose to meet its energy requirements. The physiologic adaptation to hypoglycemia includes a decrease in insulin secretion and an increase in glucagon and epinephrine secretion. In prolonged cases, there is also an increase in cortisol and growth hormone secretion. The symptoms from hypoglycemia may result from the insufficient supply of glucose to the brain (neuroglycopenia) or the action of the autonomic system.¹²¹ Neuroglycopenic symptoms include cognitive impairment, behavior changes, seizure, and coma, whereas autonomic symptoms include palpitations, tremors, sweating, and hunger. Patients may also have pallor and diaphoresis as the result of adrenergic vasoconstriction and cholinergic activation of the sweat glands, respectively. As the clinical manifestations are nonspecific, the diagnosis may be confirmed by documenting the Whipple triad, which consists of symptoms and signs of hypoglycemia, low plasma glucose

TABLE 129.6

Differential Diagnosis of Hypoglycemia

Diagnosis	Insulin	C Peptide	Circulating Hypoglycemic Agent
Insulinoma	≥3 μU/mL	≥0.2 mmol/L	Absent
NICTH	<3 μU/mL	<0.2 mmol/L	Absent
Oral hypoglycemic	≥3 μU/mL	≥0.2 mmol/L	Present
Exogenous insulin	≥3 μU/mL	<0.2 mmol/L	Absent

NICTH, nonislet cell tumor–induced hypoglycemia.

concentration, and resolution of the symptoms with the increased glucose concentration.

Once the diagnosis of hypoglycemia is established, the next step is to identify the etiology (Table 129.6). In patients with insulinoma or using oral hypoglycemic agents, both insulin levels and C-peptide are elevated. The detection of oral circulating hypoglycemic agents such as sulfonylureas allows the differentiation from insulinoma. In contrast, exogenous administration of insulin and NICTH are associated with low C-peptide levels. Insulin levels, however, are elevated with exogenous insulin and decreased in NICTH.¹²⁰

Treatment

The treatment of hypoglycemic disorders is subdivided into symptomatic relief and correction of the underlying cause. The acute treatment of hypoglycemia is with fast-acting carbohydrate replacement including oral ingestion of glucose tablets, candy, or fruit juice. Patients with severe hypoglycemia should be treated with intravenous dextrose 50% or 1 mg of glucagon by subcutaneous or intramuscular route.¹²² After the correction of the glucose levels and symptomatic improvement, further workup with imaging studies should be pursued depending on the initial serologic tests. Surgical resection of the primary malignancy, when feasible, usually provides a resolution of the fasting hypoglycemia. Chemotherapy combinations and radiation therapy may be effective in a variety of unresectable solid tumors associated with NICTH and insulinoma. The combination of diazoxide and a thiazide diuretic may improve the hypoglycemia caused by both NICTH and insulinomas.

Tumor-Induced Osteomalacia

Tumor-induced osteomalacia (TIO), also known as oncogenic osteomalacia, is a rare paraneoplastic syndrome characterized by hypophosphatemia, increased urinary phosphate excretion, reduced 1,25 dihydroxy vitamin D, and osteomalacia.¹²³ The decrease of both hypophosphatemia and 1,25 dihydroxy vitamin D appears to be related to fibroblast growth factor 23 (FGF23), which has been identified as the phosphatonin that regulates the phosphate homeostasis.^{124,125} When FGF23 binds its FGF receptor, it leads to a reduction of the sodium-dependent phosphate co-transporter 2a in the basal surface of the proximal renal tubule, which ultimately causes an increased urinary excretion of phosphorus and hypophosphatemia.¹²⁶ FGF23 also causes downregulation of α-hydroxylase and upregulation of 24-hydroxylase, leading to a decrease in 1,25 dihydroxy vitamin D.¹²⁷ TIO is caused by mesenchymal tumors that are characteristically slow-growing and polymorphous, and have been subdivided into four groups based on the histology features: phosphaturic mesenchymal tumor mixed

connective tissue type (PMTMCT), osteoblastoma-like tumors, ossifying fibrous-like tumors, and nonossifying fibrous-like tumors.¹²⁸ PMTMCT is the most common subtype, accounting for approximately 75% of the mesenchymal tumors associated with TIO. Although usually benign, there have been reports of malignant and metastatic PMTMCT.^{129,130}

Patient usually present with bone pain, muscle weakness, and fractures for several years prior to the diagnosis.¹²⁶ Although hypophosphatemia is the hallmark of TIO, it is often not identified as serum phosphorus measurements are not included in the standard comprehensive metabolic panel.¹³¹ In patients with consistent symptoms and hypophosphatemia, the next step is to confirm the presence of renal phosphate wasting, which can be accomplished by measurements of the percent tubular reabsorption of phosphate or the maximum tubular reabsorption of phosphorus corrected for the glomerular filtration rate.¹²⁶ Patients with hypophosphatemia due to increased urinary excretion of phosphorus should undergo additional tests to establish the diagnosis of TIO. Calcium and PTH are usually normal, and 1,25 dihydroxy vitamin D may be low or inappropriately normal. Elevated plasma levels of FGF23 help to confirm the diagnosis.

The treatment of choice for TIO is resection of the tumor with a wide margin, which is curative in the majority of patients. However, as the tumors are often very small and may be located anywhere in the bones of soft tissue, their location may be challenging. Both FDG-PET and ¹¹¹Indium octreotide scintigraphy combined with single photon emission computed tomography scan have been recommended as functional imaging studies for the location of the tumors.¹³² For patients whose tumors cannot be localized or treated surgically, the mainstay of therapy is phosphorus supplementation, which should be administered in multiple doses per day due to its rapid absorption and clearance.

PARANEOPLASTIC HEMATOLOGIC SYNDROMES

Anemia

Anemia, defined as hemoglobin (Hgb) <12 g/dL and 14 g/dL in women and men, respectively, is a common finding in patients with cancer, with a wide range of prevalence depending on the cancer type, geographic area, and definition of anemia, which has been arbitrarily subdivided in epidemiologic studies according to the Hgb and hematocrit cutoffs into liberal (Hgb >11 g/dl or hematocrit <33%), moderate (Hgb between 9 g/dL and 11 g/dl or HCG between 27% and 33%), and stringent (Hgb <9 g/dl or hematocrit <27%).¹³³ The etiology of anemia in patients with cancer is usually multifactorial, including a combination of blood loss, hemolysis, and decreased red cell production. Usual factors leading to anemia in patients with cancer include bleeding; treatment-related myelosuppression; hemolysis; impaired renal function; deficiency of iron, folate, or vitamin B₁₂; and the anemia of chronic disease (ACD), also known as anemia of inflammation.¹³⁴ The main etiologies for ACD include infections, autoimmune disorders, chronic kidney disease, and malignancies.¹³⁵ ACD is caused by an increased uptake and retention of iron within the reticuloendothelial cells, with a diversion of iron from the circulation to the storage sites, leading to a state of functional iron deficiency. The production of cytokines such as interleukin (IL) 6, IL-1, tumor necrosis factor-α, and interferon-γ, among others, causes an increase in the production of hepcidin by the liver, in an effect mediated by JAK and STAT3, which decreases the duodenal absorption of iron and binds to ferroportin causing its degradation.¹³⁶ Ferroportin is an important transmembrane exporter of iron and its degradation decreases the release of iron into the plasma, resulting in entrapment of iron inside the macrophages and hepatocytes. ACD is usually normochromic and normocytic, with decreased serum

iron and transferrin saturation. Ferritin, a marker of iron storage, is usually normal or increased in ACD, in contrast to low values in iron-deficiency anemia. When caused by a malignancy, ACD fits the criteria for paraneoplastic syndrome. Although the treatment of choice for paraneoplastic ACD is directed at the underlying malignancy, this approach is not always possible or successful.¹³⁷ Therefore, management of the anemia becomes important in a large fraction of patients. Red blood cell transfusion is indicated in patients with Hgb <8 g/dL, particularly in the presence of coronary artery disease. Use of erythropoiesis-stimulating agents (ESA), including erythropoietin and darbepoetin, are associated with decreased in the transfusion rates and increase in Hgb levels during or shortly after myelotoxic chemotherapy.^{138,139} However, there are no other established benefits from this class of drugs, and their indications have become more restricted after reports of increased risk of venous thromboembolism, stroke, tumor progression, and mortality. In a large meta-analysis including 13,933 patients from 53 randomized clinical trials, ESAs were associated with increased mortality by 17% during the treatment period and decrease overall survival.¹⁴⁰ Similar findings were observed in a more recent meta-analysis including 91 trials with 20,102 participants, where ESAs decreased the risk of blood transfusions but caused increased mortality during the study period, hypertension, thromboembolic complications, and thrombocytopenia with hemorrhage.¹⁴¹ ESAs are recommended only for the treatment of patients undergoing palliative chemotherapy, whereas they are currently not indicated in patients that are either not receiving chemotherapy or treated with curative intent. New therapies under development for ACD include hepcidin antagonists,^{142,143} monoclonal antibodies against IL-6 receptor,¹⁴⁴ and STAT-3 inhibitors.¹⁴⁵

Pure red cell aplasia (PRCA) is a syndrome characterized by severe normocytic anemia, reticulopenia, and absence of erythroblasts in an otherwise normal bone marrow.¹⁴⁶ PRCA may occur as a congenital or acquired syndrome, with the latter presenting as either an acute self-limited disease occurring mainly in children or as a chronic form most commonly seen in adults. There are several causes for PRCA including parvovirus B19 infection, collagen vascular diseases, drugs including erythropoietin, hematologic malignancies, and solid tumors. The diagnosis is made in cases with isolated anemia, characterized by normal white cell and platelet counts as well as normal marrow myeloid cells and megakaryocytes, with an almost complete absence of erythroblasts. Patients with thymoma-associated PRCA may benefit from tumor resection. Several immunosuppressive drugs have been successfully used, including corticosteroids, cyclophosphamide, and cyclosporin A. Other options are splenectomy and plasmapheresis. For patients with resistant disease, both rituximab and alemtuzumab have been shown to be effective.¹⁴⁷⁻¹⁴⁹

Polycythemia

Polycythemia is defined by hematocrit >48% and >52% in women and men, respectively. It may be classified as relative, when caused by decreased plasma volume, and absolute, with the latter subdivided into primary and secondary. Primary polycythemias are caused by mutations within the erythroid precursors, with the most common etiology being the polycythemia vera, which is characterized by JAK2V617F mutations in 96% of the cases and JAK2 exon 12 mutations in approximately 3% of the remaining cases.¹⁵⁰ Secondary polycythemias are usually caused by increases in circulating erythropoietin. There are several causes of secondary polycythemias, including hypoxia, endocrine disorders, renal cysts, use of androgens or erythropoietin, and tumors. The most common tumors associated with paraneoplastic erythrocytosis are hepatocellular carcinoma, renal cell carcinoma, cerebellar hemangioblastoma, pheochromocytomas, and uterine leiomyomas.^{151,152} Paraneoplastic erythrocytosis is present in approximately 2% to 10% of patients with hepatocellular carcinoma and 1% to

5% with renal cell carcinoma. The treatment for paraneoplastic erythrocytosis is surgical removal of the tumor. There is usually no need for specific therapy of the erythrocytosis, with phlebotomy indicated only in symptomatic cases.

Leukocytosis

Paraneoplastic leukocytosis is frequently observed in patients with cancer, has been reported in a variety of malignancies, is most likely caused by tumor production of granulocyte colony-stimulation factor,¹⁵³⁻¹⁵⁵ and is associated with worse prognosis compared to patients without leukocytosis, particularly in gynecologic and lung cancers.¹⁵⁶⁻¹⁵⁸ In a review of 252 patients with nonhematologic malignancies who underwent a complete workup to exclude other possible causes, 77 (30%) had leukocytosis at the time of diagnosis.¹⁵⁹ Absolute monocytosis and eosinophilia were observed in 25% and 4.8% of the patients, respectively. Among patients with non-SCLC, paraneoplastic leukocytosis has been more commonly associated with large cell histology.^{155,160} Both tumor-associated tissue eosinophilia and tumor-associated blood eosinophilia have been reported in a variety of cancers including lung, cervical, breast, colon, liver, and pancreatic sarcomas, and hematologic tumors.^{161,162} The development of eosinophils is regulated by three cytokines encoded by closely linked genes on chromosome 5q31: IL-3, IL-5, and granulocyte macrophage colony-stimulating factor. IL-5, also known as eosinophil-differentiating factor, is the most specific cytokine for eosinophil lineage and responsible for both selective differentiation of eosinophils and their release from the bone marrow.¹⁶² Several studies have reported the association between intratumoral production of IL-5 and tumor-associated blood eosinophilia.¹⁶³⁻¹⁶⁵

Thrombocytosis is defined as platelet count >450/ μ L and is usually subdivided into familial, primary, and reactive.¹⁶⁶ In a review of 732 patients with platelet counts \geq 500/ μ L, 643 (87.7%) had secondary thrombocytosis, with 85 (11.6%) of those caused by malignancies, including lymphoma, sarcomas, and GI, lung, breast, and ovarian cancers.¹⁶⁷ Paraneoplastic thrombocytosis is usually associated with poor prognosis.¹⁶⁸ The decreased survival in patients with paraneoplastic thrombocytosis may be related to the tumor-induced platelet aggregation, which correlates with the metastatic potential of cancer cells.¹⁶⁹ Platelet coating protects tumor cells from the physical stressors within the blood vessels and allows evasion from the immune system. Platelets are also a major source of proangiogenic factors such as vascular endothelial growth factor and lymphangiogenesis through vascular endothelial growth factor-C present in the α -granules.

PARANEOPLASTIC DERMATOLOGIC MANIFESTATIONS

The dermatologic manifestations of malignancy are extensive and include cutaneous metastases and changes in the skin due to anatomic obstruction, particularly due to superior vena cava syndrome and rheumatologic changes related to a paraneoplastic endocrine disorder. However, occasionally patients will present with a dermatologic symptom or physical finding that is related to a previously undetected malignancy or during the course of their malignancy. Historically, the criteria for the paraneoplastic dermatologic syndrome (PDS) are (1) concurrent onset and parallel course of dermatologic condition and malignancy, (2) characteristic type of associated malignancy, (3) statistical association of the dermatosis and the malignancy, and (4) a genetic link between the dermatosis and malignancy.¹⁷⁰ These criteria serve as a "gold standard," but the term PDS is often applied to conditions with a strong association with a specific malignancy. Importantly, the syndrome and cutaneous cells are not malignant, and the pathogenesis of the dermatologic condition is the result of imbalance in cytokines,

growth factors, or an aberrant immune response to the underlying malignancy.¹⁷¹ PDSs are the initial presentation in approximately 1% of internal malignancies and may be initially detected by a dermatologist.¹⁷¹ This section will focus on the classical PDSs rather than PDSs that have been reported in case reports or where there is a doubt about association between the dermatologic disorder and the malignancy. For simplicity, the disorders are organized by the predominant skin manifestation, although some disorders may have multiple skin manifestations. Many of cutaneous lesions are associated with malignant and nonmalignant conditions. Consultation with a dermatologist is frequently required to assist in the diagnosis and management of PDS. Appropriate treatment of the underlying malignancy is the primary therapy for most PDS, as is supportive care to alleviate the symptoms.

Hyperpigmentation

Polyneuropathy, organomegaly, endocrinopathy, and monoclonal gammopathy and skin changes (POEMS syndrome) is associated with diffuse and homogenous hyperpigmentation. Hyperpigmentation is usually diffuse and homogenous, and generally limited to the extremities or trunk or acral areas. Other cutaneous manifestations of POEMS syndrome include hypertrichosis, digital clubbing, skin thickening or scleroderma-like skin changes, and white spots or streaking of the fingernails (leukonychia).¹⁷¹

The initial presentation of malignant acanthosis nigricans is hyperpigmentation of the skinfolds and the posterior neck. The cutaneous lesions are symmetric, hyperpigmented plaques with variable amounts of epidermal hypertrophy that creates a velvety texture.^{171,172} As the malignancy progresses, the lesions may involve the oral mucosa and areola, and palmoplantar hyperkeratosis and cutaneous papillomatosis have been observed.^{172,173} Generalized pruritus has also been described.¹⁷⁴ The most common malignancy associated with this disorder is gastric adenocarcinoma, accounting for approximately 70% of the cases, with the majority of the remaining cases associated with other GI adenocarcinomas.¹⁷² Malignant acanthosis nigricans may precede the diagnosis of gastric cancer by several years and is believed to be due to the secretion of growth factors by the tumor.¹⁷⁵ Tripe refers to the edible lining of the bovine foregut, and “Tripe palms” describes a condition characterized by rough, velvety appearance of the palms with exaggerated dermatoglyphics (the lines forming the skin pattern of the palms of the hands or the soles of the feet).^{171,172} This condition is considered a variant of malignant acanthosis nigricans rather than a separate entity and is most frequently associated with gastric and lung carcinoma.¹⁷²

Leser-Trelat is the sudden increase in the size and number of seborrheic keratosis that is associated with an underlying malignancy. However, there is debate about the validity of this disorder and the association of the disorder with underlying malignancy due to its rarity, the prevalence of seborrheic keratosis and malignancy in the elderly patient population and the inexact definition of “sudden.”¹⁷²

Annular Lesions

Erythema gyratum repens is the most common type of erythematous lesion associated with cancer and is characterized by erythematous, scaly, concentric rings that progress at a rate of 1 cm a day and that occur on the trunk or proximal aspect of the extremities.¹⁷¹ The lesions are pruritic and are frequently described as having a “wood grain” appearance.¹⁷⁶ The face, hands, and feet are generally spared. An underlying malignancy is present in approximately 80% of cases. The most common malignancies are lung cancer, esophagus, and breast.^{171,177} The hypothesis is that this condition is caused by deposition of IgG and complement in the skin.^{178,179} This disorder may precede the diagnosis, occur at the same time of the diagnosis, or after the diagnosis of malignancy.

The manifestations usually improve or resolve with a successful treatment of the malignancy.¹⁷⁶

Migratory necrolytic erythema is associated with glucagon-secreting alpha-islet cell tumors and glucagonoma syndrome, which includes diabetes mellitus or glucose intolerance, weight loss, diarrhea, anemia, venous thromboembolism, and neuropsychiatric disorders.¹⁷⁷ Migratory necrolytic erythema is characterized by erythematous annular or arciform lesions that will coalesce into plaques. The edges of the lesions are characterized by blisters, erosions, and crusts. Other mucocutaneous symptoms include cheilosis, atrophic glossitis, oral mucosal inflammation, and alopecia.¹⁷⁶ The lesions are most common in the groin, perineum, buttocks, intertriginous areas, and perioral area.^{171,177} The histopathologic features are nonspecific and include epidermal necrosis, subcorneal pustules, confluent parakeratosis, epidermal hyperplasia, and marked papillary dermal hyperplasia in a psoriasiform pattern.¹⁷⁶

Erythematous and Hyperkeratotic Lesions

Bazex syndrome, also known as acrokeratosis paraneoplastica of Bazex, is a psoriasiform condition that presents with symmetric erythematous and scaling lesions on the hands, feet, elbows, and knees. This condition is considered pathognomonic of an internal malignancy.¹⁸⁰ Patients develop palmoplantar keratoderma with a violaceous color and nail dystrophy, and subsequently develop psoriasiform lesions on the ears, nose, scalp, and trunk.¹⁸¹ The syndrome may precede the diagnosis of a malignancy by a year and is most closely associated with squamous cell carcinoma of aerodigestive track including larynx, oropharynx, esophagus, and lung.¹⁸² The pathogenesis of this disorder remains unclear with proposed mechanisms including immunologic factors, exogenous production of growth factors for keratinocytes, and vitamin A deficiency. It is important to note there is the unrelated Bazex-Dupre-Christol syndrome, which consists of hypotrichosis, follicular, atrophoderma, and basal cell carcinomas arising at an early age, that is not a paraneoplastic syndrome.^{177,183}

Paraneoplastic Pemphigus

The association between pemphigus and malignancy has been controversial and debated, leading to the establishment of diagnostic criteria for paraneoplastic pemphigus (Table 129.7).¹⁸⁴ In order to be considered paraneoplastic pemphigus, all three of the major or two of the major and two of the minor criteria need to be present. The antibodies in a paraneoplastic pemphigus are directed against desmoglein 1 and 3, and against plaklin proteins that form

TABLE 129.7

Diagnostic Criteria for Paraneoplastic Pemphigus

Major	Minor
1. Polymorphous mucocutaneous eruption	1. Positive cytoplasmic staining of rat bladder epithelium by indirect immunofluorescence
2. Concurrent internal neoplasia	2. Intercellular and basement membrane zone immunoreactants on direct immunofluorescence or perilesional tissue
3. Characteristic serum immunoprecipitation findings	3. Acantholysis in biopsy specimen from at least one anatomic site of involvement

the intracellular plaques of desmosome and hemidesmosomes, mediating the attachment of cytoskeletal intermediate filaments to transmembrane adhesion molecules.^{185,186} These proteins are found in numerous tissues including the epithelium of the respiratory, intestinal, and urinary organs. Histologic evaluation of the skin biopsy reveals interface dermatitis, vacuolization of the basement membrane, necrotic keratinocytes, suprabasal clefting, and acantholysis.¹⁸⁷ Direct immunofluorescence testing reveals IgG and complement 3 deposits in the intercellular epidermal spaces and at the dermal-epidermal junction; however, paraneoplastic pemphigus without evidence Ig deposits is observed.¹⁸⁸

Paraneoplastic pemphigus is characterized by polymorphous skin lesions that progress to blistering eruptions on the trunk and extremities.¹⁷⁶ Clinically, painful stomatitis is the most characteristic finding, and frequently involves the entire mouth and lips.¹⁷⁷ The stomatitis is often intractable and may involve the esophagus and/or anogenital region. Some patients will have pulmonary involvement and can develop bronchiolitis obliterans-organizing pneumonia; pulmonary involvement portends a poor prognosis.¹⁸⁵ In the majority of the cases, the underlying malignancy is diagnosed before the onset of pemphigus, and the most commonly associated malignancies are non-Hodgkin lymphoma, chronic lymphoid leukemia, Castleman disease, and thymoma.^{176,187}

Hypertrichosis Lanuginosa

This disorder is characterized by the development of long, fine nonpigmented hairs (“lanugo hairs”) initially on the face and then on the trunk, axillae, and the extremities.^{177,187} The palms of the hands, the soles of the feet, and the genital area are characteristically spared. If the tongue is involved, patients develop painful glossitis, hypertrophy of the papillae of the tongue, and disturbance in taste and/or smell.¹⁷⁷ Among men, the most commonly associated malignancies are lung cancer and then colorectal cancer, whereas colorectal cancer, lung cancer, and breast cancer predominate in women.¹⁸⁷ Trichomegaly of the eyebrows and eyelashes and severe hypertrichosis of the face have been reported with agents that target the epidermal growth factor receptor pathway.^{189,190}

Ichthyosis Acquisita

Ichthyosis is characterized by the development of dead skin cells that accumulate and present as dry scales on the skin's surface. The scales may be delicate and localized to the trunk and legs or diffuse and thickened, and there is generally sparing of the flexures, palms, and soles.¹⁷² The scales are often described as “rhomboid” or “fish-like.” Histologically, the defining features are hyperkeratosis and occasional parakeratosis, and decreased granular layer.¹⁷² This condition can be observed in patients with nonmalignant condition such as hypothyroidism and sarcoidosis, and drugs such as butyrophenones used to treat schizophrenia. Nevertheless, it may also be associated with underlying malignancies, particularly Hodgkin lymphoma, which is the most common cause accounting for approximately 70% of the patients with paraneoplastic-acquired ichthyosis.¹⁷⁶ Other associated malignancies include T-cell lymphomas, multiple myeloma, and lung, breast, and cervical cancer. Unlike other PDSs, ichthyotic changes often occur several weeks or months after the detection of the tumor, and the cutaneous symptoms rarely are the presenting sign of an underlying malignancy.¹⁷² Supportive care with moisturizers and keratolytics, and infection prophylaxis in selected cases are valuable.

Sweet Syndrome

Sweet syndrome, also referred to as acute febrile neutrophilic dermatosis, is characterized by the sudden onset of erythematous papules and nodules that coalesce to form irregular, sharply plaques,

and associated elevated neutrophil count and fever. These lesions are painful and are predominantly observed in the face, neck, and trunk. The vesiculated appearance is sometimes seen and related to edema. The histologic appearance is of neutrophilic inflammatory infiltrate that is distributed throughout the upper dermis.¹⁷² Sweet syndrome may be associated with nonmalignant and malignant conditions, with the latter accounting for approximately 20% of the cases.¹⁹¹ In >60% of the cases of malignancy-associated Sweet syndrome, the diagnosis of Sweet syndrome is either preceded or is made at the time of the diagnosis of malignancy.¹⁹¹ Among patients with Sweet syndrome, 85% will have an underlying hematologic malignancy, with acute myelogenous leukemia being the most common followed by lymphomas, myelodysplastic syndrome, and chronic myelogenous leukemia. Solid tumors including breast cancer, genitourinary tumors, and GI tumors have also been reported in association with Sweet syndrome.^{176,191} Corticosteroid therapy alleviates the symptoms of Sweet syndrome regardless of the response of the underlying malignancy to therapy.¹⁹¹

PARANEOPLASTIC RHEUMATOLOGIC MANIFESTATIONS

Hypertrophic Osteoarthropathy

Hypertrophic osteoarthropathy (HOA) is a syndrome characterized by abnormal proliferation of the skin and osseous tissues at the distal extremities. Patients usually have digital clubbing, periostosis of the tubular bones, and synovial effusions.¹⁹² HOA is divided into primary and secondary forms, with the latter most commonly associated with intrathoracic malignancies. Patients may be asymptomatic or complain of bone pain, occasionally deep and excruciating, more prominent in the lower extremities. Periostosis is the radiographic hallmark of HOA and may be detected by radiograph or bone scan. Successful treatment of the underlying malignancy has been associated with significant improvement of HOA.¹⁹³ Patients with refractory tumors may benefit from bisphosphonates^{194,195} or radiotherapy.¹⁹⁶

Vasculitis

Cancers may be found in approximately 2% to 5% of patients with vasculitis.¹⁹⁷ The most common types of paraneoplastic vasculitis are the leukocytoclastic vasculitis and Henoch-Schonlein purpura. Leukocytoclastic vasculitis, the most common paraneoplastic vasculitis accounting for 50% to 60% of cases, is associated most commonly with hematologic malignancies. Henoch-Schonlein purpura accounts for 15% of paraneoplastic vasculitis and occurs more commonly in carcinomas of the lung, urogenital, and GI tracts.

Idiopathic Inflammatory Myopathies

Idiopathic inflammatory myopathies are a group of acquired connective tissue diseases that affect mainly the skeletal muscle and may be subdivided according to the characteristic features into DM, polymyositis (PM), and inclusion-body myositis.¹⁹⁸ Cancers may be discovered before, at the same time, or after the diagnosis of the inflammatory myopathy, with the highest risk within the first year of diagnosis and extending up to 5 years in DM.¹⁹⁹ The interval between the appearance of PM and the diagnosis of cancer may be shorter. In a review of case series of inflammatory myopathies, there were 2,439 patients with DM and 947 patients with PM, of which 574 (24%) and 97 (10.2%) had associated malignancy, respectively.²⁰⁰ The most common malignancies associated with DM were carcinomas of the nasopharynx (21%), breast (15%), lung (15%), ovary (9%), and colon (5%), with no predominant

tumor among patients with PM. In a combined analysis of six population-based cohorts, the frequency of malignancies in DM and PM ranged from 9% to 42% and 5% to 18%, respectively. The type of malignancy associated with the inflammatory myopathies depends on the geographic area. In a Scandinavian study, ovarian, lung, and GI cancers were the most commonly associated with DM, while non-Hodgkin lymphoma and bladder cancer were the most common cancers associated with PM.²⁰¹ Overall, 70% of associated malignancies for DM and PM combined were adenocarcinomas. In contrast, a study performed in Taiwan showed nasopharyngeal carcinoma as the most common malignancy associated with DM, followed by lung cancer and breast cancer,

whereas there were no dominant tumors in PM.²⁰² The muscle weakness in patients with cancer-associated myopathy is usually rapidly progressive and severe, leading to a higher frequency of immobility compared to nonparaneoplastic myopathies.¹⁹⁹ The risk for underlying malignancy is increased in older patients, males, and those with more severe disease including more severe or distal muscle weakness, dysphagia, respiratory muscle involvement, and disease refractory to treatment. Screening for malignancies in patients with inflammatory myopathies should be based according to the age, gender, and geographic area, although patients with higher risk may require a more comprehensive screening including tumor markers and imaging studies.

130 Autologous Stem Cell Transplantation

Hillard M. Lazarus, Mehdi Hamadani, and Parameswaran N. Hari

INTRODUCTION

Many decades ago, researchers determined that bone marrow cells transplanted from one animal to another could restore blood production.¹ As these preclinical investigations were taken into the clinical arena, hematopoietic cell transplantation (HCT) evolved as a potentially curative modality for selected malignant and certain nonmalignant diseases. Many malignancies show a steep dose-response to cytotoxic therapy (i.e., small increments in dose of drug or radiation markedly increase the number of cancer cells killed). Cure or effective disease control depends on delivering intensive doses of chemotherapy and/or radiation therapy. This intensity often exceeds the tolerance of bone marrow, necessitating restoration of hematopoietic marrow function in such patients to prevent irreversible and fatal marrow aplasia. This is accomplished by restoring blood production using either autologous (“self”) cells (i.e., autologous HCT) or cells collected from another individual (i.e., allogeneic) donor cells (i.e., allogeneic HCT). Autologous HCTs depend entirely upon high-dose therapy to eradicate malignancy, in contrast to allogeneic HCT in which the immunocompetent infused cells exert an “allogeneic effect” against the tumor (i.e., graft-versus-tumor effect).

The phases of autologous HCT include collection of autologous hematopoietic progenitor cells (HPC) and their cryopreservation; administration of high-dose therapy (also called conditioning or preparative regimen); thawing and intravenous administration of the autologous cells; and then vigorous supportive care including antibiotics, blood transfusions, and other measures such as electrolyte replacement while awaiting recovery of hematopoiesis.

Careful patient selection is crucial to successful outcomes after autologous HCT. Patients with poor performance status (Karnofsky performance score ≤ 60) or significant comorbidities (e.g., poor cardiac reserve [left ventricular ejection fraction $< 40\%$], compromised pulmonary function [FEV1 and/or adjusted diffusion capacity $< 40\%$ of predicted normal], advanced renal insufficiency) are not suitable candidates for high-dose therapies. Similarly heavily pretreated and chemotherapy-refractory patients are unlikely to benefit from this procedure, underscoring the need for timely transplant evaluation for suitable patients.

AUTOLOGOUS HEMATOPOIETIC PROGENITOR CELL COLLECTION

Autologous HPCs can be collected from the patient’s bone marrow or blood. The collected bone marrow or blood HPCs are suspended in a balanced salt solution containing a cryoprotectant (often dimethyl sulfoxide [DMSO]) and are cryopreserved in liquid nitrogen. Bone marrow collection involves aspiration of approximately 1,000 ml of marrow (10 to 15 ml/kg patient

weight) from the posterior superior iliac crests with the patient in the prone position under spinal or general anesthesia. However, in the last decade, nearly all autografts utilize HPCs collected from blood. HPCs are normally found in low levels in the blood but they can be released or “mobilized” from marrow in large numbers and collected via apheresis instruments. This procedure usually takes 2 to 3 hours and processes three to four blood volumes. The minimum HPC dose to successfully perform an autologous HCT is generally considered to be 2 million CD34+ cells/kg recipient body weight. A dose of ≥ 4 to 6 million CD34+ cells/kg is considered optimal. This target is based on data showing slower hematopoietic recovery with doses < 2 million CD34+ cells/kg and faster platelet recovery with doses ≥ 5 million CD34+ cells/kg.²

HPCs are generally mobilized by serial administration of hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) either alone (“cytokine only” strategy) or in combination with chemotherapy agents such as cyclophosphamide (“chemomobilization” strategy). Another agent, plerixafor, works by disrupting the chemokine receptor type 4 and stromal-derived factor tether between the HPCs and the marrow stromal cells.^{3,4} Most patients have an adequate HPCs collected after one or two apheresis procedures. Prior chemotherapy or radiation therapy can impair mobilization, which may affect mobilization or collection strategy.

AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION TOXICITIES AND SUPPORTIVE CARE

Specific regimens used for high-dose therapy vary depending on the indication for HCT and are discussed in coming sections in detail. HPCs infused after high-dose therapy require time to regenerate hematopoiesis; during this time, the patient requires intensive supportive care to prevent complications arising from prolonged cytopenias and organ damage induced by conditioning regimen. Breakdown of the normal mucosal barriers in the gastrointestinal tract leading to oral mucositis, pain, diarrhea, and increased susceptibility to infectious complications is common. Hematopoietic recovery takes approximately 2 to 3 weeks, and recombinant hematopoietic growth factor support early after HPC infusion can reduce the duration of severe neutropenia by 2 to 4 days. Red blood cell and platelet transfusions are essential to prevent or treat complications and symptoms of profound cytopenias. All blood products must be irradiated to prevent inadvertent engraftment of “contaminating” allogeneic lymphocytes from the transfused unit that may cause lethal transfusion-associated graft-versus-host disease. Major infections encountered in autologous HCT are with gram-negative and gram-positive bacteria; *Clostridia difficile* toxin-associated diarrhea, herpes simplex, and fungi, particularly

Figure 130.1 Causes of death after autologous hematopoietic cell transplantation (US data).

Candida spp. and *Aspergillus spp.* The use of prophylactic antibacterial, antiviral, and antifungal agents, recombinant hematopoietic growth factors, and blood HPCs have decreased the incidence of severe infections.^{5,6} Other common and reversible toxicities include nausea, vomiting, alopecia, poor appetite, rash, edema, and flushing. In patients with myeloma, dose-limiting gastrointestinal toxicities of melphalan (MEL) and a higher risk of posttransplant engraftment syndrome, especially in those receiving novel agent induction, is described.^{7,8}

Visceral organs may also be damaged by high-dose therapy. Rare but serious problems include hepatic veno-occlusive disease, also known as sinusoidal obstruction syndrome, idiopathic pneumonia syndrome, and diffuse alveolar hemorrhage.^{9,10} Hepatic veno-occlusive disease usually presents within the first 2 to 3 weeks of the HCT and manifests as tender hepatomegaly, jaundice, and fluid retention. Lung injury can present early or later after HCT and may take months to resolve. Compared to allogeneic HCT, treatment-related mortality is low, typically <3% during the first 100 days after transplant; relapse remains the most common cause of death (Fig. 130.1).

INDICATIONS FOR AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION

The predominant indication for autologous HCT is the treatment of cancer, although it is sometimes performed for nonmalignant diseases (Fig. 130.2). This chapter focuses on the oncologic indications of autologous HCT.

AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION FOR PLASMA CELL MYELOMA

In the United States, myeloma and other plasma cell disorders are the most common indication for autologous HCT (Figs. 130.3 and 130.4). Two large randomized trials^{11,12} and several nonrandomized comparisons¹³⁻¹⁵ have demonstrated the efficacy of autologous HCT in prolonging event-free survival (EFS) and overall survival (OS) (in some studies) compared with nontransplant therapies. The majority of autologous HCTs for myeloma are performed as “early or upfront autologous HCT” in newly diagnosed patients after induction therapy. As myeloma is incurable, even those that do not receive an upfront autograft may undergo transplant at relapse (“delayed autologous HCT”). Similarly, those who have benefited from an upfront autograft may receive a second autologous HCT after a subsequent relapse.

Early Experience with Autologous Hematopoietic Cell Transplantation for Myeloma

Randomized trials have compared autologous HCT to conventional chemotherapy in newly diagnosed patients with myeloma. The Intergroupe Francophone Myeloma (IFM)¹¹ and Medical Research Council¹² led clinical trials that demonstrated that patients randomized to receive autologous HCT had significantly higher complete remission (CR), EFS, and OS rates. Other randomized studies (Table 130.1), however, have not uniformly demonstrated a survival benefit,¹⁶⁻²⁰ although most show an improvement in EFS with the notable exceptions of Blade et al.¹⁶ and the US Intergroup study.¹⁹ Blade et al.¹⁶ randomized patients responding to induction chemotherapy to autologous HCT versus further chemotherapy. The inability to prove an

Figure 130.2 Indications for autologous transplantation in the United States. MM, multiple myeloma; NHL, non-Hodgkin lymphoma; HL, Hodgkin lymphoma; AL, amyloidosis; AML, acute myeloid leukemia; ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia.

Figure 130.3 Survival after autologous hematopoietic cell transplantation: Myeloma.

EFS benefit for autologous HCT in this setting may reflect the relatively lower incremental benefit of high-dose therapy in good responders to induction therapy. In the US Intergroup study, 52% of subjects in the chemotherapy arm received a delayed autologous HCT at the time of relapse, which may have masked differences between the two arms.¹⁹ A prior randomized French study Myeloma Auto Greffe (MAG 95) reported comparable OS between early versus delayed autologous HCT.¹⁷ In general, these studies indicate that autologous HCT improves CR rates and EFS in comparison to conventional chemotherapy. Survival benefit was not seen in studies that permitted or planned for delayed autologous HCT, as well as in studies conducted in later time periods when novel antimyeloma agents were available as an option after relapse.

Figure 130.4 Survival after autologous hematopoietic cell transplantation: Common B cell non-Hodgkin lymphoma subtypes.

Conditioning Regimens for Autologous Hematopoietic Cell Transplantation in Myeloma

Several cytotoxic agent combinations and total-body irradiation (TBI) have been evaluated as conditioning regimens for autologous HCT in myeloma. The only randomized phase 3 trial compared intravenous MEL 200 mg/m² (MEL200) to a combination of MEL 140 mg/m² (MEL140) and 8 Gy TBI.²¹ The MEL140-TBI regimen caused significantly more mucositis, delayed hematologic recovery, higher transfusion requirements, and longer hospitalization. OS and progression-free survival (PFS) were similar. Current Center for International Blood and Mar-

TABLE 130.1

Selected Randomized Trials of Conventional Chemotherapy Compared to Single Autologous Hematopoietic Cell Transplantation as Upfront Therapy in Multiple Myeloma

Study (Year)	Transplant Arm ^a	No. and Age (y)	CR % Chemotherapy versus Auto-HCT	Comments
Attal et al. ¹¹ (1996)	MEL 140 + TBI 8 Gy	200 ≤65	5 vs. 22 ^b	OS and EFS superior for HCT.
Child et al. ¹² (2003)	MEL 200	401 ≤64	8 vs. 44 ^b	OS and EFS superior for HCT.
Blade et al. ¹⁶ PETHEMA (2005)	MEL 200 or MEL 140 + 12 Gy TBI	164 ≤65	11 vs. 30 ^b	Only responders randomized. No OS and EFS benefit of HCT.
Palumbo et al. ¹⁴ (2005)	MEL 100 × 2 auto-HCT	194 50–70	6 vs. 25 ^b	EFS and OS superior for autologous HCT.
Barlogie et al. ¹⁹ (2006)	MEL 140 + TBI 12 Gy	899 <70	15 vs. 17	No OS and EFS benefit for HCT vs. conventional chemotherapy; 55% of patients relapsed after conventional chemotherapy received delayed HCT.
Ferland et al. ¹⁷ (1998)	CCNU + etoposide + cyclophosphamide + MEL + TBI	185 <56	20 vs. 57	EFS superior for autologous HCT. No OS difference as patients in conventional chemotherapy randomized to HCT at relapse. QOL superior for HCT.
Ferland et al. ¹⁸ (2005)	MEL 200 or MEL 140 + busulfan	55–65	20 vs. 36	EFS and OS similar to conventional chemotherapy. QOL superior for early autologous HCT.

CR, complete response; HCT, hematopoietic cell transplantation; MEL, melphalan; TBI, total-body irradiation; OS, overall survival; EFS, event-free survival; CCNU, lomustine; QOL, quality of life.

^a Chemotherapy doses in mg/m². Definitions of response were based on nonuniform criteria.

^b Statistically significant difference ($p < 0.05$).

row Transplant Research (CIBMTR) data indicate that most centers (>80%) use MEL200 as conditioning therapy for myeloma. Some groups have attempted to reduce the toxicity of autologous HCT by reducing the dose of MEL to 100 mg/m² (MEL100). In a randomized study of two planned, sequential autologous HCT procedures performed within 3 to 6 months of each other (e.g., tandem MEL200 versus tandem MEL100²²), hospitalization rates, transplant-related mortality (TRM), and OS were similar in both groups, but MEL200 had a superior EFS. MEL200 is considered the standard conditioning before autologous HCT in myeloma.

Older Patients and Those with Comorbidities

The presence of comorbidities and advanced age should be considered when planning autologous HCT for myeloma. While most randomized studies were limited to patients ≤65 years, a survival benefit was shown for MEL100 followed by autologous HCT compared to nontransplant therapy in the 50- to 70-year age group.²³ The IFM 99-06 trial arrived at the opposite conclusion in patients aged 65 to 75 years, showing no superiority for MEL100 over MEL-prednisone (MP); in fact, both approaches were inferior when compared with the combination of MP and thalidomide.²⁴ For vulnerable elderly patients or those with organ dysfunction, reduced intensity MEL increases treatment tolerability and optimizes efficacy. MEL140 is the preferred conditioning regimen dose in the elderly population in the United States.

Advanced renal impairment is frequent (20% to 30%) in patients with myeloma, with up to 8% requiring long-term renal replacement therapy.^{25,26} Autologous HCT is feasible, even in those with advanced renal impairment (defined as a creatinine >3 mg/dl or receiving hemodialysis). MEL200 is associated with severe toxicity, and a dose of 140 mg/m² is preferred.^{27,28} Residual DMSO in the thawed infusion can cause toxicity including histamine release, abdominal pain, hypotension, and worsening of renal function. Washing the HPC product to remove DMSO prior to infusion is especially important in the context of renal failure.²⁹

Tandem Autologous Hematopoietic Cell Transplantation

Barlogie and coworkers pioneered the tandem autologous transplant approach in their Total Therapy program.^{15,30} The IFM94 was the first randomized trial³¹ comparing single to tandem autologous HCT in patients with previously untreated myeloma. The projected 7-year EFS and OS benefits were significantly better for the tandem autologous HCT arm (10% versus 20% for EFS, and 21% versus 42% for OS, single versus double, respectively). In an unplanned subgroup analysis, there was no benefit for the second autologous HCT for patients who were in a very good partial remission (VGPR) status or better after the first autograft. Another randomized study (Bologna 96) confirmed the observation that the second HCT does not benefit patients in VGPR after the first transplant.³² More importantly, this study did not show an OS benefit for the tandem HCT. Most recently, in a combined Dutch-Belgian Hemato-Oncology Cooperative Group (HOVON) and the German Multicenter Myeloma Group (GMMG) study (HOVON65/GMMG-HD4), patients receiving tandem autologous HCT in the German (GMMG) component of the study were shown to have superior OS (70% versus 55% at 5 years) over otherwise similarly treated patients receiving a single autologous HCT.³³ Randomized studies show tandem autologous HCT produce superior CR rates and EFS overall but not OS (with the exception of IFM94) compared to single autologous HCT. Moreover, benefits of the second autograft appear to apply to patients who are not in a VGPR after the first autologous HCT.

Delaying Autologous Hematopoietic Cell Transplantation until Relapse

Given the incurable nature of myeloma despite novel agents, the timing of autologous HCT (early versus delayed) warrants reappraisal. Randomized studies (from the prenovel drug era) suggest that survival is similar whether autologous HCT is performed early or in the delayed setting after relapse.^{17,19} Early autologous HCT was associated with a longer treatment-free interval and improved quality of life.¹⁷ Boccadaro et al. randomized patients after lenalidomide/dexamethasone induction to tandem autologous HCT or MP/lenalidomide combination. Although CR rates and OS were similar, early HCT provided superior PFS (41 months versus 18 months).³⁴ Data from this trial caution against abandoning the upfront autologous HCT for myeloma. The depth of response and its duration are increasingly recognized as key prognostic factors in myeloma and the achievement of a minimal residual disease (MRD)-negative CR predicts longer PFS and OS.³⁵ Currently, the highest rates of MRD negativity are seen in early autologous HCT recipients.^{36,37} Moreover, the feasibility of autologous HCT at relapse could be negatively impacted by a decline in patient performance status or the development of comorbid illnesses. The results of ongoing studies of early versus delayed transplantation (e.g., NCT01208662 and NCT01208766) will eventually assist decision making in this setting.

Role of Autologous Transplantation in High-Risk Disease

Myeloma is a biologically diverse disease with clonal heterogeneity and genomic instability.^{38,39} The presence of t(4;14), del(17p), or high serum β₂-microglobulin concentration predict inferior OS.⁴⁰ Autologous HCT has provided suboptimal results in high-risk myeloma,⁴¹ questioning its benefit for these patients. Addition of bortezomib in induction, consolidation, and maintenance phases of therapy programs incorporating tandem HCT support the role of autologous HCT in high-risk myeloma.^{33,42,43}

Unique Considerations for Hematopoietic Progenitor Cell Collection in Myeloma

In patients with myeloma who are autologous HCT candidates, it is important to avoid factors that impair HPC mobilization (e.g., MEL-based regimens, prolonged use of lenalidomide, and radiation therapy, to significant volume of bone marrow).^{44,45} While plerixafor has improved mobilization yields in difficult to mobilize patients with myeloma,⁴⁶ intermediate-dose cyclophosphamide-based mobilization may be an equally effective and less expensive alternative.⁴⁷ Given the increasing use of autologous HCT in the salvage setting after relapse from a prior autograft, it is prudent to collect ≥6 to 10 million CD34+ cells/kg at initial mobilization attempt.

Maintenance Therapy for Myeloma after Hematopoietic Cell Transplantation

Various consolidation and maintenance strategies have been evaluated to delay the inevitable post-HCT progression/relapse in myeloma. In general, novel agents have shown superior results as maintenance therapy. Thalidomide maintenance after tandem autologous HCT has been studied in several randomized studies.⁴⁸⁻⁵¹ Lenalidomide maintenance was studied in the Cancer and Leukemia Group B 100104 and IFM 05-02 trials.^{52,53} Both studies demonstrated a superior PFS and EFS with lenalidomide maintenance, while Cancer and Leukemia Group B 100104 also demonstrated an OS benefit. A two- to three-fold increase in second primary malignancies was seen in both studies associated with the lenalidomide maintenance. Pretransplant bortezomib induction coupled with

post-HCT bortezomib maintenance in the HOVON-65/GMMG-HD4 trial was shown to have superior PFS and OS.³³ Based on these data, the risks/benefits and health-care costs of novel agent maintenance should be discussed with autologous HCT recipients.

Salvage Second or Third Transplants at Relapse

Salvage second autologous HCT is an option at relapse following a prior transplant. This is especially true for patients with available cryopreserved HPCs stored from their initial collection. A CIBMTR analysis showed that second salvage autologous HCT, while feasible, mostly benefits individuals relapsing ≥ 36 months from first autologous HCT.⁵⁴ Following an initial tandem autograft, a (third) salvage autologous HCT at relapse while providing acceptable CR rates (29%) resulted in a disappointing 19% OS at 2 years.⁵⁵

Future Directions in Autologous Hematopoietic Cell Transplantation for Myeloma

Recent advances in supportive care have made autologous HCT relatively safe and cost-effective. Current (2009–2011) CIBMTR data suggest a day 100 mortality of 1% in upfront autologous HCT for myeloma. Median 100-day cost for autologous HCT in the United States is approximately \$100,000 US dollars, and largely represents the cost of hospitalization.⁵⁶ Many institutions routinely perform autologous HCT entirely in the outpatient setting with excellent results.^{57,58} Robust quality systems, electronic chemotherapy ordering, and a support team of physicians, nurses, and pharmacists, etc., are essential to setting up an outpatient program.

Current directions being explored in HCT for myeloma include newer conditioning regimens and novel maintenance or consolidation strategies that aim to induce deeper responses. Based on the dose-response relationship of MEL in myeloma, escalated doses have been attempted with a maximum tolerated dose of 280 mg/m² (limited by cardiac and gastrointestinal toxicity).⁵⁹ Other approaches such as the combinations of busulfan and MEL^{60,61}; busulfan and cyclophosphamide⁶²; idarubicin and MEL^{63–65}; thiotepa, busulfan, and cyclophosphamide⁶⁴; bendamustine and MEL⁶⁶; as well as bortezomib and MEL⁶⁷ are without mature results.⁶⁸ Approaches at delivering higher doses of radiation therapy to the marrow prior to autologous HCT without increasing overall toxicity are also being explored with helical tomotherapy or bone-seeking radioisotopes.^{69,70} Incorporation of modern imaging (positron emission tomography [PET] scans) and MRD detection in response assessment may enhance our ability to predict post-HCT outcomes and prognosis.⁷¹

AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION FOR LYMPHOID MALIGNANCIES

Autologous HCT is standard for relapsed, aggressive non-Hodgkin lymphoma (NHL) and classical Hodgkin lymphoma (HL), and is curative in ~40% to 45% of patients.^{72–75} The role of HCT in indolent NHL and T-cell NHL is more controversial. The role of autologous HCT in lymphoma has recently been reappraised as conventional therapies have dramatically improved with the advent of monoclonal antibodies^{76,77} and radioimmunotherapy (RIT).⁷⁸

Conventional and Novel Conditioning Regimens

Commonly used conditioning regimens for lymphomas include cyclophosphamide, etoposide, and carmustine; carmustine, etoposide, cytarabine, and melphalan (BEAM); carmustine, etoposide,

cytarabine, and cyclophosphamide; and TBI-containing regimens.⁷⁹ Limited retrospective data suggest lower TRM and superior outcomes following TBI-free conditioning.⁸⁰ Several uncontrolled studies have reported efficacy and feasibility of combining rituximab with high-dose therapy,^{81,82} but convincing randomized evidence for this approach is lacking.

RIT with monoclonal antibody-radiionuclide conjugates is effective in B-cell NHL. Incorporation of RIT into preautologous HCT conditioning has been studied, either alone or in combination with high-dose therapy.^{83–86} Two randomized trials have examined the latter approach. In the Blood and Marrow Transplant Clinical Trials Network (BMT CTN) 0401 trial, iodine-131 tositumomab was prospectively compared against rituximab, both in combination with BEAM conditioning for relapsed diffuse large B-cell lymphoma (DLBCL).⁸⁷ Another study compared BEAM plus yttrium-90 ibritumomab tiuxetan to BEAM alone in aggressive NHL.⁸⁸ Neither study favored a RIT-based conditioning regimen.

Disease-Specific Indications for Hematopoietic Cell Transplantation in Lymphoid Malignancies

The indications of autologous HCT in lymphoid neoplasia are dependent on patient age, comorbidities, chemosensitivity, histologic subtype, and remission status at the time of HCT.

Hematopoietic Cell Transplantation for Follicular Lymphoma

Hematopoietic Cell Transplantation for Follicular Lymphoma: First Remission. The role of autologous HCT as consolidation for advanced-stage follicular lymphoma (FL) in first remission was examined in four randomized trials, including three trials conducted in the prerituximab era^{89–91} and one in rituximab era⁹² (Table 130.2). Autologous HCT provided a PFS benefit in three out of these four trials. OS, however, was not improved as this therapy was associated with a higher risk of second malignancies,⁹¹ including myelodysplastic syndrome/acute myeloid leukemia (AML).^{89,92} With the advent of RIT consolidation⁷⁸ and rituximab maintenance⁹³ or retreatment,⁹⁴ the routine use of upfront HCT consolidation in FL is not recommended.

Hematopoietic Cell Transplantation for Follicular Lymphoma: Relapsed Disease. The role of autologous HCT in relapsed FL is controversial. In the prerituximab era, the CUP study compared salvage chemotherapy alone versus chemotherapy followed by either unpurged or purged HCT for relapsed FL; overall, the investigators reported a PFS and OS benefit with autologous HCT (see Table 130.2).⁹⁵ More than a decade later, the superiority of autologous HCT over modern salvage chemoimmunotherapies is debated.⁹⁶ Registry data from the European Blood and Marrow Transplant Group (EBMT)⁹⁷ and CIBMTR show no plateau in relapse rates post-HCT in FL⁹⁸ and a 5% to 15% risk of second malignancies^{97,99} (see Table 130.2). Autologous HCT for relapsed FL should be considered in the context of alternative treatment choices, patient age, remission status, comorbidities, and a small but definite risk of secondary cancers. Autologous HCT is best reserved for chemotherapy-sensitive, relapsed FL in those subjects who are not candidates for curative intent allogeneic transplantation.

Hematopoietic Cell Transplantation for Transformed Follicular Lymphoma. An EBMT report of 50 patients receiving autologous HCT for chemotherapy-sensitive transformed FL described 5-year PFS and OS of 30% and 51%, respectively.¹⁰⁰ A prospective Norwegian study also reported 5-year PFS and OS of 32% and 47%, respectively.¹⁰¹ In the rituximab era, a Canadian cohort analysis suggested an OS benefit for patients undergoing HCT compared with those receiving chemoimmunotherapy alone.^{102,103}

^a Statistically significant value.

Autologous HCT is appropriate for transformed FL patients with nonbulky (nodal areas ≤ 3 cm), chemotherapy-sensitive disease.

Hematopoietic Cell Transplantation for Mantle Cell Lymphoma

The European MCL Network trial randomized patients with mantle cell lymphoma (MCL) after first-line chemotherapy to either upfront autologous HCT consolidation or interferon maintenance (see Table 130.2)¹⁰⁴ and demonstrated a superior PFS but no OS benefit for HCT. Similar randomized trials in the rituximab-era after first-line chemoimmunotherapy are not available. Rituximab-era nonrandomized trials examining upfront HCT in patients with MCL have reported encouraging 5-year PFS and OS of $\sim 60\%$ and 70% , respectively^{105–110} (see Table 130.2). Despite the lack of randomized data, autologous HCT for MCL in first remission can be considered *standard* practice as retrospective data suggest that HCT after relapse may not be as effective.^{111,112} A CIBMTR analysis reported a 5-year OS of 61% for upfront HCT versus 44% for HCT performed in chemosensitive relapse.¹¹³ In patients with chemotherapy-sensitive, relapsed MCL, who are not candidates for allogeneic transplant, autologous HCT is reasonable; however, it is not recommended for therapy-refractory MCL.

Hematopoietic Cell Transplantation for Waldenström Macroglobulinemia

Prospective data are not available to recommend the use of autologous HCT for Waldenström macroglobulinemia (WM) in first remission. On the other hand, retrospective studies and expert opinion¹¹⁴ support the role of HCT in patients with relapsed/refractory WM.^{115–118} In an EBMT study of 158 patients with mostly chemotherapy-sensitive WM,¹¹⁹ 5-year PFS and OS were 40% and 68%, respectively. Autologous HCT should be considered in patients with relapsed, chemotherapy-sensitive WM who already have received two or three different therapies.

Hematopoietic Cell Transplantation for Marginal Zone and Small Lymphocytic Lymphoma

Limited retrospective studies for HCT in marginal zone lymphoma^{120,121} indicate PFS rates similar to FL and frequent relapses after transplant. In patients with relapsed but chemotherapy-sensitive marginal zone lymphoma, autologous HCT could be considered. Data for autologous HCT for small lymphocytic lymphoma are

scant. Extrapolating the data showing lack of a survival benefit for autologous HCT^{122–124} in chronic lymphocytic leukemia, HCT is not recommended in patients with small lymphocytic lymphoma.

Hematopoietic Cell Transplantation for Diffuse Large B-Cell Lymphoma

Hematopoietic Cell Transplantation for Diffuse Large B-Cell Lymphoma: In First Remission for High-Risk Disease? Studies using autologous HCT as consolidation after first-line therapies in aggressive (mostly DLBCL) NHL in the pre-rituximab era have reported contradictory findings. While the majority reported no benefit^{125–131} or (in one case) inferior outcomes,¹³² a handful of trials reported PFS and/or OS benefit with HCT either in general^{133–135} or in patients with high or intermediate-high International Prognostic Index (IPI).¹³³ Studies from the rituximab-era restricted to higher-risk patients have also reported contradictory outcomes: two reports showed no benefit,^{136,137} whereas one intergroup US study suggested improved PFS and OS with autologous HCT consolidation high-risk IPI DLBCL.¹³⁸ Considering these discordant data and the high cure rates of DLBCL,¹³⁹ use of upfront autologous HCT for this histology is not generally recommended.

Hematopoietic Cell Transplantation for Diffuse Large B-Cell Lymphoma: In Relapsed Disease. The role of autologous HCT in relapsed DLBCL is well-defined. The PARMA trial (see Table 130.2)⁷² established that salvage chemotherapy plus HCT consolidation provided an OS benefit in subjects with relapsed, chemotherapy-sensitive disease. Several registry^{140–143} and prospective studies in the rituximab era⁷⁴ (see Table 130.2) have reproduced these results. Autologous HCT is thus the *standard-of-care* for relapsed/chemotherapy sensitive DLBCL.

Hematopoietic Cell Transplantation for Burkitt Lymphoma

Historically, brief induction therapies followed by upfront autologous HCT provided durable disease control in Burkitt lymphoma (5-year OS and PFS of 81% and 73%, respectively).¹⁴⁴ However, the contemporary intense chemoimmunotherapy regimens are curative for majority of patients,^{145,146} and autologous HCT in first CR is not necessary. Fortunately, the grim prognosis for the patient with relapsed/refractory Burkitt lymphoma is uncommon. Retrospective studies^{147,148}

describe 3- to 5-year OS and PFS rates of ~30% and 25%, respectively, after autologous HCT in chemotherapy-sensitive relapses.

Hematopoietic Cell Transplantation for Hodgkin Lymphoma

Hematopoietic Cell Transplantation for Relapsed Hodgkin Lymphoma. Autologous HCT is potentially curative for relapsed HL. The British National Lymphoma Investigation study compared autologous HCT against salvage chemotherapy alone in relapsed HL¹⁴⁹ and reported a PFS benefit in the high-dose therapy arm (53% versus 10%; $p = 0.02$). In another randomized trial, two cycles of chemotherapy were followed by two additional chemotherapy cycles versus autologous HCT.⁷⁵ In chemotherapy-sensitive patients, freedom from treatment failure was significantly better with high-dose therapy. An OS benefit was not shown in either of these studies, most likely because those subjects assigned to the chemotherapy arm could still be salvaged by later HCT. Autologous HCT is the *standard-of-care* in chemotherapy-sensitive first relapse of HL.

Hematopoietic Cell Transplantation for Primary Refractory Hodgkin Lymphoma. Primary refractory (<CR after first-line therapy) HL has a poor prognosis. Lazarus and coworkers¹⁵⁰ showed that autologous HCT can cure about a third of patients with primary refractory HL (see Table 130.2). Chemotherapy-refractory disease at autologous HCT is a poor prognostic factor (5-year PFS of <20%).¹⁵¹ While HCT is curative for HL, the 10-year late relapse rate (after the first 2 years) was 17% accounting for 25% of late mortality in a registry analysis.¹⁵² Autologous HCT is *standard-of-care* for relapsed HL, including those with primary refractory disease.

T-Cell Lymphomas

Relapsed T-cell NHLs have poor prognosis with chemotherapy alone,¹⁵³ and autologous HCT has been explored as initial therapy or at the time of tumor progression. Phase 2 studies (with heterogeneous subtypes) examining upfront HCT in T-cell NHL (see Table 130.2)¹⁵⁴⁻¹⁵⁸ suggest a 3- to 4-year PFS of ~30% to 50%. Although randomized data are not available, considering the poor outcomes with conventional therapies, it is appropriate to consider upfront autologous HCT consolidation in T-cell NHL. Because of its excellent prognosis with standard chemotherapies, autologous HCT in first CR is not recommended for anaplastic lymphoma kinase-positive anaplastic large cell lymphoma.¹⁵⁹ Relatively encouraging outcomes for a highly select group of patients with relapsed T-cell NHL with sensitive disease also have been shown with 3- to 5-year PFS and OS rates of approximately 15% to 30% and 30% to 45%, respectively.¹⁶⁰⁻¹⁶² Autologous HCT is also reasonable in those patients with relapsed/chemotherapy-sensitive T-cell NHL not deemed candidates for allogeneic HCT.

Unique Considerations for Hematopoietic Cell Transplantation Mobilization in Lymphomas

While many patients with lymphoma can successfully mobilize HPCs with “cytokine only” strategies, mobilization failure remains a concern in patients with prior radiotherapy, heavily pretreated disease; exposure to hyper-CVAD (fractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone), fludarabine-containing regimens, or RIT; advanced age; and bone marrow involvement.^{114,163-166} In such cases, consideration should be given to chemotherapy- or plerixafor-based mobilization strategies.¹⁶⁷

Tumor Cell Contamination in Autograft

Relapse after autologous HCT derives usually from proliferation of a chemotherapy-resistant clone of lymphoma cells surviving the high-dose therapy, or rarely from re-infusion of an autograft

contaminated by tumor cells. Studies of syngeneic HCT suggest that a “tumor-free” graft may prevent/delay relapse.¹⁶⁸ Ex vivo purging (by monoclonal antibodies, CD34+ cell selection, etc.)^{169,170} or in vivo purging (e.g., rituximab therapy during mobilization)^{171,172} of autografts appear to reduce or eliminate the risk of tumor-cell re-infusion at HCT. Reduction of tumor cell re-infusion, however, may not lead to improved outcomes. The CUP trial in relapsed FL⁹⁵ reported no significant difference in the outcomes of immune-magnetically purged versus unpurged autografts. Similarly, pretransplant in vivo rituximab purging has not been shown to improve HCT outcomes.¹⁷³ The lack of clear benefit in randomized data and a possible increase in infectious complications with ex vivo purging^{174,175} preclude routine use of this approach.

Posttransplant Maintenance Therapies for Lymphoid Malignancies

Disease relapse following HCT in lymphoid malignancies remains a challenge. Rituximab maintenance, effective in B-cell NHL,⁹³ has been studied in the post-HCT setting.^{174,176} In a randomized EBMT study, rituximab maintenance postautologous HCT in relapsed FL¹⁷³ was well tolerated and provided a superior 10-year PFS (54% versus 37%; $p = 0.01$) but no OS benefit. In the Collaborative Trial in Relapsed Aggressive Lymphoma (CORAL) study, post-HCT rituximab maintenance for DLBCL provided no PFS or OS benefit, but was associated with increased risk of adverse events.¹⁷⁷ Routine use of rituximab maintenance after HCT in B-cell NHL is not recommended.

Functional Imaging and Autologous Hematopoietic Cell Transplantation Outcomes

PET scanning is a powerful tool to predict autologous HCT outcomes in lymphoid malignancies. A PET-negative state before HCT either alone¹⁷⁸ or in combination age-adjusted IPI¹⁷⁹ predicts improved PFS and OS. Similarly, conversion from a PET-positive to a PET-negative state, either following pre-HCT salvage therapies¹⁸⁰ or after high-dose therapy,¹⁸¹ is predictive of improved HCT outcomes.

AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION FOR RARER PLASMA CELL DYSCRASIAS

Light chain amyloidosis (AL), light chain deposition disease, and POEMS syndrome are rare clonal plasma cell disorders. High-dose therapy with MEL has proven effective in many of these disorders, although randomized trials are lacking.^{182,183} Special challenges for HCT in these disorders include higher rates of TRM, engraftment syndrome, and severe fluid retention.^{184,185} In AL, cardiac involvement, pleural effusions, and significant fluid retention during G-CSF-based mobilization have emerged as predictors of higher TRM.¹⁸⁴ Careful patient selection, dose-adapted MEL use, and center experience are critical. A randomized multicenter trial failed to show benefit for HCT over conventional chemotherapy in AL,^{184,186} whereas experience from specialized centers seems to show a significant benefit, by inducing CRs after HCT that lead to organ function recovery from AL over time.¹⁸³

AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION FOR ACUTE MYELOID LEUKEMIA AND ACUTE LYMPHOBLASTIC LEUKEMIA

While the majority of younger patients with AML attain CR after induction therapy, postremission treatment is necessary to prevent relapse. The preferred postremission strategy in first CR is largely

dependent on patients' cytogenetic risk category. Allogeneic HCT does not add benefit for patients with AML with favorable-risk cytogenetics.¹⁸⁷ This group of patients, as well as those patients with AML in remission who have intermediate-risk characteristics, may benefit from autologous HCT if a suitable donor is not available. On the other hand, patients with unfavorable-risk AML should be discouraged from this approach. There is no evidence that an autologous HCT can replace consolidation or maintenance therapy or allogeneic HCT in any risk group of patients with acute lymphoblastic leukemia.¹⁸⁸ Limited data suggest that tyrosine kinase inhibitors plus sequential chemotherapy can lead to significant cytoreduction in Philadelphia chromosome–positive patients with acute lymphoblastic leukemia, allowing collection of HPCs not contaminated by residual lymphoblasts and thus reducing the likelihood of relapse after autologous HCT for patients without available donors.¹⁸⁹

AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION FOR GERM CELL TUMORS

Autologous HCT is potentially curative for relapsed germ cell tumors (GCT).¹⁹⁰ In the first-line setting for high-risk GCT, phase 3 studies have not demonstrated superiority of HCT over conventional chemotherapy.^{191,192} For GCTs refractory to initial therapy, however, HCT may be superior as salvage treatment.¹⁹³ Several

prognostic models have been developed for post-HCT outcomes, and these generally incorporate adverse risk factors such as platinum refractoriness, poor-risk score GCT, and third-line or later use of HCT.¹⁹⁰ Thus, for higher-risk GCT relapsing after or not responding to initial chemotherapy, HCT referral should be considered early.

LATE COMPLICATIONS AFTER AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION

Autologous recipients of HCT have a reduced life expectancy compared to the general population and are at increased risk for late complications such as opportunistic infections, iron overload, endocrine abnormalities, osteoporosis, and second malignancies.^{10,194–197} Recipients should be monitored for these potential maladies at least yearly, including administering all age-appropriate cancer screening and anti-infective vaccinations. Other recommended screenings in long-term survivors include yearly eye examinations for cataracts (especially after TBI), yearly assessment of cardiovascular risk factors, education/counseling on a “heart”-healthy lifestyle, blood pressure monitoring and aggressive management of hypertension to prevent chronic kidney disease, screening for osteopenia/osteoporosis, thyroid function evaluation, sexual/gonadal function and fertility assessment (when appropriate), and periodic psychological evaluations.¹⁹⁷

131 Allogeneic Stem Cell Transplantation

Stanley R. Riddell and Edus H. Warren

INTRODUCTION

Allogeneic hematopoietic cell transplantation (HCT) is successful in curing many patients with advanced hematologic malignancies. The premise underlying allogeneic HCT was the observation that the antitumor effects of irradiation and chemotherapy were limited by dose-related hematopoietic toxicity that led to prolonged or permanent pancytopenia and predisposed the patient to fatal infection. Studies in mice demonstrated that the transfer of splenocytes or bone marrow (BM) could rescue animals from the lethal effects of irradiation, which provided the impetus to develop HCT as a means of dose-escalating irradiation and chemotherapy to treat cancer.^{1,2} The initial efforts at applying allogeneic HCT to patients with leukemia began in the late 1950s, but were impeded by an incomplete understanding of histocompatibility antigens that imposed an immunologic barrier to durable engraftment of allogeneic donor stem cells or resulted in life-threatening graft-versus-host disease (GVHD), and by the challenges of supporting critically ill immunocompromised patients until donor hematopoietic cell engraftment ensued.^{3,4} These barriers were systematically overcome in the 1970s, notably through the work of E. Donnall Thomas, who was awarded the Nobel Prize in 1990 for his contributions to HCT.⁵ Advances in supportive care, conditioning regimens, and alternative donor sources have continued to improve outcome and expand the utility of allogeneic HCT. Currently, >8,000 procedures are performed in the United States each year.

CONDITIONING REGIMENS

Conditioning regimens for allogeneic HCT are designed to serve two purposes: to suppress the patient's immune system sufficiently to prevent rejection of donor hematopoietic stem cells and to eradicate malignant cells. The initial approach to allogeneic HCT for hematologic malignancies administered myeloablative doses of systemic chemotherapy alone or combined with total-body irradiation (TBI), and resulted in considerable toxicity to nonhematopoietic organs, which limited its use to younger patients without serious comorbidities. Even with intensive myeloablative conditioning (MAC) regimens, it soon became apparent that the elimination of leukemic cells after allogeneic HCT was partly dependent on a graft-versus-leukemia (GVL) effect mediated by donor immune cells.^{6,7} This understanding fostered the development of reduced intensity conditioning (RIC) regimens that provide sufficient immunosuppression to achieve donor cell engraftment and rely to a greater extent on GVL effects for tumor eradication. The use of RIC has made this procedure feasible in older patients and patients with comorbidities that tolerate MAC poorly. RIC is typically most effective in patients with malignancies that are highly responsive to the GVL effect and/or are in remission at the time of HCT.

Myeloablative Conditioning

The most extensively used MAC regimens were developed in parallel in the 1980s, and include cyclophosphamide (Cy) administered intravenously in a dose of 60 mg/kg on two consecutive days combined with TBI typically in a fractionated schedule to a total dose of 12 Gy (2 Gy \times 6), which is superior to a single dose of 10 Gy;⁸⁻¹⁰ or the combination of oral busulfan (Bu) in a dose of 16 mg/kg over 4 days and Cy in a dose of 120 mg/kg (Bu/Cy).^{11,12} A higher dose of fractionated TBI (15.75 Gy) reduced relapse in patients with myeloid leukemia, but was associated with higher nonrelapse mortality and did not provide a survival benefit.¹³

The major acute toxicity of MAC is irreversible damage to recipient hematopoiesis; however, these regimens often cause nausea, vomiting, fever, mild skin erythema, and oral mucositis that typically develop 5 to 7 days after transplant and require narcotic analgesia. Patient-controlled analgesia provides superior patient satisfaction for mucositis pain and results in lower cumulative doses of narcotics. TBI is associated with transient parotiditis during conditioning and a high risk of cataracts later in life. Regimens that include high-dose Cy can result in acute hemorrhagic cystitis, which can usually be prevented by the sulfhydryl compound mercaptoethanesulfonate (mesna). Rarely, Cy causes an acute hemorrhagic cardiomyopathy. As discussed later in this chapter, MAC can result in serious organ toxicity including diffuse alveolar hemorrhage, idiopathic interstitial pneumonia, and hepatic sinusoidal obstruction syndrome.

The choice of MAC regimen is in part based on the patient's underlying malignancy and stage of disease. The Bu/Cy regimen was associated with a high incidence of sinusoidal obstruction syndrome in early studies; however, this complication has been reduced by the use of ursodiol prophylaxis.^{14,15} A recent retrospective analysis of data from the Center for International Blood and Marrow Transplantation Research for patients with acute myeloid leukemia (AML) in first complete response (CR) that received HCT from human leukocyte antigen (HLA)-matched related or unrelated donors after conditioning with Cy/TBI, or with oral or intravenous Bu combined with Cy, demonstrate superior outcome with the Bu/Cy regimens.¹⁶ A prospective nonrandomized cohort study in patients with AML, chronic myelogenous leukemia (CML), and myelodysplastic syndrome (MDS) similarly concluded that intravenous Bu/Cy was superior to Cy/TBI.¹⁷ Based on data from older studies, Cy/TBI has been the generally preferred regimen for acute lymphoblastic leukemia (ALL).^{18,19} Other myeloablative regimens such as fludarabine/Bu have been developed and gained popularity at some centers, although a survival benefit has not been established.^{20,21}

Reduced Intensity Conditioning

The recognition of the immune-mediated GVL effect, both from retrospective analysis of rates of relapse in recipients of allogeneic versus syngeneic HCT and from studies in which donor

Figure 131.1 Relative intensity of conditioning regimens used for allogeneic hematopoietic cell transplantation. leukocytes were infused to treat relapse after HCT,^{6,7,22,23} suggested that RIC might be successfully employed in patients who were less able to tolerate MAC. The objective of RIC is to provide sufficient immunosuppression of the host to achieve engraftment of donor hematopoietic cells and avoid both the severe pancytopenia and nonhematopoietic toxicity of MAC regimens. Many RIC regimens have been developed that provide for donor engraftment but vary in hematopoietic and nonhematopoietic toxicity, and the choice of regimen is in part based on balancing the risks of transplant-related mortality and relapse (Fig. 131.1). A recent large retrospective analysis of >1,000 patients with hematologic malignancies that received a nonmyeloablative RIC regimen consisting of 2 Gy TBI ± fludarabine demonstrated 5-year overall survival rates from 25% to 60% depending on disease risk, comorbidities, and GVHD.²⁴ At 5 years, the nonrelapse mortality rate was 24% and the relapse mortality rate was 34.5%. Analysis of registry data shows that RIC regimens of higher dose intensity provide for similar overall and disease-free survival as MAC regimens in patients with AML and MDS, whereas the lowest intensity regimens were inferior, due to higher relapse rates.²⁵ A phase 3 randomized trial conducted by the Blood and Marrow Transplant Clinical Trials Network is in progress to compare outcomes of MAC and RIC in patients 18 to 65 years of age. The benefit of RIC is the ability to offer potentially curative allogeneic HCT to older patients. However, novel approaches to reducing relapse and preventing or diminishing the morbidity and mortality of GVHD in these patients are needed to improve outcome.

Radiolabeled Monoclonal Antibodies

Targeting radiation to leukemic cells with radiolabeled monoclonal antibodies that bind to cell surface molecules could increase the radiation dose at sites of tumor and spare normal organs such as the liver and lung. An iodine-131-labeled anti-CD45 antibody has been used for this purpose in conjunction with conventional MAC in younger patients, or with RIC in patients over the age of 55. These studies have demonstrated that it is feasible to deliver >25 Gy to the BM while limiting liver and lung exposure, and achieve long-term survival in patients with high-risk AML.^{26,27} A similar approach using an yttrium-90-labeled anti-CD20 monoclonal antibody combined with RIC for patients with refractory CD20+ B-cell malignancies has shown promise in early phase studies.^{28,29} The use of pretargeting and new radioisotopes with more favorable tissue penetration might improve therapeutic efficacy and reduce toxicity.³⁰

STEM CELL SOURCES

Donor/recipient genetic nonidentity at loci within the major histocompatibility complex (MHC) on chromosome 6p that encode specific HLA molecules is the most important risk factor for severe GVHD.⁴ Thus, hematopoietic cell grafts from donors who are identical with the recipient at the critical HLA loci are the preferred source of hematopoietic stem cells for allogeneic HCT. Although BM continues to be the most common graft source obtained from donors <20 years old in the United States, hematopoietic cells collected from the peripheral blood (PB) by apheresis after stimulation with filgrastim (granulocyte colony-stimulating factor) to mobilize CD34+ stem cells account for a majority of grafts harvested from donors >20 years of age (Fig. 131.2). For the large number of patients for whom a suitably HLA-matched donor cannot be identified, grafts derived from umbilical cord blood (UCB) or harvested from BM or PB of HLA-mismatched or HLA-haploidentical donors can provide a source of hematopoietic stem cells for allogeneic HCT.

Human Leukocyte Antigen–Matched Donors

The preferred donor for any patient who requires allogeneic HCT continues to be a full sibling who is genetically identical with the recipient for specific exons within the *HLA-A*, *-B*, *-C*, and *-DRB1* genes. BM or PB grafts from HLA-identical siblings have been associated with the lowest risks for severe acute and chronic GVHD, and with superior posttransplant hematologic and immunologic reconstitution. Filgrastim-stimulated PB grafts in general contain a several-fold higher number of CD34+ hematopoietic progenitor cells than BM, but also contain a ≥10-fold higher number of T-lymphocytes, which are the central mediators of GVHD. Several large, randomized trials of transplantation with BM or PB grafts from HLA-identical sibling donors have shown that PB provides superior hematopoietic engraftment, but at the cost of a higher risk for both acute and chronic GVHD.^{31–35} Some of these studies have shown a decreased rate of relapse and superior survival in recipients of PB as compared with BM grafts, primarily in the subset of patients with high-risk malignancies.^{31,34} Donors of BM and PB generally report similar levels of discomfort associated with the stem cell donation, but PB donors report faster resolution of symptoms.³⁶ Limited data also suggest that the economic cost of BM donation exceeds that of PB donation.³⁷ Despite the higher risk of GVHD associated with PB grafts, the superior engraftment and lower relapse risk and the strong preference of donors

Figure 131.2 Allogeneic stem cell source by recipient age (2001 to 2010). Redrawn with permission from Pasquini MC, Zang Z. Current use and outcome of hematopoietic stem cell transplantation: Center for International Blood and Marrow Transplant Research Summary Slides, 2012.

for PB as opposed to BM donation have made PB grafts the preferred and, in fact, the default source of stem cells for patients with HLA-identical sibling donors. BM remains the preferred stem cell source for patients with nonmalignant disorders such as aplastic anemia, in whom there is no need for a GVL effect.

Unrelated Donors

Most patients who are candidates for allogeneic HCT do not have an HLA-identical sibling donor available; for many such patients, suitably HLA-matched volunteer unrelated donors can be identified in worldwide registries that now include more than 22 million individuals (www.bmdw.org; accessed January 5, 2014). The annual number of transplants performed in the United States with grafts from volunteer unrelated donors has exceeded the number performed with grafts from HLA-identical sibling donors since 2005 (Fig. 131.3). Improved understanding of the role of the MHC in allogeneic HCT has driven steady evolution of the laboratory procedures used to establish that patients and prospective donors are suitably “matched.” The National Marrow Donor Program currently recommends matching recipients and prospective donors at the DNA sequence level in exons 2 and 3 of the *HLA-A*, *-B*, and *-C* genes, and exon 2 of the *HLA-DRB1* gene.³⁸ In practice, recipients and prospective donors are also “typed” and matched for exon 2 of the *HLA-DQB1* gene, primarily to ensure optimal donor/recipient matching at *HLA-DRB1*. Retrospective analysis of 3,857 unrelated donor transplants between 1998 and 2003 revealed that donor/recipient matching at *HLA-A*, *-B*, *-C*, and *-DRB1* (termed 8/8 matches) was associated with superior survival, and that a single mismatch at any one of these loci (7/8 matches) was associated with higher mortality.³⁹ Accumulating evidence suggests that donor/recipient matching at an additional HLA locus, *HLA-DPB1*, also influences the outcome of unrelated donor HCT.⁴⁰ Although donor/recipient matching at *HLA-DQB1* is typically achieved with current selection algorithms for unrelated donors, no data demonstrate that *HLA-DQB1* matching is associated with a survival benefit.

The strong preference for utilization of PB grafts in transplants between HLA-identical sibling pairs has profoundly influenced clinical practice in the unrelated donor setting, and PB grafts are currently used in over three-fourths of unrelated donor transplants. Unrelated PB grafts, like PB grafts from sibling donors, are associated with superior hematopoietic engraftment, and unrelated donors who donate PB grafts experience faster resolution of donation-related discomfort than do BM donors.³⁶ A recent multicenter international randomized trial demonstrated no significant difference in 2-year survival between the recipients of unrelated BM and PB grafts; however, trends toward more graft failure in the BM recipients and more chronic GVHD in the PB recipients were observed.⁴¹

Although the outcome of allogeneic HCT from unrelated donors was for many years inferior to that of transplants between HLA-identical siblings, advances in donor selection and in transplant practice—particularly conditioning regimens and supportive care—are steadily eliminating this critical differential. Retrospective analyses of HCT between HLA-matched related and 8/8 locus-matched unrelated donor/recipient pairs have shown comparable overall survival between the two groups, albeit with significantly more acute and chronic GVHD after unrelated donor transplant.^{42,43} The equivalent outcome of transplantation from HLA-matched related versus unrelated donors is all the more impressive given that patients who are referred for unrelated donor HCT have, on average, more advanced and higher risk disease.

Umbilical Cord Blood

The development and applications of UCB transplantation have been recently reviewed,⁴⁴ and this stem cell source provides an increasingly used alternative for patients that do not have a readily available, suitably HLA-matched family or unrelated donor. There are now >131 voluntary banks in 35 countries that house >500,000 UCB units available for searches to identify a suitable UCB unit for patients who need an allogeneic HCT.⁴⁵ The advantages of UCB include rapid availability, little or no risk to the

Figure 131.3 Transplant activity in the United States based on source of stem cells (1980 to 2011). (Reprinted with permission from Pasquini MC, Zang Z. Current use and outcome of hematopoietic stem cell transplantation: Center for International Blood and Marrow Transplant Research Summary Slides, 2012.)

mother or newborn infant, and a low risk of transmitting viruses. There is also a decreased requirement for stringent HLA matching, and UCB transplants that match at only four of six HLA class I and II molecules lead to acceptable rates of GVHD. The disadvantages of UCB include delayed engraftment, especially in patients that receive a nucleated cell dose of $<2.5 \times 10^7/\text{kg}$ or a CD34+ cell dose of $<1.2 \times 10^5/\text{kg}$, and delayed immune reconstitution, which contributes to higher transplant-related mortality.⁴⁶ The initial applications of UCB transplant focused on pediatric patients, who because of their size could receive a higher dose of CD34+ cells/kg of body weight. Data from registry studies demonstrate that the overall survival of patients receiving single UCB transplant compares favorably to HLA-matched unrelated donor BM or PB transplants.^{47,48}

To overcome the low CD34+ cell dose in a single UCB unit, two UCB units that were matched for at least four of six HLA alleles with the recipient have been administered. Such double UCB transplant improved the time to engraftment in adult recipients,^{49,50} even though chimerism analysis revealed that one UCB unit often rapidly dominated engraftment.⁵¹ A comparison of outcomes of double UCB transplant to those using HLA-matched related or unrelated donors has suggested a lower risk of relapse but higher transplant-related mortality with UCB grafts, and a similar overall survival.⁵⁰ UCB transplant has also been successfully employed with RIC, providing an option for older patients that could not tolerate MAC and do not have a suitably matched related or unrelated donor.^{52,53}

Innovations that may improve the outcome of UCB transplant are the subject of intense research. A promising approach to shorten the duration of neutropenia is to infuse an uncultured UCB unit along with in vitro expanded progenitor cells derived either by culturing UCB CD34+ cells with the Notch ligand delta 1, or with mesenchymal progenitor cells.^{54,55} These approaches currently require specialized cell culture facilities, but in the future cryopreserved banks of third-party “off-the-shelf” progenitors could be derived and used for this purpose. Strategies to improving homing of the infused stem cells to hematopoietic niches are also being explored to improve engraftment.⁵⁶ Immune reconstitution might be improved by the transfer of virus-specific cells or lymphoid progenitors derived de novo from UCB T cells,^{57,58} and GVHD reduced by infusing additional CD4+ regulatory T cells at the time of transplant.^{59,60}

Mismatched and Haploidentical Donors

HLA-mismatched or related haploidentical donors also provide a transplant option for the 40% to 50% of patients who do not have a readily available HLA-matched family or unrelated stem cell donor. Transplantation from donors mismatched at two or three HLA antigens was complicated in early studies by an unacceptably high incidence of graft rejection and severe GVHD resulting from potent bidirectional alloreactive T-cell responses.⁶¹⁻⁶³ The use of intense MAC, depletion of host and donor T cells, and infusion of high numbers of donor CD34+ T cells was necessary to overcome both the graft rejection and GVHD barriers, but resulted in a prolonged immunodeficiency and high risk of opportunistic infections, including invasive mold infection.⁶⁴ Relapse rates in AML were low, particularly in recipients in which donor-versus-recipient natural killer (NK) cell alloreactivity was present, due to the absence of MHC class I killer cell immunoglobulin-like receptor (KIR) inhibitory ligands in the recipient compared with the donor.⁶⁵

An alternative to T-cell depletion, and one that is used with RIC to prevent GVHD and graft rejection after haploidentical HCT, is the administration of high-dose Cy posttransplant. This approach has the advantage of selectively eliminating alloreactive T cells that become activated in the recipient, resulting in preservation of immune reconstitution to pathogens, thus avoiding the severe

opportunistic infections that are observed after T-cell-depleted haploidentical HCT.⁶⁶⁻⁶⁸ A recent Blood and Marrow Transplant Clinical Trials Network study of two parallel phase 2 trials of RIC and haploidentical donor BM transplant with high-dose Cy posttransplant or double UCB transplant demonstrated similar overall and progression-free survival at 1 year (62% and 48% haploidentical HCT; 54% and 46% double UCB transplant), and similar incidence of grade II to IV acute GVHD (32% haploidentical HCT; 40% double UCB transplant).⁶⁹ The 1-year cumulative incidences of nonrelapse mortality and relapse, respectively, were 7% and 45% after haploidentical HCT, and 24% and 31% after double UCB transplant. These results illustrate the vast improvements in outcomes after haploidentical HCT and suggest that randomized comparisons of UCB, matched unrelated donor, and haploidentical related donor HCT will be needed to determine if any of these procedures is superior.

IMMUNOBIOLOGY OF ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

The outcome of allogeneic HCT is in large part determined by recognition of alloantigens expressed on recipient cells by donor lymphocytes. Genetic disparity between donor and recipient is a key to the therapeutic efficacy of allogeneic HCT, but also the root cause of GVHD, which is its primary limitation. GVL and GVHD are mediated primarily by lymphocytes contained in or derived from the donor hematopoietic cell graft. GVL activity is closely linked to the development of GVHD, but clinically significant GVHD is not required for GVL, implying that important mechanistic distinctions exist between the two phenomena.

Graft-versus-Host Disease

GVHD comprises two distinct but variably overlapping clinical syndromes—acute and chronic GVHD—that differ in their time course, clinical manifestations, and response to therapy. The pathophysiology of acute GVHD is complex and involves tissue injury caused by cytotoxic conditioning and subsequent release of inflammatory cytokines, activation of donor lymphocytes and recipient antigen-presenting cells, recognition by donor lymphocytes of alloantigens on recipient antigen-presenting cells, proliferation and differentiation of activated donor lymphocytes, trafficking of donor lymphocytes to secondary lymphoid organs, and infiltration of target organs by activated donor effector cells with subsequent target organ injury. The pathophysiology of chronic GVHD is poorly understood, but it cannot readily be attributed to the same mechanisms that mediate acute GVHD. Many of the features of chronic GVHD are phenocopies of manifestations of autoimmune diseases such as scleroderma and Sjögren syndrome, and many transplant physicians view chronic GVHD as a condition in which loss of immune tolerance is a central feature. That distinct mechanisms mediate the pathogenesis of acute and chronic GVHD is underscored by the fact that pharmacologic strategies for prevention of acute GVHD have limited efficacy for preventing the chronic form of the disease (and vice versa).

The central role of donor T-lymphocytes in mediating acute GVHD is suggested by the complementary observations that depletion of T-lymphocytes from the donor graft can prevent clinically significant GVHD,⁷ whereas supplementation of conventional grafts with additional donor T cells markedly exacerbates it.⁷⁰ The occurrence of GVHD in recipients of grafts from donors that are genotypically identical throughout the entire MHC implicates donor/recipient disparity at polymorphic genetic loci outside the MHC in causing GVHD. Such loci encode short peptides (8 to 12 residues in length) termed “minor histocompatibility antigens” that are presented on the cell surface by HLA molecules encoded in the MHC. Minor histocompatibility (H) antigens are created

by the extensive sequence and structural variation present in the human genome, and all donor/recipient transplant pairs, despite selection for identity at the MHC, will be mismatched for many minor H antigens.⁷¹

The etiology of chronic GVHD is distinguished from acute GVHD by a significant role for B-lymphocytes and dysregulated B-cell homeostasis. Abnormal levels of naïve B cells are observed in chronic GVHD⁷² and are associated with elevated levels of B-cell activating factor,⁷³ which can promote the survival and activation of autoreactive B cells.⁷⁴ Autoantibodies specific for nuclear, mitochondrial, parietal cell, smooth muscle, and parotid gland antigens have been detected in patients with severe symptoms of chronic GVHD.^{75,76} Autoantibodies against platelet-derived growth factor have been detected in patients with chronic GVHD with prominent sclerosis and fasciitis.⁷⁷

Graft versus Leukemia

The elimination of malignant cells in recipients of allogeneic HCT is intimately associated with GVHD, but GVL activity is observed in the absence of GVHD, suggesting important distinctions between the two. It is clear that the GVL effect is not a single homogeneous phenomenon, and that the mechanisms that mediate GVL are determined by the genetic disparity between the donor and recipient, the source, composition, and processing of the hematopoietic cell graft from the donor and the recipient tumor type. Donor T-lymphocytes and NK cells are the primary GVL effector cells. Donor T cells specific for minor H antigens expressed on recipient malignant cells are particularly important in patients who receive T-replete grafts from HLA-identical donors. Minor H antigen-specific T cells exhibit potent antileukemic activity both *in vitro*⁷⁸ and *in vivo*,^{79,80} and specifically eliminate the leukemic stem cells that establish human leukemia in immune-deficient mice.^{79,80} Minor antigen-specific T cells with reactivity against recipient leukemic cells have frequently been detected in the blood of HCT recipients demonstrating regression of leukemia following donor lymphocyte infusion.⁸¹ It is thought that donor T cells recognizing minor H antigens that are selectively or exclusively expressed on recipient hematopoietic cells—including leukemic cells—may mediate GVL activity without contributing to GVHD.

Donor T cells recognizing nonpolymorphic antigens encoded by genes that are over- or aberrantly expressed in myeloid and lymphoid leukemic cells can contribute to GVL activity. CD8+ T cells recognizing peptides encoded by genes overexpressed in myeloid leukemic cells such as myeloblastin and neutrophil elastase,⁸² by the *WT1* oncogene that is expressed in a wide range of leukemic cells,⁸³ or from the cancer-testis gene *NY-ESO-1* that is often expressed in AML and multiple myeloma⁸⁴ have been detected in the blood of HCT recipients. Donor T-cell responses against tumor-specific antigens can also develop in allogeneic HCT recipients and contribute to GVL activity.⁸⁵ It is likely that donor T-cell responses against this class of recipient antigens are enabled and facilitated by the immunogenic milieu created by responses against recipient minor H antigens, as they have not in general been detected in recipients of syngeneic transplants.

Alloreactive donor NK cells can be major mediators of GVL in recipients of grafts from multiple HLA-mismatched and haploidentical donors, in whom extensive *in vitro* or *in vivo* T-cell depletion of the graft is required to prevent lethal GVHD.⁶⁵ The recognition of recipient target cells by cytotoxic donor NK cells in allogeneic HCT is in large part determined by donor and recipient genotypes at the KIR locus on chromosome 19q, as well as at the *HLA-A*, *-B*, and *-C* loci on chromosome 6p. KIR genes encode transmembrane receptors that are expressed selectively or exclusively in NK cells and subsets of $\alpha\beta$ or $\gamma\delta$ T cells; bind to specific subsets of HLA-A, -B, and -C alleles in a manner that is influenced by HLA-bound peptide; and participate in specific recognition of target cells by NK and T cells. In the HLA-haploidentical or multiple

HLA-mismatched setting, cytotoxic donor NK cells can eliminate recipient leukemic cells that express molecules for which they are specific. The interaction of donor NK and recipient leukemic cells is in part determined by the gene content and haplotype of the donor at the KIR locus, but the nature of the interactions have yet to be completely defined. Several models of NK alloreactivity have been proposed, but it is not yet clear which of these models has the greatest accuracy.

Accumulating evidence, much of it indirect, also suggests that donor NK cells may make a significant contribution to the elimination of myeloid leukemias after allogeneic HCT between fully HLA-matched donor/recipient pairs (reviewed in Warren and Deeg⁸⁶). The most compelling data have been provided by several large retrospective studies of MHC and KIR genotype and posttransplant relapse, and have shown significant associations between the presence in the donor of a specific type of haplotype at the KIR locus, or one or more components thereof, and decreased rate of relapse in recipients undergoing unrelated HCT for AML and other myeloid neoplasms.^{87,88}

COMPLICATIONS OF ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION AND THEIR MANAGEMENT

Acute and Chronic Graft-versus-Host Disease

The syndrome of acute GVHD is characterized by fever, skin rash, gastrointestinal symptoms referable to involvement of the upper or lower tract, and cholestatic liver dysfunction, often accompanied by elevations in hepatic transaminases. It typically occurs within the first 60 days after HCT, but can occur later, particularly in recipients of RIC. The most important risk factors for the development of acute GVHD are donor/recipient HLA mismatch, donor and recipient age, a filgrastim-stimulated PB graft rather than a BM graft, myeloablative conditioning with a TBI-containing regimen, and donor/recipient cytomegalovirus (CMV) seropositivity. The skin rash of GVHD is most commonly an erythematous, variably pruritic, macular or maculopapular eruption that can involve any part of the body surface. Blistering and desquamation is seen in severe cases (Fig. 131.4A,B). The symptoms of gut GVHD range widely in severity and can include anorexia, nausea, vomiting, abdominal cramping, and diarrhea, the latter of which can be voluminous (measurable in liters per day) and bloody. Endoscopic evaluation of gut GVHD reveals mucosal edema and erythema in mild cases, frankly hemorrhagic epithelium in more severe cases, and pseudomembranes and extensive denudation in life-threatening disease. The pathologic hallmarks of mild to moderate skin and gut GVHD are apoptotic epithelial cells and an infiltrate of inflammatory cells, composed chiefly of lymphocytes and neutrophils, the latter primarily in the gut. Hepatic GVHD is most specifically characterized by damage to bile ducts with bile stasis, often accompanied by inflammatory cell infiltration. Recent studies have identified plasma biomarkers for skin⁸⁹ and lower gastrointestinal and liver⁹⁰ GVHD, and a plasma biomarker associated with therapy-resistant, life-threatening GVHD.⁹¹

Chronic GVHD has protean manifestations that can appear in a broader range of target organs than acute GVHD, including the eyes, mouth, skin and nails, gut, liver, lungs, joints, subcutaneous tissue, and genital tract, particularly in women. Symptoms and signs of chronic GVHD include skin tightness and thickening, hypo- or hyperpigmentation (Fig. 131.4C,D), skin erosion or ulcers, pruritus, brittle and/or ridged nails, dry eyes and dry mouth, hair thinning or loss, edema, fatigue, weight loss, anorexia, dysphagia or odynophagia, joint stiffness or contractures, chronic cough, dyspnea, vaginal dryness, and dyspareunia, among others. Laboratory signs include eosinophilia, thrombocytopenia, and hypo- or, less commonly, hypergammaglobulinemia. Biopsy of involved

(Figures B, C, D are courtesy of Dr. Mary Flowers, Fred Hutchinson Cancer Research Center.)

sites reveals a spectrum of characteristic changes; fibrosis is a common feature. Evaluation of advanced lung involvement often reveals bronchiolitis obliterans. Immune deficiency is a prominent feature of chronic GVHD, and manifests as increased susceptibility to bacterial, fungal, and viral pathogens.

Pharmacologic Prophylaxis/Therapy

The incidence and severity of acute GVHD can be reduced with pharmacologic prophylaxis. Calcineurin inhibitors such as cyclosporine and tacrolimus combined with methotrexate have been the mainstay of prophylaxis in MAC transplants for several decades. Salts of mycophenolic acid have successfully replaced methotrexate in prophylaxis regimens in some RIC regimens. Two- and three-drug regimens combining tacrolimus, or tacrolimus and mycophenolic acid, with sirolimus have been extensively evaluated in clinical trials in both the MAC and RIC settings, with promising results.⁹² Novel approaches to preventing GVHD based on donor and/or recipient statin treatment⁹³ or blockade of lymphocyte chemotaxis⁹⁴ also appear to have significant potential. None of the pharmacologic strategies for preventing acute GVHD have yet been shown to be effective at preventing chronic GVHD.

Synthetic corticosteroids such as prednisone or methylprednisolone at 0.5 to 2 mg/kg per day are the cornerstone of therapy for acute and chronic GVHD that requires systemic therapy. Topical tacrolimus or halogenated steroids, and the combination of an oral photosensitizing psoralen with ultraviolet A irradiation can provide

useful, steroid-sparing adjuvant therapy for skin GVHD. Similarly, orally administered, poorly absorbed synthetic steroids such as bclomethasone⁹⁵ and budesonide are effective agents for mild to moderate gut GVHD, and facilitate a reduction in the intensity of systemic therapy. The treatment of moderate to severe (grade 3 to 4) acute GVHD that is refractory to treatment with 2 mg/kg per day prednisone equivalent continues to be an enormous clinical challenge. Anti-T-cell antibody preparations such as antithymocyte globulin of equine or lapine origin, and monoclonal anti-T-cell antibodies such as daclizumab are commonly used in this setting, but there is no agent that has been shown to be effective in a randomized, double-blind, placebo-controlled fashion.⁹⁶

Alternative Approaches to Prevention of Graft-versus-Host Disease

Several approaches to GVHD prevention have been investigated as adjuncts or alternatives to the traditional combination of a calcineurin inhibitor and methotrexate. Depletion of donor T cells in vitro, using one of several different methodologies, or in vivo, typically using polyclonal or monoclonal anti-T-cell antibodies, is effective prophylaxis for both acute and chronic GVHD, but at the cost of more frequent graft failure, slower immune reconstitution, increased opportunistic infections, and higher rates of relapse in some but not all malignancies.

T-cell depletion has been examined in randomized studies of allogeneic HCT between 8/8 or 7/8 HLA locus-matched donor/

recipient pairs. A multicenter trial in which 405 patients with hematologic malignancies were randomized to receive in vitro T-depleted BM grafts from unrelated donors and posttransplant cyclosporine A, or T-replete marrow grafts with cyclosporine A and standard-dose methotrexate demonstrated a lower rate of grade 3 to 4 acute GVHD in the T-cell depletion arm (18% versus 37%) but no significant difference in 3-year disease-free survival.⁹⁷ A subsequent randomized, multicenter trial of standard cyclosporine and methotrexate GVHD prophylaxis with or without in vivo antithymocyte globulin treatment in 202 patients receiving unrelated donor HCT similarly showed a lower cumulative incidence of grade 3 to 4 acute GVHD (11.7% versus 24.5%) and of clinical extensive chronic GVHD (12.2% versus 42.6%) in the antithymocyte globulin group, but no significant difference in overall survival between the two groups.⁹⁸

A novel approach to the prevention of acute and chronic GVHD based on administration of high-dose intravenous Cy within 3 to 4 days of infusion of the hematopoietic cell graft (high-dose Cy posttransplant) has shown promise in the prevention of both acute and chronic GVHD. Long studied in preclinical models of solid organ and hematopoietic cell transplantation,⁶⁸ this approach was first tested in the clinic for GVHD prophylaxis in haploidentical HCT.⁶⁶ These studies demonstrated that high-dose Cy posttransplant, combined with a calcineurin inhibitor, was comparable if not superior to T-cell depletion for haploidentical transplantation. High-dose Cy posttransplant alone, without additional prophylactic immunosuppression, has subsequently been studied in the setting of HLA-matched HCT from related and unrelated donors, and in both single-center⁹⁹ and multicenter studies, and has proved to be strikingly effective in the prevention of chronic GVHD, without compromising GVL activity.

Infectious Complications

Infections, both early after allogeneic HCT during the period of severe pancytopenia and later as a result of persistent immunodeficiency and/or immunosuppressive drug therapy, remain a significant cause of morbidity and mortality. Several strategies for reducing infectious complications are routinely employed, including handwashing policies for patients, families, and health-care workers; prophylactic antibiotics; screening for respiratory viruses; monitoring and preemptive therapy for CMV infection; and prompt empiric therapy for infections in at-risk patients. The types of pathogens to which the patient is most susceptible varies over time after HCT: The risk of bacterial infections is highest during the early neutropenic phase after HCT, and again later in patients with chronic GVHD. Viral infections occur most often in the first 3 months after HCT when cellular and humoral immunity are impaired by immunosuppressive drug therapy.

Bacterial Infections

Factors that predispose allogeneic HCT recipients to bacterial infections are disruption of oral and gastrointestinal mucosal barriers, neutropenia (absolute neutrophil count <500 cells/ μ L), indwelling central catheters, glucocorticoid therapy, and alterations in the microbiota from prior antibiotic therapy.^{100,101} The degree of mucosal damage and the duration of neutropenia vary depending on the intensity of the conditioning regimen, and RIC is associated with fewer early infections.

Up to 60% of HCT recipients develop a bloodstream infection with a gram-positive or gram-negative bacteria, and bacterial infections are the most common cause of infection-related mortality after allogeneic HCT.¹⁰²⁻¹⁰⁴ Antibiotic prophylaxis and prompt evaluation and empiric therapy of patients with neutropenic fever are critical to reduce the risk of life-threatening infections. Prophylaxis with a broad-spectrum antibiotic such as levofloxacin or ceftazidime is typically initiated at the onset

of neutropenia and continued until neutrophil recovery.^{105,106} Levofloxacin has broad activity against gram-positive and gram-negative pathogens, an excellent safety profile, and can be administered orally in once daily dosing. Patients that develop a fever should be evaluated by physical exam for potential portals of entry, blood and urine cultures, and a chest X-ray or other imaging studies informed by the clinical presentation. Empiric antibiotic therapy should be initiated promptly and modified depending on the results of cultures. The choice of antibiotics for empiric therapy of febrile neutropenia depends on clinical presentation, results of prior surveillance cultures, local susceptibility patterns, toxicity of individual agents, and allergic history. Typically, a third- or fourth-generation cephalosporin, carbapenem alone or in combination with an aminoglycoside, to provide coverage for pseudomonas and other gram-negative pathogens, are considered in seriously ill patients with neutropenic fever, with adjustment of the antibiotic regimen as culture data becomes available. *Nocardia*, *Legionella*, and *Mycobacterium* infections are uncommon but should be considered in patients with pulmonary infiltrates. The potential for antibiotic-resistant bacteria, such as methicillin-resistant *Staphylococcus* and vancomycin-resistant *Enterococcus*, to cause serious infections in HCT recipients who have often been heavily exposed previously to antibiotics should be carefully evaluated.

Late bacterial infections can occur after recovery from neutropenia, particularly in patients with chronic GVHD who have low serum immunoglobulin levels. Such patients are at risk from serious sinopulmonary infections and systemic infections with encapsulated organisms, and should be treated with daily prophylaxis with penicillin, trimethoprim-sulfamethoxazole, or a suitable alternative.¹⁰⁷

Clostridium difficile

There is a high incidence of *Clostridium difficile* infection in allogeneic HCT recipients because of frequent hospitalization, use of broad-spectrum antibiotics, and disruption of gastrointestinal mucosal barriers.¹⁰⁸ The incidence of *C. difficile* in allogeneic HCT recipients in one major US transplant center was 12.5%, and infection occurred at a median of 33 days after transplant.¹⁰⁹ This study also identified an association between *C. difficile* infection and acute GVHD, suggesting the possibility that alterations in the microbiome may contribute broadly to transplant outcomes. *C. difficile* infection after allogeneic HCT responds to standard treatment with oral metronidazole.¹⁰⁹ Recurrent *C. difficile* infections in nontransplant patients that do not respond to antibiotic therapy have been treated successfully with fecal microbiota transfer,¹¹⁰ and this approach has been reported to be effective in an allogeneic HCT recipient with fulminant antibiotic refractory *C. difficile* colitis.¹¹¹

Fungal and *Pneumocystis jiroveci* Infection

Allogeneic HCT recipients, particularly those that require intensive immunosuppression to treat GVHD or that receive a T cell-depleted HCT, are at risk for serious fungal infections. *Candida* and *Aspergillus* are the most common fungal pathogens; however, other organisms may be observed.¹¹² The incidence of invasive and superficial *Candida* infections is markedly reduced by administration of prophylactic fluconazole,¹¹³⁻¹¹⁵ and this is now the standard of care in transplant centers. Fluconazole has limited activity against *Candida krusei*, *Aspergillus* spp., and *Torulopsis glabrata*, and patients receiving fluconazole prophylaxis remain at risk for infections with these pathogens. Azole agents such as voriconazole and itraconazole that are active against *Aspergillus* are more effective than fluconazole in preventing *Aspergillus* infection in HCT recipients, but have a higher incidence of side effects.¹¹⁶⁻¹¹⁸ Patients that require glucocorticoid therapy for acute GVHD are at

high risk for invasive *Aspergillus* and *Zygomycetes* infection, and posaconazole has been shown to be more effective than fluconazole in this subset of patients.¹¹⁹

Pneumocystis jirovecii can cause pneumonia late after allogeneic HCT, and patients should receive prophylaxis with trimethoprim/sulfamethoxazole, or, if not tolerated, an acceptable alternative such as dapsone, atovaquone, or aerosolized pentamidine, until they are off of all immunosuppressive drug therapy.¹²⁰

Herpesvirus Infections

Reactivation of latent viruses of the herpes family occurs frequently in seropositive patients after allogeneic HCT, and in the absence of therapy can cause life-threatening disease. Historically, herpes simplex virus type 1 or 2 infection occurred in approximately 80% of seropositive patients, but is now nearly universally prevented by the administration of acyclovir beginning with conditioning. Varicella zoster virus can present late after HCT, most frequently in patients with GVHD, either as reactivation in dermatomal sites or less commonly as a disseminated infection with hepatitis, pneumonitis, and/or meningoencephalitis. Prolonged administration of prophylactic acyclovir for 1 year after HCT is effective in decreasing varicella zoster virus reactivation.¹²¹

Latent CMV infection is common in the general population and can reactivate and cause serious life-threatening invasive disease both early and late after allogeneic HCT. Prevention of CMV disease is the most effective management strategy. For patients who are CMV seronegative, it is standard practice to reduce the risk of the patient acquiring the virus by administering "CMV-safe" blood products as transfusion support, either obtained from CMV-seronegative donors or leukocyte reduced by filtration.¹²² CMV-seropositive recipients have frequent monitoring of blood for CMV reactivation using polymerase chain reaction to detect CMV DNA, and preemptive antiviral drug therapy to prevent disease is instituted in patients with reactivation to prevent progression of infection.^{123,124} Ganciclovir is most commonly used for preemptive therapy; however, foscarnet is a useful agent in patients with neutropenia.¹²² UCB transplant recipients are at particularly high risk for serious CMV infection due to the lack of transferred memory T-cell responses to CMV in the graft, the low total T-cell dose, and the delay in immune reconstitution.¹²⁵ Moreover, the delayed recovery of neutrophil counts in these patients complicates preemptive therapy with ganciclovir. Thus, some centers have implemented an intensive strategy to prevent CMV disease using ganciclovir during conditioning for UCB transplant, high-dose acyclovir prophylaxis after transplant, and preemptive ganciclovir for any positive CMV DNA polymerase chain reaction.¹²⁶ Ganciclovir and foscarnet cause myelosuppression and nephrotoxicity, respectively, and there is need for a safer drug for prophylaxis of CMV. CMX001 is an orally bioavailable acyclic nucleoside phosphonate that is converted intracellularly to cidofovir, and has potent antiviral activity against both herpesviruses and adenoviruses. A multicenter randomized study demonstrated that oral administration of CMX001 was effective as prophylaxis for CMV infection in CMV-seropositive allogeneic HCT recipients without myelosuppression or nephrotoxicity,¹²⁶ suggesting that less toxic approaches to controlling CMV infection after allogeneic HCT may be forthcoming.

CMV surveillance and preemptive antiviral drug therapy has reduced the incidence of CMV disease in the first 3 months after allogeneic HCT. However, late CMV disease still occurs in up to 15% of CMV-seropositive recipients, most commonly in the first year after transplant, and has a poor outcome.¹²⁷ Patients at high risk include recipients of T cell-depleted or UCB grafts, and those with low CD4+ T cells, absent reconstitution of CMV-specific T-cell immunity and GVHD. Extended monitoring for CMV reactivation and preemptive antiviral therapy is recommended in such patients to reduce late CMV disease.¹²⁴

Epstein-Barr virus (EBV) reactivation in donor B cells and progression to an aggressive lymphoproliferative disorder (LPD) may occur in recipients of T cell-depleted allogeneic HCT or in patients that receive T cell-depleting antibodies to treat GVHD. Strategies for T-cell depletion that also remove donor B cells from the graft reduce the incidence of EBV-LPD.¹²⁸ The pathogenesis of LPD is a deficiency of EBV-specific T cells that are necessary to control latent EBV infection. Thus, EBV-LPD can be treated effectively or prevented by infusing donor lymphocytes that contain EBV-specific T cells or are enriched for EBV-specific T cells by in vitro culture prior to infusion.¹²⁹⁻¹³² An effective alternative to adoptive T-cell therapy for patients at risk for EBV-LPD is to monitor EBV-DNA in blood and preemptively administer rituximab, an anti-CD20 monoclonal antibody that depletes B cells in vivo.^{133,134}

Other Viral Infections

Allogeneic HCT recipients have an increased susceptibility to developing lower respiratory tract disease from seasonal respiratory viruses, and mortality from influenza, respiratory syncytial virus, parainfluenza, and human metapneumovirus infections can be significant.^{135,136} Systemic or high-dose oral ribavirin therapy may be beneficial in patients with serious respiratory syncytial virus or parainfluenza virus infections, although controlled efficacy trials have not been performed.^{137,138} Active surveillance during seasonal outbreaks can identify patients with asymptomatic or symptomatic shedding, and isolation of such patients may reduce spread to health-care workers and other patients.

Adenovirus can cause disseminated infection in allogeneic HCT recipients who received T cell-depleted grafts or develop severe GVHD requiring prolonged immunosuppression. There are no antiviral drugs with proven efficacy for adenovirus; however, this infection may be susceptible to adoptive T-cell therapy with donor-derived adenovirus-specific T cells.^{139,140} BK virus is a prevalent latent polyomavirus that is increasingly recognized as a cause of urinary tract infection and hemorrhagic cystitis in allogeneic HCT recipients, particularly those with GVHD.^{141,142} The pathogenesis of symptomatic hemorrhagic cystitis associated with BK virus infection remains to be fully elucidated, and therapy is largely symptomatic.

Organ Complications

Organ complications are associated with an adverse outcome after allogeneic HCT; however, mortality has declined in recent years due to prevention strategies, improved supportive care, and the use of RIC.¹⁴³

Early and Late Pulmonary Complications

Pulmonary complications occur in up to one-third of allogeneic HCT recipients and can be divided into infectious and noninfectious etiologies.¹⁴⁴ Pretransplant pulmonary function testing is predictive of early respiratory failure and mortality, and may influence the choice of conditioning regimen in individual patients.^{145,146} The incidence of pulmonary infections has been declining due to effective preventive measures. Bacterial pneumonia in the neutropenic phase can be reduced by the use of prophylactic antibiotics. Similarly, the occurrence of CMV pneumonia has been reduced by preemptive antiviral drug therapy. Invasive pulmonary *Aspergillus* and *Zygomycetes* infections remain serious complications, particularly in patients with prolonged neutropenia and/or those who require intensive immunosuppression to treat GVHD, and prophylaxis with newer azoles is indicated in such patients.¹⁴⁶

Noninfectious pulmonary complications that occur in the first 100 days after allogeneic HCT include periengraftment respiratory distress syndrome, diffuse alveolar hemorrhage (DAH), and idiopathic pneumonia syndrome. Periengraftment respiratory distress syndrome typically develops approximately 1 to 3 weeks after HCT coincident with neutrophil recovery and is characterized by fever, hypoxemia, noncardiogenic pulmonary edema, and erythroderma. This syndrome is thought to result from release of proinflammatory cytokines and influx of neutrophils into the lung, and responds to high-dose corticosteroids.¹⁴⁷ DAH is characterized by damage to pulmonary vasculature and bleeding into the alveolar space. Diagnosis requires bronchoalveolar lavage to exclude coexisting infection. Patients that develop DAH within the first 30 days after HCT and do not require mechanical ventilation have a favorable prognosis.¹⁴⁸ Early diagnosis and treatment with high-dose steroids appear to improve survival in DAH, although prospective trials have not been performed.^{149,150} Idiopathic pneumonia syndrome occurs in 1% to 10% of HCT recipients and is defined as evidence of widespread alveolar injury and the absence of an infection, cardiac dysfunction, acute renal failure, or iatrogenic fluid overload.^{151,152} The pathogenesis is poorly understood, there are no proven treatments, and the collective mortality in large series of patients is 74%.¹⁵³

Late pulmonary complications occurring >100 days after HCT occur most commonly in patients with chronic GVHD, and include bronchiolitis obliterans (BO) and cryptogenic-organizing pneumonia (COP). BO often presents with cough and dyspnea in the absence of infection on bronchoscopy, and evidence of a mosaic pattern on high-resolution computed tomography scan. In addition to GVHD, risk factors include older age, unrelated donor, TBI dose of >12 Gy, and PB as a graft source.¹⁵⁴ Pulmonary function tests show airflow obstruction, and patients exhibit a variable clinical course typified by slowly progressive airway obstruction with episodes of exacerbation. The management of BO includes high-dose or inhaled corticosteroids, and optimization of the immunosuppressive drugs for chronic GVHD.¹⁵⁵ The clinical course is typically progressive, and overall mortality for patients diagnosed with BO is ~12% at 5 years with a worse prognosis in older patients and those with progressive GVHD.¹⁵⁶

COP is an idiopathic pneumonia with characteristic histopathology showing proliferation of granulation tissue in small airways and alveolar ducts and chronic inflammation in surrounding alveoli. COP occurs earlier than BO and has a restrictive pattern with low diffusion capacity and minimal airflow obstruction. The diagnosis is established by tissue biopsy and histopathology.¹⁵⁷ Patients with COP have a good response to systemic corticosteroids and the disease stabilizes or resolves in the majority of patients.¹⁴⁴

Hepatic Complications

Liver complications after allogeneic HCT have become less frequent with improved strategies for preexisting hepatic infections and for preventing sinusoidal obstruction syndrome (SOS) and cholestasis after HCT.^{15,158,159} Preexisting fungal liver infections should be diagnosed and treated with antifungal therapy prior to transplant. Patients with chronic liver disease due to cirrhosis or active hepatitis C virus or hepatitis B virus (HBV) infection are at increased risk for transplant-related mortality.¹⁶⁰ Patients infected with HBV should receive antiviral drug therapy.¹⁶¹ HBV and hepatitis C virus infection of the donor poses a risk of transmission to an uninfected HCT recipient, and pretreatment of HBV-positive donors to reduce viral load and prophylaxis of the recipient post HCT are indicated.

SOS, which was previously often referred to as veno-occlusive disease, is characterized by hepatomegaly, fluid retention, and elevated bilirubin resulting from damage to hepatic sinusoids by high-dose cytotoxic therapy.¹⁶² Cy is the most common offending

chemotherapy agent because its metabolism is highly variable, and patients who generate a greater amount of toxic Cy metabolites have a higher risk of fatal SOS.¹⁶³ The incidence of SOS is higher with conditioning regimens that include >12 Gy TBI with Cy, and in patients with underlying liver disease. Patients with underlying liver disease should be considered for a RIC regimen that does not contain high-dose Cy. The onset of SOS is typically 1 to 3 weeks after conditioning, and the diagnosis is established by clinical criteria of hyperbilirubinemia, weight gain, and hepatomegaly. Imaging studies of the liver are useful to demonstrate hepatomegaly, ascites, and attenuated hepatic venous flow, and exclude other causes.¹⁶⁴ Transvenous measurement of hepatic venous pressure and biopsy can be useful in difficult cases.

The majority (>70%) of patients with SOS will recover spontaneously, and therapy should be supportive and directed at management of fluid retention, preservation of renal blood flow, and paracentesis to remove ascitic fluid if associated with compromised pulmonary function. Patients with severe SOS who have a rapidly progressive course and develop pulmonary and renal dysfunction may benefit from intravenous defibrotide.¹⁶⁵

Cholestasis or hyperbilirubinemia after allogeneic HCT may be caused by systemic or local infection, medications such as calcineurin inhibitors, antibiotics and antifungal drugs, gallbladder and biliary disease, and acute GVHD. The etiology of cholestasis may be evident after clinical evaluation and imaging studies, and therapy should be directed at the causative factors. The frequency of cholestasis has been reduced by the use of prophylactic ursodeoxycholic acid, which has reduced nonrelapse mortality.¹⁵⁹

Renal Complications

The etiology of renal dysfunction after allogeneic HCT is often multifactorial and contributing factors include hemodynamic alterations in sepsis and hepatic SOS, nephrotoxic antibiotics, and thrombotic microangiopathies associated with calcineurin inhibitors or GVHD.¹⁶⁶ Early recognition of patients at risk for renal dysfunction, adjusting drug doses based on serum creatinine or drug levels, and the use of less nephrotoxic antibiotics when appropriate are important to mitigate the development of renal insufficiency.

GRAFT FAILURE

In some instances, the allogeneic stem cell graft functions briefly and then after a period of days or weeks, marrow function is lost and myeloid elements are absent on evaluation of a BM biopsy. Failure of the graft usually is the result of the persistence of host immune cells that reject the donor marrow, a phenomenon that is termed graft rejection.¹⁶⁷ Following HCT with HLA-identical donor stem cells, graft rejection occurs most commonly when the patient has received multiple transfusions prior to transplantation, little prior chemotherapy, and/or when the preparative regimen is less immunosuppressive. HLA disparity between donor and recipient and T-cell depletion of the donor graft prior to transplant increase the risk of graft rejection. A limited array of options is available to treat graft rejection. Retransplantation from another donor or the same donor with more immunosuppressive conditioning is sometimes successful for patients with primary graft failure or acute graft rejection.¹⁶⁷

Some patients may retain donor stem cells and have poor graft function in the absence of immune rejection. In this situation, a search for infectious causes of pancytopenia, or drugs that suppress graft function should be undertaken. These patients sometimes respond to treatment with a hematopoietic growth factor with an increase in the granulocyte count that may be sustained even after discontinuation of the growth factor.

OUTCOME OF ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCIES AND SOLID TUMORS

The most common indication for allogeneic HCT in the United States in 2012 was for the treatment of AML (Fig. 131.5). Allogeneic HCT is also commonly used for the treatment of MDS and ALL, and less commonly to treat non-Hodgkin lymphoma and Hodgkin disease, CML in advanced stage, multiple myeloma, chronic lymphocytic leukemia (CLL), and some solid tumors. Allogeneic HCT is potentially curative for aplastic anemia and several other nonmalignant disorders.

Acute Myeloid Leukemia

Allogeneic HCT has been an important component of standard care for AML for over two decades. It is the only therapy with curative potential for patients with primary refractory or relapsed disease, and is increasingly utilized as consolidation therapy for patients in first remission whose disease characteristics are associated with significant risk for relapse. Interpretation of HCT outcome for AML is complicated by significant evolution over the past two decades of the criteria used to define disease risk, from classification based on proportion of marrow blasts to more sophisticated nosologies incorporating cytogenetic, flow cytometric, and molecular characteristics of the leukemic cells. The use of multicolor flow cytometry to evaluate patients with AML has enabled detection of very low levels of leukemic cells. Consequently, patients who would have been classified a decade ago as being in remission on the basis of $<5\%$ marrow blasts could potentially be considered to have persistent or recurrent disease today if the marrow contained $\geq 0.01\%$ cells with an abnormal surface phenotype identical or similar to the leukemic cells at diagnosis. One consequence of this evolution in diagnostic criteria is the likely inclusion in older transplant studies of patients erroneously classified as being in remission due to the use of the $<5\%$ marrow blast criterion.

Current use and outcome of hematopoietic stem cell transplantation: Center for International Blood and Marrow Transplant Research Summary Slides, 2012.)

This should be kept in mind when comparing AML HCT studies from different decades.

Disease stage and marrow cytogenetics are important variables that influence outcome of HCT for AML. Registry data on transplants performed from 2000 to 2010 demonstrate that overall survival of patients with AML in CR1 undergoing HCT from HLA-identical sibling donors exceeds 50% at 6-years post-transplant, whereas the corresponding survival of patients receiving grafts from unrelated donors is $\sim 40\%$. Overall survival of patients with advanced disease—those beyond CR2 or not in remission at the time of HCT—is $<20\%$ (Fig. 131.6), and there is little effect of donor/recipient relation. Analysis of 560 unrelated donor transplants for patients in CR1 or CR2 suggests that cytogenetics has little influence on the outcome of unrelated HCT in CR1, but a modest influence on the outcome of HCT in CR2.¹⁶⁸ Specific chromosomal abnormalities have been identified that are associated with a poor prognosis. Retrospective analysis of 432 transplants for AML at the Fred Hutchinson Cancer Research Center revealed that a monosomal karyotype—defined as ≥ 2 autosomal monosomies or a single monosomy in the presence of other structural abnormalities—was associated with markedly inferior 4-year survival: 25% for monosomal karyotype-positive AML and 56% for monosomal karyotype-negative AML.¹⁶⁹

Patient age has historically been one of the strongest prognostic variables in AML, and this also holds true for patients with AML who undergo allogeneic HCT. The effect of age is not independent of cytogenetics, however, as the proportion of patients with AML with unfavorable cytogenetics increases steadily with age, ranging from 35% of patients <56 years to 51% of patients >75 years.¹⁷⁰ Analysis of registry data for the period 1998 to 2005 demonstrated that the adjusted 5-year overall survival of children (<15 years), adolescents and young adults (15 to 40 years), and older adults (>40 years) transplanted for AML from HLA-matched related donors was 53%, 42%, and 34%, respectively, while the overall survival of those transplanted from unrelated donors was 37%, 28%, and 23%, respectively.¹⁷¹ The development of RIC regimens has allowed a steadily increasing number of older patients who are not eligible for MAC to undergo HCT, and similar to other hematologic malignancies, the proportion of patients with AML undergoing transplants with such regimens has increased from $<5\%$ in 1998 to $>30\%$ in 2010 (Fig. 131.7). A retrospective multicenter study of RIC HCT in 274 patients with AML with a median age of 60 reported a 5-year overall survival of 33%, with 37% and 34% survival observed in patients in CR1 or CR2, respectively, and 18% in patients with advanced disease.¹⁷² Limited data indicate

Figure 131.7 Increase in the use of reduced intensity conditioning for allogeneic hematopoietic cell transplantation for acute myeloid leukemia and other hematopoietic malignancies, 1998 to 2010. Data is shown for year of transplant and disease type. AML, acute myeloid leukemia; ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia; HD, Hodgkin disease; MDS, myelodysplastic syndrome; LYM, lymphoma. Current use and outcome of hematopoietic stem cell transplantation: Center for International Blood and Marrow Transplant Research Summary Slides, 2012.)

that carefully selected patients with AML age 70 or older can safely undergo RIC HCT, but relapse in this age group remains a significant challenge.¹⁷³

Myelodysplastic Syndrome

The median age of US patients with MDS at the time of diagnosis is 70 to 75 years¹⁷⁴; therefore, most MDS patients are not suitable for MAC. Steady refinement of RIC regimens has made an increasing fraction of patients with MDS eligible for allogeneic HCT. A seminal retrospective study of registry data on patient outcomes showed that patients with MDS with int-2 and high-risk International Prognostic Scoring System (IPSS) benefit most from immediate transplantation, whereas those with low and int-1 scores optimize outcomes by delaying HCT until their disease progresses.¹⁷⁵ The central concept of this transplant strategy—immediate transplantation for advanced disease and delayed transplantation for early stage/low-grade disease—has subsequently been espoused by the National Comprehensive Cancer Network and the American Society for Blood and Marrow Transplantation. A recent analysis suggests that this strategy also optimizes outcome in older patients with MDS who undergo HCT following RIC.¹⁷⁶ These events have influenced the utilization of allogeneic HCT for MDS, which has been steadily increasing over the past decade.

The outcome of transplantation for MDS is associated with patient age, IPSS score, cytogenetic risk classification, donor type, conditioning regimen, and etiology of MDS. Retrospective data on 1,007 patients transplanted over two decades at the Fred Hutchinson Cancer Research Center demonstrate ~40% 10-year survival in a subset of generally younger patients with MDS who received myeloablative Bu/Cy conditioning.¹⁷⁷ A major challenge in patients with MDS is posttransplant relapse, even in young patients that receive myeloablative Bu/Cy conditioning, and is particularly challenging in the subset of patients with poor cytogenetic risk.¹⁷⁸ In large part due to a high incidence of relapse, the long-term outcome after HCT using RIC in older patients with MDS and those with significant comorbidities remains inferior to that observed in younger patients, with 5-year survival in remission in the range

of 20%. The poorest survival is observed in patients with int-2 or high IPSS score.¹⁷⁹ Maturing data suggest that combination of fludarabine, treosulfan, and low-dose (2 Gy) TBI may be an effective RIC regimen for MDS, with a low incidence of relapse even in patients with high-risk cytogenetics.¹⁸⁰ HCT for MDS from unrelated, as compared to HLA-matched related, donors has been reported to have inferior survival in numerous trials, particularly among patients with advanced disease (Fig. 131.8). However, more recent studies show progressive improvement of outcome following unrelated donor HCT, which in single-institution studies is approaching the results achieved with related donors. Registry data show a 2-year survival probability increasing from 39% for transplants performed in the period 1999 to 2003 to 47% for patients transplanted in 2008 to 2010.

Figure 131.8 Probability of survival after allogeneic hematopoietic cell transplantation for myelodysplastic syndrome (2000 to 2010) by disease status and donor type. (Reprinted with permission from Pasquini MC, Zang Z. Current use and outcome of hematopoietic stem cell transplantation: Center for International Blood and Marrow Transplant Research Summary Slides, 2012.)

Transplantation for therapy-related MDS has generally been associated with poorer survival than HCT for de novo MDS.^{181,182} However, the overall results are poor in this group because of the large proportion of patients with therapy-related MDS who have high-risk cytogenetics, and outcome is similar to that observed in patients with de novo disease and comparable risk karyotypes.

Acute Lymphoblastic Leukemia

The rate of cure in children with ALL approaches 90%, and allogeneic HCT is typically reserved for children that relapse after chemotherapy. Primary chemotherapy can also induce a remission in 65% to 85% of adults with ALL; however, a majority (~70%) of these patients will eventually relapse. Several studies have prospectively examined outcomes of adult patients up to age 59 with Philadelphia chromosome–negative ALL that did or did not have a matched related donor and were believed to be able to tolerate allogeneic HCT.^{183–185} Overall, these studies demonstrate that allogeneic HCT from an HLA-matched related donor is superior to autologous HCT or chemotherapy for patients with ALL in first remission, and results in cure in 40% to 60% of patients. A retrospective study comparing related and unrelated donors as a graft source showed that the overall survival data for patients that receive a matched unrelated donor is similar to that for related donors,¹⁸⁶ and registry data from the Center for International Blood and Marrow Transplantation Research demonstrates that UCB grafts provide comparable results to 8/8 and 7/8 HLA allele–matched unrelated donor grafts.⁴⁵ These results suggest that for Philadelphia chromosome–negative ALL in adults, allogeneic HCT should be considered for eligible patients aged younger than 55 in CR1, particularly if there are adverse prognostic features at presentation such as a high leukocyte count; chromosomal translocations involving t(4:11), t(1:19), or t(8:14); or evidence of minimal residual leukemia at 12 weeks by molecular or flow cytometry monitoring. Advances in the intensity of conventional chemotherapy in adult ALL may improve the outcome for patients with standard risk disease and it is conceivable that in the future, allogeneic HCT may be reserved for the subset of patients that relapse after CR1. Novel approaches such as blinatumomab and adoptive therapy with autologous T cells modified to express a CD19 chimeric antigen receptor^{187,188} have shown remarkable efficacy in patients with advanced chemotherapy refractory B-cell malignancies including ALL, and these strategies might also be incorporated earlier in treatment schedules and reduce the need for allogeneic HCT, or after HCT to reduce relapse.

The prognosis for Philadelphia chromosome–positive ALL with chemotherapy and tyrosine kinase inhibitors (TKI) is poor, particularly in older patients, and allogeneic HCT is the only curative treatment.¹⁸⁹ Allogeneic HCT from a suitably matched donor results in a 37% to 54% overall survival at 3 to 10 years after HCT, which compares favorably with the ~12% overall survival with chemotherapy alone.^{190,191} The use of TKIs prior to and after allogeneic HCT might further improve outcome for this subset of patients with ALL.^{192,193}

It has been generally thought that MAC is important to achieve cure of ALL with allogeneic HCT, and intensive conditioning is indicated in younger patients who are candidates for MAC. However, many patients with ALL are older than 60 years and are both less likely to tolerate the intensive chemotherapy that is curative in children and poor candidates for MAC. Several studies have shown that RIC followed by allogeneic HCT can provide durable remissions in a subset of patients with high-risk ALL.^{194,195} A European Society for Blood and Bone Marrow Transplant retrospective analysis compared RIC with conventional MAC and reported a higher relapse rate with RIC ($p = 0.03$; hazard ratio = 0.59), but a correspondingly decreased non-relapse mortality (NRM) ($p = 0.0001$; hazard ratio = 1.98).¹⁹⁶ These studies demonstrate that RIC and the GVL effect can be sufficient to affect cure in a subset of patients with ALL that are in CR at the time of transplant, and that RIC provides a reasonable choice for patients with advanced age or comorbidities.

Other Lymphoid Malignancies

Allogeneic HCT can be curative for a subset of patients with CLL and for patients with Hodgkin disease, non-Hodgkin lymphoma, and mantle cell lymphoma that have failed autologous HCT.^{197–203} Because CLL occurs at an average of 72 years of age, RIC is commonly used, and it is fortuitous that CLL is highly sensitive to the GVL effect.²⁰⁴ Studies from multiple institutions show long-term disease-free survival of 36% to 43%, and nonrelapse mortality of 16% to 23% after allogeneic HCT for patients with CLL that have failed chemoimmunotherapy.^{197–200} Chronic GVHD is a significant problem that occurs in approximately 50% of patients with CLL that receive allogeneic HCT after RIC.^{197–200} Because of the morbidity associated with chronic GVHD, the decision to proceed with HCT should be made based on consideration of the patient's overall health and risk of disease progression. A general guideline is that allogeneic HCT is indicated for patients who have TP53 abnormalities, fail to achieve CR or progress within 12 months of chemoimmunotherapy, or relapse within 24 months after purine analogue–based chemoimmunotherapy.²⁰⁵ The recent availability of novel drugs that target B cell–receptor signaling pathways, adoptive immunotherapy with autologous T cells engineered with CD19-specific chimeric antigen receptors, and novel monoclonal antibodies provide alternatives to allogeneic HCT in individual patients.

Allogeneic HCT for patients with Hodgkin disease, non-Hodgkin lymphoma, and mantle cell lymphoma is usually reserved for those that have failed chemotherapy and a prior autologous HCT, but can be curative even in advanced cases.^{201–203,206} Multiple myeloma is susceptible to the GVL effect; however, transplant-related mortality is high in these patients with MAC, and the role of RIC and allogeneic HCT continues to be defined.²⁰⁷

Chronic Myelogenous Leukemia

Utilization of allogeneic HCT for the treatment of CML declined precipitously after the advent of TKI therapy in 2000 to 2001. Nonetheless, transplant continues to have therapeutic utility, with 1,197 transplants performed in the United States from 2008 to 2012. TKI failure or intolerance, and disease progression beyond first chronic phase are currently the most common indications for HCT in CML. Survival after HCT for patients with these indications is comparable to that observed before the TKI era. Treatment with TKIs before HCT does not compromise the outcome of transplant,²⁰⁸ and HCT can effectively salvage many patients who develop TKI resistance due to *bcr-abl* mutations.²⁰⁹ In a multicenter study of transplants performed in the TKI era, the German CML Study Group observed a 91% 3-year survival in 56 patients who underwent HCT in first chronic phase, and 59% 3-year survival in 28 patients transplanted for advanced disease; 88% of the 84 patients who received a transplant achieved a molecular remission.²¹⁰ Collectively, these studies have confirmed that HCT is a highly effective option for second- or subsequent-line therapy of CML in both early and advanced phase.²¹¹ TKIs are widely used for adjuvant therapy following HCT for advanced-phase CML, but there are few randomized data to support this practice.

Solid Tumors

Durable regression of several metastatic solid tumor types has been observed after allogeneic HCT. Most studies of HCT for solid tumors have used RIC regimens with little, if any, tumoricidal activity, and the posttransplant tumor regression observed has thus been attributed to the activity of immune cells contained in or derived from the donor graft. Regression of renal, breast, colorectal, ovarian, and pancreatic cancer has been observed after allogeneic HCT, with the most impressive responses observed in patients with metastatic renal cell carcinoma.²¹² Responses are associated with the development of acute and chronic GVHD, or

both, and laboratory studies have suggested that donor T cells specific for tumor antigens and/or minor histocompatibility antigens may mediate tumor regression.^{85,213} An unacceptably high rate of treatment-related morbidity and mortality, much of it attributable to acute or chronic GVHD, has been observed with allogeneic HCT for metastatic solid tumors, which has dampened enthusiasm for the procedure. Future utilization of allogeneic HCT for solid tumors will require the development of strategies for selectively enhancing graft-versus-tumor activity and limiting GVHD.

MANAGEMENT OF POSTTRANSPLANT RELAPSE

Despite the many advances in allogeneic HCT, later relapse of the underlying malignancy remains a leading cause of death.²¹⁴ Relapse occurs because some of the tumor cells are resistant to the cytotoxic effects of the conditioning regimen, and because the immune mechanisms of the GVL effect are insufficient to eradicate all remaining malignant cells, either due to intrinsic resistance or inhibition of donor immune cell function by the immunosuppressive drugs given to prevent or treat GVHD.²¹⁵ The prognosis for patients who relapse is poor if relapse occurs in the first 3 months after allogeneic HCT, but many patients who relapse later can be salvaged with donor lymphocyte infusions (DLI) alone or following reinduction chemotherapy.^{216,217} The infusion of donor T cells selected for specificity with recipient minor H antigens,

for leukemia-associated antigens such as WT1, or engineered with chimeric antigen receptors has been evaluated in phase I trials, and might provide greater selectivity and potency than DLI.^{218–220} A variety of preemptive and maintenance strategies to prevent relapse after HCT are also being examined including the use of hypomethylating agents to enhance the GVL effect and combining targeted agents with DLI.^{221–223}

FUTURE DIRECTIONS

Allogeneic HCT has provided curative therapy for thousands of patients with hematologic malignancies and has served as a paradigm for translational research efforts that have provided crucial scientific insights in immunobiology, histocompatibility, antitumor immunity, and stem cell biology. Advances including large volunteer unrelated donor registries, UCB banks, improvements in supportive care and management of infections, and the development of RIC regimens have combined to make allogeneic HCT a therapeutic option for increasing numbers of patients with life-threatening malignancies. GVHD and relapse remain the two major causes of failure, and ongoing research in the pathogenesis of GVHD in animal models is identifying novel approaches for preventing this serious complication that can be translated to humans. Moreover, the rapid advances in cancer immunotherapy are providing an increasing number of targeted therapies that are likely to be evaluated for reducing relapse after allogeneic HCT.

132 Infections in the Cancer Patient

Tara N. Palmore, Mark Parta*, Jennifer Cuellar-Rodriguez, and Juan C. Gea-Banacloche

RISK FACTORS FOR INFECTIONS IN PATIENTS WITH CANCER AND ANTIMICROBIAL PROPHYLAXIS

RISK FACTORS FOR INFECTION

Cancer patients are at increased risk for infection because of their disease and its treatment. Awareness of the risk factors present in the patient is important for diagnosis and empirical management. Selected host defense defects are presented in Table 132.1.

Intrinsic Host Factors

Hematologic Malignancies

Some hematologic malignancies are associated with increased frequency of infections even in the absence of treatment. For instance, the rate of mycobacterial disease seems to be increased in hairy cell leukemia and Hodgkin lymphoma. Multiple myeloma and chronic lymphocytic leukemia are associated with a high risk of encapsulated bacterial infections due to impaired B-cell immunity. Mutations in GATA2 are associated with myelodysplastic syndrome, acute leukemia, and Epstein-Barr virus (EBV)-associated malignancies, and they result in a particular immunodeficiency syndrome (MonoMac) characterized by viral, mycobacterial, and fungal infections in the setting of monocytopenia, B, natural killer, and CD4 lymphocytopenia.¹

Solid Tumors

Tumor-related erosion of normal anatomic barriers or obstruction of the respiratory, biliary, and genitourinary tracts contributes to an increased risk of infection. The relief of obstruction remains the primary therapeutic maneuver, with ancillary antimicrobial therapy directed by a knowledge of the normal flora and its alterations in the presence of obstruction. The specific association of colon cancer with bacteremia and/or endocarditis caused by

Streptococcus gallolyticus (formerly *Streptococcus bovis*) should still be noted. Breast tumors increase the risk of mastitis and abscess formation, usually by *Staphylococcus aureus*. Adrenal corticosteroid-producing tumors and ectopic adrenal corticotrophin hormone-secreting tumors are associated with an increased risk of bacterial and opportunistic infections.

Asplenia

Functional or surgical asplenia is a risk for overwhelming sepsis by encapsulated bacteria. Functional asplenia is present after splenectomy, splenic irradiation, and with chronic graft-versus-host disease (GVHD).² The most common pathogen is *Streptococcus pneumoniae*, but other pathogens include *Hemophilus influenzae* and *Neisseria meningitidis*. Patients without a functional spleen who present with fever should be started promptly on antibiotics active against *S. pneumoniae*. The drug susceptibility of *S. pneumoniae* now is unpredictable, and local patterns should be taken into consideration. Pathogens associated with animals (*Capnocytophaga canimorsus*) and geographic risks (*Babesia*, *Plasmodium*) should be considered. The US Centers for Disease Control and Prevention (CDC) recommends that asplenic persons be immunized with the pneumococcal polysaccharide and meningococcal vaccines.³ The conjugated meningococcal vaccine is preferred in adults 55 years of age or younger because it confers longer lasting immunity than the polysaccharide vaccine. Immunization of adults with the *H. influenzae* type B vaccine is also recommended. Immunization is ideally performed at least 2 weeks in advance of splenectomy. If this is not feasible, immunization is still advisable after the procedure. Penicillin prophylaxis is advised in asplenic patients to prevent pneumococcal disease.

Treatment-Related Factors

Mucositis

Chemotherapy and radiation therapy impair mucosal immunity at several different levels. Chronic GVHD may further compromise mucosal immunity, including defective salivary immunoglobulin (Ig) secretion. Compromise of the epithelial lining may result in invasion by local flora, and bacteremia and candidemia may result. Severe mucositis is a known risk factor for viridans-group streptococcal infections,⁴ but many pathogens, including oral anaerobes, may cause invasive disease in this setting.

Chemotherapy-Induced Neutropenia

Neutropenia is a major risk factor for infections in cancer patients. Lack of granulocytes facilitates bacterial and fungal infections, and blunts the inflammatory response, allowing infections to progress much faster. The source of bacterial infections is most commonly

TABLE 132.1

Risk Factors and Infectious Disease Associations in Cancer Patients

Risk Factors	Infection	Comment
MALIGNANCY-RELATED FACTORS		
Hematologic Malignancies		
Myelodysplastic syndrome and acute leukemia	Bacteria, viruses, and fungi	Infectious risk related to prolonged neutropenia
Acute lymphoblastic leukemia	<i>Pneumocystis jirovecii</i> pneumonia	Corticosteroid treatment possible confounding factor
Chronic lymphocytic leukemia	Encapsulated bacteria	Infectious risk linked to hypogammaglobulinemia
Multiple myeloma	Encapsulated bacteria	Impaired B-cell immunity, hypogammaglobulinemia
Hairy cell leukemia	Mycobacteria, herpes viruses	Defective T-cell immunity
Hodgkin lymphoma	Mycobacteria, herpes viruses	Defective T-cell immunity
Adult T-cell lymphoma/leukemia	<i>P. jirovecii</i> , <i>Cryptococcus neoformans</i> , CMV, <i>Strongyloides stercoralis</i>	Defective T-cell immunity
Solid Tumors		
Endobronchial tumors	Postobstructive pneumonia	Mechanical obstruction
Colon carcinoma	<i>Streptococcal bacteremia</i>	
	<i>Clostridium bacteremia</i>	
Hepatobiliary tumors	Bacterial infection with enteric organisms	Mechanical obstruction plus abnormal liver function if underlying cirrhosis
Head and neck cancer	Infections with oral flora and anaerobes	Mechanical disruption
Genitourinary tumors	Gram-negative bacilli, <i>Enterococcus</i> spp.	Related to obstruction
Asplenia	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , and <i>Neisseria meningitidis</i> (encapsulated bacteria), <i>Salmonella</i> , <i>Capnocytophaga canimorsus</i> , <i>Babesia microti</i> , malaria	
TREATMENT-RELATED FACTORS		
Neutropenia	Bacterial and fungal infections	
Mucositis	Bacterial infections caused by oral and enteric flora, candidiasis	
Corticosteroids	Bacteria, <i>P. jirovecii</i> , <i>C. neoformans</i> , molds, herpes viruses	Decrease signs and symptoms of inflammation
Nucleoside analogues (e.g., fludarabine, 2-chlorodeoxyadenosine, and 2-deoxycoformycin)	Bacteria, <i>P. jirovecii</i> , <i>C. neoformans</i> , herpes viruses	Defective T-cell immunity by T-cell depletion
Alemtuzumab	Opportunistic and nonopportunistic infections, including bacteria, viruses (e.g., CMV, VZV), <i>P. jirovecii</i> , and fungi	Broad defect in host defense involving depletion of T, B, NK cells, and monocytes Occasional neutropenia
Rituximab	Bacterial infections, VZV, <i>P. jirovecii</i>	Impaired B-cell immunity
Daclizumab	Bacterial sepsis	Infections in the setting of steroid-refractory GVHD
Antibodies inhibiting cytokine signaling (e.g., infliximab)	Bacterial infections, tuberculosis, and other mycobacterial infections, mold infections in GVHD, other fungal infections (e.g., histoplasmosis)	Suppression of inflammation may allow infections to progress undetected
Calcineurin inhibitors	<i>P. jirovecii</i> , VZV	Defective T-cell immunity
Radiation therapy	Local and systemic bacterial infections, mucosal candidiasis and HSV infection	Damages mucosal surfaces, marrow suppression

CMV, cytomegalovirus; VZV, varicella-zoster virus; NK, natural killer; GVHD, graft-versus-host disease; HSV, herpes simplex virus.

the commensal flora of the gastrointestinal tract. Fungal infections may be related to prior colonization in the case of *Candida* (skin or gastrointestinal flora) or inhalation in the case of molds. Risk of fungal diseases increases with the duration of neutropenia. Aspergillosis is uncommon during neutropenic periods of <10 days, but its incidence increases in direct proportion to the length of neutropenia after 14 days.⁵

Hematopoietic Stem Cell Transplantation

Autologous and allogeneic hematopoietic stem cell transplantation (HSCT) present different infectious disease problems. Autologous transplant may be considered a form of intensive chemotherapy. As such, it is typically associated with a few days or weeks of neutropenia and mucositis, followed by a few weeks or months of defective T-cell-mediated immunity. The duration of the defect in T-cell immunity varies depending on the type of cancer (longer in hematologic malignancies), the manipulation of the stem cells preinfusion (longer with T-cell depletion), and the age of the recipients (shorter immunodeficiency in children). Autologous transplants have fewer infections than allogeneic transplants, but T-cell depletion results in risk for cytomegalovirus (CMV) and other opportunistic infections similar to allogeneic HSCT recipients.⁶

Allogeneic transplant is a more complex procedure. The character and duration of increased risk for infection varies with conditioning, human leukocyte antigen (HLA) matching, source and dose of transplanted cells, and GVHD prophylaxis. Infections after HSCT tend to follow a timeline associated with different predominant immune defects: neutropenia early on, then GVHD disease and its treatment. Active GVHD requires treatment with corticosteroids and other immunosuppressive agents and is associated with increased risk of infection.⁷ The specific role of CMV reactivation (which often accompanies GVHD) is also important, not only as a potential disease process, but as a predisposition to bacterial and fungal infections.⁸ Defects in cell-mediated immunity persist for several months even in uncomplicated allogeneic HSCT recipients, predisposing to opportunistic infections. Allografts from alternative donors (e.g., HLA-matched unrelated donors, haploidentical family donors, umbilical cord blood) may result in higher risk of infection due to higher risk of GVHD, decreased T-cell function, and delayed immune reconstitution.⁹ Recommendations for monitoring and prophylaxis are outlined in Table 132.2.

Immunomodulatory Agents and Infectious Risk

Corticosteroids

High-dose corticosteroids have profound effects on the distribution and function of neutrophils, monocytes, and lymphocytes. Corticosteroids blunt fever and local signs of infection. Patients treated with corticosteroids have impaired phagocytic function (increasing risk of bacterial and fungal infections) and cell-mediated immunity (increasing risk of infections like herpes zoster and *Pneumocystis jirovecii*). The incidence of infectious complications increases when the adult equivalent of prednisone 20 mg per day is administered for longer than 4 to 6 weeks.¹⁰

Fludarabine

Fludarabine is a lymphotoxic analogue of adenine, primarily affecting CD4+ lymphocytes. The combination of fludarabine and corticosteroids results in a uniform depression of CD4+ cells that may persist for several months after completion of therapy, resulting in opportunistic infections like *P. jirovecii* pneumonia (PCP) or listeriosis, sometimes more than a year after treatment. Mycobacterial and herpes virus infections have also been described.

Interleukin-2

Patients receiving high dose interleukin (IL)-2 for malignancy have an increased risk of bacterial infections, mainly *S. aureus* and coagulase-negative staphylococci, possibly related to indwelling catheters. High-dose, continuous infusion IL-2 causes a profound but reversible defect in neutrophil chemotaxis that may account for the increased frequency of infections. Prophylactic oxacillin led to a reduction in central venous catheter-associated staphylococcal bacteremia in IL-2 recipients in one randomized trial.¹¹

Monoclonal Antibodies

Monoclonal antibodies (mAb) that target specific cellular steps or factors have made it possible to manipulate disease pathways in such a way that it has been possible to use “targeted” cancer therapies with astonishing clinical responses.¹² However, many of these agents interfere with natural immunity and have therefore increased rates of both common and uncommon infections.¹³ As with many other immunosuppressive drugs, establishing causality is a challenge; only those associated with a probable increase in the risk of infection are described in the following (see Table 132.1).

Rituximab and Ofatumumab. There are now multiple anti-CD20 mAbs available for clinical use. Those approved in oncology are rituximab, a chimeric murine-human mAb that targets CD20 on mature B-lymphocytes, and ofatumumab, an entirely human mAb that targets different CD20 epitopes. Most evidence regarding infectious complications refer to rituximab, but it is likely that similar risks will apply to the newer anti-CD20 mAbs. These agents are used against a variety of B-cell malignancies, as preemptive treatment of EBV-associated lymphoproliferative disorder and also as immunomodulating drugs in the treatment of GVHD.

Rituximab results in rapid and profound depletion of B cells that can last up to several months. In most patients, serum Ig levels remain largely stable, as plasma cells do not express CD20. Some patients, however, develop persistent hypogammaglobulinemia, although its contribution to infection risk is unclear.¹⁴ Initial trials suggested that rituximab had minimal effect on the occurrence of infections; however, more recent meta-analyses have reported a higher relative risk of infections. The increase in the risk infection seems to be more prominent in the setting of repeated administration and in patients with underlying immune defects or concomitant significant immunosuppression.¹⁵ Hepatitis B virus (HBV) reactivation has been consistently associated with rituximab treatment, including reports of fulminant hepatitis and death in patients who experience hepatitis B flare, particularly when used in combination therapy (e.g., rituximab plus cyclophosphamide, doxorubicin, vincristine and prednisone [R-CHOP]). Also a reverse seroconversion phenomenon has been described, with loss of protective HBV surface antibodies and reactivation.¹⁶ Most reactivation occurs within 6 months of therapy, but there are cases up to a year after treatment. The US Food and Drug Administration (FDA) has issued a black-box warning regarding hepatitis B reactivation and rituximab and ofatumumab (<http://www.fda.gov/Drugs/DrugSafety/ucm366406.htm>). It is recommended to assess the HBV status in *all* patients before rituximab or ofatumumab by hepatitis B surface antigen and hepatitis B core antibody and consider pharmacologic suppression of HBV with lamivudine or lamivudine and tenofovir, and follow all patients for signs of hepatitis B while they are receiving either drug and for several months thereafter, as reactivation has been described well after completion of therapy. Periodic determination of hepatitis B DNA while on treatment should be considered.

Another opportunistic infection reported with both rituximab and ofatumumab is progressive multifocal leukoencephalopathy (PML), also called JC encephalopathy. This is a demyelinating disease caused by JC virus, a ubiquitous virus that is acquired during infancy by most people. Since the initial approval of rituximab, there have been close to 100 cases of PML associated with its use.¹⁷

TABLE 132.2

Prophylaxis of Infections in Cancer Patients

Intervention	Indication	Agent	Comments
PROPHYLAXIS FOR BACTERIAL INFECTIONS			
Prophylaxis for neutropenia	Patients who are expected to be neutropenic for >7 d	Levofloxacin 500 mg orally daily	Start the first day of ANC <1,000 and continue until resolution of neutropenia.
		TMP/SMX may be used	Other agents have been used, but there is less experience.
Prophylaxis for <i>Streptococcus pneumoniae</i>	Patients splenectomized	Penicillin V-K, 500 mg orally bid	Patient education related to early recognition of signs and symptoms of infection is imperative; consider having the patient keep systemic antibiotics (e.g., levofloxacin) at home for an emergency.
	Splenic irradiation		
	Chronic GVHD	In penicillin-allergic: TMP/SMX 1 DS tablet daily or azithromycin 250 mg/d	
PROPHYLAXIS FOR FUNGAL INFECTIONS			
Antifungal prophylaxis	Induction therapy for AML and MDS	Posaconazole 200 mg orally tid is drug of choice. In patients unable to take oral medications or who are intolerant to posaconazole, alternatives include itraconazole, voriconazole, lipid formulation of amphotericin B, or an echinocandin.	Posaconazole was superior to fluconazole/itraconazole in a randomized controlled trial, but the risk of aspergillosis in this setting is variable and some institutions may choose to use fluconazole prophylaxis if their incidence of aspergillosis is low. If fluconazole prophylaxis is used, serial monitoring with serum galactomannan and/or β -D-glucan should be considered. Begin with initiation of chemotherapy and continue until resolution of neutropenia.
	Acute lymphoblastic leukemia receiving vinca alkaloid-containing regimen	Fluconazole ^a or an echinocandin	Mold-active azoles are potent inhibitors of cytochrome P-450 isoenzymes, and are expected to interfere with metabolism of vinca alkaloids. Continue prophylaxis for duration of neutropenia.
	Autologous HSCT recipient during neutropenia	Fluconazole ^a or echinocandin	Continue prophylaxis for duration of neutropenia. Consider no antifungal prophylaxis if regimen does not have significant mucosal toxicity.
	Allogeneic HSCT recipient during neutropenia	Fluconazole, a1 itraconazole, voriconazole, and micafungin have each been evaluated in this setting and are acceptable options. Posaconazole has not been evaluated in this setting, but is reasonable.	Continue prophylaxis for duration of neutropenia.
	Allogeneic HSCT with significant GVHD receiving intensive immunosuppressive therapy ^b	Posaconazole 200 mg orally tid is drug of choice. Alternatives include voriconazole, itraconazole, lipid formulation of amphotericin B, or an echinocandin.	Continue prophylaxis for 16 wk and for at least the duration of intensive immunosuppressive therapy, ^b whichever occurs later.
	Prophylaxis against <i>Pneumocystis jirovecii</i>	Allogeneic HSCT recipients Alemtuzumab recipients Fludarabine recipients	TMP/SMX 1 DS (TMP 160 mg + SMX 800 mg) orally daily or 3 d/wk OR dapsone 100 mg orally daily OR inhaled pentamidine 300 mg every 4 wk OR atovaquone 1,500 mg/d.
Patients with gliomas receiving temozolomide and radiation or corticosteroids (≥ 20 mg of prednisone equivalent) for ≥ 1 mo in the presence of other immunosuppression or myelotoxic chemotherapy			In allo-HSCT, continue prophylaxis for 2 mo after stopping immunosuppression. In patients treated with alemtuzumab, continue prophylaxis for 2 mo after the last dose or until the CD4 count is >200, whichever occurs later.

(continued)

TABLE 132.2

Prophylaxis of Infections in Cancer Patients (continued)

Intervention	Indication	Agent	Comments
PROPHYLAXIS FOR VIRAL INFECTIONS			
Prophylaxis for HSV	HSCT recipients (HSV-seropositive recipients) Induction chemotherapy for acute leukemia (HSV-seropositive)	Acyclovir 400 mg orally bid or tid OR 800 mg orally bid OR 250 mg/m ² /12 h or valacyclovir 500 mg orally once or twice (higher doses have been used up to 1,000 mg tid) or famciclovir 250 mg orally tid.	In patients with acute leukemia and HSCT recipients, continue prophylaxis for HSV until resolution of neutropenia and mucositis.
	Consider in patients with recurrent HSV reactivation following chemotherapy, or patients receiving fludarabine and corticosteroids		In patients treated with alemtuzumab, continue prophylaxis for 2 mo after the last dose or until the CD4 count is >200, whichever occurs later.
	Patients treated with alemtuzumab		
Prophylaxis for VZV	Allogeneic HSCT recipients with a history of chicken pox or shingles	Acyclovir 800 mg orally bid OR valacyclovir 500 mg orally daily	
Prophylaxis for CMV (preemptive therapy)	Patients requiring CMV surveillance (1) Allogeneic HSCT recipients who are CMV+ or whose donor is CMV+ (standard of care) (2) Autologous SCT recipients receiving a CD34-enriched autograft (should be considered) (3) Patients treated with alemtuzumab (should be considered)	Induction for 1 wk followed by maintenance for 1 wk as follows: Ganciclovir 5 mg/kg IV q 12 h for 7 d (induction), followed by ganciclovir 5 mg/kg IV daily 5 times a wk (maintenance) OR foscarnet ^a 60 mg/kg IV q 12 h times 7 d (induction) followed by foscarnet ^c 60 mg/kg IV daily (maintenance) Oral valganciclovir (900 mg bid) is an acceptable alternative to IV formulations in patients who do not have severe gut GVHD (see text).	Time for CMV surveillance: (1) Allogeneic HSCT recipients: from day 30 to at least 6 mo after allogeneic HSCT, during periods of GVHD, and until the CD4+ count is >100 mcL. (2) Recipients of CD34-enriched autologous grafts: from day 30 to day 100 and until the CD4+ count is >100 mcL. (3) Alemtuzumab recipients: from the time of initiation until at least 2 mo after completion of therapy and until the CD4 count is >100 mcL, whichever occurs later.
			The level of CMV reactivation that triggers preemptive therapy varies with the method. The CDC recommends any positive CMV antigenemia (pp65) or two consecutive qualitative PCR results within the first 100 d, and five cells per slide after the first 100 d. Some institutions initiate preemptive CMV therapy with any positive antigenemia result as late CMV disease is well established (see text).
			Institutions with quantitative PCR systems must establish their own standards, as the results are quite variable depending on the methodology.
Prophylaxis against CMV		Ganciclovir or foscarnet at the same dose as in preemptive regimen.	Treatment is given for the first 100 d, then weekly or biweekly monitoring and preemptive management is initiated.
			Prophylaxis with ganciclovir is seldom used. The authors recommend preemptive therapy as described.
Prophylaxis against hepatitis B flare	Patients who are HBsAg+ or have detectable HBV DNA in the blood at high risk who are about to receive chemotherapy and are at high risk for hepatitis B reactivation	Lamivudine 100 mg/d	Start 7 d before chemotherapy and continue for 8 wk after completing chemotherapy.

(continued)

TABLE 132.2

Prophylaxis of Infections in Cancer Patients (continued)

Intervention	Indication	Agent	Comments
			Not all cancer treatments are associated with the same risk; lymphoma therapy seems to be the highest risk.
	Patients who are HBsAg+ or have detectable HBV DNA in the blood who are about to receive hematopoietic stem cell transplant	Lamivudine 100 mg/d starting 2–3 wks pretransplant and restart 2 wks posttransplant.	If the transplant may be delayed, start lamivudine and vaccinate the donor so anti-HBV immunity will be transplanted. It is not known how long to continue lamivudine.

ANC, absolute neutrophil count; TMP/SMX, trimethoprim/sulfamethoxazole; bid, twice daily; GVHD, graft-versus-host disease; DS, double strength; AML, acute myelogenous leukemia; MDS, myelodysplastic syndrome; tid, three times a day; HSCT, hematopoietic stem cell transplant; HSV, herpes simplex virus; VZV, varicella-zoster virus; SCT, stem cell transplant; CMV, cytomegalovirus; IV, intravenous; CDC, Centers for Disease Control and Prevention; PCR, polymerase chain reaction; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus.

^a Fluconazole is effective as prophylaxis against candidal, but not mold, infections. If prophylactic fluconazole is used in patients with prolonged neutropenia, the authors suggest a strategy of empirical modification to a mold-active drug in patients with persistent neutropenic fever (see text). The benefit versus risk of surveillance laboratory markers for invasive fungal infection (e.g., serum galactomannan or β -glucan) coupled with preemptive antifungal therapy remains to be established (see text).

^b In the pivotal randomized prophylactic trial by Ullmann et al.,⁵³ eligibility criteria required either acute grade II to IV GVHD, or chronic extensive GVHD, or treatment with intensive immunosuppressive therapy consisting of either high-dose corticosteroids (1 mg/kg of body weight per day for patients with acute GVHD or 0.8 mg/kg every other day for patients with chronic GVHD), antithymocyte globulin, or a combination of two or more immunosuppressive agents or types of treatment.

^c Doses apply to adults with normal renal function.

Most cases have been reported in patients with hematologic malignancies; the role of rituximab in the development of PML is not well understood. A few reports of PCP following the administration of rituximab are far from conclusive, given that most patients had received other immunosuppressive therapies. It is unclear whether PCP prophylaxis should be recommended.¹⁸ Other rare infections that have been described in the setting of rituximab use are enteroviral meningoencephalitis, CMV disease, disseminated varicella zoster virus (VZV), refractory babesiosis, parvovirus B19, and nocardiosis.

Alemtuzumab. Alemtuzumab (Campath-1H) is a humanized mAb that targets and lyses cells expressing CD52, a glycoprotein abundantly expressed on most B- and T-lymphocytes, macrophages, and natural killer cells. This results in profound and sustained deficits in cellular and humoral immunity. CD4 and CD8 cell count nadir within weeks and may remain at <25% of baseline for approximately 9 months. Alemtuzumab is increasingly used for a variety of hematologic malignancies. Infections associated with its use include reactivation of latent viruses (herpesvirus like CMV, EBV, VZV, and human herpesvirus [HHV]-6, as well as adenovirus and JC virus), fungal infections (PCP, cryptococcosis, disseminated histoplasmosis, aspergillosis, mucormycosis), and mycobacterial infections (both tuberculosis [TB] and nontuberculous mycobacteria).¹⁹ The incidence of these opportunistic infections varies with the dose and combination with other immunosuppressants. All patients receiving alemtuzumab should receive PCP and herpesvirus prophylaxis for a minimum of 2 months after therapy or until CD4 counts are ≥ 200 cells/ μ l (Campath package insert). Given the high incidence of CMV reactivation and disease, prophylaxis or preemptive therapy is warranted.

Daclizumab and Basiliximab. Daclizumab and basiliximab are humanized and chimeric mAbs, respectively, that target CD25, the α chain of the IL-2 receptor complex expressed on activated T-lymphocytes. They competitively inhibit IL-2 binding and prevent IL-2-mediated activation of lymphocytes and cytokine release. In hematology/oncology, they are used for steroid-refractory GVHD after allo-HSCT.²⁰ Infections described in this setting are common bacterial infections, viral reactivations (CMV, BK virus, adenovirus, HSV, RSV, influenza), EBV-associated posttransplant lymphoproliferative disease (PTLD), invasive fungal infections, as

well as legionella, nocardia, nontuberculous mycobacteria, TB, and toxoplasmosis.²¹ The specific contribution of daclizumab to the infectious risk is impossible to quantify.

Tumor Necrosis Factor- α Inhibitors: Adalimumab, Infliximab, Etanercept, Certolizumab Pegol, and Golimumab

Infliximab, adalimumab, and golimumab are mAbs directed against interferon- α ; certolizumab pegol is a pegylated Fab fragment of a humanized anti-tumor necrosis factor (TNF)- α mAb; and etanercept is a soluble receptor for TNF- α .¹³ These agents are potent immunosuppressants, but their use in oncology is very limited, mainly GVHD. TNF- α is a cytokine that plays a central role in macrophage and phagosome activation and granuloma formation and maintenance. TNF- α blockade results in increased risk of infection, particularly granulomatous infections such as TB and histoplasmosis, but also multiple others.^{22,23} The risk of serious infections appears to be lower with etanercept, than with the other TNF- α blockers. Several cases of severe HBV reactivation in patients with positive surface antigen at the start of treatment have been reported. Patients receiving anti-TNF- α therapy should be screened for TB (latent or active), HBV, and hepatitis C virus before starting treatment.²⁴

Cetuximab. Cetuximab is chimeric human-murine IgG1 that targets epidermal growth factor receptor. It is used in the treatment of epidermal growth factor receptor-expressing metastatic colorectal cancer and in advanced or metastatic squamous cell carcinoma of the head and neck. Its use has been associated with slight increase in the risk of serious bacterial infections, mainly pneumonia.²⁵ There is one case report of a disseminated *Mycobacterium chelonae* infection.²⁶

Brentuximab Vedotin. Brentuximab vedotin is an antibody-drug conjugate consisting of a chimeric IgG1 antibody that targets CD30 and the microtubule-disrupting agent monomethyl auristatin E. Brentuximab vedotin results in death of CD30+ cells. It is approved for use in relapsed Hodgkin lymphoma and relapsed systemic anaplastic large cell lymphoma.²⁷ Its use has been associated with a high frequency of upper respiratory tract infections. More relevant has been the reports of some cases of PML.^{28,29}

Bevacizumab. Bevacizumab, an inhibitor of vascular endothelial growth factor, widely used for the treatment of metastatic colon cancer, non-small-cell lung cancer, and other tumors, has been associated with increased risk of gastrointestinal perforation.³⁰ Anecdotal reports of localized aspergillosis and fusariosis could be related to the potential for reduced angiogenesis to contribute to the pathogenesis of invasive mold infections.^{31,32}

PREVENTION OF INFECTIONS

Infections may be prevented by avoidance of exposure, immunization, and chemoprophylaxis. A comprehensive guideline cosponsored by the Center for International Blood and Marrow Research, the National Marrow Donor program, the European Blood and Marrow Transplant Group, the American Society for Blood and Marrow Transplantation, the Canadian Blood and Marrow Transplant Group, the Infectious Diseases Society of America (IDSA), the Society for Healthcare Epidemiology of America, the Association of Medical Microbiology and Infectious Disease Canada, and the CDC makes evidence-based recommendations for HSCT that may be applicable to other cancer patients.³³ The National Comprehensive Cancer Network publishes and continuously updates broad guidelines for prophylaxis.^{34,35} A summary is provided in Table 132.2.

In general, antimicrobial prophylaxis reduces the number of episodes of the targeted infection. The question frequently is whether this reduction translates into a survival benefit or a clinically meaningful outcome (e.g., sepsis, hospital admission, shortened hospitalization) that outweighs the toxicities or secondary effects (e.g., generation and spreading of resistant organisms). The number of subjects that need to be treated to prevent one episode of infection and the severity of the infection should be considered.

Prevention of Bacterial Infections

Antibacterial Prophylaxis in Afebrile Neutropenic Patients

Several meta-analyses support a beneficial effect in fever, documented infections, and overall mortality by administering fluoroquinolone prophylaxis to patients who are neutropenic for ≥ 7 days.³⁶⁻³⁹ In high-risk neutropenic patients, prophylactic levofloxacin led to a reduction in infections.⁴⁰ In lower-risk neutropenic patients (e.g., those with solid tumors and short-duration neutropenia), prophylaxis showed a modest but significant reduction in febrile episodes.⁴¹ The potential risks of quinolone prophylaxis regarding selection for resistant organisms and *Clostridium difficile* colitis are important questions that have made some experts stay away from recommending levofloxacin prophylaxis except in special circumstances,⁴² but the most recent American Society of Clinical Oncology guidelines still endorse their use when neutropenia is expected to last 7 days or more.⁴³

Prophylaxis against Pneumococcal Infection

Pneumococcal prophylaxis should be considered in asplenic patients and in allogeneic HSCT recipients with chronic GVHD. The Working Party of the British Committee for Standards in Haematology recommend lifelong prophylactic antibiotics in patients who have had a splenectomy, and particularly in the first 2 years, in children up to age 16, and in patients with other immune impairment.⁴⁴ Among allogeneic HSCT recipients, pneumococcal disease typically occurs in the later transplant period, from 3 months to years after transplant. Chronic GVHD is the major risk factor. Vaccination is recommended as in asplenic patients. Penicillin prophylaxis is also recommended.³³ Some experts recommend starting penicillin prophylaxis in all HSCT recipients 3 months after transplant, whereas others reserve it for patients with active

chronic GVHD. Alternative agents may be considered based on local susceptibility patterns, although the risk/benefit ratio is not well defined.

Prevention of Fungal Infections

Candida spp. and molds are the major fungal pathogens in patients with cancer. Systemic antifungal prophylaxis may be mold-active (voriconazole, posaconazole, echinocandins, amphotericin B) or not (fluconazole). *Candida* spp. are part of our endogenous flora; the major risk factors for candidemia in patients with cancer are chemotherapy-related mucositis and central venous catheters. Patients who have undergone gastrointestinal surgeries complicated by anastomotic leaks, total parenteral nutrition, and prolonged admission in the intensive care unit are also risk factors for invasive candidiasis. In contrast, the risk of invasive mold infections is principally related to the duration of neutropenia, and, in allogeneic HSCT recipients, amount and duration of corticosteroids used to treat GVHD. The most common mold infections are aspergillosis and mucormycosis, but multiple opportunistic molds can infect neutropenic cancer patients (*Fusarium*, *Paecilomyces*, dematiaceous molds).

Antifungal prophylaxis should be risk-based: different patient groups are at risk for different pathogens, and these should be targeted accordingly.⁴⁵ Most cancer patients do not require antifungal prophylaxis. Prolonged neutropenia increases the risk of candidiasis, and this is prevented by the use of fluconazole 400 mg/day^{46,47} (which may result in colonization by azole-resistant *Candida* strains).⁴⁸ Itraconazole has similar efficacy and may reduce the risk of aspergillosis, but is poorly tolerated and has higher toxicity and worse drug interactions.^{49,50} Micafungin, an echinocandin with activity against *Candida* and *Aspergillus*, was as effective as fluconazole in preventing candidiasis and showed a favorable trend to prevent aspergillosis in a randomized, double-blinded study in HSCT recipients.⁵¹ Prevention of aspergillosis has been shown most convincingly with posaconazole, with a survival benefit demonstrated in neutropenic patients⁵² and decreased incidence of aspergillosis in transplant patients with GVHD.⁵³ A randomized trial comparing voriconazole and fluconazole prophylaxis in allogeneic HSCT recipients showed a trend toward reduction of aspergillosis cases in voriconazole recipients, but no difference in overall or fungal infection-free survival.⁵⁴ A systematic review and meta-analysis suggests that, overall, mold-active prophylaxis significantly reduces invasive aspergillosis (IA) and invasive fungal infection (IFI)-related mortality, but does not affect overall mortality and has more adverse effects than fluconazole.⁵⁵

In summary, fluconazole is a safe and well-studied agent to prevent invasive candidiasis, but it has no activity against molds. When the risk of aspergillosis is significant, a mold-active drug should be considered, but different institutions may choose different agents.⁵⁶ The mold-active azoles (i.e., itraconazole, voriconazole, posaconazole) are potent inhibitors of certain cytochrome P-450 isoenzymes to a greater degree than fluconazole. This may lead to reduced clearance of other drugs, such as calcineurin inhibitors, cyclophosphamide metabolites,⁵⁷ and vinca alkaloids with potentially serious adverse effects.⁵⁸ Careful monitoring of drug-drug interactions and appropriate dose modifications are required.

Prevention of *Pneumocystis jirovecii* Pneumonia

Defective T-cell immunity is the principal risk factor for PCP. Recommendations for prophylaxis in the non-AIDS setting are based on the expected level of risk of PCP and consensus criteria rather than on randomized clinical trials. The traditional groups of cancer patients at risk have been acute lymphocytic leukemia and allogeneic HSCT. After allo-HSCT, prophylaxis is recommended

until at least day 180 after transplant, and longer if immunosuppressive agents are continued.⁵⁹ PCP prophylaxis should be considered in patients with cancer who receive prolonged high-dose steroids (i.e., equivalent of prednisone 20 mg daily for ≥ 1 month). Other candidates for prophylaxis include alemtuzumab recipients (package insert recommends prophylaxis until at least 2 months after completion of alemtuzumab and CD4 count $\geq 200/\text{mL}$, whichever occurs later), patients with chronic lymphocytic leukemia receiving fludarabine, and patients with gliomas receiving temozolomide and radiation or corticosteroids.

The most effective agent is trimethoprim/sulfamethoxazole (TMP/SMX). A variety of dosages seem to be effective (from one double-strength tablet daily, to one double-strength tablet twice daily 2 days per week). When TMP/SMX cannot be administered because of marrow intolerance or hypersensitivity reaction, second-line agents include dapsone (50 mg twice daily or 100 mg orally daily), inhaled pentamidine (300 mg every 4 weeks), and atovaquone (1,500 mg daily) (see Table 132.2). All second-line agents are less effective than TMP/SMX, with the difference increasing with the degree of immune compromise.

Prophylaxis of Viral Infections

Prevention of Herpes Simplex Virus and Varicella Zoster Virus

Among seropositive patients, the incidence of herpes simplex virus (HSV) reactivation following induction chemotherapy for leukemia or conditioning for HSCT is 70% to 80%. HSV and VZV infections are common after alemtuzumab, bortezomib,⁶⁰ and lenolidomide.⁶¹ Antiviral prophylaxis (acyclovir, valacyclovir, or famciclovir) against HSV is advised in patients receiving chemotherapy for acute leukemia, in all HSV-seropositive allogeneic HSCT recipients, and in some autologous HSCT recipients at high risk for mucositis during the neutropenic period. Prophylaxis is recommended until mucositis resolves and engraftment takes place.³⁴ It is also advised in myeloma patients treated with bortezomib or lenolidomide.^{60,61} For alemtuzumab recipients, the package insert recommends at least 2 months after completion of therapy and CD4 count $\geq 200/\text{mL}$, whichever occurs later.

Nosocomial transmission of VZV is well documented. Patients with chickenpox, disseminated zoster, and immunocompromised patients with dermatomal zoster should be placed under contact and respiratory isolation. In the absence of varicella zoster immune globulin, oral acyclovir for 2 weeks after exposure has been used successfully for postexposure prophylaxis. The two available live attenuated varicella vaccines are Varivax (used to induce immunity in persons who have not been exposed to varicella; Merck, Inc., Whitehouse Station, NJ) and Zostavax (for older immunocompetent persons with prior exposure to varicella to augment immunity to prevent shingles; Merck, Inc.). Neither vaccine should be used in highly immunosuppressed persons because of the risk of viral disease. Household contacts of immunocompromised patients and health-care workers with no history of varicella and seronegative for VZV should receive the Varivax vaccine to prevent infection by wild-type varicella.³³ If a rash occurs following vaccination, direct contact with immunocompromised persons should be avoided.

Prevention of Cytomegalovirus Disease

CMV is a very important pathogen after allo-HSCT, but CMV disease is uncommon in other cancer patients. It has been reported mainly in patients receiving alemtuzumab (although asymptomatic reactivation without disease seems to be much more frequent) and occasionally in patients receiving therapy for acute leukemia. CMV infection happens early in life and results in viral latency. Most adults (60% to 80%) are infected, as proven by the detection of CMV-specific IgG in their serum. A transplant recipient is at risk for reactivation (if he or

she is CMV seropositive) or for primary infection (from the allograft if the donor is CMV seropositive) or from blood products.⁶²

Prevention of Cytomegalovirus Disease After Allogeneic Hematopoietic Stem Cell Transplantation

Prevention of Primary Cytomegalovirus Infection. To prevent CMV primary infection, CMV-seronegative HSCT recipients receiving allografts from CMV-seronegative donors should receive transfusion products from only CMV-negative donors or, if this is not feasible, leukocyte-depleted blood products.⁶³

Prevention of Cytomegalovirus Disease Following Reactivation. In case of preexisting CMV infection, CMV disease may be prevented by one of two approaches: prophylaxis or preemptive management. In prophylaxis, antiviral agents are administered for a variable period to all allogeneic HSCT recipients in which either the donor or recipient is CMV seropositive. In preemptive management, active surveillance of the patients at risk is followed by initiation of antiviral agents following detection of CMV reactivation.

Prophylaxis for Cytomegalovirus. Ganciclovir prophylaxis for CMV-seropositive allogeneic transplant recipients was highly effective at suppressing CMV during the early transplant period, but was associated with higher rates of neutropenia, bacterial and opportunistic infections, and late CMV disease, without improvement in overall survival.^{64,65}

Preemptive Therapy for Cytomegalovirus. CMV infection may be diagnosed early by detection of the CMV pp65 antigen in peripheral blood leukocytes or by measuring CMV DNA by polymerase chain reaction (PCR). A single positive CMV antigenemia or two consecutive positive PCR results are triggers for preemptive antiviral therapy. When compared in a randomized controlled trial, preemptive therapy and prophylaxis resulted in equivalent overall survival, but with different complications: universal prophylaxis had less early CMV disease but more invasive fungal infections, more ganciclovir use, and more late CMV disease. Preemptive therapy (using pp65 antigenemia) resulted in more CMV disease by day 100.⁶⁶ The preemptive approach is more commonly used. Foscarnet can also be used preemptively, with similar results but different toxicities (renal toxicity with foscarnet, myelosuppression with ganciclovir). Valganciclovir an orally administered prodrug of ganciclovir is another alternative, although it may result in increased exposure to ganciclovir and potentially more toxicity.⁶⁷ Similar CMV recommendations have been made for patients treated with alemtuzumab.³⁴

Prevention of Viral Hepatitis

Three etiologic agents of viral hepatitis are a matter of significant concern in cancer patients. Hepatitis B and C have special importance because of their etiologic role in hepatobiliary cancer and the enormous populations affected by with these viruses.

Hepatitis B

Carriers of HBV, even if they are asymptomatic or have undetectable HBV DNA levels, are at risk for hepatitis B flare after immunosuppressive therapy or cytotoxic chemotherapy, particularly with rituximab and high-dose corticosteroids. All patients should be screened for hepatitis B status before receiving cytotoxic chemotherapy by determining hepatitis B surface antigen (HBsAg) and anti-hepatitis B core antibody. Seronegative patients should be vaccinated if possible. HBsAg-positive patients, regardless of their HBV DNA level, should be treated with lamivudine or some other of the nucleoside/nucleotide analogues currently available during the duration of chemotherapy and for up to 12 months thereafter.⁶⁸ It is unclear what the duration and best method of monitoring are. Treatment of active hepatitis B during cytotoxic chemotherapy is

daunting and should be attempted in consultation with an expert in the use or combinations of these newer agents.

Hepatitis C

Chronic hepatitis C infection has a broad worldwide distribution and thus would be expected to occur at baseline in a substantial portion of the cancer patient population. There is little evidence to support concerns for recrudescence of latent disease in patients who are screened and not viremic at baseline, whether by natural evolution or as the result of therapy. The inflammatory disease associated with chronic hepatitis C is variable and has been associated with clinically relevant worsening, predominantly in patients with therapy for hematologic malignancy, but occasionally in solid tumor patients.^{69,70} As with hepatitis B, interferon-based therapy has prohibitive toxicities in this context, but the evolution of true antiviral agents may make consultation with an expert in the use of these drugs an important consideration.

Hepatitis E

Hepatitis E, a predominantly water-borne virus, has caused chronic infection in both solid and hematologic transplant patients. No specific antiviral therapies are available, but acquisition and recrudescence should be considered in patients receiving chemotherapy who develop new or worsening hepatic inflammation.⁷¹⁻⁷³

DIAGNOSIS AND MANAGEMENT OF INFECTIOUS DISEASES SYNDROMES

FEVER AND NEUTROPENIA

Fever is single oral $T \geq 38.3^{\circ}\text{C}$ or sustained $T \geq 38^{\circ}\text{C}$ for 1 hour.⁷⁴ Slightly different definitions may have been used in different trials over the years. Neutropenia is defined as an absolute neutrophil count (ANC) of <500 cells/ mm^3 or an ANC that is expected to decrease to <500 cells/ mm^3 during the next 48 hours.⁷⁴ In neutropenic patients, fever should be considered evidence of infection and treated accordingly.

Bacterial infections may progress quickly in the absence of granulocytes and appropriate antibiotics must be started immediately. Empirical administration of broad-spectrum antibiotics to neutropenic febrile patients showed early on to result in improved outcomes⁷⁵ and remains the standard of care. Numerous professional organizations have issued guidelines for the management of fever during neutropenia in adults and children, inpatient and outpatient.^{34,43,74,76,77} The initial evaluation consists of a complete history and physical examination. Important elements of the history include prior infections or known colonization with resistant pathogens, as well as timing of the fever in relation to manipulation of the central venous catheter if one is present. Special attention should be given to the mouth, skin, catheter exit site, and perianal region during the physical exam.

Initial laboratory studies should include complete blood count and differential, serum chemistry including liver function tests, and at least two sets of blood cultures. Other cultures (urine, sputum, stool if diarrhea) should not delay the administration of antibiotics. An initial chest radiograph in the absence of symptoms or signs of pulmonary infection is of low yield in ambulatory adult patients with fever and neutropenia.

Risk Stratification

One of the key current concepts in the management of neutropenic fever involves risk stratification: not all patients who develop fever during chemotherapy-induced neutropenia have the same risk of a poor outcome, and this has practical implications for management

(choice of antibiotics, inpatient versus outpatient setting). Most adult guidelines endorse the use of the Multinational Association for Supportive Care in Cancer (MASCC) index.⁷⁸ The pediatric guidelines support the concept of risk stratification, but emphasize the importance of using strategies that have been validated locally.⁷⁷ The MASCC index was designed as a tool to identify adult patients at low risk of complications.⁷⁸ To obtain a MASCC score, points are allocated and added up. Points are given for burden of illness (no or mild symptoms 5, severe symptoms 3), absence of hypotension (5), absence of chronic obstructive pulmonary disease (4), solid tumor OR no previous fungal infection (4), absence of dehydration (3), outpatient status (3) and age <60 years (2). The points are added up, and patients with a score of ≥ 21 points (of 26 possible) are “low risk” and can be considered for oral therapy. The index has been validated in multiple settings and performs well, although it may do so better in solid tumors than in hematologic malignancies.⁷⁹ The IDSA guidelines include “expert” clinical criteria derived from clinical trials: patients with neutropenia expected to last ≥ 7 days, clinically unstable or with significant comorbidities, or high intensity chemotherapy are all “high risk” and should be hospitalized for intravenous antibiotics.⁷⁴ Similarly, the American Society of Clinical Oncology guidelines present a list of conditions that makes the outpatients high-risk independently of their MASCC score.⁴³

For “low-risk” patients, it is still important to make sure they can tolerate oral agents and have adequate access to medical care before deciding to treat them as outpatients with oral antibiotics. The antibiotics used for adults have been ciprofloxacin + amoxicillin/clavulanic acid⁸⁰ and moxifloxacin monotherapy.⁸¹ Quinolones should not be used for treatment if patients were receiving them for prophylaxis. In penicillin-allergic patients, the combination of ciprofloxacin + clindamycin is recommended.⁴³

Neutropenic Fever Syndromes

The practical management of fever during neutropenia is easier if every episode is categorized as one of the following: first fever, persistent fever, recrudescence fever, and fever at the time of myeloid recovery.^{82,83} Although overlap may exist, these four syndromes represent useful clinical categories that should be managed differently.

First Episode of Fever

Most episodes of fever during neutropenia are supposed to be infectious in origin. Infection, however, is not always documented. The percentages are roughly as follows: fever of unknown origin, 50% to 60%; microbiologically documented infection (frequently bacteremia), 10% to 20%; and clinically documented infection (e.g., typhlitis or cellulitis without any pathogen being isolated), 20% to 30%.⁷⁴ The majority of documented infections during neutropenia are caused by the patient's own endogenous bacterial flora. In the absence of localizing symptoms, physical examination findings, or positive cultures, several antibiotic regimens may be used. For high-risk patients, most of the guidelines recommend to start monotherapy with a beta-lactam with activity against *Pseudomonas aeruginosa* (piperacillin-tazobactam, imipenem, meropenem, cefepime, ceftazidime),^{34,74,77} with the important caveat that some form of combination therapy should be chosen in patients who are clinically unstable and/or if there is suspicion (or high risk) of infection caused by resistant gram-negative (second gram-negative agent should be added) or gram-positive bacteria (vancomycin or linezolid should be added). The antipseudomonal beta-lactam of choice depends on local resistance patterns; meta-analyses suggest that, unless there is high prevalence of resistant bacteria that make its use unadvisable, piperacillin-tazobactam may offer the best combination of high efficacy and low toxicity.⁸⁴ The routine use of combination therapy (typically beta-lactam + aminoglycoside) was shown to be associated with higher toxicity and not superior outcome.^{85,86}

The so-called de-escalation approach suggests starting with broader coverage (based on local susceptibility patterns this may consist, for instance, of carbapenem + colistin \pm another agent) then de-escalate appropriately.⁷⁶ All the guidelines recommend not including vancomycin routinely in the initial regimen and not adding it empirically for persistent fever. The details regarding when to actually use vancomycin are more variable. The IDSA strongly recommends adding vancomycin in cases of hemodynamic instability, pneumonia, clinically evident catheter-related infection, severe mucositis, and known colonization with methicillin-resistant *S. aureus* (MRSA), although the quality of the evidence is low.⁷⁴ Our own approach is presented in Figure 132.1 and Table 132.3. Regarding the use of alternative agents for gram-positive bacteria, linezolid and vancomycin had similar efficacy in a randomized trial where there were no cases of vancomycin-resistant enterococci (VRE), but linezolid resulted in delayed neutrophil and platelet recovery.⁸⁷ Regardless of the initial regimen actually chosen, modifications may be required between 30% and 50% of the time, depending on clinical evolution and/or microbiologic results (see Table 132.3). If fever resolves following initiation of empirical therapy, the assumption is that an infection is responding to antibiotics. The standard recommendation is to continue antibiotics until resolution of neutropenia. If the neutropenia persists, older studies showed that 2 weeks may be adequate duration of treatment.⁸⁸ More recent data, mainly in children, suggest shorter duration of antibiotic treatment may be associated with similar outcomes as long as the antibiotics are restarted promptly if fever recurs, but it is important to pay attention to the patient population included in these trials.⁷⁶

Persistent Fever

The average time to defervescence in neutropenic fever is 4 days. Modifications of the antimicrobial regimen are not recommended during this period in the absence of new clinical or microbiologic findings. However, the persistence of fever beyond 4 days (96 hours) on broad-spectrum antibiotics identifies a population of patients with higher likelihood of IFI. The majority of persistently febrile neutropenic patients do not harbor an identifiable fungal infection, but several autopsy series in the 1970s documented occult fungal infection as a common cause of death in persistently febrile neutropenic patients.⁸⁹ Delay in initiating antifungal therapy was associated with treatment failure and death,⁹⁰ and empirical use of amphotericin B seemed to help.⁹¹ Two randomized trials established the benefit of adding amphotericin B (one after 7, the other after 4 days of persistent fever) compared with continuing the antibacterial regimen in terms of preventing fungal infection, although they were not powered to demonstrate a survival advantage.^{92,93} Of note, these studies were performed before there was systemic antifungal prophylaxis and identified *Candida* spp. as the principal fungal pathogen in this situation. Initiation of amphotericin B after 4 to 7 days of fever became standard of care, and most randomized controlled trials have focused on the choice of antifungal agent (liposomal amphotericin B,⁹⁴ voriconazole,⁹⁵ caspofungin^{96,97}). To reduce the perceived unnecessary use of empirical antifungal therapy with its attendant toxicity and cost, an alternative approach to empirical antifungal therapy has been proposed and called “preemptive antifungal therapy.”⁴⁵ The goal is to use the currently available diagnostic modalities (computed tomography [CT], serum galactomannan, and/or β -D-glucan) to postpone starting antifungal therapy until IFI is more likely. By design, this approach means that patients receiving “preemptive” antifungals are more likely to actually have an IFI than patients receiving “empirical” therapy by the time the antifungal agent is started.⁹⁸ The results of this approach are encouraging,⁹⁹⁻¹⁰¹ and it has been endorsed by the IDSA.⁷⁴ The details vary according to risk category of the patient, specific antifungal prophylaxis given, and diagnostic modalities available. The basic concept is that a persistently febrile neutropenic patient with no clinical findings, normal CT scans of chest and sinuses (where most mold infections

would start), and repeatedly negative fungal serologic markers (β -D-glucan and galactomannan) is unlikely to have an IFI, and antifungal coverage may be safely delayed. When these diagnostic options are not available, we support the addition of empirical antifungal therapy, typically caspofungin or liposomal amphotericin B, after 5 days of fever.⁹⁵

Recrudescent Fever

Recurrent fever refers to a new episode of fever that takes place after the initial episode has resolved with antimicrobial therapy when the patient remains neutropenic.⁸² This is a common occurrence in clinical practice in cases of prolonged neutropenia, and it has not been adequately studied. The one systematic investigation of this syndrome analyzed data on 836 neutropenic patients who had had a first fever that responded to antimicrobials and then had remained afebrile for 4 days.¹⁰² The important result of this analysis is that fungal infections were just as common as breakthrough bacterial infections, suggesting the appropriate management of this situation is to modify both the antibacterial and the antifungal part of the regimen, as well as perform a thorough diagnostic workup. Unfortunately, this scenario is not addressed separately from persistent fever in the guidelines.

Fever After Resolution of Neutropenia

In most cases, an undiagnosed fever that has persisted during neutropenia will resolve around the time of myeloid recovery. In a minority of patients, fever appears or worsens at this time. The three likely causes of this situation are superinfection, immune reconstitution syndrome,¹⁰³ and engraftment syndrome.¹⁰⁴ Other noninfectious causes should also be considered (e.g., drug fever, transfusion reactions, and deep venous thrombosis). A systematic, thorough diagnostic workup is more appropriate than empirical therapeutic modifications. Blood and urine cultures, complete blood cell count, serum chemistry, and liver enzyme levels should be obtained. An elevated alkaline phosphatase should prompt consideration of hepatosplenic candidiasis (which is uncommon in patients receiving yeast-active antifungal prophylaxis). A chest X-ray should be obtained. Pulmonary infiltrates identified after neutrophil recovery have a favorable prognosis and may be managed conservatively.¹⁰⁵ In contrast to the neutropenic period, empirical antibiotics can be discontinued after resolution of neutropenia in patients who are stable with fever without apparent source.

Fungal Infections in Patients with Cancer

Pathogenic fungi include yeasts and molds. *Candida* spp. are yeasts that form part of the normal flora; they gain access to the bloodstream through disruption of anatomic barriers (mucositis or indwelling catheters). Molds are ubiquitous soil inhabitants whose conidia or spores are inhaled on a regular basis. Aspergillosis is the most common mold infection in cancer patients, but other pathogenic fungi (*Mucor*, *Rhizopus*, *Fusarium*, and *Scedosporium* spp.) have become more common over the past 20 years. In-depth practice guidelines for the management of the different fungal diseases have been issued by the IDSA.^{106,107}

Candidiasis

Oropharyngeal and Esophageal Candidiasis. Cytotoxic chemotherapy, corticosteroids, and antibiotics predispose to oral candidiasis. The most common presentation is white adherent plaques on the palate, buccal mucosa, tongue, or gingiva. A wet mount or Gram stain showing pseudohyphae establishes the diagnosis. Therapy includes local treatments such as clotrimazole troches or oral fluconazole. Esophageal candidiasis causes odynophagia. The differential diagnosis includes HSV, CMV (principally in HSCT recipients), and bacteria. Initial therapy should

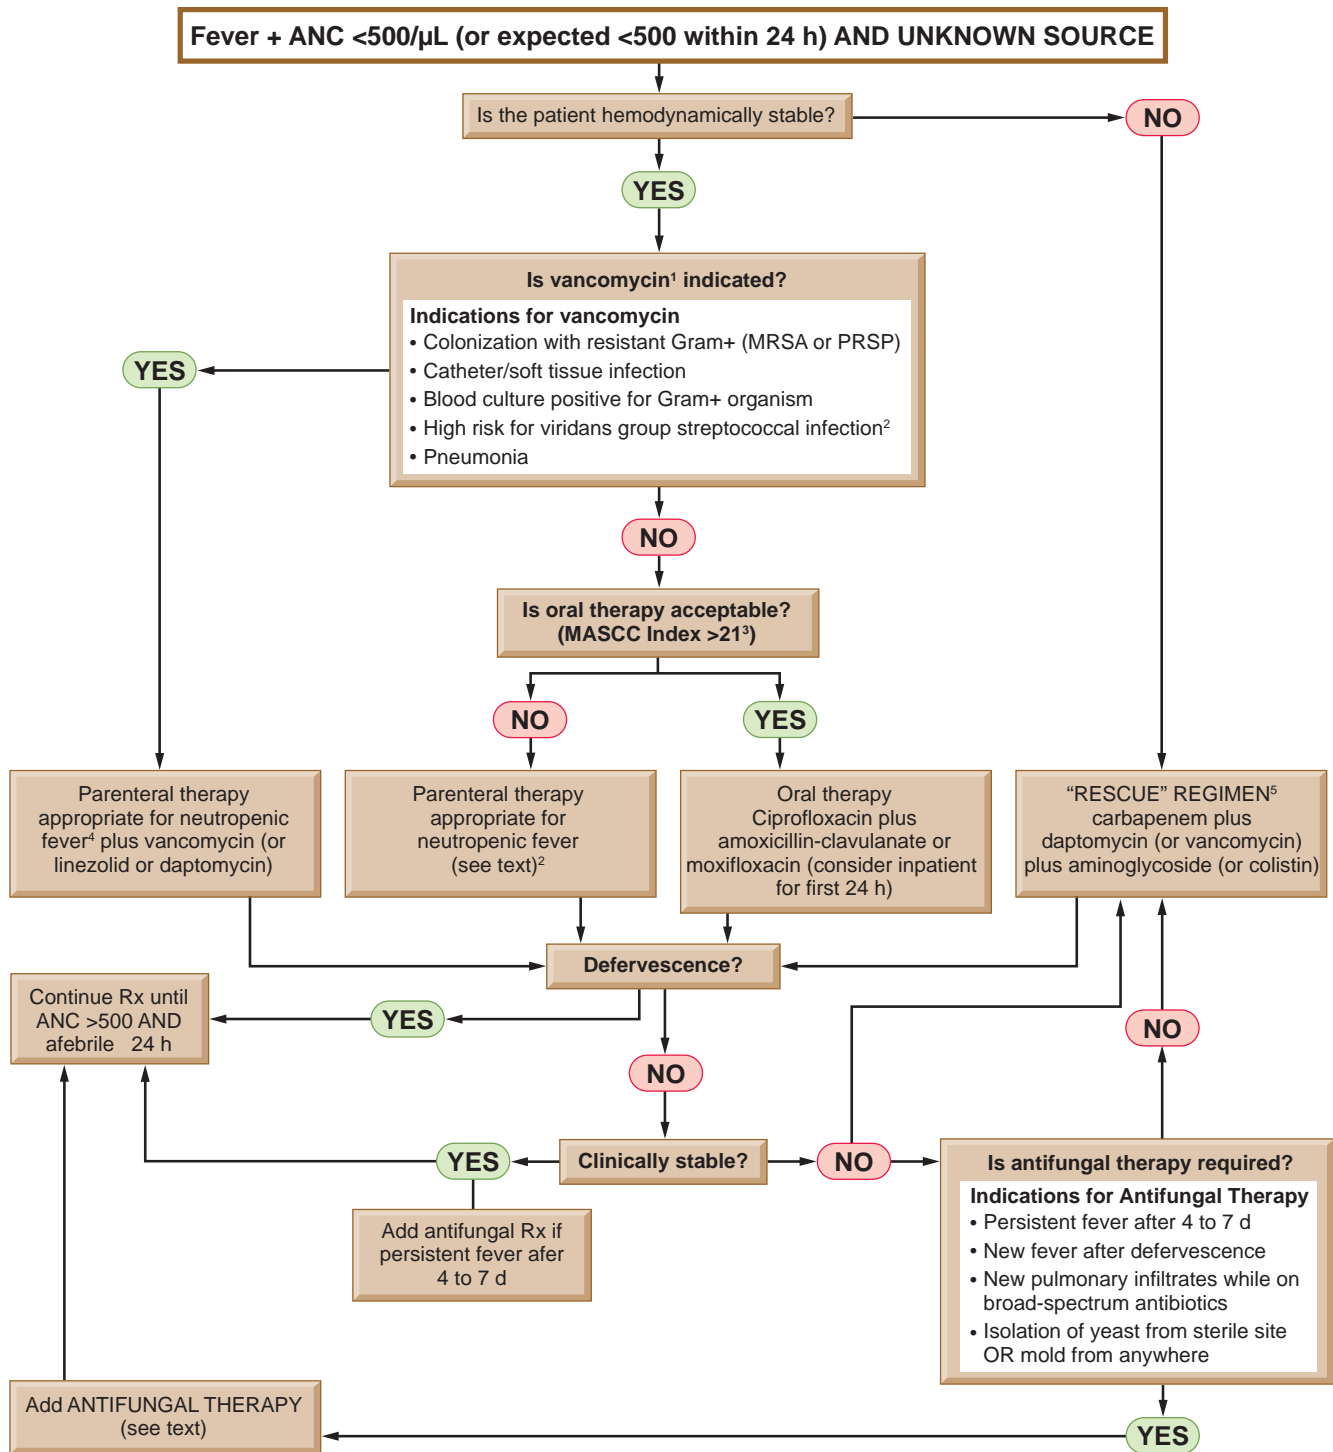

Figure 132.1 A general approach to patients with fever and neutropenia without a clinically or microbiologically documented infection. See text for more detailed descriptions. (1) Linezolid was comparable to vancomycin in this setting in a single randomized controlled trial. It may be considered instead of vancomycin for patients who are known carriers of vancomycin-resistant enterococcus, but experience is limited, and there are concerns about linezolid use (see text). (2) Some experts add vancomycin in patients with neutropenic fever at high risk for viridans streptococci (e.g., prior quinolone prophylaxis, severe mucositis associated with cytarabine-containing regimens); this must be weighed against the significant downside of selection for vancomycin-resistant pathogens. (3) Multinational Association for Supportive Care in Cancer (MASCC) index: burden of illness: no or mild symptoms, +5; moderate symptoms, +3; no hypotension, +5; no chronic obstructive pulmonary disease, +4; solid tumor or no previous fungal infection, +4; no dehydration, +3; outpatient status, +3; age <60 years, +2. A MASCC index of ≥ 21 has been associated with a relatively low frequency of severe complications. (4) See text for a detailed discussion. In a stable patient with undifferentiated neutropenic fever who does not require vancomycin, appropriate parenteral monotherapy consists of ceftazidime, cefepime, imipenem, meropenem, or piperacillin/tazobactam. For specific information on each of these agents, see text. (5) This "rescue" antibacterial regimen will vary between institutions depending on the local patterns of antibiotic resistance. Carbapenem (imipenem or meropenem) plus vancomycin plus an aminoglycoside is a reasonable initial regimen that should be tailored once culture results are known. A fluoroquinolone may be used instead of an aminoglycoside in patients with significant renal impairment in institutions where fluoroquinolones retain significant activity against the local gram-negative pathogens. In settings in which carbapenem-resistant *Acinetobacter* or carbapenemase-producing *Klebsiella* are prevalent, colistin or polymyxin B should be considered. ANC, absolute neutrophil count; MRSA, methicillin-resistant *Staphylococcus aureus*; PRSP, penicillin-resistant *Streptococcus pneumoniae*.

TABLE 132.3

Diagnostic Evaluation and Modifications of Therapy During Neutropenia

Findings	Evaluation and Modifications
Initial neutropenic fever	Take history, perform physical examination, and order appropriate cultures; initiate empirical antibiotic therapy promptly (see text and Fig. 132.1).
Persistent neutropenic fever (4–7 d)	Look for invasive fungal infection (chest CT recommended, serologic tests depending on the clinical setting). Add empirical antifungal therapy in patients not receiving mold-active prophylaxis. Options include amphotericin B deoxycholate (0.7 mg/kg/d), LAMB (3 mg/kg/d); voriconazole (IV 6 mg/kg q 12 h for two doses, followed by 3 mg/kg q 12 h; switch to oral 200 mg q 12 h may be considered); and caspofungin 70 mg × one dose, followed by 50 mg daily. Caspofungin is in general preferred over amphotericin B formulations based on similar efficacy and reduced toxicity compared with LAMB (see text).
Recurrent neutropenic fever without a source after initial response to empirical antibiotics	Signs of breakthrough sepsis (e.g., hypotension, rigors, tachypnea, decline in urine output) should prompt empirical modification of antibacterial regimen (see text), repeat blood cultures, and a chest radiograph. Consider modification of the antimicrobial regimen to include breakthrough bacterial and fungal infections while awaiting diagnostic results. Consider chest CT scan to evaluate for signs of mold infection. If a nodule or infiltrate is present, consider bronchoscopy or percutaneous biopsy depending on location. Galactomannan and β -d-glucan antigenemia assays should be considered in patients at high risk for invasive mold infections.
Persistent or recurrent fever without a source after ANC recovery	Infections are diagnosed infrequently. Consider chronic disseminated candidiasis (see text).
Positive culture from blood obtained before starting empirical antibiotics for neutropenic fever	
Gram-positive	Add vancomycin (or linezolid or daptomycin if VRE is prevalent or the patient is known to be colonized).
Gram-negative	If patient is stable, continue initial regimen. If patient is unstable, switch to imipenem, meropenem, or piperacillin-tazobactam and add an aminoglycoside or ciprofloxacin. The selection of antibiotics should be guided by local susceptibility patterns.
Positive blood culture while receiving antibacterial therapy	
Gram-positive	Add vancomycin (or linezolid or daptomycin if VRE is prevalent or the patient is known to be colonized).
Gram-negative	Suspect a pathogen resistant to initial empirical regimen. If ceftazidime was used initially, suspect extended-spectrum β -lactamase or cephalosporinase-producing organisms; switch to imipenem or meropenem and add an aminoglycoside. If a carbapenem was used initially, consider <i>Stenotrophomonas maltophilia</i> or resistant <i>Pseudomonas</i> spp.; switch to piperacillin-tazobactam plus an aminoglycoside plus trimethoprim-sulfamethoxazole. Modify regimen once identification and sensitivity are known.
Head and Neck Infection	
Necrotizing gingivitis	If ceftazidime or cefepime was used in initial regimen, change to imipenem, meropenem, or piperacillin-tazobactam, or add metronidazole for anaerobic coverage. Culture for HSV.
Oral ulcerative or vesicular lesions	Culture for HSV. For documented or suspected mucocutaneous HSV infection, acyclovir 5 mg/kg q 8 h.
Sinus tenderness	Suspect aerobic gram-negative rod (Enterobacteriaceae or <i>Pseudomonas aeruginosa</i>). Examine palate and nasal mucosa for signs of invasive infection. Perform sinus CT scan to evaluate extent of disease and to guide diagnostic and therapeutic drainage. With prolonged neutropenia or concomitant high-dose corticosteroids, invasive mold infections become more likely and initiation of empirical lipid formulation of amphotericin B (5 mg/kg/d) may be considered to cover both aspergillosis and zygomycosis.
Respiratory Tract	
Upper respiratory tract symptoms	Send nasopharyngeal washing for community respiratory viruses.
New infiltrate after resolution of neutropenia	May be inflammatory response to old infection. Conservative management results in good outcome: If the patient is asymptomatic, observe; if symptomatic and not responding to antibacterial agents, consider BAL. ^a

(continued)

TABLE 132.3

Diagnostic Evaluation and Modifications of Therapy During Neutropenia (continued)

Findings	Evaluation and Modifications
Respiratory Tract	
New infiltrate while neutropenic	Suspect resistant bacteria or mold infection. Perform chest CT scan to evaluate extent of disease and to detect other lesions. Perform sputum cultures and GM and BG antigenemia assay; if GM and BG assays are unavailable or nondiagnostic, bronchoscopy with BAL or percutaneous biopsy is warranted based on location of lesion. If pneumonia developed in hospital, broaden antibiotic regimen to cover nosocomial pathogens. Consider MRSA, resistant gram-negative pathogens, and nosocomial legionellosis. Consider empirical addition of voriconazole (IV 6 mg/kg q 12 h for two doses followed by 4 mg/kg q 12 h). Diffuse infiltrates raise concern for community respiratory viruses (particularly during winter), <i>Pneumocystis jirovecii</i> (in setting of concomitant corticosteroid therapy), bacterial pneumonia, CMV (in acute leukemia, may infrequently be associated with neutropenia), and noninfectious causes (e.g., hemorrhage, aspiration, drug toxicity, respiratory distress syndrome, congestive heart failure). BAL recommended.
Gastrointestinal Tract	
Retrosternal burning, odynophagia	Consider esophagitis. Suspect <i>Candida</i> or HSV esophagitis. Bacterial esophagitis and CMV (primarily in allogeneic HSCT recipients) also possible. Add fluconazole (400 mg oral or IV) and acyclovir (5 mg/kg q 8 h IV) empirically. If no response in 3 d, consider endoscopy.
Acute abdominal pain	Differential diagnosis includes same causes as in nonneutropenic patient (e.g., cholecystitis, appendicitis) plus typhlitis (neutropenic colitis). Ensure that antibiotic regimen has adequate anaerobic activity (e.g., imipenem, meropenem, or piperacillin-tazobactam). Provide bowel rest. Abdominal and pelvic CT scan. Monitor for need for surgical intervention (see text).
Perianal cellulitis	Consider pelvic CT scan to evaluate extent of disease. Monitor need for surgical drainage. Broaden antibiotic regimen to include anaerobic activity. Provide local care.
Central Venous Catheter (Surgically Implanted)	
Exit-site cellulitis	Add vancomycin.
Tunnel infection	Add vancomycin; remove catheter.
Collection around catheter	Incise and drain; if infected, add appropriate antibiotics and remove catheter.
Infection by molds and mycobacteria	May require excision of tunnel tract.
Catheter-associated bacteremia	Add appropriate antibiotics. Remove catheter for infection by <i>Staphylococcus aureus</i> , <i>Candida</i> spp., and mycobacteria (see text) and for antibiotic-resistant pathogens.

CT, computed tomography; LAMB, liposomal amphotericin B; IV, intravenous; ANC, absolute neutrophil count; VRE, vancomycin-resistant enterococcus; HSV, herpes simplex virus; BAL, bronchoalveolar lavage; GM, serum galactomannan; BG, β -glucan; MRSA, methicillin-resistant *Staphylococcus aureus*; CMV, cytomegalovirus; HSCT, hematopoietic stem cell transplant.

^aThe differential diagnosis of pneumonia in immunocompromised patients is broad, and the authors advise early BAL or percutaneous biopsy (depending on location of the lesion). Studies must be tailored to the individual patient. In highly immunocompromised patients, perform Gram staining; culture for bacteria, mycobacteria, fungi, *Nocardia* spp., *Legionella* spp., herpes viruses, CMV, and community respiratory viruses (particularly during winter); and cytologic analysis for *P. jirovecii*.

be with fluconazole. Options for fluconazole-resistant mucosal candidiasis include an echinocandin, voriconazole, posaconazole, or amphotericin B formulation.

Candidemia. *Candida* species are the fourth most common cause of nosocomial bloodstream infections in the United States. Clinical findings vary from asymptomatic to full-blown septic shock. The species should be identified. *Candida albicans* is the most common, and it is usually susceptible to fluconazole, but the proportion of nonalbicans *Candida* has been increasing. *Candida tropicalis* is highly virulent in neutropenic hosts but is susceptible to most agents. *Candida krusei* is always resistant to fluconazole, and *Candida glabrata* has variable susceptibility. *Candida parapsilosis* is mostly associated with vascular catheters and is usually susceptible to fluconazole but relatively resistant to echinocandins. A minority of *Candida lusitanae* and *Candida guilliermondii* isolates are resistant to amphotericin B.

It is recommended to remove all intravascular catheters in patients with candidemia.¹⁰⁶ In neutropenic patients, candidemia

may arise from defects in the gut mucosa rather than the catheter, so the need for catheter removal has been questioned.¹⁰⁸ In general, we remove the catheter where feasible, but sometimes attempt to conserve it when vascular access is limited and thrombocytopenia is present. We immediately remove all intravenous catheters in the setting of clinical instability, lack of resolution of fever within 2 to 3 days, or persistent candidemia after 2 days of appropriate antifungal therapy.

Chronic Disseminated Candidiasis. Chronic disseminated candidiasis (also called hepatosplenic candidiasis) is a complication of intensive chemotherapy regimens, such as those used as induction therapy for acute leukemia. The typical picture is persistent fever after neutrophil recovery with elevation of liver enzymes (particularly alkaline phosphatase). Numerous target lesions in the liver and spleen become apparent by CT scan, ultrasonography, or magnetic resonance imaging (MRI). A liver biopsy is required for a definitive diagnosis. Blood and biopsy cultures are almost always negative, but the pathology is diagnostic. We recommend

surgical liver biopsy when the diagnosis is in question. Chronic disseminated candidiasis that is controlled with antifungal therapy is not a contraindication to subsequent chemotherapy or HSCT.¹⁰⁹

Therapy for Invasive Candidiasis. An echinocandin (caspofungin, micafungin, or anidulafungin) or a lipid formulation of amphotericin B is recommended for candidemia in neutropenic patients.^{106,109} In patients receiving an azole who develop breakthrough candidemia, an echinocandin is advised. Azoles (generally, fluconazole) can be used as step-down oral agents or as initial therapy in certain patients at lower risk for mortality and serious complications. Voriconazole does not have a demonstrated advantage over fluconazole, but can be considered for treatment of *C. krusei* (which is intrinsically fluconazole-resistant) and when a mold-active agent is otherwise warranted (e.g., as prophylaxis in a high-risk patient). We reserve amphotericin B products for unusual complicated cases, such as meningitis and endocarditis, in which data to support optimal therapy are lacking. Some authorities still prefer a lipid formulation of amphotericin B in neutropenic patients, particularly in the presence of hemodynamic instability.

Invasive Aspergillosis

Risk Factors and Clinical Manifestations. Prolonged and persistent neutropenia is a critical risk factor for IA.⁵ Most cases, however, take place during episodes of active GVHD treated with high doses of corticosteroids. Other risk factors for aspergillosis after allogeneic HSCT include T-cell-depleted transplant, lymphopenia, CMV disease, and respiratory virus infections.^{110,111} Aspergillosis can involve virtually any organ in the immunocompromised host, but sinopulmonary disease is the most common. Angioinvasion of hyphae leading to vascular thrombosis and tissue infarction and coagulative necrosis is characteristic. Clinical manifestations are quite variable. During neutropenia, persistent fever, chest pain, and a pleural rub are common, although nonspecific, signs. When steroids are the only risk factor, the manifestations may be subtle, and sometimes a pulmonary infiltrate is found in the absence of symptoms.

Diagnosis of Invasive Aspergillosis. The most common finding on chest CT in early invasive pulmonary aspergillosis in patients with neutropenia and HSCT recipients is the presence of one or more well-circumscribed nodules. These may be inapparent on chest radiographs (Fig. 132.2). Other characteristic findings include the “halo sign,” a haziness surrounding a nodule or infiltrate representing alveolar hemorrhage, and the “crescent sign” (cavitation that usually coincides with neutrophil recovery). These signs reflect different stages of hemorrhagic infarction secondary to angioinvasive organisms. Sequential CT scans of neutropenic patients with IA demonstrated that halo signs were common at diagnosis but decreased during the first week of infection as the frequency of the “air crescent sign” increased. The median volume of lesions increased during the first week of therapy and remained stable during the second week.¹¹² Bronchoalveolar lavage (BAL) cultures have approximately 50% sensitivity in focal pulmonary lesions, and definitive diagnosis often requires an invasive procedure and is usually made only when the disease is advanced. The use of galactomannan antigen seems to be much more sensitive.^{113,114} Isolation of an *Aspergillus* sp. from sputum or BAL should be presumed to represent invasive disease in neutropenic patients.

Both the serum *Aspergillus* galactomannan¹¹⁵ and β -D-glucan¹¹⁶ assays, immunoassays that detect fungal antigens in peripheral blood, have been accepted as diagnostic adjuncts of invasive fungal infections in the revised European Organisation for Research and Treatment of Cancer/Mycosis Study Group consensus criteria.¹¹⁷ PCR-based detection is considered investigational.¹¹⁸ These immunoassays have three potential uses: (1) as a diagnostic adjunct, (2) as a surveillance tool in high-risk patients (e.g., allogeneic HSCT recipients) to detect early aspergillosis prior to clinically overt disease, and

(3) in monitoring response to antifungal therapy.¹¹⁹ The sensitivity of the galactomannan assay is significantly reduced by concomitant mold-active antifungal agents, and false-positive results may be more common in allogeneic HSCT recipients or with concomitant piperacillin/tazobactam and other antibiotics.¹²⁰ Meta-analysis suggest that the galactomannan assay has a sensitivity of 60% to 80% and specificity of 80% to 90% for proven IA, but emphasize the results are fairly heterogeneous.^{115,119} A rising serum galactomannan correlates with failure of antifungal therapy, and decreasing galactomannan correlates with a positive outcome in patients with IA.¹²¹

The serum β -D-glucan assay has recently received FDA approval as a diagnostic adjunct. In patients with acute myeloid leukemia and myelodysplastic syndrome, the assay was highly sensitive and specific in detecting early invasive fungal infections, including candidiasis, fusariosis, trichosporonosis, and aspergillosis.¹¹⁶ It does not detect mucormycosis.

Therapy for Invasive Aspergillosis. Voriconazole is currently the treatment of choice of IA,¹⁰⁷ because in a randomized controlled trials it was more effective than amphotericin B (successful outcomes: 53% versus 32%) and was associated with significantly improved survival (71% versus 58%).¹²² Voriconazole appears to have comparable safety and efficacy in children with invasive mold infections compared to adults, although the doses in children must be higher.¹²³ Three different lipid formulations of amphotericin B are available: amphotericin B colloidal dispersion, amphotericin B lipid complex, and liposomal amphotericin B. The lipid formulations have less nephrotoxicity than conventional amphotericin B deoxycholate, and are therefore more suitable for long-term administration. A randomized controlled trial has shown that liposomal amphotericin B at a dose of 3 mg/kg per day is at least as effective, and less toxic, than 10 mg/kg per day for IA.¹²⁴

Posaconazole is a broad-spectrum azole, so far only available in oral form, which has been used successfully as salvage therapy for a variety of IFIs refractory to standard therapy. Of note, 5 to 7 days are required before therapeutic serum levels are reached.¹²⁵ The overall success rate of posaconazole in patients with IA refractory or intolerant of standard therapy was 42%.¹²⁶ Monitoring levels of both posaconazole and voriconazole may be reasonable, particularly when there are questions about absorption or when the response to treatment is inadequate.¹²⁷ Echinocandins have not been evaluated as initial monotherapy for IA in controlled trials. Caspofungin as salvage therapy in patients with IA led to a favorable response in 37 of 83 patients (45%).¹²⁸

There has been significant interest in combination antifungal therapy pairing an echinocandin with either an amphotericin B preparation or a mold-active azole. The rationale is that echinocandins target a site (the β -glucan constituent of the fungal cell wall) distinct from the polyenes and azoles that target the fungal cell membrane. In vitro and animal models data have been encouraging, and uncontrolled clinical studies suggest minimal toxicity and potentially improved outcome of aspergillosis. The question of combination is far from settled, but many experts recommend its use, at least early in the course of treatment.¹⁰⁹

Patients who recover from an episode of IA are at risk for relapse of infection during subsequent immunosuppression. Secondary prophylaxis with a mold-active agent is advised for the entire period of immunosuppression.

Mucormycosis (Formerly Zygomycosis)

Risk factors for mucormycosis include diabetic ketoacidosis, protein-calorie malnutrition, iron overload, desferrioxamine (but not other iron chelators), corticosteroid therapy, and prolonged neutropenia.¹²⁹ Mucormycosis typically manifests as rhinocerebral or pulmonary disease following inhalation of spores. In rhinocerebral disease, fever, facial pain, and headache are common. Contiguous extension may lead to orbital involvement with proptosis and extraocular muscle paresis, involvement of hard palate, and spread to the brain. The use

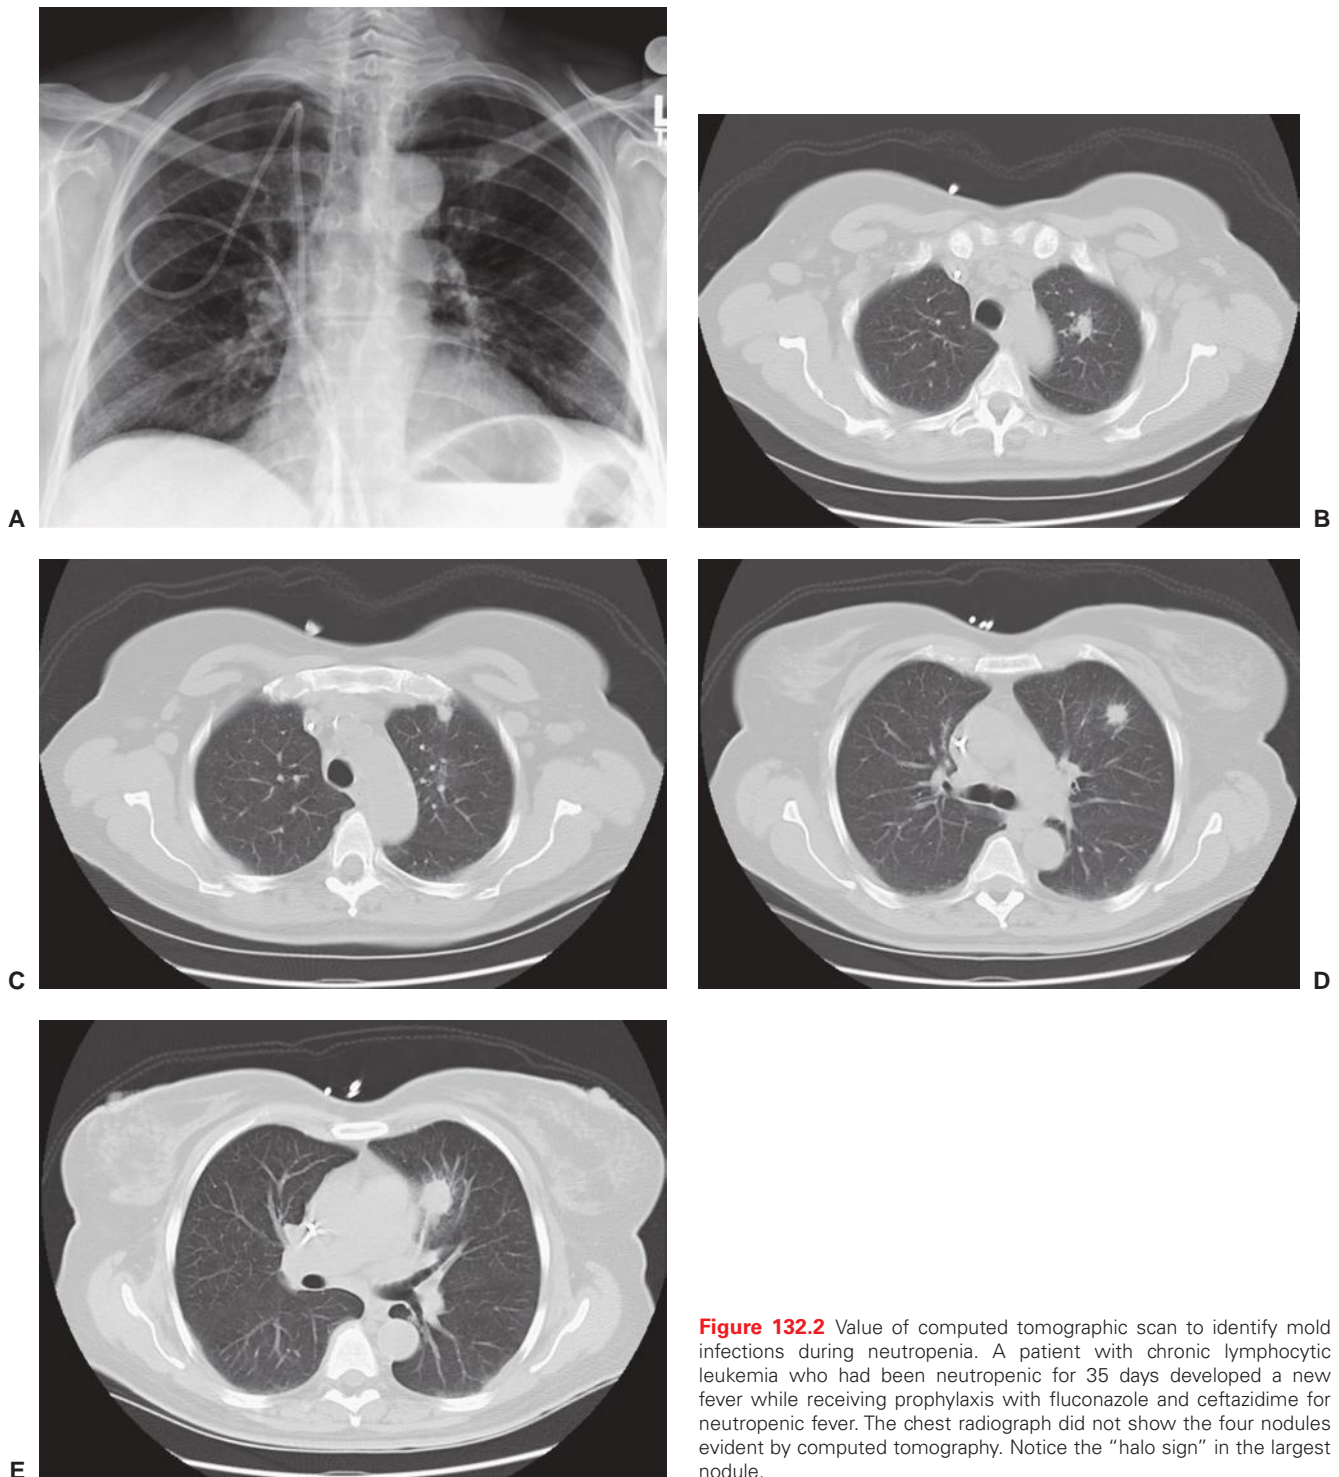

Figure 132.2 Value of computed tomographic scan to identify mold infections during neutropenia. A patient with chronic lymphocytic leukemia who had been neutropenic for 35 days developed a new fever while receiving prophylaxis with fluconazole and ceftazidime for neutropenic fever. The chest radiograph did not show the four nodules evident by computed tomography. Notice the “halo sign” in the largest nodule.

of voriconazole prophylaxis may contribute to increased incidence of mucormycosis.¹³⁰ Therapy for zygomycosis involves amphotericin B lipid formulation (5 mg/kg per day) plus early and aggressive surgical debridement in cases of localized cutaneous or sinus disease. Voriconazole and echinocandins are not active against zygomycetes. Posaconazole has shown promising results as salvage therapy.¹³¹

Less Common Molds

Fusarium, *Paecilomyces*, *Scedosporium*, and several dematiaceous molds are increasingly important causes of mortality in leukemia

and in allogeneic HSCT recipients.¹³² It is recommended to obtain infectious diseases expertise for the management of these infections. The likelihood of infection by a *Fusarium* spp. is increased by the presence of disseminated cutaneous lesions and isolation of a mold from blood culture. Different species of *Fusarium* have different susceptibilities, and it has been proposed to start empirical voriconazole and amphotericin B until the results of testing are available.¹⁰⁹ *Scedosporium apiospermum* and *Scedosporium* are usually treated with voriconazole. Dematiaceous (dark-walled) molds like *Alternaria*, *Curvularia*, and *Phaeoacremonium* can cause subcutaneous infection in immunocompetent persons following traumatic inoculation;

pneumonia, central nervous system (CNS) disease, and dissemination can occur in severely immunocompromised persons. Itraconazole, voriconazole, or posaconazole are appropriate initial therapy.

Immune Augmentation

The optimal treatment of fungal infections requires attempting to optimize the host's ability to fight infection. Corticosteroids should be tapered or discontinued if possible, therapeutic levels of the antifungal agents achieved anatomic obstacles, if present, removed. The use of colony-stimulating factors (CSF) and granulocyte transfusions is frequently a consideration.

Colony-Stimulating Factors

Granulocyte-colony stimulating factor (G-CSF) has shown to reduce the incidence of febrile neutropenia and is recommended by European¹³³ and American¹³⁴ professional organizations when the risk of neutropenic fever is $\geq 20\%$ or if the patient has experienced febrile neutropenia in previous cycles. Multiple randomized clinical trials of prophylactic CSFs have shown benefit in reducing the time to neutrophil recovery and duration of fever and hospitalization. Meta-analyses confirm its efficacy in HSCT¹³⁵ and breast cancer,¹³⁶ although reductions in mortality has not been shown.

The use of CSFs as treatment of established infection continues to be experimental. The rationale to use CSFs for established infections (as opposed to prophylaxis) stems from the quantitative and qualitative effects of these agents on phagocytic cells. Randomized trials have not shown a benefit of CSFs as adjunct therapy for patients with newly diagnosed fever and neutropenia. Although the benefit of any CSF for established infections is unproven, some experts may consider them in selected cases of profound neutropenia (ANC $< 100/\text{mcL}$) and/or with serious documented infections.

Granulocyte Transfusions

The rationale for granulocyte transfusions is to provide support for the neutropenic patient with a life-threatening infection by augmenting the number of circulating neutrophils until autologous myeloid regeneration occurs.¹³⁷ In the 1970s, apheresis technology for harvesting large numbers of donor granulocytes became available. Controlled trials of granulocyte transfusions as adjuvant therapy in neutropenic patients at the time produced mixed results. In the 1980s, the enthusiasm for granulocyte transfusions waned as more effective antibiotics became available, survival from serious bacterial infections improved, and recombinant growth factors reduced the duration of neutropenia. In addition, concerns about the toxicity of granulocyte transfusions, including acute pulmonary reactions,¹³⁸ HLA alloimmunization (which could render patients refractory to platelet transfusions and potentially impair myeloid engraftment following HSCT), and transfusion-associated infections (particularly CMV), outweighed the perceived benefits.

Today, the impetus to reexamine the role of granulocyte transfusions stems largely from improvements in donor mobilization methods (G-CSF). Currently, the mean absolute neutrophil yield per collection is in the range of 8×10^{10} cells, resulting in higher posttransfusion neutrophil counts that are sustained for 24 to 30 hours following transfusion. The qualitative functions of G-CSF- and steroid-mobilized neutrophils are intact based on in vitro testing. Published single-center experience suggests this procedure may have tolerable safety and can sometimes be helpful,^{139,140} but whether it provides overall benefit remains controversial.¹⁴¹

Catheter-Related Infections and Bacteremia

Bacteremia is a common complication of antineoplastic cytotoxic chemotherapy. Common sources are the intravenous catheter and the digestive tract. To maximize the detection of bacteremia, it is

important to obtain adequate volume of blood.¹⁴² The recommendation of the American Society of Microbiology is between 10 ml and 30 ml of blood per culture.¹⁴³ When possible, we recommend sampling all the lumens of multilumen catheters.¹⁴⁴ The importance of peripheral blood cultures obtained by venipuncture (as opposed to blood drawn from preexisting central lines) is related to the ability to determine the source of bacteremia by using a quantitative or semiquantitative method, rather than to sensitivity.¹⁴⁵

Guidelines from professional societies provide extensive reviews of the available evidence for the prevention and management of intravascular catheter-related infection.¹⁴⁶⁻¹⁴⁸ Organized systems (bundles) that place and manage vascular access should be a part of all cancer center programs.¹⁴⁹ Programs have demonstrated benefit in ambulatory populations, and we believe that this justifies the extension to the inpatient setting.¹⁵⁰

Several types of catheter-related infections have been defined: exit site infection, tunnel infection (or pocket infection in the case of ports), and catheter-related bacteremia. Bacteremia may or may not be present in the first two types.¹⁵¹ Exit and tunnel (or pocket) infections are clinical diagnoses based on whether pain, erythema, and tenderness extend > 2 cm from the exit site (tunnel infection) or not (exit site infection). Infected short-term catheters should be removed. Tunneled and implanted devices require more thorough investigation. Although some times exit site infections can be treated with systemic antibiotics and local care, signs and symptoms of infection that may reflect associated vascular thrombosis or involvement of a tunneled catheter track > 2 cm central to the exit site suggest the need for immediate removal.¹⁵² Purulence from the exit site may be present, although in neutropenic patients, local erythema and tenderness may be the only signs of infection, making it difficult to distinguish from sterile inflammation associated with mild trauma.

Catheter-related bacteremia or fungemia may occur with or without signs of localized infection. Determining whether an episode of bacteremia is associated to the catheter may be difficult, and it has important implications for management. Differential time to positivity (catheter culture positive at 2 hours earlier than peripheral blood) is the most commonly used tool.¹⁵³⁻¹⁵⁶ When used as a gold standard, it provides further justification for a modification of existing diagnostic standards for central line-associated blood stream infection.¹⁵⁷ Frequently, however, there is no peripheral blood culture to determine differential time to positivity. In these situations, "host criteria" and "organism criteria" are used to estimate the likely source of bacteremia. Some gram-positive bacteria, such as coagulase-negative *Staphylococcus* spp. and *Corynebacterium* spp. are common blood culture contaminants, but they may also represent true bacteremia in the presence of intravenous catheters. The likelihood of true bloodstream infection caused by these organisms is increased when they are isolated from more than one blood culture. On the other hand, isolation of *S. aureus* from a single blood culture should be considered evidence of true bacteremia and treated accordingly.

Neutropenia, gastrointestinal GVHD, and severe mucositis with diarrhea secondary to the treatment of solid tumors¹⁵⁸ are "host criteria" that affect the assessment of infection source. These factors are associated with different microbiology than that of bacteremias that originate in intravascular catheters.^{159,160}

Mucosal-barrier injury-associated bacteremias are the proposed events that are related to specific populations and "organism criteria." Organisms include *Candida* spp., *Enterococcus* spp., Enterobacteriaceae, viridans streptococci, and certain anaerobes (*Bacteroides* spp., *Clostridium*, *Fusobacterium*, *Prevotella*, *Peptostreptococcus*, *Veillonella*). This concept applies to patients with grade 3-4 gut GVHD, severe diarrhea, or neutropenia. Although these diagnostic criteria have been developed primarily as reporting tools for attribution of hospital-related events to preventable causes,^{161,162} they support the need for a conceptual change.^{157,163}

The standard approach for central line-associated blood stream infection is removal of the catheter and treatment of the patient

with systemic antibiotics.¹⁵¹ For permanent catheters in hemodynamically stable patients, catheter salvage may be considered.¹⁶⁴ Microbiologic factors are important in deciding whether a catheter can be saved. Coagulase-negative staphylococci are successfully treated in >93% of cases, although recurrence of infection is markedly increased with catheter retention.¹⁶⁵ Attempts to salvage catheters infected with *S. aureus* usually fail and frequently result in complications.¹⁶⁶ Similarly, catheters infected with *Candida* or mycobacteria should be removed.^{151,166} Antibiotic lock techniques are sometimes effective, almost always with concomitant systemic therapy, but failure may occur because the catheter to be salvaged needs to be used, thus limiting the dwell time of antibiotic lock solutions.¹⁶⁷⁻¹⁶⁹ The catheter should be removed if the blood cultures remain positive 3 days after starting appropriate therapy or in case of recurrent bacteremia.

Skin Lesions and Soft Tissue Infections

Consider infectious and noninfectious causes for these lesions. Some noninfectious causes include drug reactions (including chemotherapy-induced hand-foot syndrome), Sweet syndrome, erythema multiforme, vasculitis, leukemia cutis, and (in the case of allogeneic transplant) GVHD.¹⁷⁰ Early biopsy of skin lesions for histology and culture is recommended.¹⁷¹

Infections of the skin can either be localized or manifestations of systemic infection. Ecthyma gangrenosum is the most characteristic skin lesion associated with systemic *P. aeruginosa* infection, but can also be caused by *S. aureus*, enteric gram-negative bacilli infection, and molds including *Aspergillus*, zygomycetes, and *Fusarium*. Ecthyma gangrenosum begins as a raised erythematous papule or nodule that progresses to a bluish-black necrotic lesion within 12 to 24 hours. A central area of necrosis surrounded by erythema is typical. Pathologically, ecthyma gangrenosum is a necrotizing process in which masses of bacteria are often observed within the vessel wall and infiltrating white cells are absent.

A needle aspirate of the lesion showing gram-negative bacilli establishes the diagnosis of invasive infection, but a negative aspirate does not rule it out. Parenteral antibiotics with activity against *P. aeruginosa*, MRSA, and anaerobes (e.g., carbapenem + vancomycin ± a second agent against gram-negative bacteria) should be instituted emergently, pending culture results. The presence of a necrotizing process indicates surgical debridement is required.¹⁷² Sometimes surgical exploration is necessary to determine the extent of the infection.

Gram-positive bacteria that cause skin and soft tissue infections include *Streptococcus* (group A and B) and *S. aureus*. Besides *P. aeruginosa*, other gram-negative bacilli with propensity to cause dermatologic infections include *Stenotrophomonas maltophilia* (mucocutaneous ulcerations, primary cellulitis, metastatic nodular cellulitis, and ecthyma gangrenosum), *Aeromonas hydrophila*, and *Vibrio vulnificus* (septicemia with secondary cellulitis with hemorrhagic bullae after ingestion of contaminated seafood, most common in patients with underlying liver disease, or primary cellulitis with bacteremia when an open wound is exposed to seawater). *Clostridium* spp. are gram-positive anaerobes that may cause deep soft tissue infection involving the fascia and muscle. In neutropenic patients, the typical presentation is disseminated soft tissue infection with *Clostridium septicum* bacteremia. Typically, a small dusky or purplish lesion on the leg or abdominal wall rapidly expands, and as infection progresses, the lesions may become necrotic, bullous, and hemorrhagic. Systemic toxicity including fever, malaise, and mental status changes occur early. Because the infection occurs in the deep soft tissue, tenderness and evidence of vascular compromise typically precede the development of cellulitis. A rapidly progressive deep soft tissue infection with gas formation suggests clostridial myonecrosis or polymicrobial necrotizing fasciitis. Needle aspiration characteristically shows the organism in the setting of a mild or absent inflammatory response. Extensive surgical debridement

may be life-saving if initiated early, but the mortality rate is high.¹⁷³ Metronidazole plus an antipseudomonal cephalosporin (such as ceftazidime or cefepime) or single-agent therapy with imipenem, meropenem, or piperacillin/tazobactam are reasonable regimens.

The characteristic skin lesions of disseminated candidiasis are raised erythematous discrete papules, measuring about 0.5 to 1 cm in diameter. In their earliest form, the lesions resemble those of heat rash. They are usually not tender. Concurrent myalgias raise the possibility of *Candida* myositis. The yeast is cultured from skin lesions in only about half the cases. Blood cultures are typically positive. Similar lesions may appear with disseminated trichosporonosis.¹⁷⁴

Cutaneous infection by molds may be primary or result from systemic infection. The hematogenous lesions of *Aspergillus* and *Fusarium* usually begin as discrete subcutaneous nodules that may be tender, whereas traumatic inoculation appears as ulcerations. If a primary cutaneous lesion is isolated and surgically resectable, it has an excellent prognosis. In the neutropenic patient, the likelihood of systemic infection is high, and therefore systemic antifungal therapy is warranted. Clinically, these lesions resemble ecthyma gangrenosum. Histologically, hyphae are present with angioinvasion and infarction. Primary cutaneous fusariosis has a varied appearance, including cellulitis, paronychia, onychomycosis resembling dermatophyte infection, as well as papular and nodular lesions.¹⁷⁵

HSV and VZV can involve the skin. Oral or genital ulcers should be sampled to rule out HSV by immunofluorescence or PCR. Multiple well-circumscribed disseminated cutaneous ulcers can be manifestations of disseminated HSV. Disseminated HSV disease should be treated with intravenous acyclovir (10 mg/kg every 8 hours). Acyclovir-resistant HSV is occasionally observed in HSCT recipients. When acyclovir resistance is suspected, the decision to switch therapy (generally to foscarnet) should be made on clinical grounds as antiviral susceptibility testing of the isolate at a reference laboratory takes weeks. VZV presents with maculopapular or vesicular lesions, often but not always in a dermatomal distribution. Secondary bacterial infections, usually due to streptococci or *S. aureus*, may occur. Visceral involvement of VZV can manifest as hemorrhagic pneumonia, encephalitis, retinal necrosis, hepatitis, and small bowel disease. Both viruses can be detected in the blood by PCR in case of disseminated infection; this may be particularly helpful if VZV presents with pain only, with no apparent rash. Intravenous acyclovir is the established treatment for primary varicella or disseminated zoster in immunocompromised patients.

Respiratory Tract Infections

Community-Acquired Respiratory Viruses

Community respiratory viruses include influenza, parainfluenza, respiratory syncytial virus, human metapneumovirus, adenoviruses, rhinoviruses, and coronaviruses. Most respiratory viruses typically cause self-limited infection in healthy persons, but are important causes of morbidity and mortality in immunocompromised patients with hematologic malignancies and in HSCT recipients.¹⁷⁶ Immunocompromised persons with symptoms of respiratory infection should be evaluated for respiratory viruses, among other etiologies, and contact and respiratory precautions should be established. There are no significant differences in clinical presentation that allow predicting the causative virus in any individual case. Rapid immunodiagnostic tests (i.e., enzyme-linked immunosorbent assay) are insensitive: they are useful only to “rule in” these infections but a negative result cannot be used to rule out the disease. PCR is the most sensitive test.

Influenza. Influenza A and B can be treated with neuraminidase inhibitors (zanamivir and oseltamivir); influenza A can also be treated with amantadine and rimantadine. The circulating strain may be susceptible or resistant to these agents; it is important to consult the CDC to find out what is the recommended treatment

during each influenza season. The CDC advises annual administration of the inactivated influenza vaccine to immunocompromised persons and their close contacts (e.g., health-care workers and household members). Immunization should be provided ideally 2 weeks before chemotherapy, or if given during chemotherapy, immunization is preferably administered between cycles. The recently approved inhaled live attenuated influenza vaccine, FluMist (MedImmune, LLC, Gaithersburg, MD), should not be used in the severely immunocompromised patient. Use of the injected inactivated vaccine is preferred among close contacts of the immunocompromised persons, including health-care workers.

Respiratory Syncytial Virus. Respiratory syncytial virus infection is most virulent in patients with leukemia and in HSCT recipients. Upper respiratory symptoms (sinusitis, coryza, rhinorrhea) usually precede lower respiratory tract involvement (dyspnea, wheezing) and pneumonia but may be absent. Accumulating evidence suggests that severely immunocompromised HSCT recipients may benefit from treatment with ribavirin.^{177,178}

Parainfluenza. Parainfluenza viruses are important community respiratory viruses in leukemia and HSCT patients.^{179,180} Given there is no effective antiviral treatment available, emphasis should be placed on infection control measures and diagnosis and treatment of copathogens.¹⁸¹

Human Metapneumovirus. Human metapneumovirus is a recently described paramyxovirus that causes upper and lower respiratory tract infection. It occurs mostly during the winter and spring. More severe disease is reported in young children, the elderly, and immunocompromised hosts.^{182,183} The treatment is supportive.

Adenovirus

The spectrum of adenovirus in immunocompromised patients extends from asymptomatic shedding to fatal multisystem disease with pneumonia and hepatitis, and includes upper respiratory tract infection, renal parenchymal disease, hemorrhagic cystitis, hepatitis, small and large bowel disease, and encephalitis.¹⁸⁴ Viral shedding from throat secretions, urine, and stool is common, occurring in ~5% to 20% of HSCT recipients, and should not be equated with disease. Gastroenteritis and hemorrhagic cystitis are usually self-limited, whereas pneumonia and disseminated disease are associated with a high mortality rate. Adenovirus is more common in T-cell-depleted transplants and in younger patients and recipients of stem cells from unrelated donors. Cidofovir is the antiviral of choice.

Sinusitis

Congestion, sinus tenderness, and fever are common signs of sinusitis, but are nonspecific. In immunocompetent patients, respiratory bacterial pathogens, including *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* predominate, and a standard antibiotic regimen, such as amoxicillin-clavulanic acid, or a respiratory fluoroquinolone is appropriate if the diagnosis is properly established. Of note, macrolides, TMP/SMX and second-generation cephalosporins are no longer recommended.¹⁸⁵ In patients with neutropenia or who are otherwise highly immunocompromised, infections by *P. aeruginosa*, *S. aureus*, Enterobacteriaceae, and molds must be considered. We initiate standard agents for fever and neutropenia, and promptly obtain a CT scan of the sinuses and otolaryngologist consultation to obtain samples for culture and, if there are lesions suspicious for invasive mold (e.g., ischemia, necrotic eschar), biopsy. The CT may be suggestive of fungal disease if a heterogeneous mass or bony erosions are seen. *Aspergillus* and agents of mucormycosis (e.g., mucor, rhizopus) are the most common isolates, but less common molds such as *Fusarium* spp., and dematiaceous molds are being recognized more frequently. Pending

microbiologic identification, empirical therapy should include a lipid formulation of amphotericin B (5 mg/kg per day), to ensure coverage of mucormycosis. If the diagnosis of invasive fungal sinusitis is confirmed, surgical resection should be performed because medical therapy alone is unlikely to contain infection in the setting of neutropenia or severe immunosuppression. Antifungal therapy should be continued for weeks or months even if all of the visualized necrotic tissue is fully resected. An etiologic diagnosis will allow choosing the appropriate antifungal (e.g., voriconazole for aspergillosis, amphotericin for mucormycosis). For some causes of mucormycosis, posaconazole may be a useful alternative to amphotericin B for long-term therapy.^{186,187}

Pulmonary Infiltrates

There are multiple infectious and noninfectious causes of pulmonary infiltrates in cancer patients. Some noninfectious processes that should be considered include the malignancy, complications of its treatment (drug toxicity, radiation pneumonitis), congestive heart failure, pulmonary hemorrhage, pulmonary embolism with infarction, cryptogenic organizing pneumonia, and acute respiratory distress syndrome. Atypical radiographic appearances and several coexisting pulmonary processes are common in this patient population. We recommend early use of CT scans and diagnostic procedures, including bronchoalveolar lavage, fine needle aspiration, or lung biopsy if required.

Community-Acquired Pneumonia

Sputum and blood cultures should be collected prior to starting therapy if feasible. In patients with malignancies who do not require hospital admission based on a validated pneumonia severity index,¹⁸⁸ either a respiratory fluoroquinolone alone (levofloxacin, moxifloxacin) or a β -lactam plus a macrolide (e.g., high-dose amoxicillin or amoxicillin-clavulanate and azithromycin) is advised. In patients requiring hospital admission, we use monotherapy with a respiratory fluoroquinolone or combine a macrolide with either ceftriaxone, cefotaxime, or, in selected cases, ertapenem. For cancer patients with severe community-acquired pneumonia (e.g., requiring admission to an intensive care unit), we usually institute broad-spectrum coverage with an antipseudomonal β -lactam plus a respiratory fluoroquinolone. In patients with prior MRSA infection or known colonization with MRSA, we add vancomycin or linezolid. A parapneumonic effusion should be sampled for microbiologic studies and cytologic examination.

Legionella Species. *Legionella* infections are associated with compromised cellular immunity. In the cancer population, patients at highest risk include those receiving high-dose corticosteroids, T-cell-depleting agents, and allogeneic HSCT. There are no clinical or radiologic criteria that reliably distinguish legionellosis from pneumococcal pneumonia, although diarrhea, rhabdomyolysis, and lack of response to β -lactam antibiotics have been proposed as suggestive of the diagnosis. A combination of culture (special culture medium required) and urinary antigen test is the optimal diagnostic combination in most situations.¹⁸⁹ The urine legionella antigen assay is sensitive and specific for *Legionella pneumophila* serogroup 1, the isolate responsible for up to 80% of clinical disease; however, it does not detect other serogroups or *Legionella* spp. PCR on respiratory secretions is both sensitive and specific for *Legionella* detection, but standardized assays are not commercially available. Azithromycin or fluoroquinolones (e.g., levofloxacin, moxifloxacin) are standard therapy for legionellosis. Nosocomial legionellosis has been linked to contamination of hospital water.

Hospital-Acquired Pneumonia

Hospital-acquired pneumonia (HAP) is considered “early” when it happens within 4 days of admission or “late” when it occurs 5 days

or more after admission. Late HAP is more likely to be caused by multidrug-resistant pathogens. Initial therapy for early onset HAP is similar to that of community-acquired pneumonia, except when there are risk factors for colonization with multidrug-resistant pathogens (e.g., prior antibiotics within the past 90 days, recent hospitalization, nursing home, dialysis center) in which case they should be treated similar to patients with late-onset HAP. In late-onset HAP, the goal is to broadly cover nosocomial pathogens and then to deescalate the antibiotic regimen once culture results and susceptibility are known. A typical initial regimen for late-onset HAP includes an antipseudomonal β -lactam (e.g., ceftazidime, cefepime, imipenem, meropenem, or piperacillin/tazobactam) plus an antipseudomonal fluoroquinolone (e.g., ciprofloxacin or levofloxacin), plus either linezolid or vancomycin (aim for trough vancomycin level of 15 to 20 mcg/ml).¹⁹⁰

Pulmonary Infiltrates in Neutropenic Patients

In patients with <1 week of neutropenia, pulmonary infections are likely to be caused by Enterobacteriaceae, *P. aeruginosa*, and *S. aureus*. Community respiratory viruses should also be considered. Because of neutropenia, physical findings of consolidation and sputum production may be absent. We recommend the early use of CT. A CT scan of the chest may disclose lesions missed by the chest radiograph as well as findings characteristic of invasive fungal disease: well-circumscribed, dense infiltrates, the “halo sign” (see Fig. 132.2), and/or cavitation. Cavitation usually coincides with neutrophil recovery and does not indicate treatment failure. Besides molds, other angioinvasive infections including *P. aeruginosa* may cavitate. A new or progressive infiltrate developing while on broad-spectrum antibacterial agents in patients with prolonged neutropenia raises the concern about invasive mold infection, and makes the need for definitive diagnosis more pressing. Because radiographic findings are often nonspecific, we recommend early BAL. In patients at risk for invasive mold diseases, a serum galactomannan and β -D-glucan may be considered, although the interpretation of a single value of these tests (as opposed to trends) may be difficult.

In highly immunocompromised patients (e.g., chemotherapy for acute leukemia, HSCT receiving active treatment for GVHD), we suggest the following studies on BAL and lung biopsies: culture and stains for bacteria, including *Legionella*, mycobacteria, and *Nocardia* species as well as fungi; special stains or PCR for *P. jirovecii*; and rapid culture (shell vial) or PCR for virus (HSV, CMV, VZV, community respiratory viruses). Cytologic examination of the BAL may also be diagnostic of pneumocystis, nocardia, fungi, mycobacteria, CMV, and adenovirus, and can suggest diffuse alveolar hemorrhage. BAL galactomannan is more sensitive than serum galactomannan, particularly in neutropenic patients, and should be considered in patients at risk for IA.¹²⁵

The yield of induced sputum for the diagnosis of PCP in non-HIV-infected patients may be only 60%,¹⁹¹ and early consideration should be given to BAL. The yield of BAL is high for *P. jirovecii*, *Mycobacterium tuberculosis*, and respiratory viruses. For focal lesions such as nodules, the diagnostic yield is much lower (15% to 50%), and a percutaneous biopsy may be a better diagnostic choice.¹⁹² Transbronchial biopsy may be helpful in diffuse processes. Video-assisted thoracic surgery has been used successfully in cases with diffuse involvement and with peripheral lesions. Open lung biopsy is the definitive diagnostic method, and it also allows for easier visualization and control of bleeding.

Treatment

Besides the standard antimicrobials used for fever and neutropenia, we include a macrolide or fluoroquinolone to treat *Legionella* and agents of atypical pneumonia. Vancomycin or linezolid should be added for pneumonia in patients colonized with MRSA and for nosocomial pneumonia. Depending on the clinical scenario and preexistent antifungal prophylaxis, we may add voriconazole or a

lipid formulation of amphotericin B. There is disagreement between experts on which is the best antifungal strategy. *Aspergillus* spp. are by far the most common mold infections, but mucormycosis may be the cause in any individual case. Voriconazole is the drug of choice for IA,¹⁰⁷ but is inactive in mucormycosis. Amphotericin B is active in both aspergillosis and mucormycosis, but it may be significantly inferior to voriconazole in aspergillosis. Some experts might add both agents and aggressively pursue a diagnosis that will allow de-escalation.

Pulmonary Infiltrates in Patients with Defects in Cellular Immunity

Patients with impaired cellular immunity and those taking corticosteroids are at increased risk for opportunistic infections, including fungi (*Cryptococcus neoformans*, dimorphic fungi, other molds), *Legionella* spp., *P. jirovecii* (Fig. 132.3), *M. tuberculosis*, nontuberculous mycobacteria, *Nocardia* spp., and viral pathogens. CMV pneumonia principally occurs in allogeneic HSCT recipients, but can uncommonly occur in other severely immunocompromised patients. Diffuse necrotizing pneumonia by varicella and HSV are also encountered in transplant recipients.

The diagnostic evaluation in patients with impaired cellular immunity and pulmonary infiltrates is similar to neutropenic patients. Typically, broad-spectrum antibiotics for community-acquired pneumonia requiring hospitalization (see previous discussion) will be started, ideally after obtaining respiratory samples for diagnosis. The empirical addition of TMP/SMX for PCP should be considered.

***Nocardia* Species.** Patients with hematologic malignancy, allogeneic HSCT recipients, lymphopenia, and receiving corticosteroids are at highest risk.¹⁹³ Bronchopneumonia, lobar pneumonia, nodules, or necrotizing abscesses with cavitation are observed. Empyema and extension to the chest wall may occur. Dissemination may include brain abscess, meningitis, osteomyelitis, soft tissue mass, cutaneous abscess, and liver abscess. It is important to alert the microbiology laboratory when nocardiosis is suspected so that a modified acid stain is performed and that appropriate culture conditions are used and culture plates are held for weeks instead of days. Treatment of nocardial infections is based on case series. Most experience is with TMP/SMX, but other agents that have been used include carbapenems, minocycline, ceftriaxone, and linezolid. Identification is important to predict susceptibility.¹⁹⁴ Surgical drainage or resection should be considered in cases refractory to medical therapy. Therapy should be continued for several months to a year.

***Pneumocystis jirovecii*.** *P. jirovecii* (formerly *P. carinii*) is more appropriately classified as a fungus than a protozoan based on gene sequence data and cell wall constituents. Defective T-cell immunity is the principal risk factor for PCP, with the risk in people infected with HIV increasing significantly after the CD4 count declines below 200. In patients without AIDS, corticosteroid use is the main risk factor.¹⁹⁵ Fever, cough, and shortness of breath are the most common clinical features.¹⁹⁶ Patients treated with corticosteroids may develop initial clinical manifestations of PCP only during steroid taper. The most common radiographic findings are bilateral interstitial infiltrates, although unilateral or patchy infiltrates are also observed.¹⁹⁷ Nodules, cavitory lesions, and pleural effusions are less common. In a minority of patients, the chest radiograph is normal. Diagnosis of PCP relies on visualization of the organism microscopically or use of melucular methods, as it does not grow in culture. BAL is the standard diagnostic modality for PCP, but induced sputum has acceptable yield in some institutions. Immunofluorescent staining using mAbs is more sensitive than silver staining or Wright-Giemsa staining. Patients with cancer have reduced organism burden compared with people infected with HIV, which decreases the sensitivity of every diagnostic

Figure 132.3 *Pneumocystis jirovecii* pneumonia. A patient with chronic lymphocytic leukemia developed fever, hypoxemia, and shortness of breath soon after tapering a prednisone course for hemolytic anemia. He had received multiple courses of fludarabine, rituximab, and corticosteroids. He was receiving inhaled pentamidine as *Pneumocystis jirovecii* pneumonia prophylaxis. His last treatment had taken place 3 weeks prior to this illness.

modality. Quantitative PCR of respiratory samples may be the most sensitive test in this setting.^{198,199} The serum β -D-glucan test seems to have very good sensitivity and specificity.²⁰⁰

Treatment. TMP/SMX is the treatment of choice for *P. jirovecii*. If TMP/SMX is not feasible because of significant allergy or toxicity, intravenous pentamidine or pyrimethamine plus clindamycin can be used. In cases of mild or moderate PCP (which has been defined as room air $\text{Pao}_2 >70$ torr) in patients intolerant of TMP/SMX, dapsone-trimethoprim, clindamycin-primaquine, and atovaquone are acceptable options, but the efficacy of all these is less than that of TMP/SMX. In patients with moderate or severe PCP ($\text{Pao}_2 \leq 70$ torr), corticosteroids should be added based on studies of patients with AIDS-associated PCP. In patients who are not responding to therapy, repeat bronchoscopy should be considered to exclude additional pathogens.

Cytomegalovirus Pneumonitis. Pulmonary disease typically manifests as bilateral infiltrates resembling PCP with hypoxia and progression to respiratory failure. In transplant patients, the diagnosis is established by a compatible clinical syndrome with detection of CMV in BAL (by culture or cytopathology showing characteristic intracytoplasmic and intranuclear inclusions) or tissue (by culture or histologic diagnosis).²⁰¹ In nontransplant patients, CMV pneumonia is rare, and the culture alone is not considered sufficient to make the diagnosis as CMV can be shed from pulmonary secretions without causing invasive disease. Demonstration of intracellular CMV inclusions on BAL is diagnostic of disease, but is uncommon. In many cases, other pathogens are found, including *P. aeruginosa*, *Legionella*, *Aspergillus* spp., *Mycobacteria* spp., *Nocardia* spp., toxoplasmosis, or respiratory viruses.

We treat CMV pneumonia with ganciclovir or foscarnet plus Ig (either regular intravenous Ig or CMV-specific). The benefit of Ig is based on historical controls and has been questioned.⁶² Cidofovir may be considered in cases of CMV disease after failure or intolerance to ganciclovir or foscarnet.

Postobstructive Pneumonia and Pleural Effusion

There are no professional guidelines or professional society guidance statements on the indication for airway stenting to relieve malignant obstruction. There are no outcomes reported in sufficiently large series to answer the question as to whether the risk and consequence of infection outweigh the benefit of the relief of obstruction. Retrospective series suggest that stenting is followed by infection with moderate frequency and (predominantly *P. aeruginosa*) has increased mortality.

A similar lack of controlled data is present in the evaluation of intrapleural catheters placed for the relief of malignant pleural effusion, although infection as a complication seems to be infrequent.²⁰²

Epstein-Barr Virus–Induced Posttransplant Lymphoproliferative Disease

Most adults have been infected by EBV. Latent infection persists in B cells and produces no disease in the vast majority of people. EBV-specific cytotoxic T-lymphocytes are the main controllers of the replication of EBV-infected B cells. EBV lymphoproliferative diseases are encountered in patients with severely impaired T-cell immunity, such as AIDS or intensive and prolonged immunosuppressive therapy. EBV-induced PTLD is defined as an abnormal proliferation of EBV-infected B cells in a transplant recipient. The lesions may be composed of polyclonal or monoclonal populations of transformed B cells. PTLD is most common between 1 and 6 months after allogeneic HSCT. Typically, the proliferating B cells are of donor origin. Immunosuppressive therapy for GVHD and T-cell–depleted allografts increases the risk of PTLD. Uncontrolled EBV infection may also cause a hemophagocytic syndrome that is characterized clinically by fever, pancytopenia, and hepatosplenomegaly.²⁰³

Clinical manifestations of PTLD are varied. Patients may have a mononucleosis-like syndrome with fever and localized adenopathy. Disseminated disease may manifest with generalized adenopathy and extranodal organ involvement, including the bowel, liver,

bone marrow, and CNS. A CT/positron emission tomography scan is useful in a high-risk patient with unexplained fever. Diagnosis of PTLD requires a biopsy showing the characteristic histology and evidence of EBV infection by immunohistochemistry or EBV DNA detection.

Whereas PTLD in organ transplant recipients typically responds to a reduction in the intensity of immunosuppression, PTLD in HSCT recipients may not respond to such conservative measures. Antiviral agents may attenuate the lytic cycle of EBV and reduce the frequency of new B-cell clones, but they will not affect the replication of EBV-transformed PTLD B cells, and are not useful. Other strategies include rituximab,²⁰⁴ low-dose chemotherapy, anti-IL-6, donor lymphocyte infusions, and adoptive immunotherapy using donor-derived EBV-specific cytotoxic T-lymphocyte clones. However, using alloreactive T cells in such unfractionated preparations may induce GVHD. A potentially safer approach involves transfer of EBV-specific donor cytotoxic T-lymphocyte clones. Adoptive transfer of EBV-specific cytotoxic T-lymphocytes has been generally safe and effective in controlling PTLD and in preventing EBV lymphoproliferative disorders when used prophylactically.

Gastrointestinal Tract and Abdominal Infections

Oropharyngeal Infections

Oropharyngeal infections in patients with cancer usually result from the combination of neutropenia and mucositis. The distinction of chemotherapy-induced mucosal erosions and superimposed infection is difficult. HSV may produce mucosal ulcerations resembling chemotherapy-induced mucositis and necrotizing gingivitis, and it should be ruled out by culture or PCR. Oral mucosal candidiasis may present with typical thrush, but also with erosions and erythema; diagnosis is made by a wet mount or Gram stain preparation showing pseudohyphal forms (the culture is not of diagnostic value because *Candida* spp. are part of the normal oral flora). Molds (e.g., *Aspergillus* spp. and zygomycetes) can cause invasive disease of the hard palate and other oral cavity structures, principally in patients with prolonged neutropenia and allogeneic HSCT recipients with GVHD. Severe local bacterial infection may occur with spread to adjacent tissue structures and bacteremia. The antibacterial regimen should cover both common oral flora (gram-positive bacteria and anaerobes) and hospital-acquired gram-negative bacilli.

Esophagitis

Gradual onset of retrosternal chest pain or burning and odynophagia are the most common symptoms of esophagitis. The infectious differential diagnosis includes candidiasis, HSV, CMV (principally in HSCT recipients), bacterial infections, and aspergillosis. *Candida* esophagitis is probably most common, but more than one infection may be present. Radiation therapy to the chest and chemotherapy-induced mucositis may produce an erosive esophagitis that is clinically indistinguishable from infection. The definitive diagnosis requires endoscopy with brushing or biopsy. The endoscopic appearance is often misleading. In neutropenic patients, we recommend empirical therapy with fluconazole, with or without high-dose acyclovir (10 mg/kg every 8 hours) for *Candida* and HSV, respectively, followed by endoscopy if there is no improvement. In the setting of concurrent neutropenic fever, appropriate broad-spectrum antibacterial agents should of course be added. Esophagitis may be complicated by bacteremia by predominantly gram-positive pathogens (viridans group streptococci, *S. aureus*, *Bacillus* spp.).

Neutropenic Enterocolitis (Typhlitis)

Typhlitis (“inflammation of the cecum”) results from a combination of neutropenia and defects in the bowel mucosa related to

cytotoxic chemotherapy. Patients receiving chemotherapy for acute leukemia are at highest risk, but it is also observed in patients with solid tumors receiving taxanes.^{129,130} Pathologically, typhlitis is characterized by ulceration and necrosis of the bowel wall, hemorrhage, and masses of organisms. Suggestive signs include fever, abdominal pain and tenderness, and radiologic evidence of right colonic inflammation. Nausea, vomiting, and diarrhea (sometimes bloody) are the most common associated symptoms. Bacteremia with bowel flora, *P. aeruginosa*, and polymicrobial sepsis may occur. Clostridial species are the most common anaerobic pathogens.

A CT scan should be performed in neutropenic patients with suspected typhlitis or undiagnosed abdominal pain. Positive CT scan findings are present in about 80% of cases of typhlitis,²⁰⁵ and include a right lower quadrant inflammatory mass, pericecal fluid, soft tissue inflammatory changes, localized bowel wall thickening and mucosal edema, and a paralytic ileus (Fig. 132.4). Disease may be limited to the cecum, but more extensive involvement of the large bowel and terminal ileum may occur (*neutropenic enterocolitis*). The differential diagnosis includes *C. difficile* colitis, GVHD of the bowel, CMV colitis, and bowel ischemia.²⁰⁶

Treatment of typhlitis requires broad-spectrum antibiotics with activity against aerobic gram-negative bacilli and anaerobes (e.g., ceftazidime plus metronidazole, imipenem, meropenem, or piperacillin/tazobactam) and supportive care, including intravenous fluids and bowel rest. Nasogastric decompression may be indicated. The indications for surgery must be individualized, but include (1) persistent gastrointestinal bleeding after resolution of neutropenia, thrombocytopenia, and clotting abnormalities; (2) perforation; (3) uncontrolled sepsis despite fluid and vasopressor support; and (4) an intra-abdominal process (such as appendicitis) that would require surgery in the absence of neutropenia.¹³³

Anorectal Infections

Anorectal infections may be life-threatening in patients who are receiving repeated courses of cytotoxic chemotherapy. Infection may follow the development of an anal fissure. Once anorectal infection is established, fascial extension to the external genitalia, pelvic floor, retroperitoneum, and peritoneal cavity may occur. Anorectal infections, with or without extensive regional spread, may lead to bacteremia. The most common pathogens in neutropenic patients are Enterobacteriaceae, anaerobes, enterococci, and *P. aeruginosa*. In most cases, the infection is polymicrobial.²⁰⁷

Figure 132.4 Typhlitis (neutropenic enterocolitis). The computed tomographic scan shows edema of the cecal wall and “stranding” of pericolic fat in a neutropenic patient with fever and abdominal pain.

Fever often precedes symptoms and signs suggestive of anorectal infection, and perirectal pain, often exacerbated by defecation, may initially occur in the absence of findings in the physical examination. Therefore, serial examinations of the perianal region are necessary, looking for point tenderness and poorly demarcated induration.²⁰⁸ Perianal and perirectal infections are distinguished anatomically, clinically, and therapeutically. Among neutropenic patients, perianal infections are common and are usually managed medically, whereas perirectal infections are uncommon and often warrant surgical intervention. Visual inspection should assess for the presence of perianal fissures, fistulas, cellulitis, and induration. Digital rectal examination should be avoided during neutropenia. A CT scan should be obtained to show the extent of perirectal involvement and drainable collections. Stool softeners and analgesics should be provided. Most cases of anorectal infections can be managed with appropriate broad-spectrum antibiotics and supportive measures without surgical intervention.²⁰⁷ Indications for surgery include progression of disease locally or continued sepsis despite adequate antibiotics.²⁰⁸

Surgical Intra-Abdominal Infections

Esophageal Obstruction

The available literature on stents for the relief of malignant esophageal disease and gastroduodenal or colonic obstruction does not suggest an increased risk of infectious complications. Professional guidance does exist for esophageal and upper gastrointestinal malignant obstruction.²⁰⁹

Biliary Obstruction

Both gastroenterology and radiology professional guidelines exist related to the placement of devices for the relief of malignant biliary tract obstruction.^{210,211} The best current evidence does not support the need for decompression in order to allow for better surgical outcomes.²¹²

Infection (cholangitis, cholecystitis, and liver abscess) is a common adverse outcome of device placement. Prior manipulation (endoscopic retrograde cholangiopancreatogram) and incomplete drainage are the most consistently identified risk factors.²¹³ Infection rates of 22% (percutaneous transhepatic drainage) and 29.5% (endoscopic placement) with self-expanding metallic stents have been reported in unresectable hilar cholangiocarcinoma without a statistically significant difference by procedure.²¹⁴ Prophylactic antibiotics are recommended in anticipation of incomplete endoscopic drainage, which occurs most frequently in proximal obstruction.^{213,214} There is evidence that neither ursodeoxycholic acid nor antibiotics improve stent patency.²¹⁵ Antibiotic choices should be made in consultation with an expert in local susceptibility patterns. No clear evidence relates the type of device used to the risk of infection.

Central Nervous System Infections

CNS infections in patients with cancer can be divided into surgical and nonsurgical.

Infections Related to Neurosurgical Procedures

Devices are placed in the CNS/cranioskeletal system to relieve intracranial hypertension, replace structural defects, and deliver chemotherapy. As such, the dominant infectious events, which have been reported in >10% of cases, are related to contamination at placement or access.²¹⁶ Skin flora predominate, with staphylococci (both aureus and coagulase-negative) and other commensals (*Propionibacterium*). CSF indices are helpful but not adequately sensitive and cultures should always be obtained in evaluating signs or symptoms that might represent infection.^{217,218} A reasonable

assessment of treatment strategies is difficult as the vast majority of circumstances are treated with removal of the device. Intrathecal administration of antibiotics has some chance of success but should be used with caution when the infecting organism is virulent (*S. aureus*, *P. aeruginosa*).²¹⁹ Titanium devices for the correction of cranial defects are associated with infectious complications in 18.5% of cases despite their reported resistance to infection.²²⁰

Meningitis/Meningoencephalitis

Meningitis and encephalitis in cancer patients are part of a clinical spectrum of CNS disorders causing fever and meningismus. Encephalitis may manifest with signs and symptoms of meningeal inflammation, but is distinguished by the predominance of alterations of consciousness and neurologic deficits. The IDSA has published guidelines on the management of bacterial meningitis²²¹ and encephalitis.²²²

Initial evaluation generally involves an MRI and lumbar puncture. CSF studies should include cell count with differential; cytology and flow cytometry if appropriate; glucose, protein, and bacterial culture; and Gram stain evaluation. In neutropenic patients, we add fungal culture, β -D-glucan, and galactomannan antigen. In patients with impaired cellular immunity, CSF cryptococcal antigen should be ordered. Noninfectious causes of meningitis include carcinomatous meningitis, nonsteroidal anti-inflammatory medications, TMP/SMX, and serum sickness (e.g., associated with antilymphocyte gammaglobulin or intravenous Ig).

A reasonable empirical regimen for suspected bacterial meningitis in patients with cancer is ceftriaxone plus ampicillin plus vancomycin. This regimen will cover common causes of bacterial meningitis, including penicillin-resistant pneumococci and listeriosis. In the penicillin-allergic patient, the combination of vancomycin and TMP/SMX may be used. In patients at risk for *P. aeruginosa* meningitis (e.g., neutropenia, neurosurgery within the past 2 months, allogeneic HSCT, prior history of *P. aeruginosa* infection), cefepime or meropenem should be used instead of ceftriaxone.

In patients with suspected encephalitis (fever, mental status changes, CSF pleocytosis), viral etiologies should be considered and frequently treated empirically until they are ruled out. Intravenous acyclovir should be considered for HSV; it will also treat VZV. After allogeneic HSCT (particularly cord or T-cell-depleted transplants), HHV-6 is a common cause of viral encephalitis, and empirical treatment with ganciclovir or foscarnet may be considered pending PCR results.²²³ In patients at risk for TB, nucleic acid amplification methods for the diagnosis of TB should be obtained and adenosine deaminase considered. Mycobacterial culture has low yield and take many days or weeks, but should be obtained. After allo-HSCT and in other settings of impaired T-cell immunity, toxoplasmosis and CMV are possibilities; both may be diagnosed by PCR. Different virus may be considered depending on the region and time of the year; the diagnosis may be made by PCR or, in the case of West Nile virus, by determination of IgM against the virus.

Herpes Viruses. HSV meningoencephalitis has been associated with older age, steroid therapy, and brain irradiation. Typically, there is enhancement of the temporal lobe on MRI. After allo-HSCT, HHV-6 has been associated with a characteristic "limbic encephalitis" consisting of confusion, lethargy, memory loss, seizures, and (late) hippocampal enhancement on MRI fluid-attenuated inversion recovery images.²²⁴⁻²²⁶ The diagnosis is made by detection of HHV-6 DNA in the CSF by PCR.²²³ Ganciclovir, foscarnet, and the combination of both may be used, but there are no clinical data to choose one over the other. Detection of high levels of EBV DNA should raise suspicion of EBV-related lymphoproliferative disorder,²²⁷ but encephalitis and myelitis have been described. Adenovirus encephalitis also occurs in HSCT patients and is usually part of disseminated adenoviral infection; treatment with cidofovir may be attempted.

Cryptococcus Neoformans. Host defense against cryptococcal infection is principally dependent on cellular immunity. Among patients with cancer, those with hematologic malignancies, receiving high-dose corticosteroids, and allogeneic HSCT recipients are at highest risk for cryptococcosis. Meningoencephalitis is the most common presentation of cryptococcal infection, but other manifestations include primary pneumonia, pulmonary nodules, fungemia, and cutaneous and visceral dissemination. Diagnosis in disseminated disease may be obtained by determining cryptococcal antigen in the CSF and peripheral blood; in cases of localized disease, tissue must be obtained. In immunocompromised patients, the preferred regimen is amphotericin B (plus 5-flucytosine for the first 2 weeks), followed by maintenance fluconazole therapy. In neutropenic patients, reduction of the dosage of 5-flucytosine may be considered to avoid delay in myeloid recovery. Because fluconazole is well tolerated, continuing therapy with this agent for several months (or longer if intensive immunosuppressive therapy is continued) is reasonable.

Brain Abscess

Brain abscesses usually manifest with headache, focal neurologic findings, or seizures. MRI typically shows single or multiple lesions with edema and ring enhancement. Bacterial abscesses in nonimmunocompromised patients are typically caused by dental flora. In cancer patients, brain abscesses unrelated to surgery occur primarily in patients with prolonged neutropenia or profoundly depressed cell-mediated immunity, and are frequently fungal (92% of 58 cases of brain abscesses following HSCT¹⁵²). Almost all cases of CNS aspergillosis are associated with a pulmonary focus. Most cases of *Candida* brain abscess are associated with candidemia or neutropenia.

Manifestations of CNS aspergillosis include focal seizures, hemiparesis, cranial nerve palsies, and hemorrhagic infarcts due to vascular invasion.²²⁸ Serum and CSF galactomannan and β -glucan testing are also useful to make the diagnosis. Aspergillus brain abscesses are typically multiple, hypodense, and nonenhancing with little mass effect. CT scans with contrast enhancement

initially may reveal no focal lesions, but usually evolve to focal ring-enhancing or hemorrhagic lesions. MRI may show varying patterns depending on the stage of the lesion. In patients with impaired cellular immunity, other etiologies include toxoplasmosis, nocardiosis, cryptococcosis, and mycobacterial infections. Noninfectious etiologies include CNS malignancies, including secondary lymphomas and EBV-associated PTLD in patients with impaired cellular immunity. Given the broad differential diagnosis of new focal CNS lesions in immunocompromised patients, a brain biopsy is recommended if feasible. Cultures and stains should include bacteria, fungi, mycobacteria, and *Nocardia*.

In nonimmunocompromised patients with a bacterial brain abscess, initial therapy with ceftriaxone plus metronidazole is advised. In patients with prolonged neutropenia without corticosteroids or lymphocyte-depleting agents, voriconazole should be added. Voriconazole has important drug–drug interactions with certain antiseizure agents (e.g., phenytoin). In allogeneic HSCT recipients and other patients with severe T-cell impairment or high-dose corticosteroids, addition of high-dose TMP/SMX should be considered to cover toxoplasmosis and nocardiosis, pending a definitive diagnosis. In an analysis of 86 patients with CNS aspergillosis treated with voriconazole either as primary or salvage therapy, 34% had a complete or partial response.¹⁵⁴

Toxoplasmosis. Reactivation of *Toxoplasma gondii* may cause life-threatening disease in patients with profound deficits in T-cell immunity. Risk factors include therapy with corticosteroids, alemtuzumab, cytotoxic agents and/or radiation therapy, and poorly controlled malignancy. Toxoplasmosis is an uncommon complication of HSCT, occurring in <1% of patients, nearly all seropositive prior to transplantation. It tends to occur in the presence of moderate to severe GVHD (median day of onset of disease was 64 days after HSCT).^{229,230}

CNS disease with altered mental status, coma, seizures, cranial nerve abnormalities, and motor weakness are the most common findings.²³¹ MRI typically shows two or more lesions that may be ring-enhancing (Fig. 132.5). The differential diagnosis

Figure 132.5 Toxoplasmosis. A 58-year-old man developed seizures and aphasia 8 months after allogeneic stem cell transplant for chronic Epstein-Barr virus lymphoproliferative disorder. Brain biopsy showed toxoplasmosis. **(A)** Coronal T1-weighted image shows a necrotic lesion in the left anterior temporal lobe. **(B)** Axial T2-weighted image shows significant edema. The magnetic resonance imaging differential diagnosis included infection, lymphoma, and glioma.

includes bacterial infection, IA, nocardiosis, and malignancy. Differentiating toxoplasmosis from lymphoma is particularly difficult; 18-fluorodeoxyglucose positron emission tomography typically shows increased metabolism in lymphoma.²³² CSF in toxoplasmosis is usually normal; however, a mononuclear pleocytosis and elevated protein may be seen. Besides the CNS, other organs may also be involved (myocarditis, interstitial pneumonitis, culture-negative sepsis, and hemophagocytic syndrome have been described). Although definitive diagnosis of toxoplasmosis relies on demonstration of tachyzoites and cysts in histopathologic sections, PCR applied to serum and CSF has become widely used and may facilitate earlier diagnosis.^{229,233} The initial treatment of choice for toxoplasmosis is TMP/SMX or the combination of sulfadiazine and pyrimethamine. Folic acid (10 to 20 mg daily) should be administered to reduce myeloid toxicity. In patients intolerant of sulfonamides, clindamycin and primaquine may be used instead after verifying normal glucose-6-phosphate dehydrogenase activity. Atovaquone has also been used after exhausting other options.

JC Virus Encephalopathy. PML is a demyelinating disease associated with lytic infection of oligodendrocytes by the human polyomavirus JC virus. Patients may develop rapidly progressive dementia as well as focal motor or cerebellar findings. PML is occasionally seen in immunocompromised persons with hematologic malignancies and in HSCT recipients. Several cases associated with the use of rituximab²⁹ have prompted an advisory by the FDA regarding a possible association. There may also be an association with mycophenolate mofetil, an agent used sometimes for GVHD. MRI typically shows multiple white matter lesions without mass effect or enhancement. Diagnosis is generally established by detection of the JC virus in spinal fluid by PCR (90% sensitivity); if the PCR is negative, brain biopsy should be obtained. There is no established therapy for PML. In patients with AIDS, highly active antiretroviral therapy is the best option. By extrapolation, it is logical to try to reduce immunosuppressive therapy in persons with cancer and PML as a means of augmenting cell-mediated immunity. There are reports of improvement following the use of the antidepressant mirtazapine, which may interfere with virus entry.²³⁴

Genitourinary Infections

Neutropenic patients with a urinary tract infection are less likely to show pyuria and are far more likely to become bacteremic compared with nonneutropenic patients. We usually treat asymptomatic bacteriuria during neutropenia, although evidence is lacking. Asymptomatic candiduria is common in patients with bladder catheters. Removal of indwelling bladder catheters and cessation of antibacterial agents frequently leads to clearing of candiduria. Therefore, routine treatment of asymptomatic candiduria is not warranted. However, because of the risk of candidemia following genitourinary tract manipulations, candiduria should be treated before such procedures are performed. Candiduria should be treated in neutropenic patients with fever because of the possibility of occult invasive candidiasis.

Genitourinary Infections Related to Instrumentation or Devices

The American College of Radiology provides guidance to determine the appropriateness of interventions.²¹⁰ Relief of malignant obstruction of the urinary tract is best described in the context of gynecologic malignancy.²³⁵ Acute fever (10.3% to 15%) and pyelonephritis (5.9% to 3.8%) are common, respectively, for internal ureteral stent and percutaneous nephrostomy (no significant difference by procedure). Sepsis and bacteremia are common events in the placement of stents or percutaneous nephrostomy tubes when the urinary tract is infected, with septic shock in 7% to 9% of cases of pyonephrosis.²³⁶ No clear evidence favors any type of device, and

although prophylactic antibiotics are recommended, evidence for efficacy in preventing infection-related complications is lacking.²³⁷

Cystitis. Hemorrhagic cystitis is a common consequence of some cytotoxic regimens, particularly cyclophosphamide. A viral etiology should be considered in HSCT recipients and other immunocompromised patients with unexplained hematuria. The polyomavirus BK, adenovirus, and, rarely, CMV have been associated with hemorrhagic cystitis. Adenovirus hemorrhagic cystitis is usually self-limited, and the value of antiviral therapy is unclear. It is recommended to consider the possibility of adenovirus-related obstructive uropathy, hemorrhagic nephritis, and disseminated adenovirus disease.²³⁸ Low-dose cidofovir is sometimes used with the aim of preventing disseminated adenovirus disease.²³⁹ BK virus commonly reactivates after allogeneic HSCT, but only a minority of patients develop hemorrhagic cystitis; high plasma viral load correlates with risk of both BK virus-associated hemorrhagic cystitis and the less commonly seen BK nephropathy.^{240,241} A retrospective study suggested that low-dose cidofovir may be effective therapy for BK virus-associated hemorrhagic cystitis,²⁴² but the disease tends to be self-limited, so the study is inconclusive.

MULTIDRUG RESISTANT ORGANISMS OF INTEREST IN ONCOLOGY

Patients being treated for malignancy or undergoing HSCT are particularly vulnerable to health-care-associated infections. Gram-negative bacterial resistance in particular is a rising challenge that threatens to undermine outcomes of cancer therapy.²⁴³ Twenty percent of nosocomial infections in the United States are caused by multidrug-resistant bacteria.²⁴⁴ The proportions are even higher in some European and Asian countries.²⁴⁵ In fact, receipt of health care outside the United States is associated with carriage of highly antibiotic-resistant gram-negative organisms.

Multidrug resistant organisms (MDRO) not only cause serious infections, but leave patients colonized, often for months.²⁴⁶⁻²⁴⁸ Colonization refers to asymptomatic carriage on or in the body, without bacterial invasion. MRSA tends to colonize the nares and skin, while VRE and gram-negative bacteria colonize the intestinal tract. Colonization with multidrug-resistant bacteria can hasten death in patients who are already seriously ill with malignancy or HSCT. Under conditions that impair gut mucosal integrity (such as chemotherapy, GVHD, and other causes of colitis), the organisms colonizing the intestinal tract can invade and cause bloodstream or device-associated infections.^{249,250} Patients with cancer who develop infections with MDROs have a substantially higher mortality rate than those who have infections with susceptible strains of the same bacteria, due in part to misdirected empiric therapy.²⁵¹⁻²⁵³

Multidrug-resistant bacteria are shed by colonized patients and spread via the health-care environment, hands of health-care personnel, and contaminated equipment. Patients with hematologic malignancies and HSCT are particularly vulnerable to acquisition of certain MDROs because immune suppression, receipt of broad-spectrum antibiotics, and prolonged hospitalization. In addition, patients undergoing HSCT have significant derangement of their intestinal microbiota that diminish colonization resistance and allow long-term establishment of MDROs in the abnormal intestinal flora.²⁵⁴

Multidrug-Resistant Gram-Positive Bacteria

Methicillin-Resistant *Staphylococcus Aureus*

MRSA is commonly acquired in the community as well as in health-care facilities, and causes primarily skin and soft tissue infections, central line-associated bloodstream infections, and pneumonia. MRSA has declined in frequency as a cause

of invasive infections in hospitalized adults,²⁵⁵⁻²⁵⁷ due in part to widespread MRSA surveillance and infection control efforts, as well as improvements in central line care.²⁵⁶ Nonetheless, MRSA bloodstream infections carry a high mortality rate in patients with cancer.²⁵⁸ The IDSA has published guidelines for the treatment of MRSA.²⁵⁹ Though resistant to penicillins and cephalosporins, MRSA is typically susceptible to several oral and intravenous antibiotics. However, recommended empirical therapy for fever and neutropenia does not cover MRSA unless the patient is known to be colonized or presents with sepsis or pneumonia.⁷⁴ The value of screening patients before administering cytotoxic chemotherapy has not been addressed recently. Preoperative screening for MRSA and treatment with nasal mupirocin and chlorhexidine gluconate baths prior to oncologic surgery may reduce the risk of postoperative MRSA infection, though this measure has not been studied in a multicenter clinical trial.^{260,261} Besides the ongoing relevance of health-care-associated MRSA, there has been a dramatic increase in the incidence of community-acquired MRSA.²⁶² Community-acquired MRSA strains are generally susceptible to clindamycin, doxycycline, and TMP/SMX. The standard treatment for severe MRSA infections is vancomycin. Vancomycin-intermediate and vancomycin-resistant MRSA is rare.²⁶³ However, vancomycin failure in MRSA bacteremia has been associated with increasing vancomycin minimum inhibitory concentrations well within what is currently considered the susceptible range.²⁶⁴ Based on these observations, new guidelines on vancomycin dosing and therapeutic monitoring have been published.²⁶⁵ Minimum serum vancomycin trough concentrations should always be maintained above 10 mg/L to avoid development of resistance.

Linezolid seems at least as effective as vancomycin against MRSA in most published studies,^{266,267} and American Thoracic Society guidelines consider both linezolid and high-dose vancomycin (trough level of vancomycin of 15 to 20 mcg/ml) to be acceptable options for suspected or proven MRSA pneumonia. The major concern of linezolid in patients with cancer relates to duration-dependent marrow suppression. Short courses of linezolid appear to delay myeloid recovery only modestly in neutropenic patients with cancer⁸⁷; however, experience with long durations of therapy (e.g., >14 days) is limited. Peripheral and optic neuropathies have also been described with prolonged linezolid administration. Daptomycin is an acceptable option for *S. aureus* bacteremia and MRSA, based on the results of randomized controlled trials.^{268,269} Daptomycin is inactivated by lung surfactant and therefore should not be used to treat pneumonia.

Vancomycin-Resistant Enterococcus

VRE is a ubiquitous pathogen in hematology-oncology units. Once colonized, patients can carry VRE for many months, and, as with other colonizing multidrug-resistant pathogens, can cause bloodstream and device-related infections.²⁷⁰ Patients acquire VRE in health-care facilities, where 30% of nosocomial enterococcal infections are attributable to VRE. The bacteria are hardy and tenacious in the environment, and easily establish colonization in HSCT patients who have had major shifts in intestinal flora due to antibiotics and other aspects of their therapy.²⁷¹ Although VRE are less virulent than MRSA and many other MDROs, they can still cause lethal bloodstream infections in immunocompromised patients.²⁷² Screening for VRE in this high-prevalence population allows for implementation of isolation precautions to limit further spread as well as more effective empiric therapy for fever and neutropenia or sepsis.²⁷² VREs are resistant to vancomycin and usually ampicillin, but are typically susceptible to at least two other intravenous or oral antibiotics, linezolid, and daptomycin; resistance to those has been reported and may be increasing, making prevention even more crucial.²⁷³ Tigecycline often shows activity *in vitro*, but there are no good data on efficacy in clinical practice. Quinupristin/dalfopristin is a 30:70 mixture of these two semisynthetic streptogramin antibiotics. It has been shown to be safe and effective in serious

vancomycin-resistant *Enterococcus faecium* infections, but is not active against *E. faecalis*. One randomized controlled trial comparing treatments for VRE bacteremia showed that both quinupristin/dalfopristin and linezolid have similar (moderate) efficacy.²⁷⁴ The reported results with daptomycin seem to be similar.²⁷⁵

Clostridium difficile

Epidemiology. The incidence of *C. difficile* infection (CDI) has risen steadily since the early 2000s, when a new, hypervirulent strain emerged and became widespread and predominant in many North America hospitals.²⁷⁶ Since the emergence of the BI/NAP1 strain, the incidence of *C. difficile* has more than quadrupled, resulting in >300,000 infections and 10,000 deaths per year. Hospitalized patients with cancer develop CDI at twice the rate of other inpatients.²⁷⁰ The reported incidence is highest in allo-HSCT, followed by auto-HSCT and hematologic malignancies, and lower in solid tumors.^{270,277-281} Patients with malignancy develop *C. difficile* due to their exposure to the chief risk factors: antibiotics, chemotherapy, neutropenia, advanced age, and hospitalization. Proton pump inhibitors have been implicated as a risk factor, but the evidence is weak.²⁸²

Diagnosis. *C. difficile* produces exotoxins that cause colitis with a wide spectrum of severity. Mild disease is characterized by diarrhea and abdominal pain; patients with severe infection can become systemically ill, requiring intensive care and, occasionally, emergency colectomy. The disease may occur in outpatients, and patients may develop infection weeks after hospital discharge,²⁸³ or in the absence of hospitalization. Diagnosis is made via detection of bacterial toxin in diarrhea stool by enzyme immunoassay, PCR, or cytotoxin assay.^{284,285} Multistep testing using a less specific screening test followed by PCR testing of positive samples is used in some centers for cost savings. Among these methods, PCR is by far the most sensitive and specific, and its use is expanding.²⁸⁶ *C. difficile* assays should only be applied to diarrheal stools or, in patients presenting with ileus, a swab, in order to avoid detecting asymptomatic carriage.^{284,285} Repeat testing by PCR is not necessary, but repeat enzyme immunoassay tests may identify additional cases following a single negative assay in a high-risk patient.¹⁷⁶

Treatment. Because *C. difficile* is an antibiotic-associated infection, discontinuation of antibiotics, if possible, may improve the chance of cure and reduce risk of recurrence. The American guidelines from the Society for Healthcare Epidemiology of America and the IDSA suggest an expert-opinion clinical classification of the severity of CDI as mild/moderate, severe, and severe/complicated based on leucocytosis, renal dysfunction, and the presence of hypotension, shock, or toxic megacolon.²⁸⁵ How applicable these criteria would be to cancer patients is unknown. The initial therapy is targeted to the severity: oral vancomycin is recommended for severe *C. difficile*, and metronidazole (oral or intravenous) for initial episodes of mild to moderate infection.²⁸⁵ A 10- to 14-day course of metronidazole is recommended for mild to moderate infection because of its lower cost and efficacy equivalent to vancomycin for nonsevere disease.²⁸⁷ There is no need to send additional toxin assays as tests of cure during or following treatment unless there is renewed diarrhea that raises concern for relapse. Severe infection is treated with a 10- to 14-day course of oral vancomycin due to possible higher efficacy in severe cases.²⁸⁷ Complicated infection leading to critical illness or toxic megacolon is treated with vancomycin administered both orally and per rectum, as well as intravenous metronidazole²⁸⁵; patients with fulminant infection may require emergency colectomy. A first recurrence, or second episode, of CDI is typically treated with the same therapy as the first episode, depending on the disease severity. Further recurrences are often treated with progressively long courses and tapers of oral vancomycin, although there are no randomized trials to support the practice.²⁸⁵ Fidaxomicin, a newer antibiotic, is equivalent to vancomycin in improving symptoms of

infection, and may achieve a more enduring cure than vancomycin.^{288–291} Patients who have recurrent or refractory infection are treated with fecal microbiota (stool) transplantation, which has a cure rate of at least 80% to 90%.^{292,293} This approach has not been routinely attempted in patients with hematologic malignancies.

Probiotics are popular, due in part to the perception that they are harmless and may help prevent initial or recurrent CDI. Although *Lactobacillus* spp. and *Saccharomyces* spp. at varying doses are marketed for these purposes, benefits seen in clinical trials have been inconsistent.^{294,295} Furthermore, probiotics must be used with caution in hospitalized patients, as both *Lactobacillus* and *Saccharomyces* can translocate from the intestinal tract and cause bloodstream infections in immunocompromised or critically ill patients.^{296–298}

Outcome. The majority of patients experience mild to moderate infection, of whom >90% recover when treated with a standard regimen²⁸⁷; a significant minority, in particular those who are infected with the B1/NAP1 strain, develop severe disease, often requiring intensive care or emergency colectomy. About 20% to 30% of patients experience relapse,²⁸⁹ usually within 2 weeks and at approximately equivalent rates among those treated with metronidazole or vancomycin.²⁹⁹ Relapse rate may be lower in patients treated with fidaxomicin.²⁸⁹ About 40% of relapsed patients experience additional relapses of infection. A smaller proportion develop refractory disease. Advanced age and continued antibiotic therapy are risk factors for severe, recurrent, and refractory infection.

Patients with cancer have a lower rate of cure and double the time to resolution of symptoms than other patients, but do not have a higher mortality rate from CDI.^{278,289,300} HSCT recipients do not experience more severe disease than control patients, and do not have higher mortality than other HSCT patients. Among allo-HSCT recipients, there may be a self-reinforcing cycle between CDI and intestinal GVHD. Gut GVHD is a risk factor for CDI,^{278,279} and CDI is strongly associated with subsequent development of gastrointestinal GVHD.^{279,301} Allogeneic HSCT patients may also be more vulnerable to bloodstream infections following CDI, possibly due to further impairment of intestinal mucosal integrity.³⁰¹

Prevention. Implementation of facility-wide antimicrobial stewardship programs has been shown to reduce rates of CDI in health-care facilities and can reduce rates among cancer patients.³⁰² Several risk factors for CDI (e.g., broad-spectrum antibiotics) may not be modifiable in patients with malignancy and HSCT recipients. However, evidence suggests that much of the CDI that occurs in hospitals is transmitted from other patients via health-care personnel or from the hospital environment. *C. difficile* spores are extremely hardy and remain viable in the health-care environment for weeks to months. Hospitalized patients who experience recurrences of CDI are often reinfected with different strains, possibly from contamination in the health-care environment.³⁰³ Infection control precautions can contribute significantly to prevention and control of *C. difficile* spread within a health-care facility.³⁰⁴ Empirical isolation of patients while tests for diarrheal pathogens are pending is essential to prevent spread of *C. difficile* and other pathogens from patient to patient, as is effective disinfection of hospital rooms when patients are discharged or have recovered from infection.^{285,305} Strict adherence to isolation precautions (glove, gown, and hand hygiene) is crucial.³³ Hand hygiene with soap and water in lieu of alcohol-based hand gel will achieve superior removal of *C. difficile* spores.³⁰⁶

Multidrug-Resistant Gram-Negative Bacteria

Extended-Spectrum Beta Lactamase–Producing and Carbapenem-Resistant Enteric Bacteria

Multidrug-resistant gram-negative enteric pathogens, such as *Klebsiella*, *E. coli*, and *Enterobacter*, are of great concern due to both

increasing prevalence and increasing risk of treatment failure among oncology and HSCT patients.²⁴³ Enteric bacteria are common causes of bloodstream infections, device-related infections, and deep surgical site infections. Many gram-negative bacteria are resistant to fluoroquinolones, particularly in patients who have received fluoroquinolone prophylaxis.^{38,307,308} Extended-spectrum beta lactamase–producing gram-negative enteric bacteria are generally resistant to all cephalosporins and most or all penicillins. For extended-spectrum beta lactamase–producing enteric bacteria, carbapenems are the treatment of choice, but a post hoc study suggests that piperacillin-tazobactam may be used successfully.³⁰⁹ Unfortunately, resistance to carbapenems is becoming more prevalent. A rapidly expanding subset of carbapenem-resistant bacteria carry a plasmid-mediated carbapenemase enzyme that hydrolyzes the antibiotic.³¹⁰ Gram-negative enteric bacteria that have carbapenem resistance may require treatment with nephrotoxic and neurotoxic drug combinations including aminoglycosides and colistin. The dearth of additional effective antibiotics leads to frequent treatment failure even when patients are treated with antibiotic combinations. These pathogens are readily transmitted in hospital wards, and bloodstream infections carry a mortality rate of >50% in hematology-oncology patient populations.^{311–313} There are no prospective comparative data to support any particular antibiotic regimen. Frequently, a carbapenem like doripenem is administered together with colistin and tigecycline. Prolonged infusion of meropenem may result in systemic levels above the minimum inhibitory concentration of some bacteria^{314,315}; alternatively, it is possible the presence of carbapenem results in synergy.³¹⁶

Pseudomonas Aeruginosa

P. aeruginosa continues to be frequently documented during neutropenic fever.³¹⁷ Many cases of *P. aeruginosa* bacteremia now occur in outpatients.^{318,319} *Pseudomonas* also causes device-related infections and surgical site infections in patients with solid tumor malignancies. No single antimicrobial is effective against 100% of *Pseudomonas* isolates, which is the reason most authorities recommend combining an antipseudomonal β-lactam antibiotic and an aminoglycoside until results of susceptibility testing become available.³²⁰ Isolates of *P. aeruginosa* in colonized patients who receive antibiotics frequently develop progressive resistance to those antibiotics,³²¹ resulting in limited treatment options. Approximately 13% of nosocomial *P. aeruginosa* infections are multidrug resistant. Colistin administered parenterally³²² or aerosolized (in infections limited to the lung)^{323–325} may be considered as salvage therapy. The continuous infusion of ceftazidime or other β-lactam antibiotics has also been used in attempts to prevent or overcome the emergence of resistance during therapy.^{326–328}

Other multidrug-resistant pathogens that are occasional causes of nosocomial infection or even hospital outbreaks include waterborne organisms such as *Acinetobacter baumannii* and *S. maltophilia*. These bacteria can cause bloodstream infections and device-related infections, and can colonize the gastrointestinal tract, skin, and respiratory tract of immunocompromised or critically ill patients. *Acinetobacter* is a pathogen that has become endemic in many health-care facilities.³²⁹ Susceptible strains of *Acinetobacter* are found in water and soil, but health-care-associated isolates are frequently resistant to many classes of antibiotics, often including carbapenems.³³⁰ Although *Acinetobacter* causes 2% to 7% of health-care-associated infections, 63% of *Acinetobacter* isolates are multidrug resistant. *Stenotrophomonas* isolates are intrinsically resistant to carbapenems and cephalosporins, and may be selected out by prior use of broad-spectrum antibiotics, particularly carbapenems.³³¹ The majority of strains are susceptible to TMP/SMX, which is the preferred initial antibiotic. If TMP/SMX cannot be used, there have been reports of success with ticarcillin-clavulanic acid and fluoroquinolones (particularly moxifloxacin). Tigecycline and colistin are often active in vitro.

The grave danger posed by some highly antibiotic-resistant bacteria to immunocompromised patients warrants heightened

infection control efforts to prevent nosocomial acquisition of the pathogens. Surveillance efforts should be targeted identifying patient colonization with the most highly prevalent (e.g., VRE) or most clinically significant pathogens (e.g., carbapenemase-producing enteric bacteria). Rapid molecular assays that detect MRSA, VRE, and some carbapenem-resistant enteric bacteria have lowered the barrier to identification of colonized patients. Once identified, colonized patients are isolated in order to prevent transmission. Meticulous adherence to isolation precautions, rigorous hand hygiene, and effective environmental disinfection are essential to prevent transmission from colonized patients who are isolated and those whose colonization has not yet been discovered. In addition to the infection control rationale, knowledge of MDRO colonization status offers clinicians a chance to tailor empiric antimicrobial therapy to cover the most likely potential pathogens. Important drawbacks of surveillance and isolation are the adverse social and patient safety consequences of isolation.³³²

Several other measures aid in the effort to prevent nosocomial spread of multidrug-resistant pathogens. Improved antimicrobial

stewardship both in health-care facilities and the community have been shown to reduce rates of colonization with resistant bacteria. Chlorhexidine gluconate 2% daily baths have been demonstrated repeatedly to reduce the risk of acquisition of multidrug-resistant bacteria, in addition to reducing rates of central line-associated bloodstream infections.³³³ This intervention carries an extremely small risk of severe skin reaction and a potential risk of selecting out chlorhexidine-resistant skin flora.³³³ Finally, minimizing the duration of use of invasive devices such as central venous lines and urinary catheters reduces the opportunities for introduction of multidrug-resistant bacteria, and therefore the risk of serious infection.

A number of multidrug-resistant bacteria threaten oncology and HSCT patients, who are vulnerable because of impaired immunity, antibiotic use, and frequent contact with the health-care system. Measures to prevent acquisition of these bacteria are essential given the increasing complexity and declining success of managing infections with the most highly resistant pathogens.

133 Neutropenia and Thrombocytopenia

Lodovico Balducci, Bijal Shah, and Kenneth Zuckerman

INTRODUCTION

Neutropenia and thrombocytopenia are the most frequent manifestations of cytotoxic chemotherapy-induced myelosuppression.¹ During the treatment of acute leukemia, this complication may last several weeks during which the risk of mortality from infection and bleeding is increased.² In all circumstances, myelosuppression may impact the antineoplastic treatment in several negative ways that include increased mortality^{3,4} from infection or bleeding, more frequent hospitalizations,⁵ increased treatment cost,^{3,5,6} reduction in dose intensity of chemotherapy,⁷⁻¹⁰ and treatment discontinuation.^{7,8}

This chapter explores the management of neutropenia and thrombocytopenia in the course of cytotoxic chemotherapy, after a brief review of hematopoiesis.

Hematopoiesis

Hematopoiesis is a hierarchical and compartmentalized process involving early multipotent progenitors, late committed progenitors, and differentiated precursors of the mature blood elements¹¹ (Fig. 133.1). The early multipotent progenitors include the totipotent hematopoietic stem cells, capable of generating both the lymphoid and the myeloid series, and the myeloid and lymphoid stem cells. The totipotent stem cells include different populations of cells: the most primigenious ones with long-term repopulation capacity and the more mature ones with short-term repopulation capacity. The myeloid stem cell undergoes commitment into the myeloid, erythroid, and megakaryocytic progenitors, from which the differentiated marrow precursors of the circulating blood elements are derived. Both stem cells and early progenitors are indistinguishable from lymphocytes in microscopic preparation of the bone marrow and of the peripheral blood. Their existence was established from the ability to generate hematopoietic colonies containing multiple (multipotent progenitors) or single (committed progenitors) cell lines. Currently, a number of surface markers identify these elements with specific phenotypes (see Fig. 133.1).

The stem cell and to some extent the committed progenitors have high self-renewal potential and low proliferative rate, while the differentiated marrow precursors have a low self-replicative capacity and high proliferation. Low proliferation protects the stem cells and the committed progenitors from cytotoxic chemotherapy that is cycle active and damages preferentially proliferating cells. In addition, the earliest progenitors express the MDR-1 gene that encodes the P-glycoprotein, a calcium channel pump extruding natural genotoxic products from the cell.¹² These include both tumor antibiotics and plant derivatives. Thanks to the preservation of the hematopoietic reserve, the myelodepression of chemotherapy is generally fully reversible. There are exceptions, however. Some alkylating agents including busulfan, melphalan, nitrogen mustards, and the nitrosureas, and the antibiotic mitomycin C are able to overcome the protective mechanisms and to destroy the hematopoietic progenitors.^{13,14}

Hematopoiesis requires an intact hematopoietic stroma capable to home the early progenitors, and a network of growth factors that stimulate proliferation, commitment, and differentiation^{11,15-18} (Table 133.1). The homing occurs in the so-called hematopoietic niches that bind the hematopoietic progenitors through specific receptors to endothelial cells and osteoblasts. Except for erythropoietin that is produced in the kidney, and thrombopoietin that is produced both in the liver and in the kidneys, the other hematopoietic growth factors are produced by monocytes and by stromal cells of the bone marrow.

Hematopoiesis may be altered due to a reduction in the number of progenitors, the development of abnormal progenitors that have lost their ability to self-replicate or commit, abnormal production of hematopoietic growth factors, and abnormalities in the hematopoietic microenvironment. Some of these changes do occur with aging and include loss of homing, increased concentration of stem cells with reduced self-renewing capacity, and preferential differentiation of the totipotent stem cell toward the myeloid rather than the lymphoid series.^{19,20}

Neutropenia and Its Management

Definition of Neutropenia and Its Consequences

According to the Common Terminology Criteria for Adverse Event version 4.0, neutropenia is defined by a granulocyte count that is $\leq 1,500/\mu\text{l}$,²¹ and neutropenic infection is assumed for any fever episodes occurring when the neutrophil count is $< 1,000/\mu\text{l}$. When the neutrophil count is $< 500/\mu\text{l}$, the risk and severity of infection is inversely related to the neutrophil count.²² The duration of neutropenia also determines the type of infections.² Bacterial infections from gram-negative pathogens and *Staphylococcus aureus* are more common during the first week of neutropenia.²³ A number of fungal infections including *Candida*, *Aspergillus*, *Mucor*, and others may develop in patients with more prolonged neutropenia including those receiving treatment for acute leukemia.²⁴ In addition to the severity, the duration of neutropenia determines the risk of infection. Infections are rare during the first 3 days of neutropenia as the neutrophils may still be present in the tissues.

For management purposes, it is useful to identify two different conditions: the neutropenia that follows marrow ablation for the treatment of some forms of acute leukemia, and the neutropenia that develops during the treatment of solid tumors or lymphomas with cyclic cytotoxic chemotherapy. Following marrow ablation, the neutropenia may last several weeks and the risk of infections is $> 90\%$.²² The main concern in this situation is support of the patient until marrow regeneration.

The neutropenia following noncytotoxic chemotherapy of solid tumors and lymphomas causes two concerns: infectious complication and maintenance of treatment dose intensity. This may be compromised due to treatment delay or dose reductions in order to prevent neutropenia. The relative dose intensity (RDI) is the percentage of the planned treatment dose

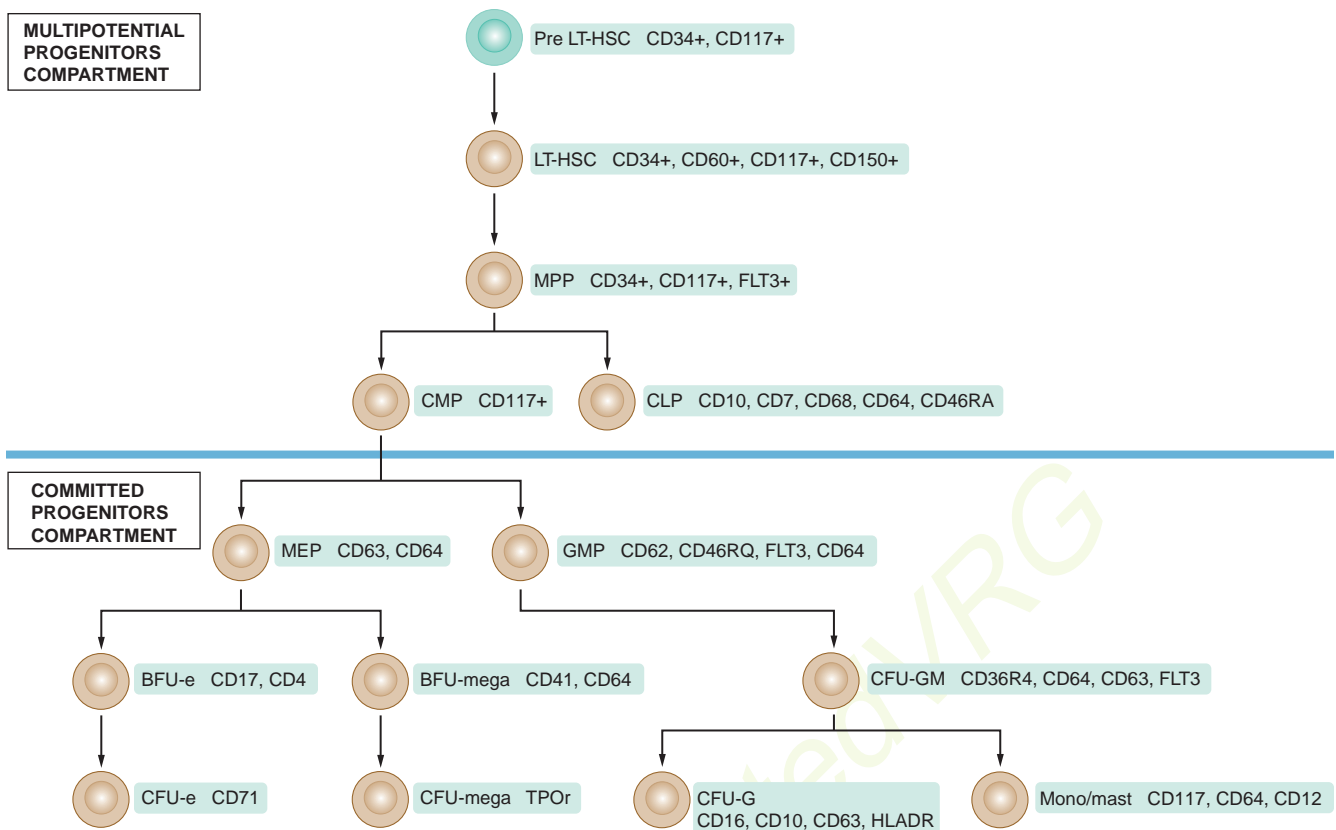

Figure 133.1 Hematopoiesis as a hierarchical compartmentalized process. Lymphopoiesis is not shown beyond CLP as it is not relevant to this chapter. LT-HSC, long-term hematopoietic stem cell repopulation capacity; MPP, multipotent progenitor; CMP, common myeloid progenitor; CLP, common lymphoid progenitor; MEP, megakaryocyte-erythroid progenitor; GMP, granulocyte monocyte progenitor; BFU, burst-forming unit; BFU-mega, burst-forming unit megakaryocyte; CFU-GM, colony-forming unit granulocyte-monocyte; CFU-e, Colony Forming Unit erythroid; CFU-megaTPOr, colony-forming unit megakaryocyte; CFU-G, colony-forming unit granulocyte.

administered during a course of treatment per unit of time and is calculated²⁵ as:

$$\frac{D/T \text{ administered} \times 100}{D/T \text{ planned}}$$

where D is the dose and T the time unit.

The effectiveness of chemotherapy may be determined by the RDI, whose preservation is essential in curable diseases. When the dose intensity of adjuvant cyclophosphamide, methotrexate, and fluorouracil was <85%, the treatment was not effective in women with early breast cancer.²⁵ Likewise, a reduction of the dose density of doxorubicin <85% was associated with reduced response rate and survival in patients with B-cell large-cell lymphoma treated with cyclophosphamide, hydroxydaunorubicin, oncovin, and prednisone (CHOP).²⁵ Neutropenia has been responsible for at least 50% of the cases in which the chemotherapy dose intensity has been reduced below 85%.²⁵

The neutrophil kinetics determines the course of chemotherapy-induced neutropenia.²⁶ The median survival of mature neutrophils is approximately 12 hours in the circulation and 3 days in the tissues. The bone marrow contains a reserve of mature granulocytes to last approximately 7 days. The development of mature granulocytes from committed myeloid progenitors takes approximately 10 to 14 days. Consequently, the nadir neutrophil count following chemotherapy every 3 or 4 weeks is expected around the 10th treatment day, with recovery beginning around the 14th and completed by the 21st day. The time-honored way to prevent neutropenia and neutropenic infections prior to the introduction

of myelopoietic growth factors included reduction of the doses of myelotoxic agents for a neutrophil count <500/ μ l at nadir or <1,500/ μ l at the beginning of the new treatment cycle, whose initiation was delayed until the neutrophil count was completely recovered.

The neutrophil kinetics may be altered by a number of factors. Drugs that affect the pluripotent progenitors, such as mitomycin C and nitrosoureas,²⁷ may cause later, more prolonged and cumulative neutropenia. In the presence of infection, the neutrophil reserve of the bone marrow may be exhausted at an earlier time and neutropenia may be more prolonged due to increased utilization of mature neutrophils. Also, hematopoiesis may be compromised by a number of factors that include age, previous chemotherapy administration, and myelophthisis.

Risk Factors for Chemotherapy-Induced Neutropenia

Clearly, the risk of neutropenia varies from patient to patient and includes both treatment- and patient-related factors. The determination of the individual risk of neutropenia and neutropenic infections is helpful to plan the most effective management of neutropenia. A number of risk factors for febrile neutropenia were identified in several studies²⁸⁻³⁰ (Table 133.2).

The risk of neutropenic infections from different treatment regimens is obtained from the original trials of those regimens. It should be underlined that the incidence of neutropenic infections may be higher in patients treated in the community than in those included in clinical trials.²⁸⁻³⁰

TABLE 133.2

Assessment of the Risk of Neutropenic Infections in Individual Patients

Risk Factors for Development of Neutropenic Fever	
Type of chemotherapy	
Age >60–65 y	
Advanced disease	
Poor performance status	
Previous chemotherapy	
Previous episodes of neutropenic infections	
Myelophthisis	
Number of comorbid condition	
Abnormal liver enzymes	
Abnormal creatinine clearance	
Low neutrophil count at the beginning of the treatment	
Lymphopenia	
Hemoglobin	
Presence of an ongoing infection	
Multinational Association for Supportive Cancer Care Risk Index (DeSouza et al. ⁴⁷ and Innes et al. ⁴⁸)	
Patient Characteristics	Score
Burden of illness	
No or mild symptoms	5
Moderate symptoms	3
No hypotension	5
No chronic obstructive pulmonary disease	4
Solid tumor or lymphoma and no previous fungal infection	4
No dehydration	3
Outpatient status	3
Age <60 y	2

Low-risk score ≥ 21 . High-risk score < 21 .

Age is probably the best identified patient-related risk factor. It is clear that the risk of neutropenic infections increases with age. A review of 500 patients with large-cell B-cell lymphoma treated in the community with CHOP or cyclophosphamide, novantrone, oncovin, and prednisone showed that the risk of neutropenic infections was 28% for the total population, 18% in the younger individuals and 40% for those 65 and older.⁵ Hospitalization for neutropenic infections was 25% longer for older individuals. This finding is important as both treatment cost and risk of deconditioning increase with hospitalization.

In most studies the age threshold was 65, and in some it was 60. The risk of breakthrough infection despite growth factor support³⁰ and of infectious mortality also increases with age.^{3,4}

In the Surveillance, Epidemiology and End Result database, the risk of febrile neutropenia in Medicare recipients increased with the number of comorbid conditions.³¹ In other studies, chronic liver and kidney dysfunctions, chronic obstructive lung disease, diabetes, congestive heart failure, osteoarthritis, and thyroid diseases were associated with increased risk of febrile neutropenia.^{10,32}

In several studies, anemia was an independent risk factor for the development of chemotherapy-induced neutropenia and neutropenic fever.^{33–38} Anemia may represent a sign of chronic diseases, of bone marrow insufficiency, and of malnutrition.³⁹ Another explanation is suggested by pharmacokinetic considerations.³⁴ As the

majority of cytotoxic agents are bound to the red blood cells, a reduction of hemoglobin may be associated with increased concentration of free drug in the circulation and consequently with increased risk of toxicity.

Protein calorie malnutrition also appears as a risk factor for chemotherapy-induced myelotoxicity.^{40–43}

Myelophthisis may occur with most tumors and is particularly common in patients with lymphoma, breast, and prostate cancer.

The relationship between lymphopenia and risk of neutropenic infections is well established albeit poorly explained.^{44–46} A drop in lymphocyte count during the first week after chemotherapy seems predictive of febrile neutropenia. A possible explanation is that lymphopenia represents poor nutrition.

A number of models to predict the risk of neutropenia or neutropenic fever in solid tumors and lymphomas were developed. The five models that have been prospectively validated are described here. The Multinational Association for Supportive Cancer Care risk index illustrated in Table 133.2 divides the patients in high and low risk according to a score obtained from the presence of different risk factors.⁴⁷ The main advantages include simplicity and reproducibility.⁴⁸ Of concern is the fact that the index has been validated prospectively in a small number of patients and only to predict the benefits of prophylactic antibiotics. Another simple index⁴⁹ divides patients in four groups according to the original neutrophil ($< 3,100/\mu\text{l}$) and lymphocyte ($< 1,500/\mu\text{l}$) count. When both counts are lowest, the risk of neutropenic fever is the highest. This model was validated in patients receiving adjuvant chemotherapy of breast cancer with docetaxel, doxorubicin, and cyclophosphamide.

Among 266 patients with non-specified hematologic malignancies, Moreau et al.³⁶ found that aggressive chemotherapy, baseline hemoglobin level, type and stage of disease, body surface area, involvement of the bone marrow, and monocyte count $< 150/\mu\text{l}$ were independent risk factors for neutropenic fever during the first course of chemotherapy. Among 240 patients with non-Hodgkin lymphoma, Pettengell et al.⁵⁰ found that a model including age, weight, previous chemotherapy, chemotherapy dose, albumin levels, and use of granulocyte–colony-stimulating factor (G-CSF) predicted individual risk of neutropenic fever with 80% accuracy. While of interest, these models have limited use due to the fact that they involve only a small number of patients with specific malignancies.

In a prospective study of 3,760 patients treated for solid tumors and lymphomas in 115 practices in the United States, Lyman et al.³⁰ were able to derive an individual risk of neutropenia, severe neutropenia, and neutropenic infection based on prior chemotherapy, low neutrophil count, abnormal hepatic and renal function, type of chemotherapy, and planned delivery of $\geq 85\%$ of the dose intensity. The index has a predictive value positive and negative of 34% and 96%, respectively. Surprisingly, age was not an independent risk factor even though one-third of the patients were 65 and older. This model is interesting for several reasons. First, it was derived and validated from the cohort study of a large number of patients. Second, it included severe neutropenia in addition to neutropenic infections among the outcomes. Severe neutropenia should be avoided, at least in curable diseases, because it may purport a reduction of RDI of chemotherapy.^{51–54} Third, it provides a determination of individual risk of neutropenic infections. Fourth, it was derived from a number of community practices and as such it reflects the situation of the majority of patients undergoing cancer chemotherapy. Fifth, it encompasses a wide array of diseases and of chemotherapy regimens. The limits of this model include the need for a calculator and the fact that the age range of the patients was not specified. While we know that one-third of the patients were 65 and older, we don't know how many of them were older than 75 or 80. In the time of electronic health records, the calculation of the index may not represent a problem anymore.

Due to the lack of prospective comparisons, it is premature to recommend a specific model for the prediction of neutropenic

infections in individual cases. In a community-based oncology practice,⁵⁵ the adoption of an instrument to assess the risk of neutropenic infections prior to the initiation of cytotoxic chemotherapy has led to a marked reduction in the incidence of neutropenic infections and of hospitalization for neutropenic infections. Also, more patients than before received chemotherapy with a RDI $\geq 85\%$.

Management of Neutropenia

Prevention of Neutropenic Infections in Patients Receiving Chemotherapy for Solid Tumors and Lymphomas

In the treatment of solid tumors and lymphomas, the management of neutropenia has two goals: reduction in the incidence and severity of infectious complications, and maintenance of the RDI of chemotherapy at $\geq 85\%$.

Prior to the introduction of the myelopoietic growth factors, it was recommended that the dose of chemotherapy be reduced in patients experiencing severe neutropenia at nadir or neutropenic infections and that the treatment be delayed for neutrophil counts $\leq 1,500/\mu\text{l}$.^{2,22} Prophylactic administration of antibiotics has been a complementary strategy toward the reduction of neutropenic infections. The fluoroquinolones and the combination of sulfamethoxazole/thrimethoprim reduce the risk of gram-negative infections from enteric pathogens in patients with prolonged neutropenia.⁵⁶⁻⁵⁹ By causing an anaerobe overgrowth in the colon, these compounds suppress the growth of gram-negative pathogens that are the most common cause of bacterial infections during neutropenia. Most of the studies were performed in patients with acute leukemia and in those undergoing bone marrow transplant, however, so that the information is limited in patients with solid tumors and lymphoma. In two large randomized controlled studies, prophylactic levofloxacin was associated with a reduction of episodes of neutropenic fever of approximately 30% without a reduction of documented infections or of infectious deaths.^{56,58} In one of these studies, stool cultures showed emergence of gram-negative organisms resistant to levofloxacin and rose the concern that this practice may lead to antibiotic-resistant hospital infections.⁵⁶ According to a meta-analysis of randomized controlled trials, the prophylactic use of fluoroquinolones was associated with a significant reduction in the incidence of neutropenic fever in patients with solid tumors and lymphomas and a nonsignificant reduction in mortality.⁵⁹ A Dutch study compared the combination of growth factors and antibiotics versus antibiotics alone in patients receiving treatment for small-cell lung cancer.⁶⁰ The combination of colony-stimulating factors and antibiotics was more effective than antibiotic alone in preventing neutropenic fever. According to this study, the role of prophylactic antibiotics is questionable in the case of solid tumors.

Based on these data, no consensus exists on the use of prophylactic antibiotics in patients treated for solid tumors and lymphomas.⁶¹⁻⁶³ This practice may be justified when the duration of neutropenia is expected to be longer than 7 days.

Myelopoietic Growth Factors

The introduction of recombinant hematopoietic growth factors (see Table 133.1) has provided a new weapon to prevent both neutropenia and neutropenic infections. Both recombinant G-CSF and granulocyte macrophage-colony-stimulating factor (GM-CSF) are available for clinical use.⁶⁴⁻⁶⁶ Recombinant forms of G-CSF include both short-acting (filgrastim, lenograstim, and tbo-filgrastim) and long-acting (pegfilgrastim and lipegfilgrastim) preparations. Unlike the short-acting preparations, pegfilgrastim and lipegfilgrastim cannot be eliminated from the kidneys. They are metabolized by the neutrophils at the time of recovery from neutropenia. As such, they linger in the circulation until recovery has occurred.

Three different recombinant human GM-CSFs are available and include sargramostim, molgramostim, and regramostim. Of these, sargramostim is the only one approved for use in the United States. Sargramostim is derived from yeast (*Saccharomyces cerevisiae*) and is O-glycosylated; molgramostim is not glycosylated recombinant human GM-CSF and is derived from *Escherichia coli*. Regramostim is fully glycosylated and is derived from Chinese hamster ovary cells. The different formulations appear to have similar pharmacologic activity.

Despite that they have been available now for more than 20 years, a number of controversies linger concerning hematopoietic growth factors. The controversies hinge on three questions: which growth factor should be used, when and how it should be used, and what are short- and long-term complications for their use.

Which Growth Factor Should be Used? In solid tumors and lymphomas, G-CSFs have reduced the incidence of neutropenia and neutropenic infections, as well as the hospitalization for neutropenic infections according to a number of randomized controlled studies examined in six meta-analyses^{8,67-71} and a review of its use in clinical practice in patients with lymphoma.⁵ In two of these meta-analysis,^{8,68} the use of these agents was also associated with reduced mortality from neutropenic infections. In addition, the most recent meta-analysis suggested that the all causes of mortality might have been reduced⁸ and that the dose intensity of chemotherapy was better preserved with these agents.⁹ At least one meta-analysis of 148 clinical trials failed to see any benefits for the use of myelopoietic growth factors.⁷² However, this study included different growth factors and different ways of administration such as delayed administration that was proven ineffective previously. According to a number of meta-analysis and systematic reviews, filgrastim and lenograstim have comparable activities.^{8,67,68,73} In a review of the drug approval process in Europe,⁷⁴ the activity of the biosimilar Tevagrastim (Teva Pharmaceuticals, North Wales, PA) also appears comparable with that of filgrastim.

A number of randomized controlled studies found that safety and effectiveness of filgrastim and pegfilgrastim were comparable in patients with lymphoma and solid tumors.⁷⁵⁻⁷⁸ According to a meta-analysis of these trials, pegfilgrastim was superior to filgrastim in reducing the risk of neutropenic infections.⁷⁰ Similar conclusions were reached by an analysis of a US claim database involving more than 18,000 patients⁷⁹ and by a review of the use of filgrastim and pegfilgrastim in Spain.⁸⁰ These results may be explained, at least in part by improved patient compliance with a single injection per cycle. In a randomized controlled trial, pegfilgrastim and lipegfilgrastim, the new long-acting form of filgrastim undergoing clinical trials, had comparable activities and safety.⁸¹

A number of studies demonstrated that GM-CSF decreases the duration of neutropenia and the risk of neutropenic infections in patients with lymphoma and solid tumors and is a reasonable choice for this purpose.^{61,82,83}

At present, the studies comparing filgrastim and sargramostim provided inconclusive and somehow conflicting evidence of the superiority of one drug over the other. In a small randomized controlled study including 181 patients,⁸⁴ filgrastim was associated with a shorter duration of neutropenia (1 day), but sargramostim was associated with decreased risk of hospitalization and shorter hospitalization for neutropenic fever. Both agents were equally well tolerated. A retrospective matched control study of national insurance claims indicated that the prophylactic use of sargramostim was associated with decreased risk of neutropenic infections and rehospitalization.⁸⁵ In another study of similar design, pegfilgrastim proved superior to both filgrastim and sargramostim in preventing neutropenic infections and hospitalizations.^{86,87} According to another report,⁸⁸ the substitution on the formulation of filgrastim with sargramostim in a single institution was associated with an increased incidence of infections and hospitalization rates as well as of treatment side effects (pain and fever). A review of 10 US outpatient practices revealed that sargramostim was associated

with increased risk of complications including unexplained fever, fatigue, and skin eruptions.⁸⁹ In a randomized comparison of filgrastim and sargramostim in patients with febrile neutropenia, sargramostim was also associated with increased risk of side effects.⁹⁰ One may conclude that the efficacy of myeloid growth factors in use in the United States is comparable, sargramostim may have increased risk of side effects, and pegfilgrastim at present is the most practical and convenient of the growth factors.

Timing of Use. The questions related to the timing include primary versus secondary prophylaxis, treatment duration with filgrastim and sargramostim, the administration of pegfilgrastim on the same day of chemotherapy, and the effectiveness of growth factors in course of neutropenic infections.

Primary prophylaxis means treatment of patients at high risk of neutropenia or neutropenic infections beginning with the first cycle of chemotherapy treatment; in secondary prophylaxis, growth factors are reserved for those patients who had already experienced an episode of neutropenic fever.

A number of randomized controlled^{91–93} and retrospective^{94–96} studies demonstrated that primary prophylaxis decreased risk of neutropenic infections throughout treatment, not only during the first course of treatment, and therefore it should be preferred^{61,65} in patients at high risk.

Filgrastim and sargramostim are administered daily for a minimum of 7 to 10 days. It is common practice to discontinue filgrastim when the neutrophil count is $\geq 3,000/\mu\text{l}$ (though the drug insert recommends $10,000/\mu\text{l}$). Several strategies have been employed for reducing the duration of growth factor treatment with inconclusive results. In a randomized controlled study, treatment of patients who had developed afebrile neutropenia did not reduce the risk of neutropenic infections.⁹⁷ Another approach included the reduction of the administration of G-CSF to 5 days⁹⁸; though it may be more effective than placebo, this approach may not be optimal. A review of several US practices revealed that administration of G-CSF for a duration shorter than 7 days was associated with increased risk of febrile infections and hospitalizations.⁹⁹ As the risk of neutropenic infections is highest during the first two courses of chemotherapy, a study addressed the question of whether the use of filgrastim could be avoided after the first two chemotherapy cycles in patients receiving adjuvant treatment for early breast cancer.¹⁰⁰ The risk of neutropenic infections was $>20\%$ during the successive chemotherapy cycles, and the authors concluded that filgrastim prophylaxis should be continued throughout all treatment cycles.

According to the current recommendations pegfilgrastim is administered once per treatment cycles between 24 and 72 hours from chemotherapy. These recommendations are based on the review of four randomized phase 2 studies including patients with breast cancer, lymphoma, non-small-cell cancer, and ovarian cancer.¹⁰¹ In the lymphoma and breast cancer studies, the duration of neutropenia was more prolonged and the neutropenia more severe in patients receiving same-day pegfilgrastim. Up to now, no new evidence has emerged supporting the use of pegfilgrastim on the same day as chemotherapy.

A meta-analysis of 13 randomized controlled studies of growth factors showed that myelopoietic growth factors do reduce the duration of hospitalization and the duration of neutropenia in patients with neutropenic infections.⁹⁰ However, they do not affect the overall mortality, though they may have a marginal influence on infectious mortality. The same conclusions were reached by a more recent review of the literature.¹⁰² This use is not recommended in the current guidelines.^{61,65}

Complications. The acute complications of growth factors include fever and skin reactions that appear more common with GM-CSF.⁹⁰ Bone pain is particularly common with pegfilgrastim, generally occurs during the first 5 days of treatment, and may lead to discontinuation of the treatment.¹⁰³ In a randomized controlled study involving 510 patients with different malignancies, naproxen

administered at 500 mg twice daily for 5 days initiated on the day of pegfilgrastim administration significantly reduced the incidence and severity of pain without appreciable side effects.¹⁰³ Of interest, the pain was more severe in African American patients who benefited most of the intervention.

The most worrisome long-term side effects of colony-stimulating factors is acute myelogenous leukemia.¹⁰⁴ In a meta-analysis of 25 prospective randomized clinical trials involving $>6,000$ patients, the risk of acute myelogenous leukemia had doubled with the use of filgrastim. In the same study, however, the overall mortality was reduced by the use of filgrastim, especially in patients treated with dose-intense chemotherapy. The authors concluded that the tradeoff of adverse outcomes was in favor of filgrastim. The risk of acute leukemia appeared mostly elevated in patients 65 and older receiving breast cancer adjuvant chemotherapy with anthracyclines^{105,106} and particularly with mitoxantrone.¹⁰⁷ There is no clear evidence that sargramostim or other forms of GM-CSF may induce acute myelogenous leukemia.

Cost should also be considered a complication of myelopoietic growth factors, as their use adds a substantial cost to treatment. It is debated whether and in which circumstances the use of these compounds is cost-effective. The controversy reflects, at least in part, the difficulty to assess cost and cost-effectiveness and the fact that in the cost estimate there may be different perspectives (that of the patient, of the third-party payers, and of the health-care provider). This confusion is well illustrated in a recent review of the pharmacoeconomics of the myeloid growth factors²⁵ that found that pegfilgrastim is more cost-effective than filgrastim, and primary prophylaxis more cost-effective than secondary prophylaxis in the United States. In Europe, where medical care is less costly, the cost-effectiveness of growth factors is substantially reduced. A number of independent factors may also affect the cost-effectiveness of these agents. For example, neutropenic infections, when treated in the outpatient setting, are less costly than in the hospital setting, which may diminish the cost-effectiveness of growth factors. A recent analysis indicates that primary prophylaxis with growth factors is cost-effective when the risk of neutropenic infections is $\geq 20\%$.¹⁰⁸ In accordance with this finding, current guidelines recommend that myeloid growth factors be used prophylactically when the risk of neutropenic infections is $\geq 20\%$ and not be used when the risk is $\leq 10\%$.^{61,65} The use for cases at intermediate risk is trusted to the practitioner's judgment.

Another area of controversy is whether these compounds should be used when the goal of the treatment is palliation instead of cure, and whether it would be wiser in these circumstances to institute a reduction of chemotherapy dose in lieu of growth factors.

As general principles one may state that:

- The cost of healthcare is an increasingly pressing social problem, and it is an ethic duty to use limited resources sparingly.¹⁰⁹
- The use of growth factors increases the cost of cancer care.
- The cost-effectiveness of these compounds increases when the risk of neutropenic infections is the highest. Practitioners should try to estimate this risk in individual situations based on chemotherapy regimen and patient's characteristics
- Cost-effectiveness considerations are secondary when an intervention may be life-saving as the use of myeloid growth factors may be in the treatment of older individuals.
- Patients receiving palliative chemotherapy should not be automatically excluded from treatment with growth factors. For example, patients with stage III ovarian cancer may enjoy several years free of disease thanks to platinum-based chemotherapy. Likewise, maintenance of adequate chemotherapy dose intensity may be life-saving in face of life-threatening metastases, such as lymphangitic lung metastases.

Conclusions Related to Myeloid Growth Factors Use. From this review, one may conclude that myeloid growth factors reduce the risk of neutropenic infections and hospitalizations in patients

receiving chemotherapy, allow the administration of more effective dose intensities of chemotherapy, and may reduce the infectious mortality. In the meantime, there is no evidence that growth factors improve the cancer-related survival. The use of growth factors appear cost-effective in patients in whom the risk of neutropenic infections is $\geq 20\%$. Pegfilgrastim may be more effective and certainly appears more cost-effective than the short-acting preparations.

Prevention of Neutropenic Infections in Patients with Acute Leukemia

In the management of acute leukemia, neutropenia may last several weeks, and virtually all patients are susceptible to neutropenic infections. The use of a protected environment including reverse isolation¹¹⁰ and neutropenic diet¹¹¹ are still of common use, though the evidence supporting them is controversial. Three interventions have been studied in randomized controlled studies: antibiotic prophylaxis, myelopoietic growth factors, and granulocyte transfusions.

Antibiotic Prophylaxis. A meta-analysis of 109 trials including 13,579 patients, the majority of whom had acute leukemia or had undergone bone marrow transplant,⁵⁷ demonstrated that prophylactic treatment with fluoroquinolones or trimethoprim-sulfamethoxazole was associated with a reduction in infectious mortality, overall mortality, and neutropenic fever without documented infection. This practice is recommended in patients in whom the neutropenia is expected to last 7 days or longer. Though the difference between the two types of antimicrobials was not significant, there was a trend favoring the fluoroquinolones.

Myelopoietic Growth Factors. The use of these agents is controversial. A meta-analysis of 18 randomized controlled trials involving 5,256 patients¹¹² failed to demonstrate any benefits for the use of growth factors in acute myelogenous leukemia after induction therapy. The same investigators in a previous meta-analysis established that growth factors were safe in acute leukemias.¹¹³ This should dispel concern about growth factor-induced stimulation of the neoplastic growth.

A systematic review of 14 studies established that the use of growth factors led to a decreased duration of neutropenia and early hospital discharge without effect on overall mortality.¹¹⁴ An early meta-analysis¹¹³ yielded similar results.

Some considerations are necessary prior to being convinced of the conclusion that myeloid growth factors have at best a marginal role in the management of acute myeloid leukemia. These studies were conducted in the 1990s,¹¹⁵⁻¹²² when many prognostic factors of acute leukemia were poorly defined, so they might have compared different patient populations. Some studies utilized GM-CSFs^{115,118-122} and other G-CSFs,^{116,117} and the source of these compounds was sometimes different. For example, the Eastern Cooperative Oncology Group¹¹⁵ utilized GM-CSF from *Candida* and the Cancer Acute Leukemia Group B the one from *E. coli*.¹¹⁹ One of the studies found increased response rates and increased survival with GM-CSF, while the other study found the growth factor ineffective. Also, the treatment with growth factors was started at different times in different studies and induction regimens were different.

In all studies, the growth factors reduced the duration of neutropenia and of antibiotic use in elderly patients (55 and older). In four studies,^{115,116,121,122} the use of growth factors after induction chemotherapy was associated with increased remission rate, and in one study with increased survival and reduction of treatment-related death.¹¹⁵ One can conclude that growth factors at the very least reduce the duration of neutropenia, of neutropenic infections, and of hospitalization in patients aged 55 and over, who are also the patients more vulnerable to the treatment complications.

More recently, other randomized controlled studies have explored the use of growth factors in remission induction of acute leukemia with inconclusive results.^{123,124} In one study, the use of

G-CSF was associated with shorter disease-free survival in individuals younger than 40,¹²⁴ but other factors might have contributed to the poorer outcome.

In a randomized controlled study, G-CSF reduced the duration of neutropenia and the duration of antibiotic treatment, and hospitalization for neutropenic infections in patients receiving consolidation therapy with high-dose cytarabine, but it did not change the overall survival or the infectious death rate.¹²⁵ A retrospective analysis of adult acute leukemias treated at a single institution with G-CSF during consolidation therapy reached similar conclusions.¹²⁶

In conclusion, in the management of acute myelogenous leukemia, myeloid growth factors decrease the duration of neutropenia and neutropenic infections after induction chemotherapy in individuals 55 and older, they decrease the duration of neutropenia and hospitalization after consolidation treatment with high-dose cytarabine, and they do not promote the growth of the neoplastic cells. In one study,¹¹⁵ the use of GM-CSF was associated with improved response rate and survival and decreased mortality, but these results were not confirmed in any of the other studies.

A number of randomized controlled trials demonstrated that both G-CSF and GM-CSF after induction treatment for acute lymphoblastic leukemia reduced the duration of neutropenia and of neutropenic infections, and that they can be safely used in these patients.¹²⁷⁻¹²⁹ At present, there is no evidence that they affect response rate or survival.

Granulocyte Transfusions. A meta-analysis of 10 studies performed decades ago did not show any reduction in infections related mortality from granulocyte transfusions.¹³⁰ However, these studies were conducted at a time when antibiotic treatment was more limited and antifungal treatment almost nonexistent. It would be reasonable to explore the value of granulocyte transfusions in conjunction with modern supportive care.

Thrombocytopenia

Definition, Epidemiology, and Causes. According to the Common Terminology Criteria for Adverse Event, thrombocytopenia is defined as a platelet count $< 100^3/\mu\text{l}$.²¹ The main risk of thrombocytopenia is hemorrhage, which is increased for platelet counts $\leq 50^3/\mu\text{l}$. The risk of spontaneous bleeding including intracranial hemorrhage is increased when the platelet count drops to $< 10^3/\mu\text{l}$.¹³¹⁻¹³³

In patients with malignant diseases, there are many causes of thrombocytopenia. The most common is cytotoxic chemotherapy. With most agents, the nadir platelet count is observed 10 to 14 days from the beginning of the treatment cycle and the recovery is completed by 3 weeks. If the platelet count is $< 100^3/\mu\text{l}$ at the beginning of a new cycle, the chemotherapy is delayed and the successive dose of treatment is decreased.¹³⁴

Thrombocytopenia from drugs that affect the early hematopoietic progenitors, such as the nitrosoureas, mitomycin C, busulfan, and melphalan, may be delayed and cumulative. In addition to cytotoxic chemotherapy, some of the new biologic agents may also cause thrombocytopenia. This complication is particularly common with lenalidomide.¹³⁵

Thrombocytopenia is a well-recognized complication of cytotoxic chemotherapy,¹³⁶ but its impact on morbidity, mortality, and decrease in chemotherapy RDI is not well established in patients with lymphomas and solid tumors. Among Medicare recipients with breast cancer treated with chemotherapy, thrombocytopenia accounted for only 0.6% of the hospital admission, whereas neutropenia and neutropenic infections accounted for 24%.¹³⁷

Myelosuppression is the most common, albeit not the only mechanism of chemotherapy-induced thrombocytopenia. Some chemotherapy agents, in particular mitomycin C, dacarbazine, and cisplatin, may induce thrombocytopenia as part of a hemolytic uremic syndrome.¹³⁸

The other major cause of thrombocytopenia is myelophthisis. In patients with acute leukemia, thrombocytopenia is almost universal at presentations and hemorrhages represent a common cause of death in these patients.¹³⁹

Other causes of thrombocytopenia may include hypersplenism, idiopathic thrombocytopenic purpura, disseminated intravascular coagulation,¹⁴⁰ and heparin-induced thrombocytopenia,¹⁴¹ as the use of heparin is becoming common in patients with cancer to maintain vascular access devices and to manage cancer-related thrombosis.

Management. Platelet transfusions remain the mainstay of the management of thrombocytopenia. One may distinguish prophylactic and therapeutic transfusions.¹³¹ Currently, prophylactic transfusions are recommended in patients with decreased platelet productions in two circumstances. In all individuals with a count $\leq 10^6/\mu\text{l}$ to prevent spontaneous intracranial bleeding and individuals with a count $< 50^3/\mu\text{l}$ for whom a surgical procedure is planned.¹³¹ Therapeutic transfusions are those administered to actively bleeding patients and are indicated for platelet count $< 50^3/\mu\text{l}$. It should be underlined that the threshold for both prophylactic and therapeutic transfusions are controversial. Two current studies are being conducted in Germany and in the United Kingdom to establish whether the threshold for prophylactic transfusions may be lowered, to prevent the risk associated with the transfusions and especially platelet refractoriness.^{142,143}

A recombinant preparation of interleukin-11 has been approved for use in patients with solid tumors or lymphoma.¹³⁶ This

compound is associated with substantial toxicity including fever, malaise, and fluid retention, which limit its use. It may be indicated in the rare cases when thrombocytopenia is the main factor preventing the administration of adequate RDI of chemotherapy.

None of the currently available thrombopoietin mimetics has been approved as of yet for the management of chemotherapy-induced thrombocytopenia. These include romiplostin, which is a peptide, and eltrombopag, a nonpeptide mimetic that is administered orally.^{144,145} Four phase 1 and 2 trials of romiplostin were performed in patients with solid tumor and lymphoma, but the results have not been published. A phase 1/2 study of eltrombopag has been concluded in patients with osteosarcoma and soft tissue sarcoma, but the results are not available at the time of this writing.

In conclusion, thrombocytopenia is associated with risk of severe bleeding and death in patients with acute leukemia. In patients with lymphoma and solid tumors, chemotherapy-induced thrombocytopenia is rarely life-threatening. The current indications for platelet transfusions include a count $< 10^3/\mu\text{l}$ for prophylactic transfusions and $< 50^3/\mu\text{l}$ for therapeutic transfusions for patients undergoing invasive procedure. These thresholds are based on soft data. Ongoing clinical trials explore whether these thresholds could be safely lowered.

Oprevelkin is indicated for the prevention of chemotherapy-induced thrombocytopenia in patients with lymphomas and solid tumors. This compound has a number of adverse effects that limit its usefulness.

134 Cancer Associated Thrombosis

Agnes Y. Y. Lee and Alok A. Khorana

INTRODUCTION

Cancer is a prothrombotic state. Cancer and anticancer therapies are frequently complicated by the development of vascular events, often with devastating clinical consequences. The most frequent vascular events include deep venous thrombosis (DVT) and pulmonary embolism (PE), together described as venous thromboembolism (VTE). Arterial events including stroke and myocardial infarction can also occur, particularly with regimens containing antiangiogenic agents. Subclinical abnormalities in the hemostatic system can be observed in up to 90% of patients with cancer. Recent preclinical and translational data suggest that this prothrombotic state is driven by oncogenic events and the close linkage between regulation of angiogenesis and coagulation, and is integral to cancer growth and metastasis.

The association of cancer with thrombotic events is commonly linked to Armand Trousseau, who was one of the first to comprehensively describe the eponymous syndrome. In one of medical history's great ironies, Professor Trousseau himself developed thrombophlebitis prior to succumbing to gastric cancer. The past decade has seen a renewal of awareness, owing to a rising incidence of cancer-associated thrombosis, particularly in the setting of chemotherapy and antiangiogenic therapy.^{1,2}

The occurrence of vascular events has significant clinical consequences: VTE recurs at an annual risk of 21%, requires long-term anticoagulation with a 12% annual risk of major bleeding complications, impacts negatively on patients' quality of life, and consumes health-care resources.³ Most importantly, thrombosis is the second-leading cause of death in patients with cancer, accounting for 9% of deaths in one study of cancer outpatients receiving chemotherapy.⁴ Cancer patients with VTE have a two-fold or greater increase in mortality compared with cancer patients without VTE, even after adjusting for stage.^{5,6} This impact on prognosis likely reflects the close association between activation of coagulation and an unfavorable tumor biology. In this chapter, we will review the mechanisms underlying the prothrombotic state in cancer and the incidence, risk factors, prevention, and treatment of cancer-associated thrombosis.

MECHANISMS OF CANCER-ASSOCIATED THROMBOSIS

The pathogenesis of the prothrombotic state in cancer is complex, principally involving procoagulant molecules produced by tumor cells, suppression of fibrinolytic activity, and platelet activation (Fig. 134.1). The genetic mechanisms responsible for malignant transformation such as oncogene activation (*RAS* or *MET*) or tumor suppressor gene inactivation (*P53* or *PTEN*) also directly induce the expression of genes regulating hemostasis.⁷⁻⁹ Extrinsic factors such as antineoplastic therapy, surgery, and vascular access devices further exacerbate this prothrombotic state.

The most important procoagulant expressed by tumor cells is tissue factor (TF), a transmembrane glycoprotein and the physiologic initiator of coagulation. TF is present on neoplastic cells as well as tumor-associated endothelial cells in a variety of cancers. TF expression occurs early in neoplastic transformation, driven by oncogenic mutations in *KRAS* and *TP53* genes.⁹ TF may contribute to tumor growth, metastasis, and angiogenesis through a variety of mechanisms including the formation of the TF/VIIa complex and activation of protease-activated receptor 2.¹⁰ TF expression is associated with increased angiogenesis, tumor invasiveness, and worsened prognosis in various malignancies.¹¹ Secretion of TF-containing microvesicles into the circulation may also account for the systemic coagulopathy of cancer. Emerging reports suggest that the degree of TF expression by tumor cells or elevated levels of circulating systemic TF may be predictive of VTE and mortality in some cancers, particularly pancreatic.¹²⁻¹⁴

Tumor cells also express plasminogen activator inhibitor-1, a potent inhibitor of the fibrinolytic system that has prothrombotic properties and also promotes tumor growth and angiogenesis. Proinflammatory cytokines such as tumor necrosis factor, interleukins-1 and -6, and interferons are elevated in malignancy. Their enhanced expression results from activation of monocytes or direct release from tumor cells, and can in turn activate coagulation. Finally, interactions mediated by platelet P-selectin between circulating carcinoma mucins and platelets lead to platelet aggregation and platelet-rich thrombus formation without accompanying thrombin generation, and this may also contribute to the prothrombotic state in cancer.¹⁵

Antineoplastic therapy further exacerbates the prothrombotic state in cancer. Several studies have documented changes in the markers of thrombin generation within hours of chemotherapy administration.¹⁶ Chemotherapy can induce endothelial cell activation leading to increased TF expression, elevated levels of plasma von Willebrand factor and factor VIII coagulant protein, and decreased levels of natural anticoagulants antithrombin and proteins C and S.¹⁷ Chemotherapy can induce release of cell-free DNA, with neutrophils as a predominant source and this in turn acts as a trigger for the intrinsic pathway.¹⁸ DNA and RNA from platelets and neutrophils generate neutrophil extracellular traps (NET). These form a specialized extracellular matrix that can activate coagulation. In animal models, cancers can induce an increase in peripheral blood neutrophils that are sensitized toward NET formation and spontaneous thrombosis is associated with NET generation in vivo.¹⁹ Thus, extracellular chromatin released through NET formation is a potential novel cause for cancer-associated thrombosis.

Most recently, scientists are exploring the complex crosstalk between the coagulation cascade, complement pathway, and the immune system in their synergistic roles in tumor growth.²⁰⁻²² It is possible that cooperation among these pathways also contributes to the hypercoagulability in malignancy and may explain the high frequency of anticoagulant failure in patients with cancer-associated thrombosis.

Figure 134.1 Proposed mechanisms for cancer-associated thrombosis. Multiple mechanisms have been postulated including tissue factor upregulation on tumor cell surface as well as release associated with microvesicles into the systemic circulation, platelet activation by carcinoma mucins and other factors, endothelial cell activation by chemotherapy, release of cell-free DNA by chemotherapy, and formation of neutrophil extracellular traps.

EPIDEMIOLOGY OF CANCER-ASSOCIATED THROMBOSIS

Incidence and Prevalence

The incidence of VTE is increased several-fold in patients with cancer when compared with patients without cancer.^{1,23-25} In general, the risk among patients with cancer is estimated to be 13 per 1,000 person-years (95% confidence interval [CI] = 7 to 23) in a recent systematic review.²⁶ However, rates vary significantly depending on specific cancer subgroups, settings, and over time, with more contemporary studies demonstrating higher incidence. Among ambulatory patients, the reported incidence of VTE varies from 7.8% during 26 months (0.3% per month) to 1.93% during a median follow-up of 2.4 months (0.8% per month) to 12% during 8 months (1.5% per month).^{27,28} The cause of this increase in the rate of VTE is likely related to improved diagnostic technologies as well as a true increased incidence related to newer antineoplastic drugs and regimens. The advent of highly sensitive multidetector-row computed tomography scans for routine staging has also led to an increased diagnosis of “incidental” PE.²⁹ The term incidental does not, however, indicate a more benign natural history. Retrospective studies show that the consequences of incidentally discovered PE are no different than those following symptomatic VTE including risk of recurrent VTE and mortality.^{30,31}

Rates of arterial thromboembolism (ATE) are less well studied. The use of bevacizumab-containing regimens is clearly associated with a high risk of arterial events.³² In a pooled analysis of five randomized studies, 4.4% of patients receiving bevacizumab and chemotherapy developed arterial events, compared with 1.9% of patients receiving chemotherapy alone. Rates were particularly high in older patients. In a large meta-analysis of clinical trials with sunitinib and sorafenib, both oral vascular endothelial

growth factor receptor inhibitors, the incidence of ATE was 1.4% (95% CI = 1.2% to 1.6%).³³

Risk Factors

Patients with cancer comprise a heterogeneous group and include patients undergoing surgery, hospitalization, receiving antineoplastic therapy, or end-of-life care. The risk of VTE differs across these various cancer subpopulations as well as over the natural history of the disease. A recent update by the American Society of Clinical Oncology VTE Guidelines Panel recommends that patients with cancer be assessed for VTE risk at the time of chemotherapy initiation and periodically thereafter (recommendation 6.1).³⁴ Table 134.1 provides a comprehensive list of cancer-related, treatment-related, and patient-related risk factors and biomarkers for cancer-associated VTE.

Cancer-related risk factors include the primary site, stage, and time after initial diagnosis. The primary site of cancer is historically the best-known and commonly used risk factor. Cancers of the pancreas, stomach, brain, ovary, kidney, and lung have long been associated with VTE; hematologic malignancies, particularly lymphomas, are also strongly associated with VTE.^{23,27,28,35} Patients with metastatic disease have a 2- to 20-fold increased risk of VTE.^{5,23} VTE is more likely to occur in the initial period after diagnosis. In a population-based study, the adjusted odds ratio for developing VTE in the first 3 months was 53.5 (95% CI = 8.6 to 334.3), declining to 14.3 (95% CI = 5.8 to 35.2) and 3.6 (95% CI = 2.0 to 6.5) in the 3-month to 1-year and 1- to 3-year intervals, respectively.²³

Treatment-related risk factors include surgical interventions, central venous access devices, hospitalization, and systemic therapy. Patients with cancer undergoing surgery have a two-fold increased risk of postoperative DVT and a three-fold increased risk of fatal PE compared with patients without cancer. The risk

TABLE 134.1

Risk Factors for Cancer-Associated Thrombosis

Cancer-related

Primary site of cancer (gastrointestinal, brain, lung, gynecologic, renal, bladder, lymphoma, myeloma)
 Initial period after diagnosis (highest in first 3 to 6 mo)
 Histology (higher for adenocarcinoma and high-grade tumors)
 Stage (higher with regional and metastatic disease)

Treatment-related

Major surgery
 Hospitalization
 Chemotherapy
 Antiangiogenic therapy (bevacizumab, sunitinib, sorafenib for arterial events)
 Immunomodulatory agents (thalidomide- or lenalidomide-based combination regimens)
 Certain hormonal therapy agents (e.g., tamoxifen)
 Erythropoiesis-stimulating agents
 Central venous access devices
 Transfusions

Patient-related

Age (higher in older patients)
 Race (higher in African Americans, lower in Asian-Pacific Islanders)
 Patient comorbidities
 Obesity, infection, renal disease, pulmonary disease, arterial thromboembolism
 Prior history of thrombosis
 Inherited prothrombotic mutations (e.g., factor V Leiden, prothrombin gene mutation)
 Performance status
 Varicose veins

Biomarkers

Prechemotherapy leukocyte count $>11,000/\text{mm}^3$
 Prechemotherapy platelet count $\geq 350,000/\text{mm}^3$
 Hemoglobin <10 g/dL
 Tissue factor (antigen expression, circulating microparticles, antigen, or activity)
 D-dimer
 C-reactive protein
 Soluble P-selectin
 Peak thrombin generation
 Factor VIII

of VTE increases significantly when patients with cancer are hospitalized. Patients with cancer on active therapy are at greater risk for VTE. Specific chemotherapeutic agents are associated with higher rates of VTE. In a prospective study, platinum-based regimens were significantly associated with VTE.³⁶ Even within this class of agents, rates were higher in patients receiving cisplatin as compared with oxaliplatin.³⁷ Studies of newer cancer regimens that include drugs such as thalidomide, lenalidomide, and bevacizumab have reported very high rates of VTE and ATE events. For thalidomide-containing regimens, rates of VTE up to 34% in patients with myeloma have been reported.^{38,39} Bevacizumab, an antivascular endothelial growth factor antibody, has been clearly associated with an increased risk of ATE; data on its association with VTE are conflicting.^{1,32,40,41} Even supportive therapy drugs have been associated with increased VTE. In a large meta-analysis, erythropoiesis-stimulating agents were associated with a 1.6-fold increased risk of thromboembolism.⁴²

Finally, *patient-related* risk factors further add to risk. In particular, comorbid conditions including infection, ATE, renal disease, pulmonary disease, and anemia can strongly affect risk.

Biomarkers range from tests as simple as the complete blood count to novel assays that may be predictive of VTE in cancer.⁴³ Prechemotherapy platelet counts of $\geq 350,000/\text{mm}^3$ (odds ratio = 1.8; 95% CI = 1.1 to 3.2) and leukocyte counts $>11,000/\text{mm}^3$ (odds ratio = 2.2; 95% CI = 1.2 to 4.0) have been independently associated with VTE.⁴⁴ Other candidate biomarkers predictive of VTE include D-dimer, tissue factor, thrombin generation assays, soluble P-selectin, factor VIII, and C-reactive protein.⁴⁵ These are not recommended for clinical use until validation studies have been completed.

Risk factors for arterial events are less well investigated. In hospitalized patients receiving chemotherapy, variables associated with ATE included age 65 years or older; male gender; African American ethnicity; sites of cancer including leukemia, colon, prostate, and lung; and presence of comorbid illnesses.³⁵ For patients receiving bevacizumab-containing regimens, age over 65 years and prior history of ATE were significant risk factors in a pooled analysis of clinical trials.⁴⁰ The relative risk of arterial events associated with sorafenib and sunitinib is 3.03 (95% CI = 1.25 to 7.37; $p = 0.015$) compared with control patients.³³

Risk Assessment Score

Multiple randomized studies have attempted to evaluate the benefit of thromboprophylaxis in patients with cancer, utilizing one or two risk factors to select a high-risk group.^{45,46} Low event rates in the control arms of these studies indicate that a high-risk population was not selected. Hence the updated American Society of Clinical Oncology VTE Guidelines Panel recommends against the use of single risk factors or biomarkers to identify high-risk patients.³⁴ Instead, the panel recommends the use of a validated risk score that incorporates five variables to identify high-risk patients (Table 134.2). This risk score was originally developed and validated in a US national cohort study.^{34,44} Observed rates of VTE over median follow-up of 2.5 months in the development and validation cohorts were 0.8% and 0.3% for low-risk, 1.8% and 2% for intermediate-risk, and 7.1% and 6.7% for high-risk patients, respectively. This model was subsequently externally validated in a prospective European cohort study, with rates of 17.7% in the high-risk cohort as compared to 1.5% in low-risk patients, over a 6-month follow-up period.⁴⁷ Multiple other cohort studies have further validated this score, although absolute rates vary between studies based on heterogeneous populations and follow-up periods.⁴⁸

TABLE 134.2

Predictive Risk Score for Cancer-Associated Venous Thromboembolism⁴⁴

Patient Characteristics	Risk Score
Site of cancer	
Very-high-risk (stomach, pancreas)	2
High-risk (lung, lymphoma, gynecologic, bladder, testicular)	1
Prechemotherapy platelet count $\geq 350,000/\text{mm}^3$	1
Hemoglobin level <10 g/dl or use of red cell growth factors	1
Prechemotherapy leukocyte count $>11,000/\text{mm}^3$	1
Body mass index ≥ 35 kg/m ²	1

High-risk ≥ 3
 Intermediate risk = 1–2
 Low-risk = 0

PREVENTION OF CANCER-ASSOCIATED THROMBOSIS

Prophylaxis in Major Surgery

Few clinical trials have been conducted to study the efficacy and safety of thromboprophylaxis specifically in patients with cancer having major surgery. Randomized controlled trials of in-hospital prophylaxis in patients having major abdominal surgery for cancer have shown no difference in the incidence of DVT or major bleeding between unfractionated heparin (UFH) administered three times daily and a low-molecular-weight heparin (LMWH) enoxaparin given once daily.^{49,50} Overall, up to 15% of patients with cancer will develop DVT following surgery, despite standard prophylaxis with UFH or LMWH. In addition to LMWH and UFH, fondaparinux is approved for prophylaxis following major abdominal surgery. This selective inhibitor of activated factor X is given once daily subcutaneously and is associated with a lower risk of heparin-induced thrombocytopenia compared with UFH and LMWH. In a phase 3 randomized trial, fondaparinux was found to be comparable to LMWH dalteparin in patients undergoing high-risk abdominal surgery.⁵¹ A post hoc analysis of patients with cancer suggested that fondaparinux was associated with a statistically significant reduction in VTE (4.7% versus 7.7%; $p = 0.02$).

Mechanical methods of prophylaxis, such as graduated compression stockings or intermittent pneumatic calf compression devices, can lower the risk of VTE but are less effective than anticoagulants.⁵² Their use should be limited to patients in whom anticoagulation is contraindicated. There is weak evidence that combined mechanical and pharmacologic prophylaxis may further reduce VTE, especially in the patients who are at highest risk.

Extending prophylaxis beyond hospitalization can further reduce the risk of VTE in patients with cancer. In a multicenter, placebo-controlled trial, patients undergoing elective, curative abdominal surgery for cancer received LMWH enoxaparin for the first 6 to 10 days after surgery and then were randomized to continue with enoxaparin or placebo injections for 4 weeks.⁵³ Extended prophylaxis with enoxaparin significantly reduced the rate of VTE by 60% (12.0% versus 4.8%; $p = 0.02$) at 1 month, and this benefit was maintained at 3 months. The absolute risk reduction of 7% means that 14 patients must be treated to avoid one case of DVT. Overall, there

was no difference in bleeding during the treatment period and no difference in mortality up to 1 year of follow-up. Similar results were also reported in a subgroup analysis of an open-label randomized trial in which patients having abdominal surgery were randomized to receive LMWH dalteparin once daily and compression stockings, or to stockings alone for 21 days after hospital discharge.⁵⁴ Dalteparin significantly reduced the incidence of DVT from 19.6% to 8.8% ($p = 0.03$) as well as that of proximal DVT from 10.4% to 2.2% ($p = 0.02$). Accordingly, 9 patients must be treated to avoid one episode of DVT while 12 must be treated to avoid one episode of proximal DVT.

The increased risk of postdischarge symptomatic VTE has been shown to peak at 3 weeks after cancer surgery in two large prospective studies.^{55,56} One study found that 46% of the deaths occurring within the first month after cancer surgery were due to fatal PE, and the other study reported that 1 in 85 women will develop VTE within the first 12 weeks after cancer surgery.⁵⁵ The American Society of Clinical Oncology and the American College of Chest Physicians (ACCP) recommend that extended prophylaxis in patients undergoing cancer surgery should be considered, especially in patients with high-risk features.^{34,57} These include previous history of VTE, anesthesia lasting ≥ 2 hours, bed rest for ≥ 4 days, advanced malignancy, and older age.⁵⁵

Prophylaxis for Central Venous Catheters

Contemporary trials have provided evidence that neither warfarin (dose fixed at 1 mg daily or adjusted to an international normalized ratio [INR] between 1.5 and 1.9) nor prophylactic doses of LMWH is effective in reducing symptomatic catheter-related thrombosis.⁵⁸⁻⁶⁰ With or without prophylaxis, symptomatic catheter-related thrombosis rates of approximately 4% were reported in these studies, and bleeding may be increased in those who received an anticoagulant. Based on these data, the ACCP guidelines have recommended against routine prophylaxis using LMWH and fixed-dose warfarin.⁵² Although high-risk patients may still benefit from prophylaxis, the selection criteria of such patients and the optimal anticoagulant regimen are not defined.

Prophylaxis in Medical Patients

Randomized trials have studied the efficacy and safety of anticoagulant prophylaxis in outpatients receiving chemotherapy (Table 134.3).

TABLE 134.3

Randomized Controlled Trials of Primary Prophylaxis in Patients with Solid Tumors

Study Population (Ref.)	No. of Patients	Anticoagulant Prophylaxis	VTE in Anticoagulant Group (%)	VTE in Control Group (%)	P Value
Stage IV breast cancer ⁶⁰		Warfarin 1 mg/d \times 6 wk then INR 1.3–1.9	0.7	4.4	0.03
Advanced breast cancer ⁶²	351	Certoparin 3,000 units once daily	4.0	3.9	NS
Advanced NSCLC ⁶²	532	Certoparin 3,000 units once daily	4.5	8.3	0.07
Grade III/IV malignant glioma ⁶³	186	Dalteparin 5,000 units once daily	11.0	17.0	0.3
Advanced cancer of breast, lung, GI, pancreas, ovary, head and neck ⁴⁴	1,150	Nadroparin 3,800 units once daily	2.0	3.9	0.02
Advanced cancer of lung, pancreas, stomach, colon or rectum, bladder, or ovary ⁴⁵	3,212	Semuloparin 20 mg once daily	1.2	3.4	<0.001
Advanced pancreatic cancer ⁶⁶	312	Enoxaparin 1 mg/kg once daily \times 12 wk then 40 mg once daily	14.5	5.0	<0.01
Advanced pancreatic cancer ⁶⁴	123	Dalteparin 200 U/kg once daily \times 4 wk then 150 U/kg \times 8 wk	31.0	12.0	0.02

VTE, venous thromboembolism; INR, international normalized ratio; NS, nonsignificant; NSCLC, nonsmall-cell lung cancer; GI, gastrointestinal.

One small randomized trial found that very-low-dose warfarin was effective in reducing symptomatic DVT in women with stage IV breast cancer receiving multiagent chemotherapy,⁶¹ while small, placebo-controlled trials in patients with a number of different solid tumors provided inconsistent evidence for prophylactic doses of LMWH.^{62,63} But two large placebo-controlled clinical trials have demonstrated LMWH or an ultra-LMWH are effective in reducing symptomatic thrombosis. The PROTECHT study reported a relative risk reduction of 49% associated with nadroparin prophylaxis and the SAVE-ONCO trial found a relative reduction of 64% associated with semuloparin in patients with locally advanced or metastatic solid tumors. There were no differences in bleeding or overall survival.^{45,46}

Two open-label studies in patients with advanced pancreatic cancer reported significant and dramatic reductions in clinically relevant VTE when therapeutic or half-therapeutic doses of LMWH were given in conjunction with standard chemotherapy. In one study, enoxaparin at 1 mg/kg daily for 3 months reduced the incidence of symptomatic VTE by 66% (from 14.5% to 5.0%; $p < 0.01$), whereas dalteparin at therapeutic dosing reduced the incidence from 31% to 12% (relative risk = 0.38; $p = 0.02$).⁶⁴⁻⁶⁶ In the latter study, the risk of fatal PE was also significantly lowered (relative risk = 0.08; $p = 0.03$). Bleeding was not increased in the LMWH groups in these studies. Overall, the findings suggest that patients with specific tumor types or who have a high risk of thrombosis do benefit from anticoagulant prophylaxis and that doses that are higher than what is used for standard primary prophylaxis are very effective and well tolerated. Identifying high-risk patients using a risk-assessment model will also improve the benefit-risk ratio of anticoagulant prophylaxis.

Another population in whom primary prophylaxis may be beneficial is patients with multiple myeloma who are receiving thalidomide or lenalidomide in combination with chemotherapy or high-dose steroids. Incidences of symptomatic VTE of 20% to 30% have been reported, but the pathophysiologic mechanisms remain elusive.³⁹ This high risk has prompted the use of aspirin, warfarin, and LMWH in uncontrolled settings and guidelines to recommend anticoagulation prophylaxis in patients receiving thalidomide- or lenalidomide-based regimens.^{34,52} Randomized trials are urgently needed to identify a safe and effective prophylaxis regimen, given the potential for serious bleeding in this patient group.

Randomized trials in a cancer-specific population have not been done in acutely ill medical patients admitted to hospital. Recommendations regarding the efficacy and safety of thromboprophylaxis in these patients are based on three large randomized studies that included only a minority (5% to 15%) of patients with cancer. However, post hoc and meta-analysis of these studies do not show a significant reduction with standard LMWH prophylaxis in medically ill cancer patients.⁶⁷ Nonetheless, given the known high risk of VTE during hospitalization for patients with cancer and its attendant consequences, all of the guidelines recommend thromboprophylaxis in the absence of contraindications.^{34,52} There continue to be ongoing concerns regarding the risk of bleeding in these patients, for which few cancer-specific data are available.

TREATMENT OF CANCER-ASSOCIATED THROMBOSIS

Anticoagulants are the cornerstone agents for the treatment of acute VTE. Although these agents are highly efficacious and have an acceptable safety profile in most patients, patients with cancer have a three-fold higher risk of recurrent VTE and two-fold higher risk of anticoagulant-related bleeding compared with patients without cancer.^{68,69} These complications reflect the prothrombotic state associated with malignant diseases and the multiple comorbidities in patients with cancer that may alter their response to anticoagulant therapy and their risk of bleeding. LMWH is the preferred treatment for initial and long-term treatment because of its favorable efficacy, safety, and convenience profile compared with UFH and vitamin K antagonists (VKA).^{34,70-72}

Initial Therapy

Formal comparisons of LMWH, UFH, and fondaparinux for initial treatment of VTE in patients with cancer have not been conducted. Based on results extracted from randomized trials that evaluated these agents, LMWH and UFH appear equally effective in reducing recurrent thrombosis in patients with cancer, but LMWH is associated with a 3-month survival benefit over UFH.⁷³ Furthermore, LMWH can be given safely as once-daily subcutaneous injections in an outpatient setting without the need for laboratory monitoring and have a lower risk of heparin-induced thrombocytopenia. Fondaparinux given once daily is also comparable to heparins for the initial treatment of VTE and may eliminate the risk of heparin-induced thrombocytopenia. However, a post hoc analysis of a randomized trial suggests that it is less effective than enoxaparin for outpatient treatment of DVT in patients with cancer.⁷⁴ New oral anticoagulants that inhibit activated factor X (e.g., rivaroxaban, apixaban, edoxaban) or thrombin (e.g., dabigatran) are comparable to traditional therapy with a LMWH followed by a VKA for treatment of acute VTE. In some of these trials, monotherapy with the new oral anticoagulant was compared with LMWH followed by warfarin; however, efficacy and safety data for the initial treatment period have not been published. Because these trials included only a small number of highly selected patients with cancer, further investigation is essential to show efficacy and safety in the general cancer population.⁷⁵ The major concerns about these new anticoagulants in patients with cancer include potential interaction with chemotherapeutic agents, altered metabolism in patients with renal dysfunction or hepatic metastases, lack of antidote when patients are actively bleeding, and whether treatment doses in patients without cancer are as effective in these hypercoagulable patients.

Long-Term Therapy

Despite their pharmacologic and practical limitations, VKAs were the mainstay of long-term anticoagulant treatment for VTE in patients with cancer for many years. Although VKAs are highly effective in reducing recurrent thrombosis in the general population, treatment failures, serious bleeding, and difficulties with maintaining the INR within the therapeutic range are common problems in patients with cancer. A prospective cohort study reported that the 12-month cumulative incidence of recurrent VTE in patients with cancer was 20.7%, versus 6.8% in patients without cancer, and the corresponding estimate for major bleeding was 12.4% versus 4.9%, respectively.⁶⁹ Patients with cancer also experience recurrent VTE despite having therapeutic INR levels and suffer serious bleeding complications even without receiving excessive anticoagulation.⁶⁸

Clinical trials have now established LMWH as the preferred long-term treatment for VTE. The CLOT trial randomized 676 patients with cancer with symptomatic proximal DVT, PE, or both, to receive usual treatment with dalteparin initially followed by 6 months of therapy with either VKA or dalteparin alone.⁷⁶ In the dalteparin group, patients self-injected therapeutic doses at 200 U/kg once daily for the first month followed by 75% to 80% of the full dose for the next 5 months. The VKA group was treated to maintain a therapeutic INR between 2 and 3. The cumulative risk of recurrent VTE at 6 months was reduced from 17% in the VKA group to 9% in the dalteparin group, resulting in a statistically significant risk reduction of 52% ($p = 0.002$; Fig. 134.2). Accordingly, one episode of recurrent VTE is prevented for every 13 patients treated with dalteparin. Overall, there were no differences in major or any bleeding between the groups. By 6 months, 39% of the patients had died in each group, with 90% of the deaths being from progressive cancer. A post hoc subgroup analysis showed that, among patients who had no known metastatic disease at randomization, those who were randomized to dalteparin had better survival compared with those who had received a VKA.⁷⁷

Figure 134.2 The cumulative risks of recurrent venous thromboembolism comparing 6 months of treatment with low-molecular-weight heparin dalteparin versus a vitamin K antagonist (hazard ratio = 0.48; 95% confidence interval = 0.30 to 0.77; $p = 0.002$). (From Lee AY, Levine MN, Baker RI, et al. Low-molecular-weight heparin versus a coumarin for the prevention of recurrent venous thromboembolism in patients with cancer. *N Engl J Med* 2003;349:146–153, with permission.)

No. at risk							
Dalteparin	336	301	264	235	227	210	164
Oral anticoagulant	336	260	242	221	200	194	154

Whether this was the result of an anticoagulant or an anticancer effect remains uncertain. The observation that the separation of the survival curves occurred only after the discontinuation of dalteparin suggests that the survival benefit is not the result of a reduction in fatal PE. Ongoing research is being done to determine if LMWH offers antineoplastic effects in specific cancers and to explore the potential biologic mechanisms. In contrast to the CLOT study, three randomized trials reported nonsignificant reductions in symptomatic VTE with LMWH compared with VKA therapy.^{55–57,78–80} It is likely that these other trials were underpowered (two were terminated prematurely prior to achieving target sample size) or that the dosing of other LMWHs were inadequate. Nonetheless, the finding of LMWH superiority over warfarin was consistent in all the trials. This led to major consensus guidelines to recommend LMWH over warfarin therapy.^{34,71,72} Fondaparinux has not been evaluated against LMWH for long-term treatment in patients with cancer, but a small study suggests it is effective and well tolerated.⁸¹ Ongoing randomized controlled trials are being conducted to examine the role of novel oral anticoagulants for long-term treatment of cancer-associated thrombosis. As discussed previously, robust data are not yet available to demonstrate that they are comparable to warfarin or LMWH in the oncology setting. Issues unique to patients with cancer such as unpredictable gastrointestinal absorption, drug interaction with chemotherapy, and renal or liver dysfunction may render these novel agents inferior to LMWH.

There is no evidence to guide the choice of anticoagulant after the first 6 months of treatment. For patients who have tolerated LMWH or VKA for the first 6 months, continuing with the same anticoagulant is a sensible option if ongoing anticoagulation is needed. It is recommended that the risks and benefits of LMWH versus VKA therapy are discussed with the patient in order to individualize treatment. Besides the risk of bleeding, there does not appear to be any significant side effects associated with long-term use of LMWH or VKA. Although animal studies suggest that LMWH exposure may reduce bone density, this has not been shown to be a concern in patient populations (e.g., pregnant women with VTE) that also need extended treatment with LMWH.

Based on the evidence to date, long-term treatment with a LMWH for patients with cancer with DVT or PE is recommended by the ACCP Consensus Guidelines, the National Comprehensive Cancer Network Clinical Practice Guidelines in Oncology, and the American Society of Clinical Oncology.^{34,71,72}

Therapy for Recurrent Venous Thromboembolism

Although recurrent VTE is frequent in patients with cancer, optimal treatment has not been investigated in clinical trials.^{70,82} Insertion of an inferior vena cava filter is commonly used in patients with recurrent thrombosis despite anticoagulation, but evidence supporting this practice is lacking. In fact, studies have shown that patients with filters have a higher risk of recurrent DVT than those without the device, and fatal PE has been reported in patients with cancer following filter insertion. It is recommended that the use of filters be limited to situations in which anticoagulant therapy cannot be used because of serious, active bleeding. Success has been reported with using LMWH in patients who break through VKA therapy and with using higher doses of LMWH in those who break through usual LMWH treatment doses.⁷⁰ In a small series of patients with cancer with recurrent thrombosis, 9% of patients treated with dose escalation of LMWH had a second thrombotic event and 1% had a major bleed over a 3-month follow-up period.⁸³ Mortality in patients who developed recurrent thrombosis was high, with a median time between recurrence and death at 11 months. This observation reinforces the concept that activation of coagulation is associated with unfavorable tumor biology.

Duration of Therapy

Although clinical trial evidence is lacking, it is generally recommended that patients with metastases should continue with “indefinite” anticoagulant therapy after a single thrombotic event because metastatic malignancy is a risk factor for recurrent thrombosis. In patients without metastases, anticoagulant treatment is recommended for as long as the cancer is “active” and while the patient is receiving antitumor therapy. Although this period is sometimes difficult to define, patients who have not experienced any complications often prefer to continue anticoagulant therapy to avoid recurrent thrombosis. Given the complex and changing clinical courses of most patients with cancer, periodic evaluation of the risk-benefit ratio of continuing anticoagulant therapy in individual patients is absolutely essential. The decision should take into consideration the patient’s preference, the anticancer treatments, the comorbid conditions, and most importantly, the patient’s quality of life and life expectancy.

135 Nausea and Vomiting

Elizabeth M. Blanchard and Paul J. Hesketh

INTRODUCTION

Nausea and vomiting associated with cancer treatment have historically been among the most difficult side effects that patients face while being treated for cancer. Chemotherapy-induced nausea and vomiting (CINV) in particular remains one of the most dreaded side effects from a patient perspective. Patient surveys have consistently listed CINV as one of the most severe and troublesome adverse events related to treatment.¹ Although intuitive, nausea and vomiting related to chemotherapy have also been shown to negatively impact a patient's functional status as tested by objective measures.² In fact, CINV has been shown to negatively impact all aspects of quality of life for patients including emotional, social, and physical functioning as well as global quality of life.³ The last 20 years have seen tremendous progress in this area, which has significant implications for patients in improving their quality of life as well as compliance with cancer treatment.

In the era before the use of newer antiemetics, nearly 80% of patients would experience an episode of nausea or vomiting during the 5 days following chemotherapy of moderate to high emetogenic potential.⁴ The prevalence of CINV has been dramatically decreased with the introduction of the 5-hydroxytryptamine-3 (5-HT₃) receptor antagonists in the early 1990s and with the subsequent introduction of a new class of antiemetic, the neurokinin (NK)-1 (NK₁) receptor antagonists. Despite the progress, CINV remains suboptimally controlled for a significant minority of patients. An important remaining challenge is the recognition and management of the symptom of nausea following chemotherapy treatment.

Optimizing the control of treatment-induced nausea and vomiting should be a high priority for all health-care providers involved in the care of patients with cancer. Knowledge of the extent of the problem, understanding the basic pathophysiologic principles, recognition of patients at risk, and applying available pharmacologic treatments in an evidence-based manner are all key elements in attaining this goal.

NAUSEA AND VOMITING SYNDROMES

CINV does not describe a single clinical entity but rather three relatively distinct clinical syndromes including acute, delayed, and anticipatory nausea and vomiting. Although these distinctions have limitations and are somewhat arbitrary, they are nevertheless useful in terms of characterizing the problem and optimizing treatment. Acute CINV is defined as nausea and vomiting that develop within the first 24 hours after chemotherapy administration. With most emetogenic chemotherapy agents, in the absence of effective prophylactic therapy, nausea and vomiting will develop within a few hours of chemotherapy administration. Delayed CINV is defined as nausea and vomiting occurring >24 hours after chemotherapy administration. It is generally not as well understood as acute emesis and has been described in association with a number of chemotherapy agents such as cisplatin, carboplatin, cyclophosphamide, and the anthracyclines. It appears to be less severe than acute emesis but can last for a longer period of time.^{5,6} Delayed CINV has been best characterized in relation to cisplatin.⁷ In the absence

of antiemetic treatment, it will develop in $\geq 90\%$ of patients receiving this agent. It peaks between 24 and 72 hours after cisplatin and gradually dissipates during the next several days. Anticipatory nausea and vomiting occur as the result of a conditioned response to prior episodes of CINV. Symptoms occur after exposure to a variety of stimuli that remind the patient of their prior emetic experiences such as returning to clinic, seeing health-care personnel, or the apparatus involved with chemotherapy administration.⁸

Unlike CINV, radiation-induced nausea and vomiting (RINV) has not been broken down into distinct clinical syndromes. Risk of nausea and vomiting is generally related to the body area exposed to treatment with fields encompassing small bowel and stomach associated with the greatest risk. This issue is further addressed in the section on defining the risk of nausea and vomiting.

PATHOPHYSIOLOGY OF TREATMENT-INDUCED NAUSEA AND VOMITING

The mechanisms underlying the control of nausea and vomiting are extraordinarily complex and still incompletely understood at the present time. The central nervous system (CNS) is thought to play a critical role in the physiology of nausea and vomiting, serving as the primary site where a variety of emetic stimuli are received and processed. The CNS is also believed to have the primary role in generating the efferent signals to a number of structures in the body that eventually result in the development of nausea and vomiting.

The mechanisms by which chemotherapy causes nausea and vomiting are only partially delineated. Our current understanding of the pathophysiology of this process is based on the pioneering studies of Borison and Wang⁹ conducted more than 60 years ago and more recent insights provided during the development process of the newer antiemetic agents.¹⁰ Borison and Wang⁹ proposed that two sites within the brainstem were critical in the control of emesis. The first of these sites is the area postrema, which is a circumventricular structure located at the caudal end of the fourth ventricle. It is positioned outside the blood-brain barrier and therefore is accessible to emetic substances borne in either blood or cerebral spinal fluid. Given its central role in processing a variety of emetogens, it has often been termed the *chemoreceptor trigger zone*. The area postrema cannot independently initiate the emetic process but does so indirectly through neural projections to a second site proposed by Borison and Wang: the vomiting center. According to their theory, a vomiting center located in the lateral reticular formation of the medulla is the final common pathway through which efferent signals are generated to initiate the emetic process. It is now appreciated that an anatomically distinct vomiting center does not exist and that the motor outputs are coordinated by a variety of brainstem nuclei such as the parvocellular reticular formation, the Botzinger complex, and the nucleus tractus solitarius.^{11,12} These nuclei have been collectively referred to as the *vomiting center*.¹⁰

In addition to the area postrema, three other sources of afferent input to the vomiting center appear to have importance in the generation of the emetic response.^{9,13} Of greatest importance with respect to CINV is the stomach and proximal small bowel.

Chemotherapy agents can either directly or indirectly access the gut mucosa causing release of local mediators from the enterochromaffin cells, stimulating vagal and splanchnic afferent fibers within the bowel wall. These vagal afferents can then transmit afferent signals to the brainstem either directly to nuclei within the vomiting center such as the nucleus tractus solitarius or indirectly via the area postrema initiating the emetic reflex. Direct stimuli arising within the limbic system in the CNS can also apparently trigger emesis by poorly defined mechanisms. This process may be operative in patients experiencing anticipatory emesis. Finally, input from the vestibular system may also induce emesis. This appears to be a predominant mechanism associated with motion sickness but is likely to have a modest role in CINV.

It is now appreciated that a number of neurotransmitters appear to have important roles in the emetic process. More than 30 neurotransmitters have been identified within the area postrema and nuclei of the vomiting center.¹⁴ Some neurotransmitters such as histamine and acetylcholine, which have established roles in certain types of emesis such as motion sickness, appear to have minimal involvement in CINV. The most clinically relevant neurotransmitters involved in CINV include dopamine, serotonin (5-HT), Substance P, and the cannabinoids.^{10,15} Much of our current understanding of the neurotransmitters relevant to CINV has come from preclinical studies that preceded the introduction of a number of our current antiemetics. The role of dopamine receptors in CINV forms the basis of some of the earliest interventions in the prevention of emesis related to chemotherapy. Dopamine D2 receptors are found in the area postrema. Stimulation of these receptors has been shown to induce emesis in animal models.¹¹ Phenothiazines, which are dopamine antagonists, represented the first class of agents with antiemetic efficacy when introduced into clinical practice nearly 50 years ago.

Over the past 25 years, the role of 5-HT has been gradually elucidated and ultimately surpassed dopamine as the most relevant neurotransmitter in the treatment of CINV. Of the more than a dozen known subtypes of 5-HT receptors, the type 3 (5-HT₃) receptor has been found to play the most important role in emesis, and antagonism of these receptors has had a significant impact on prevention of acute CINV.¹⁰ 5-HT₃ receptors are found on vagal afferent fibers, within the area postrema, and the nucleus tractus solitarius.^{16–18} The precise mechanisms of 5-HT involvement in treatment-related emesis are incompletely understood. It appears that the most clinically relevant site of action of 5-HT occurs at the peripheral level by increasing afferent stimuli from the gut to the vomiting center and area postrema. Whether 5-HT has meaningful central activity is unclear.

Another neurotransmitter, Substance P, has emerged during the past decade as playing a major role in the development of acute and delayed emesis. It is part of a class of regulatory peptides belonging to the tachykinins, which bind to NK receptors¹⁹ and was first noted to cause emesis in animal models. Three tachykinin receptors have been identified, of which the NK₁ receptor is preferentially bound by Substance P.¹⁹ The NK₁ receptors are found in the gastrointestinal tract, the area postrema, and the nucleus tractus solitarius.²⁰ NK₁ receptor antagonists demonstrated wide-ranging antiemetic effects in ferrets, which prompted their development for clinical use.^{21,22} Animal models have demonstrated that the site of action of Substance P appears to be mainly central, as experimental NK₁ antagonists that do not cross the blood–brain barrier are ineffective in preventing cisplatin-induced emesis.²³

Unlike dopamine, 5-HT, and Substance P, which all appear to have a “proemetic” role, other neurotransmitters such as the endogenous cannabinoids, enkephalins, and γ -amino butyric acid appear to exert an agonist antiemetic effect. This area of antiemetic research has received much less attention than efforts devoted to the development of neurotransmitter antagonist antiemetics. Of the endogenous neurotransmitters, only the cannabinoids have relevance in the treatment of CINV at present.²⁴

There appear to be differences in the relative importance of the various neurotransmitters in the different emetic syndromes. Acute CINV as well as RINV are thought to be primarily due to 5-HT-mediated pathways. The effectiveness of the 5-HT₃ receptor antagonists in both

of these settings is thought to be primarily secondary to the ability of these agents to antagonize the binding of 5-HT to the 5-HT₃ receptors on the afferent fibers of the vagus and splanchnic nerves, stimulating afferent nerves in the upper small intestine. Dopamine also appears to be most relevant to acute CINV and to a lesser extent in RINV given the utility of dopamine D2 antagonists in these settings.

Dopamine and 5-HT appear to be less important in delayed CINV, given the limited clinical utility of the 5-HT₃ receptor antagonists and dopamine D2 antagonists in this setting. The mechanisms underlying delayed CINV are very poorly defined. Changes in the gastrointestinal tract as a result of chemotherapy such as altered gastrointestinal secretions and motility may play a role. In addition, chemotherapy-induced enhanced cell breakdown and turnover with the resulting release of cytokines and inflammation may be important contributors to delayed CINV.²⁵ The clinical utility of the corticosteroids in delayed CINV may be partly due to their anti-inflammatory effect. Of the known clinically relevant neurotransmitters, Substance P may have the most important role in the pathophysiology of delayed emesis. This is strongly supported by the unique preclinical and clinical efficacy of the NK₁ antagonists in the delayed emesis setting. In addition, an analysis of the time course of cisplatin-induced emesis demonstrated that 5-HT mechanisms appeared to predominate in the first 8 to 12 hours after cisplatin administration, but thereafter NK₁-dependent mechanisms appeared to be more important.²⁶

The pathophysiology of RINV likely involves several mechanisms. If the gastrointestinal tract is included in the field of radiation, direct effects are likely with stimulation of afferent pathways in the upper gastrointestinal tract.^{25,27} In addition, it is theorized that the chemoreceptor trigger zone in the area postrema may also be involved, possibly from radiation-induced tissue breakdown products.

DEFINING THE RISK OF NAUSEA AND VOMITING

There are a number of factors that can influence the development of CINV, including those related to the patient receiving therapy as well as the chemotherapy treatment itself. The most important patient-related factors include gender, age, history of ethanol consumption, and history of nausea or vomiting with prior chemotherapy treatment.^{28–35} Gender is a strong and uniform predictor of difficulty with CINV, with women consistently experiencing poorer control of CINV than men.^{28–32} Age is also an important risk factor, with younger patients having more difficulty than older patients.^{28,32} A history of chronic alcohol consumption seems to decrease the risk of emesis.^{28,30,31} Patients who have experienced CINV with prior chemotherapy treatment are also at greater risk of developing CINV with subsequent treatments.³³ A history of nausea and vomiting associated with pregnancy and a history of motion sickness have been suggested to predict for poor control of CINV, but definitive data are lacking. There is some genetic variation in the metabolism of 5-HT₃ receptor antagonists, and patients who are rapid metabolizers are at risk for more significant CINV.³⁴ In addition, genetic variations in the 5-HT₃ receptor may also predispose to a decreased response to this class of medication and more difficulty with CINV.³⁵

Treatment-related factors include the actual chemotherapy agent, its dose, rate, and route of administration. Of all the known predictive factors for CINV, clearly the most important is the intrinsic emetogenicity of the chemotherapeutic agent employed. The emetogenicity schema that is most widely used is modified from the Hesketh classification, which was first described in 1997.³⁶ This system, based on an extensive literature review, classifies chemotherapeutic agents according to their intrinsic emetogenicity and establishes a framework for the development of antiemetic treatment guidelines. What was originally described as five levels of emetogenicity has been subsequently modified to a four-level schema (Table 135.1) classifying agents as having a high, moderate, low, or minimal risk of inducing emesis.^{37,38} Oral agents are considered separately and have been classified by emetic risk into four categories.^{38,39}

Risk of RINV is defined primarily by the anatomic area receiving treatment as well as the type of treatment.³⁸ The most commonly employed category includes four levels of risk: high, moderate, low, and minimal.^{37,38} High-risk therapy consists of total-body irradiation. Moderate risk includes the upper abdomen, which carries a 60% to 90% risk of emesis without prophylaxis. Low risk includes the lower thoracic region and pelvis as well as

the cranium (with radiosurgery) and craniospinal therapy. Minimal risk includes cranium, head and neck, extremities, and breast.

ANTIEMETIC AGENTS

Highest Therapeutic Index

There are several classes of drugs that are effective in the prevention of CINV (Table 135.2). Those of highest therapeutic index include the 5-HT₃ receptor antagonists, the NK₁ receptor antagonists, and corticosteroids. The most widely available first generation 5-HT₃ receptor antagonists include dolasetron, granisetron, ondansetron, and tropisetron. They have been shown to be superior to high-dose metoclopramide⁴⁰ and have replaced it as first-line therapy in prevention of acute emesis. They have proven to be most effective in the prevention of acute CINV in the settings of highly and moderately emetogenic chemotherapy. All first-generation 5-HT₃ receptor antagonists are considered therapeutically equivalent and are used interchangeably.^{37,38,41} Oral formulations of the first-generation 5-HT₃ receptor antagonists have similar efficacy to intravenous formulations.⁴²

Palonosetron is a second-generation 5-HT₃ antagonist that differs from other agents in this class by virtue of a longer half-life of 40 hours and a higher binding affinity to the 5-HT₃ receptor. It has been compared with first-generation 5-HT₃ antagonists in two randomized phase 3 trials in patients receiving moderately emetogenic chemotherapy.^{43,44} Both trials were designed as non-inferiority trials and met their primary end point. Post hoc analyses indicated superiority for palonosetron in a number of parameters to the comparator agents. In one trial, palonosetron 0.25 mg was superior to dolasetron 100 mg in complete response (no emesis or use of rescue medications) during the delayed (24 to 120 hours) and overall study periods.⁴³ In the other trial, palonosetron 0.25 mg was superior to ondansetron 32 mg in complete response during the first 24 hours, delayed period, and overall 5-day study period.⁴⁴ A third phase 3 trial in patients receiving highly emetogenic chemotherapy also reached its end point of noninferiority in comparing palonosetron with ondansetron 32 mg.⁴⁵ Unlike the moderately emetogenic trials, there was no significant difference between palonosetron and ondansetron in the control of acute or delayed emesis. Approximately two-thirds of patients also received corticosteroids at the discretion of the investigator in the highly emetogenic trial. A post hoc secondary subgroup analysis of the patients receiving dexamethasone demonstrated superior control of acute and delayed emesis in the group receiving palonosetron. In another phase 3 trial,⁴⁶ patients receiving either cisplatin or the combination of doxorubicin or epirubicin and cyclophosphamide were randomized in a double blind fashion to either a single dose of palonosetron at a dose of 0.75 mg or a single dose of granisetron (40 µg/kg) on day 1 of chemotherapy. In this trial, steroids for acute and delayed emesis were mandated. Palonosetron was more efficacious than granisetron, with 56.8% of patients in the palonosetron group experiencing an overall complete response (no vomiting or use of rescue medications) compared with 44.5% in the granisetron group ($p < 0.0001$). This was also true for delayed emesis (56.8% versus 44.5%, $p < 0.0001$). Palonosetron was found to be comparable to granisetron in the acute phase, with 75.3% complete response in the palonosetron group versus 73.3% in the granisetron group (difference of 2.29, 95% confidence interval = 2.70 to 7.27; p not done). The results of the phase 3 trials with palonosetron suggest that this agent is superior in efficacy to the first-generation 5-HT₃ antagonists when used as a single agent or with dexamethasone. The relative efficacy of palonosetron compared with first-generation 5-HT₃ receptor antagonists when used with NK₁ antagonists remains unknown given the lack of randomized data. Most of the studies done with palonosetron have used the 0.25 mg dose given intravenously. Boccia et al.⁴⁷ compared

TABLE 135.1

Classification of Emetic Risk of Intravenous Antineoplastic Agents

Emetic Risk (Estimated Incidence without Prophylaxis)	Antineoplastic Agent
High (>90%)	Cisplatin Methotrexamine Streptozotocin Cyclophosphamide ($\geq 1,500$ mg/m ²) Carmustine Dacarbazine
Moderate (30%–90%)	Oxaliplatin Cytarabine (>1 g/m ²) Carboplatin Ifosfamide Cyclophosphamide (<1,500 mg/m ²) Doxorubicin Daunorubicin Epirubicin Idarubicin Irinotecan Azacitadine Bendamustine Clofarabine Alemtuzumab
Low (10%–30%)	Paclitaxel Docetaxel Mitoxantrone Doxorubicin HCl liposome injection Ixabepilone Topotecan Etoposide Pemetrexed Methotrexate Mitomycin Gemcitabine Cytarabine (≤ 100 mg/m ²) 5-Fluorouracil Bortezomib Cetuximab Trastuzumab Panitumumab Catumaxumab
Minimal (<10%)	Bleomycin Busulfan 2-Chlorodeoxyadenosine Fludarabine Vinblastine Vincristine Vinorelbine Bevacizumab Rituximab

TABLE 135.2

Doses of Commonly Used Antiemetic Agents

Drug	Prechemotherapy Dose (Day 1)	Postchemotherapy Dose
Highest Therapeutic Index		
Aprepitant	125 mg orally	80 mg orally days 2 and 3
Fosaprepitant	150 mg IV	
Dexamethasone With aprepitant or fosaprepitant Without aprepitant	12 mg orally or IV 20 mg orally or IV ^a 8 mg orally or IV ^b	8 mg days 2–4 ^a 8 mg bid days 2–4 ^a 8 mg days 2 and 3 ^c
Ondansetron	24 mg orally ^a ; 8 mg orally bid ^b 8 mg or 0.15 mg/kg IV	8 mg bid days 2 and 3
Granisetron	2 mg orally 1 mg or 0.01 mg/kg IV	—
Tropisetron	5 mg orally or IV	—
Dolasetron	100 mg orally	—
Palonosetron	0.25 mg IV 0.5 mg orally	—
Lower Therapeutic Index		
Prochlorperazine	10 mg orally or IV	—
Dronabinol	5 mg/m ² orally	5 mg/m ² orally q2–4 hr p.r.n.
Nabilone	1–2 mg orally	1–2 mg bid or tid p.r.n.
Olanzapine	5 mg orally daily for 2 d preceding chemotherapy; 10 mg on day 1	10 mg days 2–4

IV, intravenously; bid, twice daily; tid, three times a day; p.r.n., pro re nata.

^aWhen used with highly emetic chemotherapy, day 4 is optional.

^bWith moderately emetic chemotherapy.

^cWhen used with moderately emetic chemotherapy with potential for delayed emesis.

three oral doses of palonosetron to the standard 0.25 mg intravenous dose in 651 patients receiving moderately emetogenic chemotherapy. Patients were also randomized to dexamethasone or placebo. The oral dose of 0.5 mg was found to be noninferior to the intravenous 0.25 mg dose in the acute and overall phase. However, none of the oral doses attained noninferiority to the intravenous dosing in the delayed emesis phase.

Corticosteroids are a mainstay in the prevention of both acute and delayed CINV. In a large meta-analysis that included data from >5,000 patients, dexamethasone, the most commonly employed corticosteroid, was found to significantly improve the prevention of CINV compared with placebo or other antiemetics.⁴⁸ Most of the studies involved the use of highly emetogenic chemotherapy. In the acute phase, it was estimated to increase the chance of complete prevention of vomiting by 25% to 30% versus placebo. Similar results were seen with delayed emesis. With moderate to highly emetogenic chemotherapy regimens, corticosteroids are typically not used alone but in combination with other antiemetics. Single-agent use is appropriate with mildly emetogenic regimens. The appropriate doses of dexamethasone for use with highly and moderately emetogenic therapy (in the absence of a NK₁ antagonist) are 20 mg and 8 mg, respectively, based on the results of two large phase 3 trials.^{49,50}

The most recent advance in CINV prevention has been the introduction of selective antagonists of Substance P's binding to the NK₁ receptor. Aprepitant is the first approved agent in this new class of antiemetics. In a phase 3 randomized study that included >500 patients, aprepitant significantly increased the overall 5-day complete response (no emesis or use of rescue) rate (72.7% versus 52.3%) when added to the standard therapy of ondansetron and dexamethasone in patients receiving high-dose cisplatin chemotherapy.⁵¹ Superiority for the aprepitant arm was demonstrated

in both the control of acute and delayed emesis. Similar results were found in an identically designed phase 3 trial enrolling patients from Latin America.⁵² The addition of aprepitant may also improve the durability of antiemetic control over multiple cycles of cisplatin-based chemotherapy.⁵³ Benefit for the addition of aprepitant has also been demonstrated in patients receiving a combination of an anthracycline and cyclophosphamide, a combination now recognized to be highly emetogenic. In a phase 3 trial in patients with breast cancer receiving an anthracycline plus cyclophosphamide, patients were randomized to an aprepitant-containing regimen, which included dexamethasone and ondansetron, or a standard regimen that consisted of dexamethasone and ondansetron.⁵⁴ Aprepitant alone was used as delayed emesis prevention in the aprepitant arm, while ondansetron alone was used for delayed emesis protection in the comparison arm. A superior rate of complete response (50.8% versus 42.5%) during the 5-day study period was noted in the aprepitant arm.

A possible benefit for aprepitant in the prevention of CINV associated with moderately emetogenic chemotherapy has been demonstrated. Rapoport et al.⁵⁵ reported the results of a phase 3 trial evaluating aprepitant with a variety of moderately emetogenic chemotherapy regimens as well as doxorubicin and cyclophosphamide. Patients were treated with aprepitant or placebo plus ondansetron and dexamethasone on day 1 and either aprepitant (experimental arm) or ondansetron (control arm) for delayed emesis. Overall, patients randomized to the aprepitant containing arm had significantly higher proportions of patients with complete response, including overall (62.8% versus 47.1%, $p < 0.01$), in the acute setting (84.3% versus 72.5%, $p < 0.01$), and in the delayed setting (64.8% versus 52.9%, $p < 0.01$). Retrospective analysis was done comparing patients receiving doxorubicin/cyclophosphamide with those receiving moderately emetogenic

combinations, which confirmed the superiority of aprepitant in those patients treated with doxorubicin/cyclophosphamide. For the non-doxorubicin/cyclophosphamide arm, while the addition of aprepitant statistically improved the proportion of patients who did not experience vomiting, the overall complete response rate did not differ between the aprepitant-containing group and the non-aprepitant-containing group. An additional trial prospectively evaluating aprepitant in moderately emetogenic chemotherapy did not demonstrate value for the addition of the NK₁ antagonist. Hesketh et al.⁵⁶ investigated the use of a single dose of casopitant, an NK₁ receptor antagonist, in oxaliplatin-based chemotherapy. All patients were treated with ondansetron starting prior to oxaliplatin administration and continuing until day 3, dexamethasone day 1, and randomized to receive casopitant or placebo day 1. The primary end point was complete response (no vomiting and no use of rescue medications), and a total of 710 patients were included in the intention to treat analysis. Casopitant did not improve outcome compared to the dexamethasone and ondansetron regimen with similar rates of complete response overall (85% in the placebo arm versus 86% in the casopitant arm; odds ratio = 1.1054; 95% confidence interval = 0.73 to 1.68; $p = 0.6373$), in the acute phase (96% in the placebo arm versus 97% in the casopitant arm), and in the delayed phase (85% in the placebo arm versus 86% in the casopitant arm). Given the limited and somewhat conflicting data on the value of aprepitant in the moderately emetogenic setting, the most recent European Society of Clinical Oncology-Multinational Association of Supportive Care in Cancer³⁵ and American Society of Clinical Oncology (ASCO) antiemetic guidelines³⁷ do not recommend the use of aprepitant with moderately emetogenic chemotherapy.

In 2008, an intravenous formulation of aprepitant (fosaprepitant) received regulatory approval for use with moderately and highly emetogenic chemotherapy. A single intravenous dose of fosaprepitant 150 mg was compared with 3-day oral dosing of aprepitant in a randomized double blind active-control designed trial and was found to be equivalent in efficacy in patients treated with cisplatin at doses of at least 70 mg/m².⁵⁷ This held true for both the delayed emesis period and the overall study period.

Of note, aprepitant is an inhibitor of the cytochrome P450 enzyme CYP3A4, which is involved in the metabolism of many drugs, including dexamethasone and certain chemotherapeutic agents. A pharmacokinetic study demonstrated that the plasma concentration of dexamethasone as measured as the area under the curve was more than two-fold higher with aprepitant compared with the same dose of dexamethasone without concomitant aprepitant.⁵⁸ A dose reduction of dexamethasone from 20 to 12 mg (day 1) and 8 to 4 mg (days 2 and 3) yielded similar plasma dexamethasone levels to those in patients not taking aprepitant. The slowed metabolism of dexamethasone in the presence of aprepitant accounts for the recommendation to reduce dexamethasone doses by approximately 50% when administered with aprepitant.³⁷ However, if the corticosteroids are given as part of the chemotherapeutic regimen rather than for antiemetic prophylaxis, the corticosteroid dose should not be adjusted.³⁷ There is also a theoretical concern that chemotherapeutic agents that are metabolized by CYP3A4 may have a slowed clearance, leading to higher drug exposure, and increased toxicity. However, analysis of the completed phase 3 trials with aprepitant has not demonstrated a significant increase in adverse events in patients receiving aprepitant.

Recently, data on a new selective NK₁ receptor antagonist netupitant has been presented. In a phase 2 study,⁵⁹ 694 patients receiving cisplatin-based chemotherapy were randomized to four study arms comparing three oral doses of netupitant (100 mg, 200 mg, 300 mg), all combined with oral palonosetron 0.50 mg, all given on day 1. All patients received oral dexamethasone on days 1 to 4. An exploratory aprepitant + ondansetron/dexamethasone arm was included. The study arm, combining 300 mg of netupitant with palonosetron, was superior to the palonosetron and dexamethasone arm in control of acute and delayed nausea and emesis as

well as complete protection ($p \leq 0.05$). A subsequent phase 3 study including 1,455 patients receiving cyclophosphamide combined with doxorubicin or epirubicin evaluated a fixed-dose tablet containing netupitant 300 mg combined with palonosetron 0.5 mg termed NEPA. Patients were randomized to receive NEPA or oral palonosetron 0.5 mg on day 1 prior to chemotherapy. All patients also received dexamethasone (12 mg NEPA arm; 20 mg palonosetron arm) on day 1. NEPA plus dexamethasone was found to be superior to palonosetron plus dexamethasone in rates of complete response during acute ($p = 0.001$), delayed ($p = 0.047$), and overall ($p = 0.001$) phases as well as in rates of no significant nausea.⁶⁰

Lower Therapeutic Index

Drugs of lower therapeutic index include metoclopramide, butyrophenones, phenothiazines, cannabinoids, and olanzapine (see Table 135.2). These drugs in general are all associated with less efficacy than the high therapeutic index agents and can have troublesome adverse effects. These drugs are most commonly used in patients who are unable to tolerate or who do not respond to 5-HT₃ receptor antagonists, aprepitant, or dexamethasone. Of the lower therapeutic index agents, the phenothiazines are probably used most often either as monotherapy with patients receiving mildly emetogenic chemotherapy or as an as-needed agent in patients failing frontline antiemetics. Another class of agents that may have value in selected situations is the benzodiazepines. Although limited in their antiemetic efficacy, the anti-anxiety properties of these agents can be useful. The most commonly employed agent in the class is lorazepam, which has demonstrated value with anticipatory emesis and can be useful as an adjunct to other antiemetics in patients failing to completely respond to their frontline regimens. Olanzapine, which is an antagonist of multiple neurotransmitter receptors including those of dopamine and serotonin, may be effective in preventing both acute and delayed CINV. Olanzapine has been investigated in place of aprepitant in a phase 3 trial⁶¹ of patients receiving highly emetogenic chemotherapy including both cisplatin (at ≥ 70 mg/m²) and the combination of doxorubicin and cyclophosphamide. In this trial, 247 patients were randomized to either (1) olanzapine, palonosetron, and dexamethasone given on day 1 with olanzapine 10 mg daily given on days 2 to 4 or (2) aprepitant, palonosetron, and dexamethasone with dexamethasone given on days 2 to 4. Both groups had similar rates of complete response to emesis. In the olanzapine arm, there was a complete response of 97% in the acute phase, 77% in the delayed phase, and 77% overall compared, with the aprepitant arm, which had complete response rates of 87% in the acute phase and 73% in the delayed phase and overall ($p > 0.05$). A majority (87%) of patients in both groups experienced no nausea; however, olanzapine was more effective at controlling nausea in the delayed setting with 69% of patients in the olanzapine arm reporting no nausea compared with 38% in the aprepitant arm ($p \leq 0.01$).

ANTIEMETIC TREATMENT BY CLINICAL SETTING

In planning antiemetic therapy in patients with cancer receiving chemotherapy, it is important to consider a few basic principles: (1) the primary goal should be complete prevention; (2) to minimize the risk of anticipatory emesis, antiemetic therapy should be appropriately maximized from the initial cycle of chemotherapy; (3) antiemetic therapies should be chosen to match the intrinsic emetogenicity of the chemotherapy; and (4) consider prescribing antiemetics for use in the event breakthrough emesis develops. If emesis does develop in the patient receiving chemotherapy, an assessment should be made to exclude nonchemotherapy causes of the patient's nausea and vomiting. These include bowel obstruction or dysmotility; concomitant medications, particularly opioids;

TABLE 135.3

Recommended Antiemetic Therapy for Single-Day Intravenous Chemotherapy

Emetic Risk Category	Prevention of Acute Emesis (Day 1 Prechemotherapy)	Prevention of Delayed Emesis
High ^a	5-HT ₃ receptor antagonist <i>plus</i> dexamethasone <i>plus</i> aprepitant or fosaprepitant	Dexamethasone days 2–4 ^b
Moderate	Palonosetron <i>plus</i> dexamethasone	Dexamethasone days 2 and 3
Low	Dexamethasone <i>or</i> prochlorperazine	No preventive measures
Minimal	As needed	No preventive measures

5-HT₃, 5-hydroxytryptamine-3.

^aThe combination of doxorubicin and cyclophosphamide is considered highly emetogenic.

^bDay 4 is optional.

metabolic disturbances such as hyponatremia and hypercalcemia; and occult CNS metastasis.

ASCO guidelines³⁷ have moved the combination of doxorubicin and cyclophosphamide from the moderate to the highly emetogenic risk category, reflecting a myriad of data on the high intrinsic emetogenicity of this regimen. For patients receiving single-day intravenously administered highly emetogenic chemotherapy such as cisplatin and now including the combination of doxorubicin and cyclophosphamide, recommended prophylaxis involves the use of a 5-HT₃ receptor antagonist on day 1, dexamethasone on days 1 to 4, and fosaprepitant day 1 only or aprepitant on days 1 to 3 (Table 135.3). For moderately emetogenic chemotherapy given intravenously, prophylaxis using palonosetron is recommended on day 1, along with dexamethasone on day 1. Patients should also receive either a 5-HT₃ antagonist (if palonosetron is not used) or dexamethasone on days 2 to 3 after chemotherapy. For intravenously administered chemotherapy of low emetogenic potential, single-agent dexamethasone or prochlorperazine is recommended on day 1 with no routine prophylaxis for delayed emesis. For minimal-risk chemotherapy agents, no routine antiemetic prophylaxis is indicated.

SPECIAL CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING PROBLEMS

There are a number of situations in addition to single-day intravenously administered chemotherapy that pose emetic challenges. Regimens containing highly emetogenic chemotherapy, such as cisplatin given on multiple days, require special attention, though there is limited data for this setting. ASCO guidelines³⁷ suggest antiemetic prophylaxis corresponding to the level of emetogenicity for the duration of the chemotherapy administration plus 2 days after, when applicable, and the use of aprepitant, dexamethasone, and a 5-HT₃ antagonist for 5-day cisplatin regimens. In 2008, the U.S. Food and Drug Administration approved the use of a transdermal granisetron patch for use in patients receiving multiple-day regimens of chemotherapy based on a phase 3 multinational, double blind, double dummy, noninferiority study.⁶² In this trial, 641 patients receiving chemotherapy regimens of 3- to 5-day duration were randomized to the granisetron patch applied on the day prior to chemotherapy and kept on for 7 days or oral granisetron 2 mg daily prior to chemotherapy. The primary end point of this study was complete control: no vomiting, use of rescue medication, or more than mild nausea. The study met its primary end point of noninferiority with complete control in 60% of patients using the patch and 65% of patients taking single daily oral granisetron (difference of 5%, 95% confidence interval = -13% to 3%). A related problem is noted in patients receiving high-dose chemotherapy in the setting of hematopoietic stem cell transplantation. Chemotherapy regimens are often administered during several days in sequence, and there are data supporting the value of daily 5-HT₃ receptor antagonist and dexamethasone in this setting as well.⁶³ A randomized trial in patients receiving preparative regimens for hematopoietic stem cell transplantation noted improved outcome with the addition of aprepitant to ondansetron

and dexamethasone.⁶⁴ No emesis rates of 73.3% and 22.5% were noted for the entire study period in the aprepitant and control arms, respectively ($p = 0.001$). In addition, complete response (no emesis and no mild nausea) was seen in 48.9% versus 14.6% in the aprepitant and control arms, respectively ($p < 0.001$).

Anticipatory nausea and vomiting pose additional special CINV challenges. These symptoms are often poorly responsive to common antiemetics. Fortunately, given the recent improvements noted in the control of CINV in general, anticipatory nausea and vomiting are much less commonly seen. Therapies that have been studied with some success include systemic desensitization and hypnosis. One series showed benefit for alprazolam when combined with a psychological support program.⁶⁵

Oral chemotherapeutic agents are increasingly used in clinical oncology practices and also have a propensity to cause varying degrees of CINV. There is a scarcity of data on the emetogenicity of oral drugs; therefore, the risk of CINV has not been as well defined. The lack of clinical trials addressing the issue of oral agent-induced CINV precludes definitive treatment recommendations.

Finally, if patients receive appropriate evidence-based prophylaxis for CINV and still develop so-called breakthrough emesis, this can also be a troublesome problem. As with oral chemotherapy, there is little prospective data evaluating treatment approaches for this problem. If other causes of nausea and vomiting are excluded, adjunctive medications such as benzodiazepines or dopaminergic antagonists can be added. One double-blind trial in patients who failed initial prophylaxis found that switching from one 5-HT₃ receptor antagonist to another afforded significantly higher rates of complete protection compared with those patients remaining on the original 5-HT₃ receptor antagonist.⁶⁶ Olanzapine has also been studied for breakthrough nausea and vomiting. In a randomized double-blind phase 3 trial,⁶⁷ olanzapine was compared with metoclopramide for breakthrough nausea and vomiting after guideline-specific prevention for highly emetic chemotherapy, which included both high-dose cisplatin and the combination of doxorubicin and cyclophosphamide. Breakthrough medications were started at the onset of vomiting or moderate to severe nausea on a visual and numeric scale. Approximately 40% of patients in each arm developed breakthrough vomiting or moderate to severe nausea. In the 72-hour period after breakthrough medications were initiated, 70% of patients using olanzapine for breakthrough had no emesis compared with 31% of patients taking metoclopramide ($p < 0.01$). Nausea after breakthrough antiemetics were given was measured on the MD Anderson Cancer Center Symptom Inventory scale, with 68% of patients reporting no nausea compared with 23% of patients taking metoclopramide ($p < 0.01$).

RADIOTHERAPY-INDUCED NAUSEA AND VOMITING

Radiotherapy can also clearly cause nausea and vomiting in a number of settings and warrants appropriate prophylactic therapy (Table 135.4). Updated guideline recommendations^{37,38} have

TABLE 135.4

Recommended Antiemetic Therapy for Radiotherapy-Induced Emesis

Risk Level	Irradiated Area	Antiemetic Guidelines
High (>90%)	Total-body irradiation, total nodal irradiation	Prophylaxis with 5-HT ₃ antagonists + DEX
Moderate (60%–90%)	Upper abdomen, HBI, UBI	Prophylaxis with 5-HT ₃ antagonists + optional DEX
Low (30%–60%)	Cranium, craniospinal, H&N, lower thorax region, pelvis	Prophylaxis or rescue with 5-HT ₃ antagonists
Minimal (<30%)	Extremities, breast	Rescue with dopamine receptor antagonists or 5-HT ₃ antagonists

5-HT₃, 5-hydroxytryptamine-3; DEX, dexamethasone; HBI, half-body irradiation; UBI, upper-body irradiation; H&N, head and neck.

Note: In concomitant radiochemotherapy, the antiemetic prophylaxis is according to the chemotherapy-related antiemetic guidelines of the corresponding risk category, unless the risk of emesis is higher with radiotherapy than chemotherapy.

Adapted with permission from Roila F, Herrstedt J, Aapro M, et al. Guideline update for MASCC and ESMO in the prevention of chemotherapy- and radiotherapy-induced nausea and vomiting: results of the Perugia consensus conference. *Ann Oncol* 2010;21:v232–243.

been provided. Optimal prophylaxis for total-body or total-nodal radiation is the use of a 5-HT₃ receptor antagonist plus dexamethasone. Reasonable prophylaxis for radiation of moderate emetic risk would be 5-HT₃ receptor antagonist before each fraction with the

optional use of dexamethasone for fractions one to five. Prophylaxis or rescue with 5-HT₃ antagonists is appropriate for low-risk radiation. Minimal-risk radiation is treated with 5-HT₃ receptor antagonists or dopamine antagonists as needed.

136 Diarrhea and Constipation

Nathan I. Cherny and Batsheva Werman

INTRODUCTION

Constipation and diarrhea are both common problems in patients with advanced cancer. They are a source of major morbidity and distress. Treatment-induced diarrhea can be severe and be associated with life-threatening dehydration and electrolyte abnormalities. Treatment-induced constipation is, as a result of very widespread use of opioid analgesics for cancer pain, more common than diarrhea. Oncologists must be familiar with the common causes of constipation and diarrhea among patients with cancer and the strategies to evaluate and manage these common and distressing symptoms.

DIARRHEA

Diarrhea is defined as the frequent passage of loose stools with urgency. Objectively defined, it is the passage of more than three unformed stools in 24 hours. As with constipation, the patient's definition of diarrhea varies and needs to be clarified by medical staff.

Diarrhea is a common and significant problem among patients with advanced cancer. Increasingly, it is seen as a major treatment complication, particularly among patients receiving fluoropyrimidines and irinotecan.¹ The causes of diarrhea among patients with advanced cancer are diverse and some require specific therapies. Thus, careful evaluation of the underlying cause is necessary.

Severe diarrhea can be debilitating and at times, even life-threatening.¹ It contributes to dehydration, electrolyte imbalance, malnutrition, declining immune function, and pressure ulcer formation.

Chemotherapy-Induced Diarrhea

The chemotherapy agents commonly causing diarrhea include 5-fluorouracil (5-FU), capecitabine, and irinotecan.¹ This is usually a dose-related adverse effect and may be associated with other features of toxicity. Chemotherapy-induced diarrhea appears to be a multifactorial process whereby acute damage to the intestinal mucosa (including loss of intestinal epithelium, superficial necrosis, and inflammation of the bowel wall) causes an imbalance between absorption and secretion in the small bowel.

5-Fluorouracil

Mechanism. 5-FU causes mitotic arrest of intestinal epithelial crypt cells resulting in an increase in the ratio of immature secretory crypt cells to mature villous enterocytes. This results in abnormal absorption and secretion of fluids and electrolytes. Opportunistic infections, causing local inflammation and factors released by necrosis secondary to chemotherapy, directly stimulate intestinal secretion of fluids and electrolytes. The diarrhea associated with 5-FU therapy may be watery or bloody. Disruption of the integrity of the gut lining may permit access of enteric organisms into the bloodstream, with the potential for overwhelming sepsis,

particularly if the granulocyte nadir coincides with diarrhea. Severity is variable but it may be severe and at times life-threatening. Pathologic changes range in severity from a mild colitis to severe necrotizing enterocolitis with pneumocystic colitis.

Risk Factors. Diarrhea is most commonly observed when 5-FU is coadministered with leucovorin (LV). It is slightly more common with bolus rather than infusional administration of 5-FU/LV, in particular with high-dose LV (500 mg/m²),^{2,3} but it occurs with all administration schedules.⁴ In the initial reports of weekly 5-FU/LV, diarrhea was seen in up to 50% of patients, with one-half of these requiring hospitalization for intravenous fluids^{2,3} and, in one study, a 5% mortality rate.³ Other risk factors have been identified including unresected primary tumor, previous episodes of chemotherapy-induced diarrhea, and female gender.

Dihydropyrimidine Dehydrogenase Deficiency. 5-FU is normally metabolized to inactive dihydro-5-FU after an intravenous dose; 80% of the drug is metabolized to the inactive dihydro-5-FU by dihydropyrimidine dehydrogenase (DPD) in the liver. Administration of 5-FU to patients with DPD deficiency can lead to life-threatening complications, including severe diarrhea, mucositis, and pancytopenia.⁵ DPD deficiency is relatively common among Caucasians (3% to 5%).⁵ Although the diagnosis can be made by radioimmunoassay for the DPD enzyme, this test is not readily available. More recently, a simple breath test has been developed, and this may provide an effective screening tool.⁵

Irinotecan

Irinotecan can cause acute diarrhea (immediately after drug administration) or a delayed diarrhea. Immediate-onset diarrhea is caused by acute cholinergic properties, and it is often accompanied by other symptoms of cholinergic excess, including abdominal cramping, rhinitis, lacrimation, and salivation. The mean duration of symptoms is 30 minutes, and it usually responds rapidly to atropine.⁶

Delayed-onset diarrhea usually occurs at least 24 hours after drug administration and can be potentially life-threatening, especially in combination chemotherapy regimens with bolus intravenous fluorouracil and leucovorin.⁶ The late diarrhea associated with irinotecan is unpredictable, noncumulative, and occurs at all dose levels. It is more common with 3-weekly dose schedules than with lower weekly dosing.⁶ The median time to onset is 6 to 14 days. The mechanism of irinotecan-induced delayed diarrhea is not known, but it is believed to result from the deconjugation of irinotecan's metabolite, 7-ethyl-10-hydroxycamptothecin (SN38) glucuronide, by intestinal bacteria, thus enabling direct effect of the active agent on colonic epithelium. It is suggested that the active agent binds to topoisomerase I and induces apoptosis of intestinal epithelia, leading to the disturbance in the absorptive and secretory functions of mucosa. Additionally, both irinotecan and SN-38 may also stimulate the production of proinflammatory cytokines and prostaglandins, thus contributing to an inflammatory/secretory diarrhea.⁷

Genetic factors may influence the glucuronidation of SN-38, the active metabolite of irinotecan, and thus increase this risk of diarrhea. Polymorphisms that alter UDP-glucuronosyltransferase activities have been identified; the homozygous presence of the UGT1A1*28 polymorphism, leading to less efficient glucuronidation of SN-38, has been identified as a potential risk factor for the occurrence of delayed-type diarrhea and grade 3 to 4 neutropenia.⁸ In one study, heterozygote had a two-fold elevation of risk of severe diarrhea.⁹

Capecitabine

Capecitabine, a precursor of 5-FU, is an oral fluoropyrimidine cytotoxic agent developed with the aim of providing a more effective, less toxic alternative to 5-FU, with the added advantage of oral administration. Administered at usual doses (2,000 mg/m² per day for 14 of every 21 days), the prevalence of diarrheas is 30% to 40%; in 10% to 20%, it is severe.¹⁰

Other Cytotoxics

The taxane docetaxel commonly causes a relatively mild diarrhea. Data from phase 2 and 3 studies indicated a prevalence of approximately 30%.¹¹ In most cases, the diarrhea is mild; however, cases of severe enteritis and colitis have been reported (see the following).^{12,13}

Similarly, the antifolate pemetrexed can also cause mild diarrhea. In phase 2 and 3 trials, mild diarrhea has been reported in about 10% to 15% of patients.¹⁴

Neutropenic Colitis

Neutropenic enterocolitis (also called necrotizing enterocolitis or typhlitis) is an acute life-threatening complication of chemotherapy that is most commonly observed with high-dose treatments in the setting of myeloablative therapies.^{15,16} It is, however, also observed with nonmyeloablative therapies,^{17,18} particularly with taxanes.^{16,19,20}

Clinical Presentation

Neutropenic enterocolitis usually occurs when the absolute neutrophil count falls to <500/μL. Patients present with fever, abdominal pain, nausea, vomiting, diarrhea, and not uncommonly, sepsis. Abdominal pain may be diffuse or localized to the right lower quadrant. Sometimes pain is absent, particularly if the patient has received steroid therapy.

Pathogenesis

The pathogenesis of neutropenic enterocolitis is multifactorial: mucosal injury by cytotoxic drugs or other means, profound neutropenia, and impaired host defense to invasion by microorganisms.^{16,21,22} The microbial infection leads to necrosis of various layers of the bowel wall. Anatomically, the cecum is almost always affected, and the process often extends into the ascending colon and terminal ileum. The predilection for the cecum is possibly related to its dispensability and its relatively diminished vascularization. Various bacterial and/or fungal organisms, including gram-negative rods, gram-positive cocci, anaerobes (e.g., *Clostridium septicum*), and *Candida* spp., are often seen infiltrating the bowel wall. Polymicrobial infection is frequent. Bacteremia or fungemia is also common, usually with enteric organisms such as *Pseudomonas* or yeasts such as *Candida*.

Diagnostic Investigations

The diagnosis is based upon signs and symptoms in the appropriate clinical setting as well as imaging studies. Plain abdominal radiographs may demonstrate dilated loops of bowel, thickening of the bowel wall, “thumbprinting” resulting from bowel wall edema,

or indications of a right lower quadrant mass or phlegmon. Free intraperitoneal air indicates perforation of the bowel wall. Pneumatosis intestinalis is often seen.

Computed tomography scanning is the preferred imaging modality. Computed tomography scanning techniques can evaluate the entire abdomen for pathology, especially in patients with distended loops of bowel and ileus for whom ultrasound would not be possible. Scans commonly demonstrate concentric thickening of the bowel wall, a fluid-filled cecum, pericolic fluid collections or abscesses, pneumatosis intestinalis, and free air if an underlying perforation exists. Bowel wall thickening of >3 mm to 5 mm is considered abnormal and is consistent with, but not diagnostic of, necrotizing enterocolitis.²³ Indeed, *Clostridium difficile*-related colitis in patients with neutropenia may be associated with substantial or even greater wall thickening.²⁴ *Pneumatosis intestinalis* along with cecal and colonic wall thickening is very suggestive.²⁴

Abdominal ultrasonography can identify thickening of the bowel wall that produces a target or halo sign. Indeed, a bowel wall thickening of >5 mm was associated with a higher mortality (29% versus 0%). If one takes a cutoff of >10 mm, the mortality was 60% versus 4.2%.²⁵ Ultrasound is useful as a follow-up tool to assess the gradual decrease in bowel wall thickening. Additionally, signs of pericolic fluid and intramural or abdominal free air often indicate perforation.

Diagnostic Criteria

Established standardized diagnostic criteria include the presence of neutropenia (absolute neutrophil count <500 × 10⁶ cells/L), bowel wall thickening of >4 mm on radiographic imaging, and the exclusion of other diagnoses such as *C. difficile*-associated colitis, graft-versus-host disease, or other abdominal syndromes.^{20,26}

Targeted Therapy–Associated Diarrhea

Almost all of the recently developed small molecule targeted therapies cause diarrhea as a side effect. Diarrhea, which can be severe, has been reported in 30% to 50% of patients receiving bortezomib,²⁷ erlotinib,²⁸ gefitinib,²⁹ sorafenib,³⁰ sunitinib,³¹ and imatininib,³² and the mammalian target of rapamycin inhibitors temsirolimus³³ and everolimus.³⁴

The monoclonal therapies targeting the epidermal growth factor receptors cetuximab³⁵ and panitumumab^{36,37} both cause diarrhea in 10% to 20% of patients, which may be severe in a small subset of patients.

Radiotherapy-Induced Diarrhea

Radiation injury to the lower intestine is usually encountered following treatment of cancers of the anus, rectum, cervix, uterus, prostate, urinary bladder, and testes, and as part of total-body irradiation. Radiotherapy of the abdomen or pelvis damages intestinal mucosa, causing prostaglandin release and bile salt malabsorption. These two factors increase intestinal peristalsis, causing diarrhea.

Acute radiation enteritis/proctitis occurs within 6 weeks of therapy. Symptoms include diarrhea, cramping, rectal urgency or tenesmus, and, uncommonly, bleeding. These symptoms usually resolve without specific therapy within 2 to 6 months.^{38,39}

Late radiation enteritis/proctitis generally occurs 8 to 12 months after therapy and in some cases it may be delayed by years.⁴⁰ It may manifest as malabsorption and/or diarrhea, with more rapid transit times occurring in the affected bowel. Bacterial overgrowth causes malabsorption and contributes to the nausea, abdominal pain, and diarrhea, and it should be suspected in patients with intestinal strictures or enterocolic fistulae.⁴⁰ Although the large intestine is less radiosensitive, some patients can develop a pancolitis that resembles inflammatory bowel disease.^{41,42}

Other Causes of Treatment-Related Diarrhea

Clostridium Difficile Diarrhea

C. difficile diarrhea occurs when the normal intestinal flora is altered, allowing *C. difficile* to flourish in the intestinal tract and produce a toxin that causes a watery diarrhea.⁴³ It can be triggered by repeated enemas, prolonged nasogastric tube insertion, gastrointestinal tract surgery, and the use of antibiotics, especially penicillin (ampicillin), clindamycin, and cephalosporins. Occasionally, however, it is reported after chemotherapy in the absence of antibiotic therapy.⁴⁴⁻⁴⁶ The most common confirmatory study is an enzyme immunoassay for *C. difficile* toxins A and B, which yields results in 2 to 4 hours. Specificity of the assay is high (93% to 100%), but sensitivity ranges from 63% to 99%, and this limited sensitivity may require two to three repeat stool samples to document disease.⁴³ Recently, a Polymerase chain reaction test Xpert *C. difficile* test (Cepheid, Sunnyvale, CA) has been approved by the US Food and Drug Administration. Limited data indicates that this may have greater sensitivity.⁴⁷

Enteral Feeding

Tube feedings, either by nasogastric tube, gastrostomy, or jejunostomy, may be associated with the development of diarrhea.^{48,49} This is a common problem occurring in 10% to 60% of patients.^{48,49} Many potential factors may contribute to the problem and indeed it is often multifactorial.⁴⁹ Both formula osmolality and rate of delivery may be associated with diarrhea.⁴⁹

Partially hydrolyzed guar gum is a soluble fiber added to enteral formulas and has the largest body of evidence supporting its use in diarrhea prevention when compared against fiber-free formulas.⁴⁹ There is some data indicating that partially hydrolyzed guar gum may be preferable to insoluble fiber in this setting. There is conflicting evidence of efficacy of probiotics in preventing diarrhea in patients receiving enteral nutrition, and there is no consensus regarding the use of this approach prophylactically.⁴⁹

Contamination of the enteral formula may be a contributing or causative factor. Recommendations to reduce the risk of contamination include hand washing before handling the feeding system, use of clean equipment to prepare and mix feedings, bag and tubing change at least once a day, limitation of "hanging time" of individual bags to under 6 hours, and refrigerated storage of prepared bags until use.⁵⁰

Celiac Plexus Block

Celiac plexus block is commonly associated with a self-limiting acute diarrhea. Occasionally, diarrhea may be persistent.⁵¹ This diarrhea may be amenable to treatment with atropine.⁵²

Assessment

The National Cancer Institute grading for the severity of diarrhea is presented in Table 136.1. For chemotherapy induced diarrhea, the severity of the diarrhea, as reflected in its grading, is an important consideration in treatment selection (see the following).

Assessment includes a detailed medical history, dietary history, medication review, description of stools, and a physical examination focused on the identification of dehydration abdominal and rectal areas. When appropriate, abdominal radiographs can be ordered to evaluate for abdominal obstruction or fecal impaction. Biochemical parameters should be checked for evidence of dehydration, hypokalemia, or renal impairment. If enteric infections are suspected, stool samples should be sent for fecal leukocytes, *C. difficile* toxins A and B, and culture for organisms including *C. difficile*, *Salmonella*, *Escherichia coli*, *Campylobacter*, and infectious colitis.

As described previously, when neutropenic enterocolitis is suspected, computed tomography or ultrasound imaging of the abdomen should be undertaken and additional prognostic information may be obtained by ultrasound evaluation of bowel wall thickness.

General Principles in the Management of Diarrhea

Patients must be rehydrated either orally or when appropriate by parenteral infusion. In cases of large-volume diarrhea, there is the potential for very rapid dehydration with risk of prerenal impairment or even, in extreme cases, shock. Patients may suffer electrolyte imbalance particularly from hypokalemia. In general, milk products should be avoided if an infectious cause is suspected because a transient lactase deficiency sometimes may occur. Special attention should be given to patients who are incontinent of stool due to the risk of pressure ulcer formation. Skin barriers should be used to prevent skin irritation caused by fecal material.

Antidiarrhea Medications

Opioids

Loperamide is generally the opioid of choice because it has local activity in the gut and is absorbed only minimally (this accounts for the lack of systemic effects). It reduces stool weight, frequency of bowel movements, urgency, and fecal incontinence in acute and chronic diarrhea. Loperamide can be started at an initial dose of 4 mg followed by 2 mg every 2 to 4 hours or after every unformed

TABLE 136.1

National Cancer Institute Common Toxicity Criteria for Grading of Diarrhea

Toxicity	0	1	2	3	4
Patients without a colostomy	None	Increase of <4 stools/d over pretreatment	Increase of 4–6 stools/d or nocturnal stools	Increase of ≥7 stools/d	>10 stools/d
	None	None	Moderate cramping, not interfering with normal activity	Severe cramping and incontinence, interfering with daily activities	Grossly bloody diarrhea and need for parenteral support
Patients with a colostomy	None	Mild increase in loose, watery colostomy output compared with pretreatment	Moderate increase in loose, watery colostomy output compared with pretreatment, but not interfering with normal activity	Severe increase in loose, watery colostomy output compared with pretreatment, interfering with normal activity	Physiologic consequences requiring intensive care; hemodynamic

Adapted from National Cancer Institute. Cancer Therapy Evaluation Program Common Toxicity Criteria, Version 2.0. 1999:11.

stool.^{53,54} Other opioids, such as tincture of opium, morphine, or codeine, can be used.

Tincture of opium is a widely used antidiarrheal agent. It is often recommended as an alternative to loperamide. Deodorized tincture of opium contains the equivalent of 10 mg/ml morphine, and the recommended dose is 10 to 15 drops in water every 3 to 4 hours. It is important not to confuse this with paregoric, which is a camphorated (alcohol-based) tincture. The latter is a less-concentrated preparation that contains the equivalent of 0.4 mg/ml morphine. The recommended dose is 1 teaspoon (5 ml) in water every 3 to 4 hours.

Somatostatin Analogues

In cases of severe or persistent diarrhea, the somatostatin analogue octreotide should be considered. Octreotide has multiple antidiarrheal actions including suppression of release of insulin, glucagon, vasoactive intestinal peptide, and gastric acid secretion; reduction in motility and pancreatic exocrine function; and increased absorption of water, electrolytes, and nutrients from the gastrointestinal tract. The usual starting dose for octreotide is 100 to 150 µg subcutaneously/intravenously three times a day.⁵⁵ As there is a dose response relationship for its antidiarrheal effect, the dose can be titrated up to 500 µg subcutaneously/intravenously three times a day or by continual intravenous infusion 25 to 50 µg/hour.⁵⁶ A microencapsulated, long-acting formulation of octreotide has been developed for once-monthly intramuscular dosing. This formulation has demonstrated efficacy in resolving severe diarrhea^{57,58} and preventing further episodes of diarrhea in patients receiving ongoing therapy.^{57,58}

Other Agents

Budesonide is an orally administered, topically active steroid with high activity in inflammatory bowel disease, a 90% first-pass effect in the liver, and therefore low systemic availability. It is commonly used in the management of diarrhea in patients with low- to medium-grade inflammatory bowel disease. A small study demonstrated efficacy of oral budesonide in the management of chemotherapy-induced diarrhea that was refractory to loperamide⁵⁹; however, studies did not show benefit in prophylactic use to prevent diarrhea induced by irinotecan⁶⁰ or ipilimumab.⁶¹

Specific Management Guidelines

Chemotherapy-Induced Diarrhea

Chemotherapy-induced diarrhea is a major problem in the management of patients with gastrointestinal cancer in which the drugs irinotecan and fluorouracil are commonly used. Diarrhea can be severe and in some cases life-threatening. The most recent American Society for Clinical Oncology guidelines for management of treatment-induced diarrhea were published in 2004.⁵⁶ Patients are classified as uncomplicated or complicated on the basis of clinical features, and this classification guides treatment approach.

Prevention. Although a randomized trial did not show any advantage of neomycin in the primary prevention of late irinotecan diarrhea,⁹ there is limited evidence supporting its use as secondary prevention in selected patients.⁶²

“Uncomplicated” Diarrhea. *Step 1:* Patients with grade 1 or 2 diarrhea with no other complicating signs or symptoms may be classified as “uncomplicated” and managed conservatively with oral hydration and loperamide. Initial management of mild to moderate diarrhea should include dietary modifications (e.g., eliminating all lactose-containing products and high-osmolar dietary supplements), and the patient should be instructed to record the number of stools and report symptoms of life-threatening sequelae (e.g., fever or dizziness on standing). Loperamide should be started at an initial dose of 4 mg followed by 2 mg every 4 hours or after every unformed stool (not to exceed 16 mg/day).

If diarrhea resolves with loperamide, patients should be instructed to continue dietary modifications and to gradually add solid foods to their diet. In the case of chemotherapy-induced diarrhea, patients may discontinue loperamide when they have been diarrhea-free for at least 12 hours.

Step 2: If mild to moderate diarrhea persists for more than 24 hours, the dose of loperamide should be increased to 2 mg every 2 hours, and oral antibiotics may be started as prophylaxis for infection.

Step 3: If mild to moderate chemotherapy-induced diarrhea has not resolved after 24 hours on high-dose loperamide (48 hours total treatment with loperamide), the patient should be seen in the physician's office or outpatient center for further evaluation, including complete stool and blood workup. Stool workup should include evaluation for pathogens. Fluids and electrolytes should be replaced as needed. Loperamide should be discontinued, and the patient should be started on a second-line antidiarrheal agent such as SC octreotide (100- to 150-µg starting dose, with dose escalation as needed) or other second-line agents (e.g., oral budesonide or tincture of opium).

“Complicated” Chemotherapy-Induced Diarrhea. Patients with mild to moderate diarrhea complicated by moderate to severe cramping, nausea and vomiting, diminished performance status, fever, sepsis, neutropenia, bleeding, or dehydration, and patients with severe diarrhea are classified as “complicated” and should be evaluated further and monitored closely and treated aggressively.

Aggressive management of complicated cases usually necessitates admission and involves intravenous fluids; octreotide at a starting dose of 100 to 150 µg subcutaneously three times a day or intravenously (25 to 50 µg/hour) if the patient is severely dehydrated, with dose escalation up to 500 µg subcutaneously three times a day until diarrhea is controlled, and administration of antibiotics (e.g., fluoroquinolone). These patients should be evaluated with complete blood count, electrolyte profile, and a stool workup evaluating for blood, fecal leukocytes, *C. difficile*, *Salmonella*, *E. coli*, *Campylobacter*, and infectious colitis.

Radiation Therapy–Induced Diarrhea

The most recent American Society for Clinical Oncology guidelines for management of treatment-induced diarrhea were published in 2004.⁵⁶ The initial management of uncomplicated radiation-induced diarrhea is the same as for chemotherapy-induced diarrhea: starting with low-dose loperamide and then progressing to high-dose loperamide if diarrhea persists beyond 24 hours.

If diarrhea has not resolved after a further 24 hours on high-dose loperamide, continue loperamide (2 mg every 2 hours). In such cases, the patient should be evaluated; in severe cases, octreotide therapy may be indicated.

Patients with mild to moderate diarrhea complicated by moderate to severe cramping, nausea and vomiting, diminished performance status, fever, sepsis, neutropenia, bleeding, or dehydration, and patients with severe diarrhea are classified as “complicated.” Complicated radiotherapy-induced diarrhea needs intensive monitoring and aggressive management either in hospital or an intensive home care nursing program or an outpatient facility able to provide a high level of care. Patients with severe symptoms or features suggestive of sepsis should undergo complete stool and blood workup and should be treated with octreotide and intravenous antibiotics.

Management of Neutropenic Enterocolitis

Management of neutropenic enterocolitis is challenging and the risk of mortality is high. There are roles for both medical and surgical interventions.

The initial treatment for neutropenic enterocolitis is medical, with the administration of broad-spectrum antibiotics, granulocyte colony-stimulating factors, nasogastric decompression, intravenous fluids, bowel rest, and serial abdominal examinations.^{16,20,22} In most patients, these measures are sufficient, and symptoms resolve after correction of the neutropenia. The administered antibiotics should have a broad spectrum of activity to cover enteric gram-negative organisms, gram-positive organisms, and anaerobes. Causative microorganisms include *Pseudomonas*, *Staphylococcus aureus*, *E. coli*, and group A *Streptococcus*.²⁰ Reasonable initial choices include monotherapy with piperacillin-tazobactam or imipenem-cilastatin or duotherapy with cefepime or ceftazidime along with metronidazole.¹⁵ In cases that do not respond to antibacterial agents, amphotericin should be considered, because fungemia is common.²⁰ Blood transfusions may be necessary because the diarrhea is often bloody. Anticholinergic, antidiarrheal, and opioid agents should be avoided as they may aggravate ileus.

The indications for and timing of surgical intervention are controversial. The mortality of patients who fail to respond to medical interventions is high, and many patients may not be salvageable. Nonetheless, in selected patients, surgery may be helpful to avoid progressive bowel necrosis, perforation, and to help control sepsis. Commonly cited indications for surgery include (1) persistent gastrointestinal bleeding after correction of thrombocytopenia and coagulopathy, (2) evidence of free intraperitoneal perforation, (3) evidence of abscess formation, (4) clinical deterioration despite aggressive supportive measures, and (5) to rule out other intra-abdominal processes such as bowel obstruction or acute appendicitis examinations.^{16,20,22,63,64}

If exploratory surgery is performed, resection of grossly involved bowel is necessary. All necrotic material must be resected, usually by a right hemicolectomy, ileostomy, and mucous fistula. Failure to remove the necrotic focus in these severely immunocompromised patients is often fatal.⁶⁴ Primary anastomosis is not generally recommended in such severely immunocompromised patients because of the increased incidence of anastomotic leak.⁶⁴

Diarrhea Prophylaxis

Prevention of Radiation Diarrhea

Multiple clinical trials have focused on prevention of diarrhea in patients receiving pelvic radiotherapy.⁶⁵ There is limited data to support the use of probiotic treatment containing *Lactobacillus*⁶⁵⁻⁶⁷ and/or prophylactic 500 mg sulphasalazine administered orally twice a day for prevention of radiotherapy-induced diarrhea.^{65,68,69}

Prevention of Chemotherapy Diarrhea

Other than the use of atropine to prevent acute irinotecan diarrhea,⁷⁰ prophylactic antidiarrheal treatment is not a standard approach for any chemotherapy regimen. Small studies in the prevention of irinotecan-induced diarrhea have suggested the potential utility of oral alkalinization of the intestinal lumen,⁷¹ activated charcoal,⁷² and oral administration of probiotics microorganisms such as *Lactobacillus rhamnosus*.⁷³

Negative studies have been reported with prophylactic octreotide,⁷⁴ long-acting octreotide,⁷⁵ oral racecadotril,⁷⁶ and oral neomycin.⁹

CONSTIPATION

Definition

Constipation is the slow movement of feces through the large intestine resulting in infrequent bowel movements and the passage of dry, hard stools. Constipation is a symptom, not a disease. It is usually a temporary condition and is not considered serious.

According to the “Rome 2 Criteria” proposed by a working group of gastroenterologists,⁷⁷ the clinical definition of chronic constipation is the presence of any two of the following symptoms for at least 12 weeks (not necessarily consecutive) in the previous 12 months:

- Straining during bowel movements
- Lumpy or hard stool
- Sensation of incomplete evacuation
- Sensation of anorectal blockage or obstruction
- Manual maneuvers to remove stool
- Fewer than three bowel movements per week

Prevalence

The prevalence of constipation in patients who have advanced cancer is approximately 40% to 60%⁷⁸; the greatest prevalence occurs in the opioid-treated population.⁷⁹⁻⁸¹ Constipation is a major cause of patient distress and is often underappreciated and undertreated.⁸²

Treatment-Related Causes

Medications, in particular opioids, serotonin antagonist antiemetics, and vinca alkaloid chemotherapy agents, are the most common causes of constipation among patients with cancer.

Opioid Analgesics

All opioids cause constipation, and tolerance to this effect is not observed over time. Importantly, the dose response relationship to this effect is very flat and the severity does not appear to be strongly dose-related. There is some data to indicate that the severity is less severe with fentanyl and, possibly, methadone,^{83,84} and with oxycodone/naloxone combined formulation tablets.^{85,86} Other medications that are commonly implicated are listed in Table 136.2.

Serotonin 5-Hydroxytryptamine-3 Receptor Antagonists

The 5-hydroxytryptamine-3 receptor antagonist antiemetics slow colonic transit, increase fluid absorption, and increase left colon compliance.⁸⁷ Overall, these agents are very well tolerated but 2% to 5% of patients report constipation,⁸⁸ and laxative therapy is often indicated.

Vinca Alkaloids

All the vinca alkaloids have pronounced neuropathic effects and reduce gastrointestinal transit time. Severity appears to be most pronounced with vincristine and vindesine, less so with vinblastine, and least with vinorelbine. Among patients receiving vincristine,

TABLE 136.2

Drugs Commonly Causing Constipation in Patients with Cancer

Opioids
Serotonin antagonists
Antidepressants
Aluminum- or calcium-containing antacids
Iron supplements
Diuretics
Antihypertensive medications
Anticonvulsants

it is dose-related and is more common and more severe among patients receiving doses <2 mg total dose.^{89,90} Severity can range from mild to severe and in one series of 392 patients, 2.8% required hospitalization for adynamic ileus.⁹¹ Rarely, life-threatening ileus or megacolon have been reported.⁹²

Thalidomide

Other than sedation, constipation is the most common adverse effect of thalidomide.⁹³

Other Medications

Other constipating drugs commonly used in the care of cancer include those with anticholinergic actions (antispasmodics, antidepressants, phenothiazines, haloperidol, antacids), some anticonvulsants or antihypertensive drugs, iron supplements, and diuretics.⁹⁴

Differential Diagnosis

Other causes of constipation are also common among patients with advanced cancer. Among other causes that need to be considered are the following:

1. *Low-fiber diet*: A low-fiber diet or a diet rich in processed and low-fiber foods may exacerbate constipation.⁹⁵
2. *Dehydration*: Liquids like water and juice add fluid to the colon and bulk to stools, making bowel movements softer and easier to pass. Liquids that contain caffeine and alcohol have a dehydrating effect.
3. *Lack of exercise*: Lack of exercise can lead to constipation, although the reason is unclear.⁹⁵ For example, constipation often occurs after an injury or during an illness that promotes immobility.
4. *Colonic pathology*: Many patients have coexisting irritable bowel syndrome or diverticular disease. In many instances, constipation may be the first symptom of an impending obstruction due to tumor, adhesions, or a stricture.
5. *Neuromuscular disorders*: Neurogenic factors may impair normal colonic function including brain tumors, spinal cord compression, or the autonomic failure that is common in patients with far advanced cancer.⁹⁶ Neural integration of anal sphincter control and rectosigmoid propulsion occurs in the sacral segments of the spinal cord. Damage to sacral segments of the spinal cord or to efferent nerves may lead to severe constipation.⁹⁷
6. *Metabolic disorders*: Certain disorders of metabolism commonly seen in patients with cancer can lead to constipation and include the following: hypercalcemia, hyponatremia, hypokalemia, and uremia.⁹⁴
7. *Psychological disorders*: Constipation is a common manifestation of depression.⁹⁸

Diagnosis

The medical history can assist in identifying the causes of constipation. An accurate history should elicit the change in bowel movements; frequency of bowel movements; whether defecation is associated with blood or mucus (suggestive of obstruction or hemorrhoids), pain, or straining; presence or absence of defecation urge (hard stool or rectal obstruction in former, colon inertia in latter); and manual maneuvers by patient. Questions should also be aimed to determine the cause of the change in bowel movements, in particular eating and drinking habits, medication use, and level of physical activity.

The physical assessment could include a rectal examination to evaluate sphincter tone and detect tenderness, obstruction, or blood. Digital rectal examination may reveal:

1. Hard impacted feces
2. Soft stool due to fecal leakage

3. Complete absence of stool (colonic inertia, high obstruction or impacted stools)
4. Tumor masses
5. Concomitant disease: hemorrhoids, anal fissure, perianal ulceration, rectocele or anal stenosis

If constipation manifests as part of a spinal cord compression syndrome, full neurologic examination is necessary including assessment of anal sphincter tone (lax with colonic hypotonia) and rectal sensation.

Investigation

Investigations are not routinely necessary; however, plain abdominal radiography may be indicated to exclude bowel obstruction.⁹⁹ Despite the common use of plain abdominal X-rays to assess “fecal loading,” this is well correlated to constipation scale self-reports.¹⁰⁰

If clinically suspected, corrected calcium levels and thyroid function should be checked. More extensive testing can proceed for patients with severe symptoms, for those with sudden changes in number and consistency of bowel movements or blood in the stool, and for older adults.

General Measures

Diet

All constipated subjects should be advised as an initial measure to increase their dietary fiber intake as the simplest, most physiologic, and cheapest form of treatment. Patients should be encouraged to increase their intake of fiber-rich foods such as bran, fruits, vegetables, and nuts. Prune juice is commonly used to relieve constipation. The recommendation is to increase fiber intake gradually as adding fiber to the diet too quickly may cause excessive gas and bloating.

Fluid Intake. Dehydration or salt depletion is likely to lead to increased salt and water absorption by the large intestine, leading to the passage of small, hard stools. Children or adults with fever, or subjects in hot environments, should therefore be advised to consume plenty of fluid.

Physical Activity. Increasing physical activity is commonly recommended though the evidence supporting efficacy of this recommendation is scant.

Laxatives

Bulk Laxatives

Bulk laxatives are a concentrated form of nonstarch polysaccharides useful for patients who cannot take adequate dietary fiber. Common formulations include ispaghula, sterculia, psyllium and methylcellulose, and carboxymethylcellulose. These agents are useful for patients who are able to ingest ample volumes of fluid, though their effect appears to wane with time.^{101,102} Bulk laxatives are generally not recommended for opioid-induced constipation.¹⁰⁵

Osmotic Laxatives

Polyethylene Glycol. Polyethylene glycol 3350 (macrogol 3350) is an inert polymer that is not absorbed by the gut and is excreted unchanged in the feces. It is formulated with electrolytes to ensure that there is virtually no net gain or loss of sodium and potassium. It is generally well tolerated with a low tendency to gas formation. This approach is strongly endorsed in systematic reviews of chronic constipation.^{102,104}

Lactulose. Lactulose is a synthetic disaccharide that is not absorbed by the small bowel.¹⁰⁵ The recommended dose for adults is 15 to 30 ml of the syrup two to three times daily, reducing as necessary. It usually has a latency of 2 to 3 days before onset of effect. Some patients are intolerant to the sweet taste, and others complain of abdominal distention or discomfort, presumably resulting from colonic gas production.

Magnesium and Sulfate Salts

Magnesium hydroxide, citrate, sulfate, and sodium sulfate are commonly used laxatives. The magnesium and sulfate ions are poorly absorbed from the gut, and the action of these agents is mainly osmotic. In mildly constipated patients, regular magnesium hydroxide 1.2 to 3.6 g/day is a useful, safe laxative.¹⁰⁶ Magnesium sulfate (Epsom salt) is a more potent laxative that tends to produce a large volume of liquid stool. Excessive doses of magnesium salts by mouth can lead to hypermagnesemia, and these medications should be used with caution in patients with renal impairment and in children.¹⁰⁷

Stimulant Laxatives¹⁰⁸

Anthranoid Laxatives. Anthranoid laxatives, such as senna, aloe, cascara, and frangula, are plants compounds that are hydrolyzed by glycosidases of the colonic bacteria to yield the active molecules.¹⁰⁸ The active compounds have both motor and secretory effects on the colon. These preparations are best taken in the evening or at bedtime, with the aim of producing a normal stool the next morning. The usual dose is 15 mg of sennosides at bedtime. There is wide variation in clinical effectiveness, and some patients are not helped by this class of laxatives.

Polyphenolic (Diphenylmethane) Compounds. The effects of bisacodyl and sodium picosulfate on the colon are similar to those of the anthranoid laxatives.¹⁰⁹ Bisacodyl is available as enteric-coated 5-mg tablets, and the recommended adult dose is 5 to 10 mg taken at night. Sodium picosulfate is available as a liquid containing 5 mg per 5 ml. The recommended adult dose is 5 to 10 ml at night. These agents are generally recommended for short-term use in situations of refractory constipation.

Detergents/Stool Softeners

The detergent dioctyl sodium sulfosuccinate (docusate sodium) was developed as a stool softener. It stimulates fluid secretion by the small and large intestine. A Cochrane systematic review concluded that the use of docusate for constipation in palliative care is based on inadequate experimental evidence,¹¹⁰ and recent studies do not support its use.¹¹¹

Liquid Paraffin

Liquid paraffin is a mineral oil commonly used to soften and lubricate stools. Aspiration may cause lipoid pneumonia¹¹²; some patients suffer from anal seepage and a foreign body reaction if there is a break in the anorectal mucosa.¹¹³ There is evidence that it is less effective than polyethylene glycol.¹¹⁴

Opioid Antagonists for Opioid-Induced Constipation

Methylnaltrexone is a quaternary derivative of naltrexone that does not cross the blood-brain barrier in humans. As a result, it antagonizes only peripherally located opioid receptors while sparing centrally mediated analgesic effects of opioid pain medications.¹¹⁵ There is evidence of very predictable effectiveness after administration by either the oral¹¹⁶ or parenteral routes of administration,¹¹⁷ with most patients achieving defecation within 90 minutes of administration.

The injectable formulation of methylnaltrexone is approved by the US Food and Drug Administration. It is administered as a subcutaneous injection, initially once every other day. The frequency of administration can be increased if needed to once daily. The approved dosage is 8 mg for patients weighing 38 to 61 kg and 12 mg for those weighing 62 to 114 kg; for those outside these ranges, the recommended dose is 0.15 mg/kg.

Enemas and Suppositories

Self-administration of enemas or suppositories is an alternative approach for patients who do not respond to oral laxatives. Osmotic microenemas are often useful when oral agents have not provided adequate laxation. Commercial preparations contain mainly sodium lauryl sulfoacetate (a stool softener wetting similar to docusate) and osmotic agents and glycerol.

Saline or water enemas act by distending the rectum and softening the feces. Large-volume watery enemas risk water intoxication if the enema is retained. Alternatively, polyethylene glycol can be used or incorporated in a suppository for its osmotic effect.

Hypertonic sodium phosphate enemas such as Fleet Enema (C.B. Fleet Company, Inc., Lynchburg, VA) both distend and stimulate rectal motility. They are commonly used, and side effects are uncommon. These enemas cause some superficial disruption of the surface epithelium, which heals rapidly. Rarely when phosphate enemas are administered to patients who cannot evacuate promptly, they can cause hyperphosphatemia and severe hypocalcemic tetany.

Glycerin (suppositories), bisacodyl (suppositories or enema), and oxyphenisatin (veripaque) are all stimulants to rectal motility that are commonly used for short-term treatments and are often effective.

Managing Fecal Impaction

A fecal impaction is a large mass of dry, hard stool that can develop in the rectum due to chronic constipation.¹¹⁸ This mass may be so hard that it cannot be excreted. Watery stool from higher in the bowel may move around the mass and leak.

Fecal impaction is a complication of chronic constipation. Patients may present with no bowel movement over a prolonged period or diarrhea resulting from overflow incontinence. The diagnosis is confirmed by rectal examination findings of hard, formed stool present in the rectal vault.

The complications of a fecal impaction are uncommon but include urinary tract obstruction, perforation of the colon, dehydration, electrolyte imbalance, renal insufficiency, fecal incontinence, decubitus ulcers, stercoral ulcers, and rectal bleeding.

The treatment of a fecal impaction usually requires the digital fragmentation and extraction of the stool. Lubricating enemas and suppositories may be helpful. As this is a very uncomfortable procedure, sedation is generally recommended and anesthesia may occasionally be needed. Occasionally, it may be necessary to use a colonoscope with a snare to fragment fecal material in the distal colon. Once the impaction is relieved, it is crucial that the patient start a prophylactic daily bowel regimen.¹¹⁹

There is limited experience to suggest a noninvasive approach using a trial of high-dose polyethylene glycol (1 mg/kg for 3 days).¹²⁰

CONCLUSION

Constipation and diarrhea are major management issues for cancer clinicians. There is a clinical imperative for oncologists to be familiar with the common causes of these problems, their evaluation, and management strategies. These areas still demand ongoing clinical and basic investigation.

137 Oral Complications

Eliezer Soto, Jane M. Fall-Dickson, and Ann M. Berger

INTRODUCTION

The effectiveness of cancer therapies to improve cure rates and to extend survival time, including chemotherapy (CT), radiation therapy (RT), and conditioning regimens used for hematopoietic stem cell transplantation (HSCT), is tempered by intolerable and quality-of-life (QOL)-impairing side effects. Oral complications are one such side effect, including CT- and RT-related oral mucositis and oral chronic graft-versus-host disease (cGVHD) and associated oropharyngeal pain, xerostomia, and oral infection. Pathogenesis of and management strategies for these oral complications, and future clinical research directions, are presented in this chapter.

ORAL MUCOSITIS

Oral mucositis is an inflammation of the mucous membranes of the oral cavity and oropharynx characterized by tissue erythema, edema, and atrophy, often progressing to ulceration.¹ The clinical significance of CT- and RT-related oral mucositis as a dose- and treatment-limiting side effect is related to pain and impairment in patient's QOL and functional status.²⁻⁴

The frequency and severity of oral mucositis are influenced by patient- and treatment-related risk factors (Table 137.1).^{5,6} Risk factors for CT-related oral mucositis are complex. Although women have reported more frequent severe oral mucositis than men, and children are three times more likely than adults to develop mucositis, Driezen⁷ reported no age or gender risk for this oral condition. In a study of 332 ambulatory patients undergoing CT, no increased risk for oral mucositis was seen for outpatients with dental appliances, previous oral lesions, a history of smoking, or diverse oral care practices, than patients who did not.⁶ Conflicting study results may derive from lack of defined risk factors for entry into clinical trials.⁷ Risk factors include continuous CT infusion therapy for breast and colon cancer (5-fluorouracil [5-FU] and leucovorin); selected anthracyclines, alkylating agents, taxanes, vinca alkaloids, antimetabolites, and antitumor antibiotics; myeloablative conditioning regimens for HSCT (e.g., high-dose melphalan or carmustine, cytarabine, melphalan [BEAM])⁸⁻¹⁰; and RT to the head and neck. Individual drug metabolism affects oral mucositis incidence and severity.

CHEMOTHERAPY-INDUCED MUCOSITIS

Approximately 40% of patients undergoing CT develop oral mucositis,¹¹ and approximately half of these patients develop painful lesions requiring parenteral analgesia or total parenteral nutrition (TPN) and treatment modification.¹² Incidence rates of 60% are seen in the HSCT setting and 78% for ulcerative oral mucositis.¹³ Oral mucositis is a risk factor for life-threatening infections for patients with neutropenia. Oral infections, such as herpes simplex virus (HSV) may increase oral mucositis severity. There is a four times greater relative risk of septicemia in patients with oral mucositis and oral infections due to mucosal barrier injury.

The relationship between severe oral mucositis and clinical outcomes in patients who receive conditioning chemotherapy has been reported.^{14,15} McCann et al.¹⁴ conducted an observational study in 197 patients with multiple myeloma (MM) or non-Hodgkin's lymphoma treated with either high-dose melphalan or BEAM chemotherapy, respectively. Severe oral mucositis (World Health Organization grades 3 and 4) increased TPN duration by 2.7 days, opiates by 4.6 days, and antibiotics by 2.4 days. Oral mucositis presents with asymptomatic erythema and progresses from solitary, white, elevated desquamative patches that are slightly painful to large, contiguous, pseudomembranous, painful lesions. Typical oral sequelae of CT agents include epithelial hyperplasia, collagen and glandular degeneration, epithelial dysplasia, atrophy, and localized or diffuse mucosal ulceration. Nonkeratinized mucosa areas are most affected. The loss of basement membrane epithelial cells exposes underlying connective, innervated tissue stroma, which contributes to more severe oropharyngeal pain.

RADIATION-INDUCED MUCOSITIS

Oral mucositis is virtually universal when RT targets the oropharyngeal area, with severity dependent on type of ionizing radiation, volume of irradiated tissue, daily and cumulative dose, and duration. Oral mucositis is a dose- and rate-limiting toxicity of RT for head and neck cancer and of hyperfractionated RT and CT. Atrophic changes in the oral epithelium usually occur at total doses of 1,600 to 2,000 cGy, administered at a rate of 200 cGy/day.¹⁶ Doses >6,000 cGy or concomitant CT are risk factors for permanent salivary gland changes.^{16,17} The addition of total-body irradiation to HSCT increases oral mucositis severity through both direct mucosal damage and xerostomia. CT-induced dental effects are related to the treatment field including salivary glands. Teeth in the irradiated field may be desensitized, leading to asymptomatic early caries. Therefore, daily fluoride application is necessary.

Significant health-care costs and resource use are associated with oral mucositis in head and neck cancer.^{18,19} In a prospective, longitudinal study of 75 patients with head and neck cancer receiving RT with or without CT,¹⁹ 76% had severe oral pain requiring an increased number of health-care visits, 51% had a feeding tube, and 37% were hospitalized for an average of 4.9 days.

RADIATION THERAPY-RELATED COMPLICATIONS

Long-term effects of head and neck RT include soft tissue fibrosis, trismus, nonhealing or slow-healing mucosal ulcerations, and slow healing dental extraction sites. RT-induced fibrotic changes may occur in the masticatory muscles or the temporal mandibular joint up to 1 year posttherapy. Early phases of fibrogenesis following RT are seen as wound healing characterized by upregulation of tumor necrosis factor (TNF)- α and other proinflammatory cytokines.²⁰ As radiation fibrogenesis continues, it functions as a nonhealing wound.²⁰

TABLE 137.1

Patient- and Treatment-Related Risk Factors for Stomatitis**Patient-Related**

Age older than 65 or younger than 20
 Gender
 Inadequate oral health and hygiene practices
 Periodontal diseases
 Microbial flora
 Chronic low-grade mouth infections
 Salivary gland secretory dysfunction
 Herpes simplex virus infection
 Inborn inability to metabolize chemotherapeutic agents effectively
 Inadequate nutritional status
 Exposure to oral stressors including alcohol and smoking
 Ill-fitting dental prostheses

Treatment-Related

Radiation therapy: dose, schedule
 Chemotherapy: agent; dose, schedule
 Myelosuppression
 Neutropenia
 Immunosuppression
 Reduced secretory immunoglobulin A
 Inadequate oral care during treatment
 Infections of bacterial, viral, or fungal origin
 Use of antidepressants, opiates, antihypertensives, antihistamines, diuretics, and sedatives
 Impairment of renal or hepatic function
 Protein or calorie malnutrition, and dehydration
 Xerostomia

Risk factors for CT-induced oral mucositis: dental appliances, oral hygiene, previous oral lesion, and a history of smoking. *Cancer Invest* 1999;17:278–284, with permission.

Osteoradionecrosis is a relatively uncommon condition related to hypocellularity, hypovascularity, and tissue ischemia. Higher incidences are reported with total doses to the bone exceeding 65 Gy.²¹ Osteoradionecrosis is usually related to trauma and is reported following tooth extractions not timed to allow extraction site healing for 10 to 14 days before the start of RT. Osteonecrosis of the jaw bone is strongly associated with bisphosphonate use.^{22,23}

PATHOGENESIS OF CHEMOTHERAPY- AND RADIATION-INDUCED ORAL MUCOSITIS

Current knowledge of oral mucositis pathogenesis is informed by translational research that applies advances in molecular-genetic technique and cell biology to this clinical condition.²⁴ Cancer therapy affects rapidly dividing cells including oral basal epithelium with a 7- to 14-day cell turnover rate, thus placing them at risk for CT targeting. Sonis et al.²⁵ reported a “burst” of cyclooxygenase (COX)-2 expression relative to RT-related oral mucositis progression, suggesting that COX-2 plays an amplifying role. In a small pilot study exploring the role of the COX pathway in three patients undergoing autologous HSCT, pain scores significantly correlated with COX-1, microsomal prostaglandin-E synthase, and salivary prostaglandin, suggesting a role for the COX pathway in oral mucositis, possibly via upregulation of proinflammatory prostaglandins.²⁶

Sonis²⁴ has described a five-phase oral mucositis pathogenesis model including initiation, message generation, signaling and amplification, ulceration, and healing. Initiation occurs after administration of CT as a result of DNA damage and generation of reactive

oxygen species. The relatively acute inflammatory or vascular phase occurs shortly after CT or RT administration.¹² Message generation involves upregulation of transcription factors, including nuclear factor κB and activation of cytokines and stress response genes. Signaling and amplification involves the production of proinflammatory cytokines from epithelial tissue, including TNF-α, which is related to tissue damage, and interleukin (IL)-1, which incites the inflammatory response and increases subepithelial vascularity that may lead to increased local CT levels. Logan et al.²⁷ reported preliminary results in 20 patients undergoing CT demonstrating elevated nuclear factor κB and COX-2 after CT, even though histologically the tissue was similar pre- and post-CT. The epithelial phase shows reduced epithelial renewal and atrophy, and typically begins 4 to 5 days after CT administration. The cell cycle S-phase-specific agents, including methotrexate, 5-FU, and cytarabine, are most efficient for this phase. The ulcerative or bacterial phase begins approximately 1 week post-CT in parallel with maximum neutropenia¹²; is the most complex, symptomatic phase; and is probably not CT agent class-specific. Patients often experience acute oropharyngeal pain, leading to dysphagia, decreased oral intake, and difficulty speaking. Bacterial colonization of mucosal ulceration occurs, and gram-negative organisms release endotoxins that induce the release of IL-1 and TNF and production of nitric oxide that may increase local mucosal injury. RT and CT are likely to amplify and prolong this proinflammatory cytokine release, leading to exacerbated tissue response. Genetic expression of cytokines and enzymes critical in tissue damage may be modified by transcription factors.¹² Fall-Dickson et al.²⁸ described oropharyngeal pain related to oral mucositis in patients undergoing HSCT with CT and measured TNF-α concentration in blood, saliva, and oral buccal brush biopsy samples. Oral mucositis severity was significantly associated with overall intensity of oral pain. TNF-α RNA content in oral buccal brush biopsy samples correlated with worst intensity of oral pain with swallowing. Healing of oral lesions in nonmyelosuppressed patients occurs 2 to 3 weeks after cancer treatment, with decrease in oropharyngeal pain seen in parallel with mucosal healing.

Avivi et al.²⁹ evaluated salivary antioxidant and immunologic capacities in 25 patients with MM treated with conditioning melphalan for HSCT who developed oral mucositis. Oral mucositis was associated with a reduction in secretory immunoglobulin A and antioxidant activity. The increase in salivary Alb and carbonyl indicated mucosal and oxidative damage, respectively.

CHRONIC GRAFT-VERSUS-HOST DISEASE ORAL MANIFESTATIONS

Patients who have undergone allogeneic HSCT (alloHSCT) frequently develop GVHD, an alloimmune condition derived from an immune attack mediated by donor T cells recognizing antigens expressed on normal tissues. GVHD occurs following alloHSCT due to disparities in minor histocompatibility antigens between donor and recipient, inherited independently of HLA genes.³⁰ cGVHD was historically defined as occurring at or beyond 100 days post HSCT,³¹ and is now classified based on the characteristic clinical presentation.

cGVHD is reported to occur in 30% to 60% of patients more than 100 days post alloHSCT.³² Approximately 80% of patients with extensive cGVHD have some type of oral involvement³³ that is a major contributing factor to the morbidity seen with alloHSCT. Although oral lesions are most common with extensive cGVHD, patients may also present with disease involving only the oral cavity, thus making comprehensive oral assessment important. Oral cGVHD presents with tissue atrophy and erythema, lichenoid changes, and pseudomembranous ulcerations, occurring typically on buccal and labial mucosa and the lateral tongue, angular stomatitis, and xerostomia.³³ Treister et al.³⁴ correlated the distribution, type, and extent of oral cGVHD lesions with oral pain and discomfort. The buccal and labial mucosa and tongue were the sites of 93% of ulcerations, 72% of erythematous lesions, and 76%

of reticular lesions. Ulcerations in the soft palate, although uncommon, were associated with increased pain. Functional impact was significant as seen by restriction of oral intake due to discomfort. Decreased oral intake leads to weight loss and malnutrition, which remain serious problems. Despite the importance of oral cGVHD as a major long-term complication of alloHSCT, little is known about its pathogenesis. Imanguli et al.³⁵ proposed a model of cGVHD pathogenesis in which the production of type 1 interferon by plasmacytoid dendritic cells plays a central role in initiation and continuation of cGVHD. Fall-Dickson et al.³⁶ analyzed associations among clinical characteristics of oral cGVHD and related oral pain and dryness, salivary proinflammatory cytokine IL-6 and IL-1 α concentrations, and health-related QOL. Salivary IL-6 correlated with oral cGVHD severity, oral ulceration, and erythema, suggesting its potential utility as a biomarker for active oral cGVHD.

The importance of oral cGVHD was recognized by the National Institutes of Health (NIH) Consensus Development Project on Criteria for Clinical Trials in cGVHD³⁷ and the outcomes of a 2009 conference sponsored by the German-Austrian-Swiss working party for bone marrow and blood stem cell transplantation held in Regensburg, Germany.³⁸ Outcomes of the international conference included a summary of evidence for diagnosis, first- and second-line therapies, topical treatments, and practical treatment guidelines. The authors concurred that a comprehensive, interdisciplinary treatment approach for oral cGVHD must include assessment of mucosa, salivary glands, musculoskeletal tissues, teeth, periodontium, and combined oral function.³⁸ The Schubert Oral Mucositis Rating Scale was validated under the auspices of this NIH Consensus Development Project.³⁷ Treister et al.³⁹ analyzed inter- and intraobserver variability in the component and composite scores using the NIH oral cGVHD Activity Assessment Instrument. Twenty-four clinicians from six major HSCT centers scored high-quality intra-oral photographs of 12 patients with a second evaluation 1 week later. Although mean interrater reliability was poor to moderate and unacceptable for the clinical trial setting, greater concordance among the oral medicine experts, high intrarater reliability, and participant feedback suggest formal training may decrease variability. Bassim et al.⁴⁰ examined the construct validity and internal consistency of the NIH Oral Mucosal Score (OMS) and its individual components (erythema, lichenoid, ulcers, mucocoeles), as well as measures of oral pain, function, and related QOL, nutrition, and laboratory parameters in 198 patients diagnosed with cGVHD. The NIH OMS is based only on clinicians' assessment of oral mucosa in the patient who has undergone peripheral blood stem cell transplantation/bone marrow transplant (BMT). Results supported the construct validity of the discrete components of the NIH OMS as seen through strong associations between erythema and lichenoid and poor oral QOL, function, and nutrition, and lower serum albumin levels. Oral cGVHD ulceration was correlated primarily with oral pain. Validated assessment measures for oral cGVHD are needed to test agents in the clinical trial setting to advance the science of oral cGVHD, and to increase the treatment options.

SEQUELAE OF ORAL COMPLICATIONS

Oropharyngeal Pain

Oral mucositis is the principal etiology of most pain experienced during the 3-week post-BMT time period. This oral pain is often described as the most unforgettable ordeal of BMT. McGuire et al.⁴¹ reported in a sample of patients undergoing autologous and allogeneic BMT that pain was reported before observed mucositis, that pain intensity did not correlate directly with extent of mucosal injury, and that some patients reported limited or no pain after BMT. A descriptive, cross-sectional study of women with breast cancer undergoing autologous HSCT conducted by Fall-Dickson et al.⁴² showed a significant positive correlation between oral pain and oral mucositis severity.

The sensory dimension of oral mucositis-related pain reported with general mucosal inflammation and breakdown ranges from mild discomfort to severe and debilitating pain requiring opioids.⁴³ Oral pain is associated strongly with cGVHD and has been described as severe, burning, and irritating with dryness and loss of taste. Mucositis-related oral pain reported with CT is usually of <3 months' duration, contrasting with the usually chronic oral pain accompanying oral cGVHD.

Gender differences have been reported for pain. Women reported higher pain levels in a study to test capsaicin efficacy for oral mucositis-related pain. Pain management is critical to avoid suffering and psychological distress.⁴⁴ Adequate assessment of oral pain requires a comprehensive pain assessment tool such as the Pain-O-Meter (Dola Health Systems, Baltimore, MD),⁴⁵ which assesses overall intensity, sensory, and affective dimensions of pain.

Xerostomia

Xerostomia experienced by patients who receive head and neck RT is a major sequela, with severity dependent on RT dosage and location and volume of exposed salivary glands. Patients may also develop xerostomia as a late oral complication of HSCT. Brand et al.⁴⁶ reported in a cross-sectional study of patients with history of autologous or alloHSCT significantly higher levels of xerostomia compared to the comparison group. Xerostomia severity was not significantly associated with RT given before HSCT or the type of HSCT. Xerostomia can affect taste, oral comfort, prosthetic fit, speech, swallowing, and promote caries-producing organisms.

A recent cross-sectional study by Imanguli et al.⁴⁷ evaluated sicca signs and symptoms in 101 patients with cGVHD using assessment tools used in Sjögren syndrome. Of the 77% of patients reporting xerostomia, those with salivary dysfunction showed histopathologic changes consisting of mononuclear infiltration and fibrosis or atrophy, suggesting that salivary gland involvement is common in cGVHD. A valid, reliable assessment tool is needed to evaluate salivary function in clinical trials. Salivary antioxidant capacity and function were assessed in 30 patients after HSCT by Nagler et al.⁴⁸ Salivary gland function was assessed measuring total protein, secretory immunoglobulin A, the antioxidant peroxidase, uric acid, and total antioxidant status in a saliva sample. In patients who developed GVHD, there was a significant decrease in salivary flow rate pre- and post-HSCT with no recovery and a reduction in salivary protein content and salivary antioxidant capacity. In patients without GVHD after HSCT, salivary flow rates returned to normal in 3 to 5 months. Decreased salivary flow rate with related decrease in its protective functions for oral mucosa contribute to oral cGVHD severity. Bassim et al.⁴⁹ tested the feasibility of using liquid chromatography tandem mass spectrometry to identify and elucidate protein biomarkers related to oral cGVHD. Pooled saliva from five patients with moderate or severe oral cGVHD was compared to saliva from a gender- and age-matched pool of five patients with GVHD without oral mucosal findings. Reported reduction in salivary lactoperoxidase, lactotransferrin, and several cysteine proteinase inhibitor family proteins suggests impaired oral antimicrobial host immunity in oral cGVHD.⁴⁹

STRATEGIES FOR PREVENTION AND TREATMENT OF ORAL COMPLICATIONS

Pretherapy Dental Evaluation and Intervention

Oral or dental stabilization prior to CT and RT is critically important to avoid serious sequela and requires an experienced dental team and informed patients working together for adequate cleaning, elimination oral infection and trauma, and appropriate oral hygiene.⁵⁰

Patients scheduled for CT or head and neck RT should receive dental screening at least 2 weeks before therapy starts for proper healing of extraction sites, recovery of soft tissue manipulations, and restoration of teeth to promote optimal mucosal health before, during, and following cancer treatment. The initial dental appointment includes examination of dentition for caries and defective restorations, the periodontium, pulp vitality, and denture fit to avoid ill-fitting dentures causing irritation of irradiated tissue and ulceration to underlying bone.⁵¹

A panoramic radiograph combined with intraoral radiographs as needed is necessary to detect periodontal disease, periapical infections, cysts, third-molar pathology, unerupted or partially erupted teeth, and residual root tips. Significant oral or dental problems to be addressed before cancer treatment include inappropriate oral hygiene, periapical pathology, third-molar pathology, periodontal disease, defective restorations, dental caries, orthodontic appliances, and ill-fitting prostheses. Bacterial load should be reduced prior to cancer treatment via root planning, scaling, and prophylaxis, excluding visible tumor located at the site of anticipated dental manipulation. The decision to extract asymptomatic teeth prior to the commencement of RT is related to radiation exposure, type, portal field, fractionization, and total dosage in addition to tumor prognosis and expediency of control of the cancer.⁵² Teeth that are class II or III mobility without use as abutment teeth for prosthetic retention should also be considered for extraction before RT. Extractions of residual root tips and impacted teeth should be performed atraumatically. Alveolectomy and primary wound closure eliminate sharp ridges and bone spicules that could project to the overlying soft tissues. This is important for prosthetic consideration because negligible bone remodeling is predicted after RT. Patients need written instructions for use of oral care agents and instruments for effective daily plaque removal, use of prescribed fluoride treatments, and reportable oral observations and symptoms.

Assessment of the Oral Mucosa

Consistent and frequent oral cavity assessment is needed to assess clinical signs before, during, and after treatment. No standard grading system for severity of oral complications of cancer treatment exists, and available oral complications grading tools are based on two or more clinical parameters combined with functional status, such as eating ability. One commonly used tool is the National Cancer Institute Common Terminology Criteria for Adverse Events v.3.0, which includes descriptive terminology and a severity grading scale for each reportable adverse event.⁵³ Frequently used oral mucosal assessment tools include those that capture both objective and subjective data—the Oral Assessment Guide⁵⁴ and the World Health Organization Index^{11,55}—and instruments that assess only observed oral changes—the Oral Mucositis Rating Scale,^{43,56} the Oral Mucositis Index,⁵⁷ and the Oral Mucositis Assessment Scale (OMAS).^{58,59} The OMAS was developed as a scoring system for anatomic extent and severity of oral mucositis in clinical research studies.^{58,59} Oral cavity regions assessed are lip (upper and lower), cheek (right and left), right and lateral tongue, left ventral and lateral tongue, floor of mouth, soft palate or fauces, and hard palate.⁵⁸ Erythema is rated on a scale from 0 to 2 (0 = none, 1 = not severe, and 2 = severe), and ulceration or pseudomembrane is a combined category rated on scores based on estimated surface area involved (0 = no lesion, 1 = <1 cm², 2 = 1 cm² to 3 cm², and 3 = >3 cm²) and summed with a possible score range of 0 to 162.^{52,60} Validity and reliability have been demonstrated for the OMAS through clinical research studies.^{59,61}

TREATMENT STRATEGIES

The optimal treatment strategies for oral complications and related sequelae are unknown. Treatment strategies for oral mucositis and related oropharyngeal pain are mainly empirical, and testing is needed

in the randomized controlled clinical trial setting (Table 137.2). Zlotolow and Berger⁶² presented a comprehensive review of clinical research regarding treatment strategies for oral complications of cancer strategies demonstrating conflicting study results. The only standard forms of care are pretreatment oral or dental stabilization, saline mouthwashes, and oropharyngeal pain management.⁶³

The need for standardized treatment for oral mucositis was appreciated by the Mucositis Study Section of the Multinational Association of Supportive Care in Cancer and the International Society for Oral Oncology through their “Clinical Practice Guidelines for the Prevention and Treatment of Cancer Therapy-Induced Oral and Gastrointestinal Mucositis.”⁶⁴ These guidelines are based on a comprehensive review of more than 8,000 English-language publications (1966 to 2001) using criteria for level of evidence and quality of research design.⁶⁵

A standardized approach for the prevention and treatment of CT- and RT-induced oral mucositis is essential. The prophylactic measures usually used for the prevention of oral mucositis include chlorhexidine gluconate, ice-cold water, saline rinses, sodium bicarbonate rinses, acyclovir, and amphotericin B. Regimens used commonly for the treatment of oral mucositis and related pain include a local anesthetic such as lidocaine or dyclonine hydrochloride, magnesium-based antacids, diphenhydramine hydrochloride, nystatin, or sucralfate. These agents are used either alone or in various combinations as a mouthwash formulation. Oral and parenteral opiates are used to relieve oral mucositis-related pain.

RADIOPROTECTORS

Vitamins and Other Antioxidants

Vitamin E has been tested in CT-induced oral mucositis because it can stabilize cellular membranes and may improve herpetic gingivitis, possibly through antioxidant activity. Wadleigh et al.⁶⁶ demonstrated the efficacy of vitamin E in a sample of 18 patients undergoing CT who were randomized to receive topical vitamin E or placebo.

Other antioxidants that have been tested for efficacy with oral mucositis include vitamin C and glutathione. Osaki et al.⁶⁷ reported findings from a study of 63 patients with head and neck cancer who were treated with chemoradiation. Twenty-six patients received regimen 1 (vitamins C and E and glutathione) and thirty-seven patients received regimen 2 (regimen 1 plus azelastine). In the azelastine arm, 21 patients remained at grade 1 or 2 oral mucositis, 6 patients had grade 3 oral mucositis, and 10 patients had grade 4 oral mucositis. In the control group, grade 3 or 4 oral mucositis was observed in more than half the patients. Azelastine may be useful to prevent CT-induced oral mucositis.⁶⁷ Watanabe et al.⁶⁸ investigated the effect of polaprezinc on CT- and RT-induced oral mucositis, pain, xerostomia, and taste disturbance in patients with head and neck cancer. Thirty-one patients were randomly assigned to polaprezinc or azulene solution as a control for 3 minutes four times a day until the end of the therapy. There was a marked decrease in the incidence of oral mucositis, pain, xerostomia, taste disturbance, and analgesic requirement, and significant increase in food intake in the polaprezinc group.

Zinc sulfate has not been proven to have any benefit in the prevention of RT- and CT-induced oral mucositis when compared to placebo.^{69,70} In a randomized, double-blind, placebo-controlled trial, Sangthawan et al.⁶⁹ determined the efficacy of zinc sulfate supplementation in reducing radiation-induced oral mucositis and pharyngitis in patients with head and neck cancer. A total of 144 patients with head and neck cancer receiving RT alone or postoperative RT were enrolled. Zinc sulfate (50 mg) and placebo were administered three times a day at mealtime, on the first day of RT and continued until RT completion. This intervention showed no benefit in relieving radiation-induced oral mucositis and pharyngitis, when compared to placebo.

TABLE 137.2

Formulary of Common Treatments for Oral Complications^a

	Instructions
Prevention of Stomatitis	
Amifostine	200 mg/m ² daily, as 3-min IV infusion 15 to 30 min preradiotherapy. Hydrate adequately, monitor blood pressure, and use antiemetics.
Cryotherapy Distilled water, 1 gallon	Place ice chips in mouth for 30 mins beginning 5 min prior to bolus administration of chemotherapy.
NAHCO ₃ powder, 3 tablespoons or 11.6 g	Rinse mouth twice a day for 30 s. Do not swallow.
NaCl powder, 3 tablespoons or 11.6 g	Combine all ingredients. Rinse mouth 2 to 4 times daily. Do not swallow.
Povidone iodine 0.5% oral rinse	Rinse mouth 2 to 4 times daily. Do not swallow.
Treatment of Stomatitis-Related Pain	
Carafate suspension, 1 g	Rinse mouth 4 times daily. Do not swallow.
Diphenhydramine (Benadryl, McNEIL-PPC, Inc., Fort Washington, PA), 12.5 mg/5 ml; kaolin and pectin (Kaopectate, Chattem, Inc., Chattanooga, TN)	Use equal amounts of each. Rinse mouth with 10–15 ml 4 to 6 times daily. Do not swallow.
Diphenhydramine (Benadryl), 12.5 mg/5 ml: 30 ml; Maalox (Novartis, Basel, Switzerland), 30 ml; nystatin, 100,000 U/mL: 30 ml	Combine all ingredients. Rinse mouth with 15 ml 4 to 6 times per day. Do not swallow.
Diphenhydramine (Benadryl), 12.5 mg/5 ml: 30 ml; viscous lidocaine (xylocaine) 2%, 30 ml; Maalox, 30 ml	Combine all ingredients. Rinse mouth with 15 ml 4 to 6 times per day. Do not swallow.
Diphenhydramine (Benadryl), 12.5 mg/5 ml: 30 ml; tetracycline, 125 mg/5 ml suspension 60 ml; nystatin oral suspension, 100,000 U/ml 45 ml; viscous lidocaine (xylocaine) 2%, 30 ml; hydrocortisone suspension, 10 mg/5 ml: 30 ml; sterile water for irrigation, 45 ml	Combine all ingredients. Rinse mouth with 15 ml 4 to 6 times per day. Do not swallow.
Dyclonine hydrochloride 0.5% or 1.0% solution	Rinse mouth with 10–15 ml every 2–3 h. Do not swallow.
Gelclair (Sinclair Pharmaceuticals, Surrey, England)	Mix one Gelclair packet per manufacturer's directions with 40 ml or 3 tablespoons of water. Stir and rinse immediately for at least 1 min, gargle, and spit out at least three times a day.
Opiates	Oral, transdermal, or parenteral opiates may be used, such as PCA. Use tablet form of oral analgesics. Do not use elixir because alcohol exacerbates stomatitis.
Viscous lidocaine (xylocaine) 2% solution	Rinse mouth with 10–15 ml every 2–3 h. Do not swallow.
Xerostomia	
Biotene chewing gum (GlaxoSmithKline, Brentford, England)	Use as needed.
Pilocarpine	5 mg oral three times a day
Salivart synthetic saliva spray (Gebauer Company, Cleveland, OH)	Spray mouth four to six times per day.
Xerolube salivary substitute (Colgate-Palmolive Company, New York, NY)	Rinse mouth four to six times per day

IV, intravenously; NaCl, sodium chloride; NAHCO₃, sodium bicarbonate; PCA, patient-controlled analgesia.

^a Many of the medications listed have been used alone or in combination to treat stomatitis.

Adapted from Fall-Dickson JM, Berger AM. Oral manifestations and complications of cancer treatment. In: Shuster JL, Von Roenn JH, eds. *Principles and practice of palliative care and supportive oncology*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2006, page 210.

Amifostine

Amifostine is a thiol compound, selective cytoprotective agent that has been approved by the US Food and Drug Administration for salivary gland protection in patients receiving RT. A retrospective study conducted by Kouloulis et al.⁷¹ reported reduced severity of oral and esophageal toxicity. A total of 177 patients with a diversity of tumors were treated with amifostine before RT. Based on a meta-analysis that included patients who received amifostine before RT, there was significant reduction in oral mucositis severity at doses >300 mg/m².⁷² A multicenter, open-label, randomized controlled trial analyzed the use of amifostine in patients with MM

who received conditioning CT with melphalan prior to autologous HSCT.⁷³ Ninety patients were randomized to receive or not receive amifostine (910 mg/m²). The use of amifostine was associated with a reduction in median grade and frequency of severe oral mucositis. However, there was no reduction in parenteral nutrition and analgesics use and no significant difference between the median progression-free or overall survival times.

Glutamine

Glutamine is an amino acid, immunomodulator, and mucosal protective agent that has been studied in multiple clinical trials with

conflicting results. An extensive literature review performed by Savarese et al.⁷⁴ reported that glutamine supplementation may have an impact on incidence and severity of anthracycline-associated oral mucositis. A randomized, double-blind, placebo-controlled trial on glutamine supplementation in patients who underwent autologous HSCT reported increase in severe oral mucositis and opiate, and prolonged hospital stay.⁷⁵ Another randomized controlled study comparing oral glutamine supplementation (30 g/day) versus placebo in 58 patients undergoing HSCT reported no difference in length of hospitalization, nutrition, oral mucositis and diarrhea severity, engraftment time, survival, and relapse between both groups.⁷⁶

Other clinical trials have reported more promising data on the use of glutamine.^{77,78} A retrospective cohort study including 117 patients treated with RT for cancer of the head and neck or chest tested if oral glutamine prevents oral mucositis or acute radiation-induced esophagitis and favors nutritional status.⁷⁹ Overall, glutamine was associated with significant reduction of mucositis, weight loss, and enteral nutrition. The risk difference for developing oral mucositis in patients receiving glutamine when compared with controls was -9.0% (95% confidence interval = -18.0% to -1.0%). The majority of patients not receiving glutamine developed severe malnutrition. No differences were seen in interruption of RT, hospitalization, opioid use, or death during RT.

In a double-blind, randomized, placebo-controlled trial of oral glutamine in the prevention of oral mucositis in children undergoing HSCT, 120 patients were randomized to receive glutamine or glycine twice a day until 28 days post-HSCT. The glutamine group showed a significant reduction in days of intravenous opiates use and TPN, but no difference in toxicity was observed between the two groups.⁸⁰

A phase 3 study of topical AES-14, which is a novel drug system designed to concentrate delivery of L-glutamine to oral mucosa for ulceration treatment, was conducted with 121 patients at risk for oral mucositis.⁸¹ Patients were randomized to either AES-14 or placebo and received protocol treatment from day 1 of CT until 2 weeks following the last CT dose or oral mucositis resolution. Results showed a potential 20% reduction of moderate-to-severe oral mucositis in the AES-14 group and a 10% increase in grade 0 oral mucositis.

Anti-Inflammatory Agents

Prostaglandins are a family of naturally occurring eicosanoids, some of which have shown cytoprotective activity. Misoprostol, a synthetic analog of prostaglandin E1, has been studied as prevention and treatment option for oral mucositis due to its anti-inflammatory and mucosa-protecting properties. A randomized, double-blind, placebo-controlled, parallel-group study conducted by Lalla et al.⁸² evaluated the efficacy of misoprostol oral rinse in reducing the severity of oral mucosal injury caused by high-dose CT. Forty-eight patients receiving myeloablative high-dose CT were randomized to misoprostol ($n = 22$) or placebo rinse ($n = 26$). Results showed no significant effect of misoprostol rinse in mucositis.

Topical dinoprostone was administered four times daily in a nonblinded study to 10 patients with oral carcinomas who were receiving 5-FU and mitomycin with concomitant RT.⁸³ The control group comprised 14 patients who were receiving identical treatment. Eight of the ten subjects who received dinoprostone were evaluable; no patient developed severe oral mucositis as compared with six episodes in the control arm. A second pilot study was conducted with 15 patients who received RT to the head and neck, showing that an inflammatory reaction was detected in 5 patients in the vicinity of their tumor when treated with topically applied PGE₂, and that no patients developed any bullous or desquamating inflammatory lesions.⁸⁴ A double-blind, placebo-controlled study of PGE₂ in 60 patients undergoing BMT showed no significant

differences in incidence, severity, or duration of oral mucositis. Incidence of HSV was higher in the PGE₂ arm. Increase in oral mucositis severity was seen in patients who developed HSV.⁸⁵

Benzydamine is a nonsteroidal anti-inflammatory drug with reported analgesic, anesthetic, and antimicrobial properties without activity on arachidonic acid metabolism. It has been shown to reduce the severity of oral mucositis and associated pain in patients who undergo RT. Epstein and Stevenson-Moore⁸⁶ reported in a double-blind, placebo-controlled trial that benzydamine produced statistically significant relief of pain from RT-induced oral mucositis and a reduction in both the total area and the size of ulceration. Positive responses to benzydamine have been reported in three other studies.⁸⁷⁻⁸⁹ In a small prospective, double-blind, randomized study comparing the efficacy of chlorhexidine gluconate and benzydamine hydrochloride oral rinse in patients with head and neck cancer to prevent and treat RT-induced oropharyngeal mucositis, a trend showed decrease in mucositis, oropharyngeal pain, and dysphagia in those receiving benzydamine.⁹⁰ Given the proposed importance of the prostaglandin pathway in the pathogenesis of oral mucositis, additional studies are warranted.

Current evidence does not support the use of systemic steroids to reduce the frequency or severity of oral mucositis.⁹¹

BIOLOGIC RESPONSE MODIFIERS

Epidermal Growth Factors

Studies on epidermal growth factor (EGF) as a treatment option for CT- and RT-induced oral mucositis have reported conflicting data. EGF may function as a marker of mucosal damage and could facilitate the healing process.⁹² In a phase 1 trial conducted by Girdler et al.,⁹³ EGF mouthwash used by patients treated with CT showed onset delay and severity reduction of recurrent ulcerations. No statistical difference was seen in resolution of established ulcers. A double-blind, placebo-controlled, prospective phase 2 study reported potential benefit from EGF oral spray for oral mucositis in patients undergoing RT for head and neck cancer. One hundred and thirteen patients were randomized into one of four arms: EGF-treatment groups (10, 50, and 100 mcg/ml doses twice daily) and placebo. The 50 mcg/ml dose showed the best efficacy.⁹⁴

Kim et al.⁹⁵ evaluated efficacy and safety of recombinant human EGF (rhEGF) oral spray for CT-induced oral mucositis with HSCT. Fifty-eight patients were randomly assigned to either the rhEGF group or placebo group. The incidence of National Cancer Institutes grade ≥ 2 oral mucositis was higher in rhEGF than placebo group (78.6% versus 50%; $p = 0.0496$), respectively. Duration of mucositis with National Cancer Institutes grade ≥ 2 was shorter in the rhEGF group (8.5 days versus 14.5 days). rhEGF significantly reduced limitations in swallowing and drinking, and reduced hospitalization duration, administration of TPN, and opioid usage, in patients with grade ≥ 3 . Results were better for patients with advanced oral mucositis in the rhEGF group for several secondary end points.

Hematopoietic Growth Factors

Hematologic growth factors are standard treatment for patients who are treated with high-dose CT because of well-established efficacy to decrease the duration of CT-induced neutropenia. In vitro studies have demonstrated that EGF is present in saliva with ability to affect growth, cell and migration, and repair mechanisms.⁹⁶ The development of increased oral toxicity or mucosal repair may be dependent on timing of EGF administration in relation to CT treatment.⁹⁷ Gabrilove et al.⁹⁸ reported from a sample of 27 patients with bladder cancer who received escalating doses of granulocyte-colony-stimulating factor (G-CSF) during treatment

with methotrexate, vinblastine, doxorubicin, and cisplatin. The patients received the G-CSF during the first of two cycles of CT. Although significantly less oral mucositis was seen during cycle one of G-CSF, positive results may be biased related to possible cumulative CT toxicity with resultant increase in oral mucositis severity. Conversely, Bronchud et al.⁹⁹ reported from a study of 17 patients with breast or ovarian carcinoma treated with escalating doses of doxorubicin with G-CSF that G-CSF did not prevent severe oral mucositis. A third study compared clinical outcomes in 55 adult patients who received CT for non-Hodgkin's lymphoma and G-CSF with clinical outcomes in 39 patients who received CT alone. Patients who did not receive G-CSF had neutropenia as the primary cause of treatment delay compared with those patients who did receive G-CSF and experienced oral mucositis as the main cause of treatment delay.¹⁰⁰ Granulocyte macrophage–colony-stimulating factor (GM-CSF) has demonstrated conflicting results in patients who received diverse cancer treatments.^{101–104} An open, randomized controlled phase 3 trial conducted by Masucci et al.¹⁰² analyzed the efficacy of GM-CSF in patients with head and neck cancer with RT-induced oral mucositis. A significant reduction in oral mucositis severity was observed in the GM-CSF treatment group. Conversely, results from a Radiation Therapy Oncology Group sponsored a double-blind, placebo-controlled, randomized study ($n = 121$) to analyze efficacy and safety of GM-CSF in reducing severity and duration of oral mucositis and related pain in patients with head and neck cancer receiving RT.¹⁰⁴ GM-CSF had no significant effect on severity or duration of oral mucositis.

Keratinocyte Growth Factors

Palifermin, a recombinant human keratinocyte growth factor and member of fibroblast growth factor family, has shown efficacy in reducing oral mucosal injury related to cytotoxic therapy.¹⁰⁵ Spielberger et al.¹⁰⁵ reported from a double-blind study comparing the effect of palifermin with a placebo for development of oral mucositis in 212 patients with hematologic cancers. Palifermin or placebo was administered intravenously for 3 consecutive days immediately before initiating conditioning therapy with fractionated total-body radiation plus high-dose CT. The palifermin group had significant reductions in grade 4 oral mucositis, soreness of the mouth and throat, opioid use, and incidence of TPN use. Luthi et al.¹⁰⁶ reported lower grade 3 or 4 oral mucositis in 34 patients who received melphalan or BEAM with HSCT and were treated with palifermin (0.06 mg/kg) injections 3 days before conditioning CT and 3 days after HSCT compared with controls. Nasilowska-Adamska et al.¹⁰⁷ reported palifermin 60 mcg/kg per day for 3 consecutive days before and after conditioning therapy for HSCT significantly reduced incidence, severity, and duration of oral mucositis in 106 patients. In a subsequent study,¹⁰⁸ 53 patients with hematologic diseases used the same regimen, also showing a significant reduction in incidence and median duration of oral mucositis, decreased incidence of opioid and TPN use, and less prevalence of acute GVHD.

A randomized, placebo-controlled, double-blind study conducted by Le et al.¹⁰⁹ evaluated efficacy and safety of palifermin to reduce CT-induced oral mucositis in patients with locally advanced head and neck cancer. A total of 188 patients received palifermin (180 mcg/kg) or placebo before chemoradiotherapy and then weekly for 7 weeks. The group receiving palifermin showed a lower incidence of severe oral mucositis when compared with the placebo group (54% and 69%, $p = 0.041$). However, opioid analgesic use, average mouth and throat soreness, and chemoradiotherapy compliance were not significantly different between treatment arms. After median follow-up of 26 months, overall survival and progression-free survival and other secondary outcomes such as opioid use were similar between treatment arms.

A multicenter, double-blind, randomized study investigated the effectiveness of palifermin in reducing severe oral mucositis

in patients with postoperative chemoradiotherapy for head and neck cancer.¹¹⁰ A total of 186 patients with carcinoma of the oral cavity, oropharynx, hypopharynx, or larynx (stages II to IVB) were randomly assigned to receive weekly palifermin (120 mcg/kg) or placebo from 3 days before and throughout radiochemotherapy. A total of 47 of 92 patients (51%) in the palifermin group developed severe oral mucositis versus 63 (67%) of 94 administered placebo ($p = 0.027$). In addition, palifermin decreased the duration and prolonged the time to develop severe mucositis. Although palifermin reduced the occurrence of severe oral mucositis, its role in the management patients with head and neck cancer undergoing postoperative chemoradiotherapy remains to be elucidated.

Palifermin has also been studied in patients with solid tumors. In a randomized controlled trial conducted by Rosen et al.,¹¹¹ 64 patients with metastatic colorectal cancer who received 5-FU and leucovorin were randomized to receive palifermin (40 mcg/kg) for 3 consecutive days before each of two cycles of CT. The incidence of oral mucositis World Health Organization grade 2 or higher was significantly lower, and patients reported less severe symptoms in the treatment arm. Brizel et al.¹¹² compared palifermin (60 mcg/kg) versus placebo in patients with locally advanced head and neck cancer treated with chemoradiation. Patients received two types of RT—standard (total dose of 70 Gy delivered in 2 Gy–daily fractions) and hyperfractionated (total dose 72 Gy delivered in 1.25-Gy fractions twice a day for 7 weeks)—and CT including cisplatin (20 mg/m² for 4 days) and continuous infusion of 5-FU (1,000 mg/m² per day for 4 days in weeks 1 and 5 of RT). Palifermin was well tolerated and decreased incidence of oral mucositis, dysphagia, and xerostomia in patients treated with hyperfractionated RT but not standard RT. However, palifermin did not reduce the morbidity of concurrent chemoradiotherapy.

A randomized, double-blind, placebo-controlled trial conducted by Vadhan-Raj et al.¹¹³ evaluated efficacy of palifermin as a single dose before each cycle in patients receiving multicycle chemotherapy. Forty-four patients with sarcoma were randomized in a 2:1 ratio to receive palifermin (180 mcg/kg), single dose 3 days before each chemotherapy cycle (maximum of six cycles), or placebo. Palifermin decreased incidence of moderate to severe mucositis (44% versus 88%, $p < 0.001$) and severe mucositis (13% versus 51%, $p = 0.002$). Reported adverse effects include thickening of oral mucosa and altered taste. Eighty-eight percent (seven of eight) patients with severe mucositis in the placebo group received palifermin in an open-label fashion. Palifermin as a single-dose before each chemotherapy cycle reduced incidence and severity of oral mucositis in patients with sarcoma.

Antimicrobials

Antimicrobial approaches have included systemic types such as antibiotics, antivirals (acyclovir, valacyclovir, ganciclovir), antifungal (fluconazole), as well as topical therapy. Donnelly et al.¹¹⁴ evaluated the evidence regarding the role of infection in the pathophysiology of oral mucositis via a comprehensive review of 31 prospective randomized trials. No clear pattern of patient type, cancer treatment, or type of antimicrobial agent used was seen, and there was a lack of consistent oral mucositis assessment.

Oral candidiasis is a common acute and chronic oral sequela of head and neck RT, with lesions presenting as removable (whitish) chronic or hyperplastic (nonremovable) and chronic erythematous (diffused as patchy erythema), which frequently appear as angular cheilitis (first signs or symptoms). Treatment approaches for oral candidiasis include Mycostatin (troche; Bristol-Myers Squibb Company, New York, NY), nystatin (liquid or ointment), or clotrimazole. Pseudomembranous candidiasis is successfully treated topically. Chronic candidiasis usually requires much longer treatment, and it may be necessary to use oral ketoconazole, fluconazole, or intravenous amphotericin B.

Acyclovir prophylaxis is currently accepted treatment for HSV and patients with are cytomegalovirus seropositive and undergoing HSCT. A randomized controlled clinical trial in patients undergoing HSCT compared fluconazole with placebo showing that fluconazole prevented systemic fungal infections (7% fluconazole versus 18% placebo) and significantly reduced the incidence of mucosal infection and oropharyngeal colonization by *Candida albicans*.¹¹⁵

Conflicting reports have been published regarding chlorhexidine mouthwash for alleviating oral mucositis and reducing oral colonization by gram-positive, gram-negative, and *Candida* species in patients receiving CT, RT, or HSCT. The majority of studies have not demonstrated efficacy of chlorhexidine mouthwash for oral mucositis reduction in patients receiving intensive CT.¹¹⁶ Dodd et al.¹¹⁷ tested the efficacy of the PRO-SELF Mouth Aware (PSMA) program combined with randomization to one of two mouthwashes (0.12% chlorhexidine or sterile water) for prevention of CT-related oral mucositis in 222 patients. Although chlorhexidine was no more effective than water regarding oral mucositis incidence, days to onset, and severity, the PSMA program appeared to reduce oral mucositis incidence. A double-blind, placebo-controlled, randomized study of chlorhexidine prophylaxis for 5-FU–based CT-induced oral mucositis in patients with gastrointestinal malignancies conducted by Sorensen et al.¹¹⁸ suggested a role for chlorhexidine in prevention of oral mucositis. A total of 225 patients were randomized to chlorhexidine mouth rinse three times a day for 3 weeks versus placebo or cryotherapy with ice 45 minutes during CT. The frequency and duration of oral mucositis were significantly improved in the chlorhexidine and cryotherapy arms.

Sutherland and Browman¹¹⁹ reviewed 59 studies assessing prophylaxis of RT-induced oral mucositis in patients with head and neck cancer. Interventions chosen based on the biologic etiology of oral mucositis were effective. Spijkervet et al.¹²⁰ evaluated efficacy of lozenges containing polymyxin E₂ 2 mg, tobramycin 1.8 mg, and amphotericin B 10 mg taken four times daily for oropharyngeal flora related to oral mucositis. These researchers compared 15 patients receiving RT using polymyxin E₂ 2 mg, tobramycin 1.8 mg, and amphotericin B 10 mg, and two other groups of 15 patients each, one using 0.1% chlorhexidine and the other using placebo. The selectively decontaminated group had significantly reduced severity and oral mucositis extent when compared with the chlorhexidine and placebo groups.

A randomized, double-blind study conducted by Sharma et al.¹²¹ evaluated the effects of administering *Lactobacillus brevis* CD2 lozenges on incidence and severity of oral mucositis and tolerance to chemoradiotherapy in patients with head and neck squamous cell carcinoma. Two hundred patients received daily treatment with lozenge containing either *L. brevis* CD2 or placebo during and for 1 week after completion of chemoradiation therapy. Severe oral mucositis (grades 3 and 4) developed in 52% and 77% of patients in the treatment and placebo arms, respectively ($p < 0.001$). There was a significant difference in anticancer treatment completion rates among groups ($p = 0.001$). *L. brevis* CD2 lozenges were associated with a lower incidence of CT/RT-induced severe oral mucositis and a higher rate of treatment completion.

Triclosan, an antibacterial agent used commonly in periodontal therapy has also been evaluated in the management of RT-induced oral mucositis. Satheshkumar et al.¹²² conducted a randomized study to determine the effectiveness of this therapy in the management of RT-induced oral mucositis. Twenty-four patients with oral cancer with grade 1 RT-induced oral mucositis were randomized to receive either triclosan mouthwash (0.03%) or sodium bicarbonate (2 mg) mouthwash. The use of triclosan reduced the progression to grade 4 oral mucositis in most patients. Changes were also noticed in food intake and weight loss. Triclosan mouthwash was effective in reducing the severity of RT-induced oral mucositis; however, the small sample size was a major study limitation. Further studies are needed to confirm this observation.¹²³

Cryotherapy

Cryotherapy, which is administered as ice chips and flavored ice products, has been used to prevent oral mucositis and to improve patient's overall QOL by decreasing its severity and improving nutritional status. Efficacy of cryotherapy for the reduction of 5-FU–induced oral mucositis severity was seen through a North Central Cancer Treatment Group and Mayo Clinic–sponsored controlled randomized trial.¹²⁴ A subsequent study with a sample of 178 patients randomized to 30 minutes versus 60 minutes of oral cryotherapy reported similar severity of oral mucositis in both groups.¹²⁵ The study recommended use of 30 minutes of oral cryotherapy prior to bolus administration of 5-FU–based CT. Additional studies have confirmed these results.^{126–128} Cryotherapy used to induce vasoconstriction should be considered for patients receiving 5-FU or melphalan¹²⁹ administered for short infusion times.

The effectiveness of aggressive oral care in combination with cryotherapy has also been evaluated in the literature. In a pilot randomized controlled study, 46 patients admitted for autologous HSCT were randomly assigned to the experimental arm ($n = 23$) or usual care ($n = 23$).¹³⁰ The patients in the experimental arm received an hour regimen of oral cryotherapy. The overall mean of oral mucositis severity for the treatment arm was significantly lower than for the control group: 0.43 versus 1.14, on a 0 to 4 scale ($p < 0.001$). In terms of overall mean pain score, for the treatment arm's mean pain score was significantly lower: 0.30 versus 1.64 ($p < 0.001$). Oral cryotherapy added to aggressive oral care protocols appears to reduce mucositis and related pain severity compared with oral care alone.

Use of intravenous opioids has become a common practice for patients with CT- and RT-induced oral mucositis. Cryotherapy is an important adjuvant technique to opiate analgesia. A randomized controlled trial conducted by Svanberg et al.¹³¹ showed that this technique may alleviate development of oral mucositis and oral pain, resulting in decreased days and total dose of intravenous opiates in patients treated with autologous BMT.

Laser

Several studies have confirmed the effectiveness of low-energy laser for prevention and treatment of CT- or RT-induced oral mucositis.^{132–137} A phase 3 double-blind, placebo-controlled randomized study compared two different low level GaAlAs diode lasers (650 nm and 780 nm) to prevent oral mucositis in patients undergoing HSCT treated with either CT or chemoradiotherapy.¹³⁵ Seventy patients were randomized into treatment with 650 nm or 780 nm laser or placebo. Low-level laser therapy was safe and more effective for decreasing oral mucositis and related oral pain. The efficacy of low-energy He/Ne laser was studied in a sample of 30 and 24 patients in two randomized controlled clinical trials.^{133,138} Low-energy He/Ne laser demonstrated a reduction in the severity and duration of oral mucositis.

In a triple-blinded randomized controlled trial conducted by Gautam et al.,¹³⁹ prophylactic low-level laser therapy was tested to prevent CT-induced oral mucositis. A total of 221 patients with head and neck cancer scheduled to undergo chemoradiation were randomized into laser ($n = 111$) and placebo ($n = 110$) groups. The laser group received (HeNe) $\lambda = 632.8$ nm, power-density = 24 mW, dosage = 3.0 J/point, total dosage/session = 36 to 40 J, spot-size = 1 cm², five sessions/week; and the placebo group received sham treatment daily prior to radiation. In the laser group, there was significant reduction in incidence of severe oral mucositis ($p < 0.0001$), associated pain ($p < 0.0001$), dysphagia ($p < 0.0001$), and opioid use ($p < 0.0001$) when compared to the placebo group. The same researchers demonstrated efficacy of low-level laser therapy in improving patients' subjective experience of oral mucositis and QOL in patients with head and neck cancer.¹⁴⁰

Miscellaneous Agents

Mangoni et al.¹⁴¹ analyzed the protective efficacy of a heparan mimetic biopolymer, RGTA-OTR4131, alone or with amifostine, in the management of oral mucositis and evaluated its effects on tumor growth in vitro and in vivo. A single dose of 16.5 Gy was delivered to the snout of mice and the effects of OTR4131 were analyzed by macroscopic scoring and histology. OTR4131 was well tolerated and effective in reducing RT-induced oral mucositis without affecting tumor sensitivity to RT. These results need to be confirmed in clinical trials.

A prospective, randomized, multicenter study conducted by Wu et al.¹⁴² investigated the role of Actovegin (Nycomed Austria GmbH, Linz, Austria), a deproteinized extract of calf blood, in the prevention and treatment of CT-induced oral mucositis in patients with nasopharyngeal carcinoma. A total of 156 patients were randomized to receive Actovegin for prevention ($n = 53$) or treatment ($n = 51$) or to a control group ($n = 52$). Actovegin 30 ml/daily (5 days/week) was given for the duration of the radiotherapy for Group 1 and from the onset of grade 2 mucositis for Group 2. The incidence of grade 3 mucositis was lower in Group 1 versus Group 3 ($p = 0.002$), and Group 2 had a lower progression rate of mucositis (grade 2 to 3) when compared to the placebo group ($p = 0.035$). Thus, Actovegin showed efficacy in the prevention and treatment of CT/RT-induced oral mucositis.

Rhodiola algida, a traditional Chinese medicine widely used to stimulate the immune system, also has been tested as a treatment option for patients with cancer with oral ulcers. Loo et al.¹⁴³ investigated the effect of *R. algida* on healthy lymphocytes in vitro, the homeostasis of patients with cancer, and the healing time of oral ulcers. A total of 462 subjects were treated with 100 µg/ml *R. algida* for 48 hours. Lymphocytes were isolated, and the level of several cytokines and mRNA content were determined. A total of 138 patients with breast cancer were randomized to receive *Rhodiola* (for 14 days after each cycle) and placebo after modified total mastectomy with adjuvant chemotherapy. *R. algida* favored the proliferation of lymphocytes, as well as an increase of IL-2, IL-4, GM-CSF, and the mRNA content of these cytokines. The white blood cell count increased faster in the treatment group. The patients also presented with smaller and fewer oral ulcers. This study suggests that *R. algida* increases immunity of patients receiving adjuvant chemotherapy and decreases the quantity of oral ulcers.

Other therapies such as phenylbutyrate mouthwash and visible-light therapy have also shown to mitigate oral mucositis during CT/RT in patients with head-and-neck cancer or in patients undergoing HSCT, respectively.^{144,145} Larger randomized trials are needed to confirm these results.

TREATMENT FOR ORAL CHRONIC GRAFT-VERSUS-HOST DISEASE

Almost all patients with extensive cGVHD require systemic immunosuppressive therapy. Thus, there is a critical need for adjuvant therapies that are both efficacious and avoid the long-term consequences of these corticosteroid therapies. In general, advances in the treatment of cGVHD have been modest, and no standard therapy exists for cGVHD that fails to respond to initial therapy or recurs. Granitto et al.,³² Imanguli et al.,¹⁴⁶ and Mays et al.¹⁴⁷ have presented comprehensive reviews of available therapies for oral cGVHD. Most commonly recommended therapy for management of mucosal involvement of oral cGVHD is topical high and ultrahigh potency corticosteroids, calcineurin inhibitors, and analgesics.¹⁴⁷ The most common systemic therapy is corticosteroids with or without cyclosporine. Other agents such as tacrolimus, sirolimus, pentostatin, mycophenolate mofetil, and hydroxychloroquine have been used as salvage treatment.¹⁴⁶ Emerging systemic therapies include monoclonal antibodies such as

infliximab, etanercept, daclizumab, and rituximab.^{146,148} Extracorporeal photopheresis, a process that separates a patient's mononuclear cells through apheresis and exposes them to ultravioletlight A, has shown promise.

Patients with symptomatic disease limited to the oral cavity have been found to benefit from topical steroids such as dexamethasone elixir (0.5 mg/ml) as a mouth rinse (10 ml) for 2 to 3 minutes at least four times daily.^{44,149} Clobetasol 0.05%, which is a topical high-potency steroid, has been administered four times daily for 2 to 3 weeks depending on the severity of the ulcerative oral cGVHD to decrease inflammation and oral pain. If local steroids alone are not adequate to control oral disease, then topical cyclosporine¹⁵⁰ or topical tacrolimus may be tried.^{44,151,152} Intraoral psoralen plus ultraviolet A irradiation may be appropriate based on the patient's condition.^{44,146} Although topical and local therapy for oral cGVHD offers several advantages to systemic therapy, including fewer side effects, there currently exists no evidence that one topical therapy is superior to another. Most trials have been open label with very small numbers of subjects. Oral topical treatments need further evaluation in multicenter randomized clinical trials such as conducted by Elad et al.,¹⁵³ who reported that a new mouthwash formulation using effervescent tablets of budesonide (3 mg/10 ml) improved oral cGVHD and reduced pain in all four treatment arms ($n = 18$).

St. John et al.¹⁵⁴ examined the efficacy of topical thalidomide gel 20 mg in patients with oral ulcerative cGVHD through a phase 2, randomized, placebo-controlled, double-blind clinical trial. Results suggested that topical thalidomide gel 20 mg has single-agent activity for oral ulcerative cGVHD. This therapy also decreased cGVHD-related oropharyngeal pain and decreased TNF- α and IL-6 expression levels in oral saliva and oral ulcer exudate. There is an ongoing randomized, double-blind, placebo-controlled pilot study examining the safety and efficacy of a clobetasol oral rinse in 34 subjects with oral cGVHD who are being randomized to clobetasol 0.05% rinse or placebo at the NIH Clinical Center in Bethesda, Maryland.¹⁵⁵

SYMPTOM MANAGEMENT

Oropharyngeal Pain

Oral mucositis is the principal etiology of most pain experienced during the 3-week post-HSCT time period. This pain is often described as the most unforgettable ordeal of HSCT. Oral mucositis-related oropharyngeal pain is multidimensional. The sensory dimension of this oral pain has been described with general mucosal inflammation and breakdown as ranging from mild discomfort to severe and debilitating pain, requiring opioids for pain management.⁵⁵ Immunocompromised patients with cancer who are also HIV-positive develop larger, more painful lesions than those experienced by patients without cancer. Oral pain associated with cGVHD has been described as severe, with symptoms of burning, irritation, dryness, and loss of taste being reported. In contrast to the often long-lasting oral pain with oral cGVHD, oral mucositis-related oral pain with CT is usually of <3 months' duration.

Sucralfate

Sucralfate is an aluminum salt of a sulfated disaccharide that has shown efficacy in the treatment of gastrointestinal ulcerations and has been tested as a mouthwash for the prevention and treatment of oral mucositis. Sucralfate creates a protective barrier at the ulcer site via the formation of an ionic bond to proteins. Study results with sucralfate are conflicting. A phase 3 study conducted by the North Central Cancer Treatment Group compared sucralfate suspension versus placebo for 5-FU-related oral mucositis. Results demonstrated that in the 50 patients who experienced oral

mucositis, the sucralfate suspension provided no beneficial reduction in 5-FU–induced oral mucositis severity or duration, and also had considerable additional gastrointestinal toxicity.¹⁵⁶ Additionally, no efficacy was demonstrated for a sucralfate mouthwash for prevention and treatment of 5-FU–induced oral mucositis in a randomized controlled clinical trial with 81 patients with colorectal cancer who received either sucralfate suspension or placebo four times daily during their first cycle of 5-FU and leucovorin.¹⁵⁷

A prospective, double-blind study compared the effectiveness of sucralfate suspension to a formulation of diphenhydramine hydrochloride syrup plus kaolin-pectin for RT-induced oral mucositis in patients with head and neck cancer. Results showed no statistically significant differences between the two groups. In a study comparing outcomes between 21 patients who received standard oral care and 24 patients who received sucralfate suspension four times daily, the sucralfate group had a significant difference in mucosal edema, oral pain, dysphagia, and weight loss.¹⁵⁸ Conversely, a double-blind, placebo-controlled study with sucralfate in 33 patients who received RT to the head and neck showed no statistically significant differences in oral mucositis.¹⁵⁹ However, the sucralfate group did experience less oral pain and required a later start of topical and systemic analgesics throughout RT.¹⁵⁹ Dodd et al.¹⁶⁰ used a pilot randomized controlled clinical trial to evaluate the efficacy of a micronized sucralfate mouthwash compared with a salt and soda mouthwash in 30 patients who received RT. All patients also used PSMA, which is a systematic oral hygiene program. Results demonstrated no significant difference in efficacy between the two groups.

Gelclair

Gelclair (Sinclair Pharmaceuticals, Surrey, England) is a concentrated, bioadherent gel that has received US Food and Drug Administration approval as a 510(k) medical device indicated for the management of oral mucositis–related pain. Gelclair adheres to the oral surface, creating a protective barrier for irritated tissue and sensitized nociceptors. The safety and efficacy have been evaluated in small clinical trials with mixed results. Innocenti et al.¹⁶¹ reported a 92% decrease in oral pain from baseline 5 to 7 hours after Gelclair administration in patients with oral mucositis, severe diffuse oral aphthous lesions, and postoral surgery pain. More than half of these patients reported that the maximum effect of Gelclair lasted longer than 3 hours, and 87% of patients reported overall improvements from baseline for pain with swallowing food, liquids, and saliva following 1 week of treatment. DeCordi et al.¹⁶² reported from a clinical study in which Gelclair was administered to patients with oral mucositis three times daily before meals as a 2- to 3-minute swish and spit for 3 to 10 days. Significant improvements were reported for pain, oral mucositis severity, and function. No adverse effects were reported during either trial. Patients reported that the taste, smell, texture, and use of Gelclair were acceptable. Barber et al.¹⁶² conducted a prospective, randomized controlled trial comparing Gelclair versus standard therapy with sucralfate and oxethazaine (Mucaine, Wyeth, Dallas, TX) in patients with RT-induced oral mucositis. This study showed no significant difference between both therapies in terms of general pain. Gelclair can be an important adjuvant to opiate therapy in the management of oral mucositis–related oral pain, with the caveat that more research in the clinical setting is needed.

Anesthetic Cocktails

Anesthetic cocktails, composed of agents such as viscous lidocaine or dyclonine hydrochloride, have been used with some success for oral mucositis–related oral pain for temporary pain relief. These agents may alter taste perception, which may decrease oral intake. Other analgesics and mucosal-coating agents used for

pain control include kaolin-pectin, diphenhydramine, Orabase (Colgate-Palmolive Company, New York, NY), and Oratect Gel (MGI Pharma, Woodcliff Lake, NJ). Hospital-based pharmacies commonly formulate and dispense topical mixtures containing an analgesic, an anti-inflammatory agent, and a coating agent for use as an oral comfort measure for patients during cancer treatment. One large clinical research center uses a topical formulation containing viscous lidocaine 2% (40 ml), diphenhydramine 12.5 mg/5 ml (40 ml), and Maalox (Novartis, Basel, Switzerland) 10 mg (40 ml) and prescribes its use every 3 to 4 hours as needed.

Doxepin

Doxepin is a tricyclic antidepressant used for many years in the management of patients with chronic benign or malignant pain. Its topical application is prescribed for pruritus and neuropathic pain. Pilot studies on topical doxepin rinse in patients with oral mucositis pain have shown adequate analgesia for up to 4 hours after application.^{163,164} Epstein et al.¹⁶⁵ assessed the effectiveness of oral doxepin rinse for oral mucositis–related pain in patients with head and neck cancer in the RT or HSCT setting. Nine patients rinsed with doxepin (5 ml) three to six times per day during a week and returned for a follow-up visit. Oral mucositis was scored using the OMAS and oral pain was assessed using a visual analog scale. There was a statistically significant reduction in visual analog scale scores for 2 hours following doxepin rinse at the initial visit and also over a 1-week period, showing that repeated dosing continues to bring significant pain relief. Further randomized controlled trials are needed to confirm these results.

Opioids

Severe oral mucositis–related oropharyngeal pain may interfere with hydration and nutritional intake and affect QOL. Management of this pain may require use of opioids, often administered at high doses by patient-controlled analgesia pumps. Other routes of administration are oral, transmucosal, transdermal, and parenteral. The efficacy of oral transmucosal fentanyl citrate was compared with morphine sulfate immediate release in a randomized, controlled clinical trial for the treatment of breakthrough cancer pain in 134 adult ambulatory patients with cancer.¹⁶⁶ Study results showed that oral transmucosal fentanyl was more effective than morphine sulfate immediate release in treating breakthrough pain. Darwish et al.¹⁶⁷ conducted a phase 1 open-label study to investigate the absorption profile of fentanyl buccal tablets in patients with or without oral mucositis. Sixteen patients (50% with oral mucositis), received a single 200 mcg dose of fentanyl buccal tablet, which was well tolerated and showed a similar absorption profile within both groups. Transdermal fentanyl has also shown to be an effective, convenient, and well-tolerated treatment in patients with oral mucositis pain in the RT and in the HSCT setting.^{168,169}

Topical morphine for mucositis-related pain was evaluated in 26 patients following chemoradiation for head and neck cancer.¹⁶⁹ Patients were randomized to morphine mouthwash (1 ml 2% morphine solution) or magic mouthwash (equal parts of lidocaine, diphenhydramine, and magnesium aluminum hydroxide). Patients in the morphine group demonstrated both significantly shorter duration and lower intensity of oral pain than the magic mouthwash group. Swisher et al.¹⁷⁰ described an oral mucositis pain management algorithm to promote symptom management for patients undergoing HSCT who are transitioning from inpatient to ambulatory care. A key component of this successful program was use of a multidisciplinary team who could respond to the report of oral pain. No standard treatment has been defined for the prevention or treatment of oral mucositis–related pain; thus, it is essential to continue clinical trials testing promising agents such as sublingual methadone, transdermal buprenorphine, and ketamine mouthwash.^{171–173}

Xerostomia

Xerostomia is a major negative sequela for patients who receive RT to the head and neck. Xerostomia severity depends on radiation dosage, location, and volume of exposed salivary glands. Significant xerostomia has not been shown with CT alone. The severity of xerostomia can affect oral comfort, fit of prostheses, speech, and swallowing. Many of the enzymes (mucin) found in patients with xerostomia contribute to the growth of caries-producing organisms. Oral hygiene regimens that include the use of water/saline and daily fluoride application with brushing teeth at least three times daily may reduce colonization of oral pathogens.

Treatment guidelines for the management of xerostomia are designed to increase patient comfort.¹⁷⁴ Sialagogues have been investigated as stimulants for the residual salivary parenchyma (pilocarpine, 5- and 10-mg doses), with reported subjective improvement in some patients.¹⁷⁵ Extreme caution with the use of pilocarpine is warranted because of reported side effects of glaucoma and cardiac problems. A randomized, controlled trial tested the efficacy of amifostine in a

sample of 315 patients with head and neck cancer.¹⁷⁶ The patients received standard fractionated radiation with or without amifostine, administered at 200 mg/m² as a 3-minute intravenous infusion 15 to 30 minutes before each treatment fraction. Patient eligibility criteria required that the radiation field encompassed at least 75% of both parotid glands. The Radiation Therapy Oncology Group Acute and Late Morbidity Score and Criteria was used to rate the severity of xerostomia. The incidence of grade ≥ 2 acute xerostomia (90 days from start of radiotherapy) and late xerostomia (9 to 12 months after radiotherapy) was significantly reduced in patients receiving amifostine. Whole saliva collection 1 year following RT showed in the amifostine group that more patients produced 0.1 g of saliva (72% versus 49%) and that median saliva production was greater (0.26 g versus 0.1 g). Stimulated saliva collections showed no differences between the treatment arms. Supporting these improvements in saliva production were subjects' reports of oral dryness. Artificial saliva has not demonstrated increased oral cavity comfort. Patients have reported subjective improvement in comfort levels through the frequent use of sugarless gum, mints, or candies.

INTRODUCTION

Pulmonary disease can be caused by a wide spectrum of pathogenic mechanisms in patients with cancer. These include a variety of infectious agents and neoplastic disorders as well as pulmonary thromboembolic disease, pulmonary hemorrhage, pulmonary edema (cardiogenic and noncardiogenic), and leukocyte agglutinin reactions. Pulmonary toxicity caused by antineoplastic agents is being recognized more frequently, and the number of drugs known or suspected to cause lung disease is steadily increasing. Because continuing the offending agent may cause death and because withholding the agent may result in resolution of the pulmonary toxicity, it is important to recognize radiation- and drug-induced pulmonary disease. In this chapter, parenchymal lung disease caused by irradiation and chemotherapy is discussed. Mechanisms of lung injury, histopathologic findings, clinical and laboratory features, diagnosis, and treatment of the abnormalities produced by these agents are reviewed.

RADIATION-INDUCED PULMONARY TOXICITY

Mechanisms of Lung Injury and Histology

Radiation can affect dividing and nondividing cells and can cause genetic and nongenetic damage. The first phase of radiation-induced lung injury (RILI) is the production of reactive oxygen species (ROS) and reactive nitrogen species. These species cause oxidative damage to cellular proteins, lipids, and DNA.¹

Nonlethal ionizing radiation also activates a stress response in cells, which leads to upregulation of specific nuclear transcription factors such as nuclear factor κ B and transcription of specific early response genes such as *c-abl*, *c-jun*, *egr-1*, and *c-fos*. This leads to sloughing and denudation of type I pneumocytes, which make up 90% of alveolar epithelium, while type II pneumocytes proliferate in an effort to replace dying type I cells. In addition to pneumocyte injury, capillary endothelial cells are also injured, leading to the loss of barrier function. This microvessel damage leads to ongoing tissue hypoxia as well as chronic inflammation.²

The second phase of RILI includes inflammation in response to injury. Abnormalities in the intermediate stage (2 to 9 months after radiation) are characterized by obstruction of pulmonary capillaries by platelets, fibrin, and collagen. Alveolar-lining cells (primarily type II pneumocytes) become hyperplastic and the alveolar walls become infiltrated with fibroblasts and mast cells. Inflammatory cells are recruited to the site of radiation injury and perpetuate the inflammatory response. Cellular activation initiates a repair process that involves cytokines and growth factors, such as basic fibroblast growth factor, vascular endothelial growth factor (VEGF), and platelet-derived growth factor, as well as tumor necrosis factor- α , interleukin (IL)-1, IL-6, and transforming growth factor (TGF)- β . Prostaglandin synthesis is also upregulated. This second burst of cytokine release leads to more ROS/reactive nitrogen species damage, tissue hypoxia, and TGF- β 1 expression.^{2,3}

Impairment of the regulation of the inflammatory response is thought to contribute to late RILI.¹ Although bronchiolitis obliterans with organizing pneumonia (BOOP) is an unusual histopathologic pattern for cancer therapy-related lung injury, radiation damage resulting in BOOP has been reported.⁴

The last stage of RILI is characterized by a process of repair. These cellular changes include capillary regeneration and alveolar epithelium repopulation by type II cells as well as fibrosis, a process that is dominated by TGF- β release. Several cytokines mediate chemoattraction of fibroblasts and recruitment of myofibroblast precursors from the circulation followed by differentiation into myofibroblasts as well as direct epithelial to mesenchymal transition. If the initial injury is severe, damage to extracellular matrix components of the lung, such as basement membrane glycoproteins and proteoglycans, takes place. Due to previous damage from the first phase of RILI, endothelial cells are unable to respond fully to VEGF and continue to die. Hypoxia is thought to be an important component of chronic injury.⁵

If the radiation injury is mild, these changes may subside entirely; however, when the injury is severe, a chronic phase (≥ 9 months after radiation) ensues that may persist or progress for months or years. The histopathologic appearance is then dominated by dense fibrosis, thickening of the alveolar walls, vascular subintimal fibrosis, and luminal narrowing. In some instances, the lung may shrink to less than half its original size, with a thickened adherent pleura and scarred hilar structures.

Patient Considerations

Certain factors are known to promote the development of classic radiation pneumonitis. These include female sex, lower lobe site of primary lung cancer, concurrent chemotherapy, previous irradiation, and withdrawal of steroids.⁶⁻¹⁰ Current tobacco use has been associated with a decreased incidence of injury and relative protection from inflammatory damage.¹¹ Most of the cases of radiation-related BOOP, however, have occurred in patients receiving radiation treatment to the breast.

Damage to the lung increases as the volume of lung tissue irradiated increases. A threshold effect also appears to occur, such that irradiation of at least 10% of the lung is required to produce significant pulmonary toxicity. This threshold may be reached in the treatment of some patients with breast cancer, depending on the specifics of their individualized treatment program. The toxic effects of radiation as measured by symptoms and signs, radiographic changes, and physiologic tests are proportionate to the total amount delivered to the lung. Radiation pneumonitis seldom occurs with fractionated total doses of < 20 Gy but is more likely when doses exceed 60 Gy.

Besides the volume of lung irradiated and the total radiation dose, the number of fractions into which it is divided and, to a lesser extent, the time span over which it is delivered are important factors. The greater the number of fractions in which the radiation is given, the lower is the damaging effect. However, the incidence of radiation pneumonitis exhibits a threshold effect and a steep

sigmoidal dose-response curve. Fractionation is different from dose rate, which refers to output of the machine during radiation therapy. Dose rate has an effect on lung tolerance: radiation delivered as 0.05 Gy/min is less damaging than radiation delivered at 0.30 Gy/min. In sum, the incidence and severity of radiation damage to the lungs are related to the volume of lung tissue irradiated, the total dose, the fractions into which the total dose is divided, and the quality of the radiation.

Combined positron emission tomography/computed tomography (CT) imaging offers some advantages in designing the radiation port and in detecting metastases not evident on CT, thus changing the intent of the radiotherapy from curative to palliative.^{12,13} Other newer technologies have allowed for refined and localized radiation therapy for the curative treatment of early stage medically inoperable lung cancer and palliation of small pulmonary metastases including minimally invasive image-guided delivery of thermal energies, specifically radiofrequency ablation, microwave ablation, cryoablation, and more conformal stereotactic body radiation therapy (SBRT). These techniques are performed percutaneously under CT guidance and can be done under conscious sedation with a short hospital stay (in the case of radiofrequency ablation) or as an awake outpatient procedure (as in SBRT). Radiofrequency ablation involves the emission of high-frequency alternating currents that cause ion agitation in the surrounding tissue and induce heat production. This heat then causes intracellular protein denaturation, melting of lipid bilayers, and necrosis of nearby tumor cells.^{14,15} Some studies have suggested that local control with this modality is comparable to surgery with minimal morbidity; however, pneumothorax has been described.^{16,17}

Clinical Features

Signs and Symptoms

The clinical syndrome of radiation pneumonitis develops in 5% to 15% of patients receiving high-dose external beam radiation for treatment of lung cancer. No significant difference is seen in the incidence of radiation pneumonitis between the young and elderly, but the pneumonitis is inclined to be more severe in the latter. Underlying chronic obstructive pulmonary disease does not appear to potentiate radiation damage.

Symptoms of acute radiation pneumonitis usually become evident 2 to 3 months after the completion of therapy; rarely, they occur within the first month and occasionally as late as 6 months after irradiation.¹⁸ Early onset of symptoms often implies a more serious and more protracted clinical course. The cardinal symptom of radiation pneumonitis is dyspnea. It may be self-limited or may progress to severe respiratory distress. Patients may also have a nonproductive cough or a cough productive of small amounts of pinkish sputum. Frank hemoptysis early in the clinical course is distinctly uncommon; massive hemoptysis has been reported as a late complication of pulmonary irradiation. Fever is unusual but can be high and spiking; in severe cases, other constitutional symptoms may occur. Chest pain, which is rarely a prominent feature, may be due to fractured ribs, pleural changes, or coughing. Symptoms of airway obstruction can occur in the first few days of radiation therapy and are usually associated with swelling of a central bronchogenic carcinoma. Severe respiratory distress can result and may be prevented by the administration of steroids the day before and several days after the initiation of radiation therapy. Hemoptysis and other manifestations of radiation pneumonitis may also occur in patients given palliative endobronchial brachytherapy or after surgical implantation of radioactive seeds. Whereas dyspnea is the hallmark of radiation-induced pneumonitis, fever and cough are the predominant features of radiation-related BOOP.

On physical examination, signs of pulmonary involvement are minimal. Occasionally, rales, a pleural friction rub, or evidence of

pleural fluid may be heard over the area of irradiation. In severe cases, tachypnea and cyanosis may be present, and occasionally evidence of acute cor pulmonale appears, usually predicting a fatal outcome. Finger clubbing due to radiation is distinctly unusual and is most likely caused by the underlying malignancy. Skin changes corresponding to the ports of irradiation are often present but provide no clue as to the presence or severity of the pulmonary reaction beneath.

Although patients with acute pneumonitis may show complete resolution of signs and symptoms, most develop gradual progressive fibrosis. In some cases, patients present with radiation fibrosis without a previous history of acute pneumonitis. The permanent changes of fibrosis take 6 to 24 months to evolve but usually remain stable after 2 years. Patients with fibrosis can be asymptomatic or can have varying degrees of dyspnea. The major complications of radiation pneumonitis occur late in the disease and are secondary to persistent fibrosis of a large volume of lung. These include cor pulmonale and respiratory failure.

Diagnostic Imaging

Although radiographic abnormalities are found at the time clinical radiation pneumonitis is present, these changes may be seen in asymptomatic patients as well. Early radiographic changes include a ground glass opacification (GGO), diffuse haziness, or indistinctness of the normal pulmonary markings over the irradiated area. Later, the chest radiograph may show alveolar infiltrates or dense consolidation with or without air bronchograms. As the pneumonitis progresses to fibrosis, the radiographic appearance changes to that of linear streaks radiating from the area of pneumonitis and of contraction toward the hilar, the perimedastinal, or the apical areas. Pleural effusions, if present, are usually small and always coincident with the pneumonitis. They can persist for long periods but often disappear spontaneously and never increase during a period of stability unless secondary complications occur such as radiation-induced pericarditis. Mediastinal or hilar adenopathy and cavitation are almost always due to causes other than radiation pneumonitis. Pneumothorax is occasionally associated with radiation fibrosis but not with acute pneumonitis.

One of the most characteristic features of radiation pneumonitis and fibrosis is that the radiologic changes are confined to the outlines of the field of radiation. In a few cases, extensive changes outside the field, even in the contralateral lung, have been observed. This syndrome, which occurs in a minority of patients, is characterized by a bilateral lymphocytic alveolitis of activated CD4+ T-lymphocytes 4 to 6 weeks after strictly unilateral lung irradiation. Other explanations for this phenomenon include obstruction of lymphatic flow from radiation-induced mediastinal fibrosis and absorption of X-rays by regions outside the irradiated ports. BOOP, which is most commonly seen in patients with breast cancer after radiation to the chest wall, can begin in areas of the lung contiguous with the irradiated soft tissues but progresses outside the portal in approximately 40% of cases and may include the lung contralateral to the irradiated breast.

SBRT changes can differ from those of standard radiation therapy; however, lung toxicity is rare due to the small fields. Several different patterns of early (acute pneumonitis) and late changes (fibrosis) have been described including GGOs, consolidations, and patchy or diffuse patterns, as well as late bronchiectasis and scar formation.¹⁹ Due to the hypofractionated dose of radiation used in stereotactic radiotherapy and the delivery of radiation in a spherical volume with a gradient between the high dose and the low dose within normal adjacent tissue, the shape of the SBRT-induced injury mimics the tumor and does not have a linear pattern that may be seen with conventional radiation therapy. Similar to conventional therapy, late fibrosis may develop after 6 to 9 months without a preceding acute pneumonitis.

Pulmonary Function Tests

Prediction of changes in pulmonary function after high-dose irradiation to the lung has proven to be problematic.^{20,21} No gross physiologic changes occur in the lung until 4 to 8 weeks after completion of irradiation, usually coincident with the period of clinical pneumonitis. Then, there is a decrease in lung volumes, which can progress. These changes persist indefinitely, with little evidence of recovery. Small changes in spirometric values and gas exchange abnormalities, which include a decrease in diffusing capacity and arterial hypoxemia, especially with exercise, occur at approximately the same time but show some tendency toward recovery after 6 to 12 months.²² A fall in compliance coincident with the clinical pneumonitis is seen in most subjects. Accordingly, the elastic work of breathing is increased, and dyspnea, resulting from the increased workload, ensues. Air-flow parameters remain close to normal in most studies.²³

Diagnosis

The diagnosis of radiation pneumonitis can sometimes be made clinically based on the timing of irradiation in relation to symptoms and the typical chest radiographic appearance (i.e., infiltrates corresponding to the margins of the irradiated portal).²⁰ Differentiation from recurrent malignancy or infection often poses a problem, in which case lung biopsy is necessary. Although histopathologic changes are nonspecific for radiation pneumonitis, when elements of the acute stages (fibrin exudate in the alveoli) are seen adjacent to the more chronic stages (alveolar fibrosis and subintimal sclerosis), this entity can be diagnosed with reasonable certainty.

Several biomarkers have been investigated in order to predict those who may go on to develop RILI. TGF- β has shown mixed results as a potential marker but may predict those at low risk.²⁴⁻²⁶ IL-1, -6, -8, and -10 have been evaluated to predict progression of RILI as has surfactant A and D, cytokeratin 19, and thrombomodulin. KL-6, a glycoprotein that is expressed on type II pneumocytes and bronchiolar epithelial cells, was evaluated in 16 patients whom underwent radiation therapy with or without concurrent chemotherapy. Higher levels of KL-6 were associated with more severe RILI that was unresponsive to steroid treatment and lower levels corresponded to RILI in the radiation field alone.²⁷⁻²⁹ CD-36, a protein required for TGF- β activation, has been examined and shown to increase with onset of radiation-induced pneumonitis.³⁰ Other proteins such as TGF- β 1 have also been evaluated for their potential role in identifying those who might be susceptible to radiation pneumonitis but have failed to show strong enough predictive values.²⁷ Currently, research is focusing on patient genotypes that may hold promise in identifying patients in whom radiation pneumonitis is most likely. In particular, single nucleotide polymorphisms for genes encoding DNA repair and response genes have been evaluated and suggest certain single nucleotide polymorphisms are associated with increased risk of severe RILI.^{31,32} The TGF- β Leu10Pro and 509CT polymorphisms have also been associated with late RILI in breast cancer.³³

Treatment

Corticosteroid administration during irradiation in mice markedly improves the physiologic abnormalities and decreases mortality without an effect on late pulmonary fibrosis. No controlled clinical trials in humans are available on the efficacy of steroid therapy in radiation pneumonitis.³⁴ Nonetheless, clinicians often begin prednisone 1 mg/kg as soon as the diagnosis is reasonably certain. The initial dose is maintained for several weeks and then reduced cautiously and slowly. If steroids are tapered too rapidly, symptoms can be exacerbated, necessitating higher doses for longer periods. Similarly, if corticosteroids are part of a recent

chemotherapeutic regimen, stopping them abruptly can precipitate clinically evident radiation pneumonitis. What parameters, if any, to follow during the tapering schedule are not known, and no studies are available. Generally, physicians follow symptoms. Most clinicians agree that corticosteroids have no place in the treatment of radiation fibrosis.

Free radical scavenging agents have also been investigated. Amifostine, a thiophosphate, and captopril, which has a thiol group as well, have been investigated but failed to come to fruition.^{35,36} Inhibition of endothelial cell apoptosis by therapeutic administration of basic fibroblast growth factor or VEGF has been beneficial in some animal models, but no human trials have been attempted. Many experimental therapies are being investigated in mouse models including the use of nitric oxide, superoxide dismutase, statins, matrix metalloproteinase inhibitors, growth factors, and other antioxidants.³⁷ None have as yet been demonstrated to have efficacy in humans.

CHEMOTHERAPY-INDUCED PULMONARY TOXICITY

The list of chemotherapeutic agents reported to cause cytotoxic drug-induced lung disease continues to grow. The true incidence of toxicity is unknown, but the reported frequency of pulmonary toxicity ranges from 10% to 30%. True toxicity must be distinguished from other factors that affect the lung in patients with cancer including cardiac-induced pulmonary edema, infection, lymphangitic carcinomatosis, and diffuse alveolar hemorrhage. With the development of targeted monoclonal antibodies used in cancer treatment, new toxicities are continuously being reported. Classes of drugs added to the list include tyrosine kinase inhibitors, anti-VEGF agents (such as bevacizumab), rituximab, granulocyte-colony-stimulating factor (G-CSF), and the mammalian target of rapamycin inhibitors (Table 138.1).³⁸⁻⁹⁸ There are also reports of lung injury with trastuzumab, ifosfamide, irinotecan/topotecan, oxaliplatin, and temozolomide.^{34,99-104} A summary of the mechanisms of lung damage; the pathologic findings; common clinical, radiographic, and physiologic features; and the diagnosis and treatment of the more common chemotherapeutic drugs that cause pulmonary toxicity are discussed in this section (see Table 138.1).

Mechanisms of Pulmonary Injury and Histology

Except for a few chemotherapeutic agents (e.g., bleomycin), the details of the pathophysiology of lung injury are unknown. Various mechanisms of pulmonary toxicity have been proposed based on the mechanisms of action of different classes of therapeutic agents. These include a direct toxic effect on alveolar epithelial cells, the induction of an inflammatory immunologic response and endothelial cell injury, or activation causing capillary leak syndrome. These events can result in a variety of clinical presentations including nonspecific interstitial pneumonitis, hypersensitivity reaction syndrome, noncardiogenic pulmonary edema, infusion reaction, capillary leak syndrome, eosinophilic pneumonia, bronchospasm, acute lung injury, diffuse alveolar damage, or fibrosis.

The histopathologic changes of drug-induced pulmonary toxicity show common features. Similar to radiation-induced damage, abnormalities are seen in endothelial and epithelial cells. The vascular damage is characterized by endothelial swelling with exudation of fluid into the interstitium and the intra-alveolar spaces. Destruction and desquamation of type I pneumocytes occurs with delamination and proliferation of type II pneumocytes. Mononuclear cell infiltration and fibroblast proliferation with fibrosis are common findings; the character of the inflammatory cellular infiltrate may be a feature that distinguishes the toxicity of one drug from another.

TABLE 138.1

Characteristics of Pulmonary Toxicity Caused by Commonly Used Chemotherapeutic Agents

Drug (Reference)	Mechanism of Injury and Histopathology	Clinical Presentation	Imaging and Diagnosis	Treatment and Prognosis
Alkylating Agents				
Busulfan ^{38,39}	Direct alveolar epithelial toxicity. Pneumocyte hyperplasia, mononuclear cells, fibrosis.	4% incidence; rare <500 mg dose; XRT enhance toxicity. Onset 8 mo to 10 y. SOB, cough, weight loss, weakness, fever.	Most common bibasilar reticular pattern. Rarely pleural effusion, pulmonary ossification. Definitive dx by SLB.	Withdrawal of drug. Anecdotal reports of response to high-dose steroids. Mean survival 5 mo after dx.
Cyclophosphamide ^{38,40}	Reactive oxygen species. Endothelial swelling, pneumocyte dysplasia, mononuclear cells, fibrosis.	<1% incidence; no dose dependence. Synergy with O2 and other agents. Acute sx early; subacute up to 8 y.	Commonly bibasilar reticular pattern. Rarely pulmonary edema. Diagnosis of exclusion. May require surgical bx.	Withdrawal of drug. Steroids may hasten improvement. Recovery approximately 65%.
Chlorambucil ⁴¹⁻⁴³	Unknown mechanism. Histology similar to busulfan. Interstitial pneumonitis, fibrosis.	Rare reports; subacute onset (5 mo to 10 y). Cough, dyspnea, anorexia, bibasilar rales.	Bibasilar reticular pattern. Rarely normal radiograph. Alveolar infiltrates not reported.	Half of reported patients died despite stopping drug and using steroids.
Melphalan ^{41,44}	Unknown mechanism. Histology similar to busulfan. Pneumocyte dysplasia > fibrosis.	Rare; onset 1 to 48 mo after therapy. Progressive dyspnea.	Reticular and alveolar infiltrates. May require TBBX/SLB.	Despite cessation of drug, three-fifths of reported patients died. Most were already on steroid for tumor Rx.
Antibiotics				
Bleomycin ^{41,45-60}	Direct endo/epithelial toxicity via O2 free radicals. TNF- α , inflammation. TGF- β , fibrosis. Endothelial blebbing, interstitial edema, type I cell necrosis, metaplastic type II cell, neutrophilic infiltration; fibroblast proliferation and fibrosis; rare eosinophilic infiltration; rare BOOP.	Incidence up to 10%. Risk factors: older age, higher dose, renal dysfunction, O2 therapy, thoracic irradiation. Occurs during and up to 6 mo after stopping therapy. Cough dyspnea, fever, tachycardia, crepitant rales. Hypersensitivity pneumonitis variant may occur.	Bibasilar reticular pattern; multiple nodules similar to metastases: acinar pattern, especially with hypersensitivity. Rarely localized infiltrates and cavitory nodules. BALF with neutrophilic alveolitis. TBBX or open lung biopsy may be required to rule out other cause.	Drug withdrawal. Excellent response to steroids in hypersensitivity, but less clear efficacy otherwise. Reported mortality between 3% and 50%.
Mitomycin ^{41,61,62}	Endothelial injury; alveolar macrophage activation, cytokine release. Several patterns: capillary leak and DAD especially with vinca alkaloids; thrombotic microangiopathy; fibrosis.	3%–14% incidence; usually not dose-related. Possible synergy with O2, XRT and other agents, especially vinca. Dry cough, dyspnea. Fever not seen. Bibasilar rales.	Diffuse interstitial and/or alveolar infiltrates. May have normal CXR. Clinical picture is suggestive; lung biopsy may be required to rule out other causes.	Drug withdrawal. Steroids. Mortality 14%–50%.
Nitrosoureas (e.g., carmustine) ⁴¹	Direct injury through oxidative stress; possible involvement of depletion of the antioxidant glutathione. Histology similar to bleomycin. Fibrosis predominates.	20%–30% incidence; dose-related. Increased risk with preexisting lung disease, tobacco use; synergism with other agents. Reported up to 17 y after drug.	Bibasilar reticular pattern. Lung biopsy may be needed. No BALF studies reported.	Recognition and drug withdrawal. Questionably benefit of steroids. Reported mortality 24%–90%. Worst prognosis in patient <5 y of age.
Antimetabolites				
Methotrexate ^{41,63,64}	Hypersensitivity suggested by T lymphocytes and eosinophils in BALF. Interstitial and alveolar infiltration with lymphocytes, eosinophils, plasma cells. Occasionally poorly formed granuloma.	2%–8% incidence. Days to weeks after start therapy. Acute: fever, cough, malaise, headache. Subacute: Dyspnea, cough. Rales on exam. Skin rash in 17%. Blood eosinophilia in 40%. Progression to fibrosis in 10%.	Early: Interstitial infiltrates. Later: Alveolar infiltrates. Hilar and mediastinal adenopathy. Pleural effusions. CXR can be normal. BALF suggestive if T-cell predominance, but biopsy may be required.	Drug withdrawal. Reports of reinstitution without recurrence of abnormalities. Dramatic response to steroids reported. Mortality 1%. Favorable outlook.

(continued)

TABLE 138.1

Characteristics of Pulmonary Toxicity Caused by Commonly Used Chemotherapeutic Agents (continued)

Drug (Reference)	Mechanism of Injury and Histopathology	Clinical Presentation	Imaging and Diagnosis	Treatment and Prognosis
Cytokine arabinoside ⁶⁵	Pulmonary edema; proteinaceous exudate, extravasation of RBCs; no inflammatory cells.	Abrupt onset of dyspnea; coexistent gastrointestinal toxicity.	Diffuse interstitial and alveolar infiltrates. Clinical picture suggests diagnosis.	Supportive therapy. No studies.
Gemcitabine ⁶⁶⁻⁶⁸	Reports of DAD.	Dyspnea may be severe and progress to respiratory failure and ARDS. Low-grade fever.	Reticular nodular infiltrates or ground glass opacities. Exclude other causes.	Drug withdrawal. Usually, brisk response to steroids, but fatalities have been reported.
Fludarabine ⁶⁹	Unknown mechanism. Rare reports of granulomatous or diffuse nonspecific inflammation.	Hypoxemia, fever, CD4 lymphopenia.	Interstitial or nodular infiltrates. Associated with pneumocystis, so must rule out infection.	Drug withdrawal. Probably response to steroids.
Taxanes				
Paclitaxel/ docetaxel ⁷⁰⁻⁷³	(1) AR: Mast cell activation, histamine release. Caused by suspension in Cremophor (BASF Inc., Florham Park, NJ). (2) HP: BALF with lymphocytes, biopsy with mononuclear cells and septal thickening. May also present with DAD or fibrotic NSIP.	AR: up to 5% incidence. Erythematous rash, urticaria, hypotension, bronchospasm during or soon after the infusion. HP: dyspnea and/or cough several days to weeks after treatment. Fever may occur. Creptant rates or normal chest exam.	AR: normal CXR; highly suggestive clinical picture HP: patchy reticular, nodular, or diffuse alveolar infiltrates. Rule out infection or progression of disease. Bronchoscopy and biopsy may be necessary.	AR: slow infusion; pretreatment with steroids, H1/2 blockers reduces incidence to <2%. HP: Can resolve on its own; if severe, steroids. May not recur with rechallenge.
Tyrosine Kinase Inhibitors				
EGFR inhibitors: Gefitinib, erlotinib ^{42,74-79}	Augmentation of inflammation, alteration of repair capability, potentiation of damage by other chemo agents. DAD, NSIP, BOOP, DAH, fibrosis.	<1% incidence in Caucasians; 2%–6% in Asians. Usually in first month of Rx. Pulmonary fibrosis is a risk factor. Dyspnea with/without cough and fever.	GGO with/without airspace consolidation. Diagnosis of exclusion. Rule out progression of disease or infection.	Discontinue the drug; steroids; small series report high mortality rates.
Kit/BCR-ABL inhibitors: Imatinib/dasatinib ⁸⁰⁻⁸³	Hypersensitivity suggested by lymphocytic exudate with high CD4/CD8 in plural fluid. Eosinophilic infiltration; interstitial inflammation/fibrosis.	Low-grade fever; dry cough; dyspnea with/without hypoxemia	Pleural effusions; GGO; nodular opacities, consolidation. Clinical picture suggestive, especially if with exudative lymphocytic pleural effusion.	Discontinuation of the drug; may need steroids; may need repeated thoracentesis.
Myeloma Therapies				
Bortezomib ⁸⁴	BOOP, DAD, and DAH have been reported.	Rare. ARDS reported only in Asians and African Americans. Rapid onset of dyspnea, hypoxemia, respiratory failure.	Bilateral infiltrates, GGOs, effusions.	May occur even with pretreatment with steroids. Variable response to treatment with high-dose steroids. High mortality.
Thalidomide, lenalidomide, pomalidomide ⁸⁵	Antiangiogenic properties may predispose to PE. BOOP, cellular NSIP; HP, and eosinophilic pneumonia have rarely been reported.	8%–12% incidence of PE. ILD very rare; presentation acute or subacute. Increased risk of opportunistic infections especially with dexamethasone.	Pulmonary embolism on CTA. Diffuse bilateral air space and interstitial infiltrates; must rule out infection, especially PJP; if on concurrent steroids.	DVT prophylaxis recommended with thalidomide (black box warning).

Mammalian Target of Rapamycin Inhibitors				
Sirolimus, temsirolimus, everolimus ⁸⁶⁻⁹¹	May possibly bind to plasma proteins and evoke TH1 response. BOOP.	0.5%–5% incidence. Dyspnea, fatigue, fever. Risk factors include late switch to the drug.	Focal consolidation, GGO. May be waxing and waning.	Stop drug if symptomatic. No data on effectiveness of steroids, but recommended with severe or progressive disease.
Monoclonal Antibodies				
VEGF inhibitors: Bevacizumab ⁹²⁻⁹⁴	Effects on vascular integrity and regeneration; procoagulant effects. Pulmonary hemorrhage and venous thromboembolism.	Risk of hemoptysis highest in patients with lung cancer, especially squamous cell carcinoma.	GGO and air space opacification, tumor cavitation, pulmonary embolism.	Withdrawal of the drug. Anticoagulation for PE. Role for steroids, aminocaproic acid, factor VIIa in pulmonary hemorrhage is unknown.
EGFR inhibitors: Trastuzumab ⁹⁵	Neutrophilic alveolitis, eosinophilic pneumonia, and organizing pneumonia have been described.	Sx range from exertional dyspnea to rapidly progressive respiratory failure.	Interstitial and alveolar opacities or consolidations can be seen. Diagnosis of exclusion.	Resolution with discontinuation of the drug described. Steroids may speed improvement.
Immunotherapeutic Agents				
Ipilimumab ^{96,97}	Presumably through activation of cytotoxic T cells via inhibition of CTLA4. Sarcoid-like granulomata. BOOP.	May be asymptomatic or present with cough, dyspnea.	Micronodular pattern on CT, hilar and mediastinal LAD; peripheral air space consolidations. Biopsy to rule out POD or infection.	Withdrawal of the drug. Steroids are usually not needed, but highly effective in symptomatic disease.
Nivolumab ⁹⁸	Mechanism unknown, but presumably through activation of T-lymphocytes. BOOP.	Reports of pneumonitis. Dyspnea, cough, hypoxemia.	Migratory infiltrates: GGO and consolidations; interstitial opacities. Biopsy to rule out malignancy or infection.	Stop drug and start steroids. Additional infliximab, cyclophosphamide have been used.

XRT, radiation therapy; SOB, shortness of breath; dx, diagnosis; SLB, surgical lung biopsy; O2, oxygen; sx, symptom; bx, biopsy; TBBX, transbronchial biopsy; Rx, treatment; TNF, tumor necrosis factor; TGF, transforming growth factor; BOOP, bronchiolitis obliterans with organizing pneumonia; BALF, bronchoalveolar lavage fluid; DAD, diffuse alveolar damage; XRT, radiation therapy; CXR, chest X-ray; RBC, red blood cell; ARDS, acute respiratory distress syndrome; AR, anaphylactoid reaction; HP, hypersensitivity pneumonitis; NSIP, nonspecific interstitial pneumonitis; EGFR, epidermal growth factor receptor; DAH, diffuse alveolar hemorrhage; GGO, ground glass opacity; PE, pulmonary embolism; ILD, interstitial lung disease; CTA, computed tomography angiography; PJP, *Pneumocystis jirovecii* pneumonia; DVT, deep vein thrombosis; VEGF, vascular endothelial growth factor; CTLA4, cytotoxic T-lymphocyte antigen 4; CT, computed tomography; LAD, lymphadenopathy; POD, progression of disease.

Pathways involved in chemotherapy-induced lung disease include apoptosis, impaired repair response, and angiogenesis. Apoptosis pathways include the death receptor pathway and the Fas ligand as well as the mitochondrial pathway and Bcl-2 protein. Both of these lead to activation of caspases, which activate degradative enzymes within the cell. Cells affected can be immune cells, endothelial cells, or epithelial and other parenchymal cells. Impaired pathways involving epidermal growth factor and TGF may contribute to alterations in repair mechanisms; both factors are expressed in type II pneumocytes and epithelial cells.

The older chemotherapy agents are the best described in their mechanism of lung injury. It is thought that a major contributor to the toxicity from these agents results from ROS including superoxide anions, hydrogen peroxide, and hydroxyl radicals, primarily from activated neutrophils.¹⁰⁵ Bleomycin induces reactive oxygen radicals by forming a complex with Fe³⁺. Consistent with a direct pathologic role for this mechanism, iron chelators ameliorate the pulmonary toxicity of bleomycin in animal models.⁴⁵ ROS formed after bleomycin therapy can produce direct toxicity through participation in oxidation-reduction reactions and subsequent fatty acid oxidation, which leads to membrane instability.⁴⁶ Oxidants also cause other inflammatory reactions within the lung. For example, the oxidation of arachidonic acid is an initial step in the metabolic cascade that produces active mediators, including prostaglandins and leukotrienes.⁴⁷ Because ROS are so highly tied to bleomycin toxicity, high-dose oxygen can exacerbate its effects, and toxicity can be seen years after its administration.^{48,49} In addition to ROS direct toxicity, cytokines such as IL-1, macrophage inflammatory protein-1, monocyte chemoattractant protein-1, and TGF- β are released from alveolar macrophages in animal models of bleomycin toxicity resulting in fibrosis.^{50,51,105} Through modulation of fibroblast proliferation, bleomycin can cause excessive interstitial and intra-alveolar collagen deposition leading to pulmonary fibrosis.⁵¹ Bleomycin directly upregulates collagen synthesis in fibroblasts by stimulating transcription. There is some evidence to support a role for a mast cell/fibroblast interaction in the generation of this fibrosis as well.⁵³

One of the potential determinants of bleomycin toxicity is the bleomycin hydrolase, which is the major enzyme responsible for metabolizing bleomycin to a nontoxic molecule.⁵⁴ Interestingly, the two organs that are the most common targets for bleomycin toxicity (lung and skin) have the lowest levels of the enzyme. Studies are needed to determine if genetic variability of this enzyme accounts for individual susceptibility or immunity to bleomycin pulmonary toxicity in humans, as it does in animals.⁵⁵⁻⁵⁷ Likewise, with linkage and association studies, genetic susceptibility to bleomycin-induced pulmonary fibrosis has been investigated in mice. Polymorphisms in *Cep55*, a gene encoding proteins involved in autophagy, and *Masp2*, a gene encoding complement pathway proteins, as well as several others, have been identified as potentially increasing toxicity susceptibility.^{58,59} However, these associations have not been replicated in other studies and are currently not being used clinically.⁶⁰

Because the lung is exposed to many substances that can activate its immune system, there appears to be a pulmonary immune tolerance state to avoid overreactions. This tolerance state in part may be a result of an effector and suppressor cell balance. Cytotoxic drugs can alter the normal balance, which may cause tissue damage.⁴¹ For example, lymphocytic alveolitis is a consistent finding in methotrexate pneumonitis, with an imbalance of the CD4-to-CD8 ratio.¹⁰⁶ Bronchoalveolar lavage studies in patients with methotrexate pulmonary toxicity have shown the presence of a T-lymphocytic alveolitis, whereas studies on some patients with bleomycin toxicity have revealed a polymorphonuclear alveolitis.¹⁰⁶⁻¹⁰⁷ G-CSF is also implicated in pulmonary toxicity through its effects on neutrophil activation. G-CSF toxicity is thought to be secondary to activation of inflammatory pathways and ROS within the neutrophils, causing pulmonary edema and acute respiratory distress syndrome.¹⁰⁸

IL-2, used to treat metastatic melanoma and renal cell cancer, stimulates the immune system by stimulating CD4+ T cells and increasing natural killer cell activity. These effects likely contribute to a generalized inflammatory state, contributing to the capillary leak syndrome and noncardiogenic pulmonary edema associated with this drug. IL-2 has been shown to directly increase endothelial permeability and indirectly increases vascular leak by increasing cytokine levels, particularly tumor necrosis factor (TNF)- α , leukocyte adhesion, and inflammation, and altering the extracellular matrix.¹⁰⁹

Tyrosine kinase inhibitors, although generally well tolerated, can show serious pulmonary toxicity. Epidermal growth factor receptor (EGFR) is a target of these newer molecular-targeted chemotherapies including gefitinib and erlotinib. Inhibition of the EGFR pathway can exacerbate damage from other chemotherapy agents or sepsis by altering the repair capability of cells. It has been shown that inhibition of the EGFR pathway can upregulate genes that promote prolonged inflammation.¹¹⁰ Angiogenesis, which involves VEGF, TNF- α , TGF- β , and platelet-derived growth factor, also are targets of tyrosine kinase inhibitors, and impaired function of these factors likely also contribute to pulmonary toxicity. Inhibition of the platelet-derived growth factor pathway, seen with dasatinib, is thought to contribute to the pathogenesis of pleural effusions, which is seen in up to 54% of patients treated with this agent. Interestingly, pulmonary hypertension can also be seen with this agent, although the mechanism is unclear. Other Abelson gene inhibitors do not show this effect.¹¹¹ Dasatinib, axitinib, crizotinib, pazopanib, and sunitinib have been reported to cause pulmonary embolism.¹¹²

Mammalian target of rapamycin inhibitors, such as everolimus and sirolimus, which inhibit cell proliferation, growth, and angiogenesis by inhibiting phosphatidylinositol kinases, specifically mTORC1, also are thought to cause a pneumonitis by a T-cell-mediated delayed-type hypersensitivity.⁸⁷ In bronchoalveolar lavage (BAL) fluid of patients with pneumonitis from sirolimus, a CD4+ T-cell lymphocytosis is found. Re-exposure to sirolimus may result in antigen presentation and the activation of Th1-cells and recruitment of macrophages and production of proinflammatory cytokines.^{87,113}

Bortezomib, thalidomide, and lenalidomide are all used to treat multiple myeloma. Bortezomib, a proteasome inhibitor, has been associated with parenchymal changes, organizing pneumonia, and pleural effusions; thalidomide, which downregulates TNF- α and has antiangiogenic properties, is associated with pulmonary embolism, organizing pneumonia, and pneumonitis.^{114,115} The mechanism of pulmonary toxicity associated with bortezomib and thalidomide is unclear.

Bevacizumab and other anti-VEGF therapies can cause epistaxis. Pulmonary hemorrhage and pulmonary embolism have been reported. The mechanism of hemorrhage and thrombosis likely reflects the multiple actions of VEGF on vasculature and on the coagulation system. Inhibition of VEGF reduces regeneration of endothelial cells and can cause defects that expose procoagulant phospholipids on the luminal plasma membrane or underlying matrix, leading to thrombosis or hemorrhage.¹¹⁶ VEGF also increases production of nitric oxide and prostacyclin (prostaglandin I₂); suppresses pathways involved in endothelial cell activation, apoptosis, and procoagulant changes; and inhibits proliferation of vascular smooth muscle cells.¹¹⁷ Reduction in nitric oxide and prostaglandin I₂ by anti-VEGF agents may predispose to thromboembolic events. A few cases of pulmonary arterial hypertension have been reported with bevacizumab.⁸⁵

Clinical Features

Combination chemotherapy, concurrent radiation treatments, oxygen therapy, renal dysfunction, preexisting pulmonary disease such as idiopathic pulmonary fibrosis, chronic obstructive

TABLE 138.2

Factors Associated with Increased Risk of Drug-Induced Pulmonary Toxicity

Risk Factors	Drugs
Total dose	Bleomycin Carmustine
Advanced age	Bleomycin Carmustine Methotrexate
Oxygen therapy	Bleomycin Cyclophosphamide Mitomycin
Simultaneous or prior radiation therapy to lungs	Bleomycin Busulfan Mitomycin Gemcitabine
Increased toxicity when given with other drugs	Carmustine Mitomycin Cyclophosphamide Bleomycin Methotrexate Etoposide Gemcitabine Docetaxal
Preexisting pulmonary disease	Carmustine
Renal dysfunction	Bleomycin

pulmonary disease, radiation pneumonitis, extensive pulmonary metastases, and poor functional status and advanced age have been associated with increased pulmonary toxicity. Table 138.2 lists some of the drugs that have been associated with these predisposing factors.⁴¹ Because bleomycin toxicity is relatively common, it deserves special mention. Although toxicity drastically increases with doses in excess of 450 to 500 mg, it can occur with much lower doses, especially when other risk factors are present. Renal damage after cisplatin administration, with subsequent accumulation of bleomycin, was a likely cause of pulmonary toxicity and 67% mortality reported early in its use. If possible, bleomycin should precede cisplatin infusion to minimize the risk. Although supplemental oxygen has been a classic cofactor in bleomycin pulmonary toxicity, there are no large controlled studies.⁴¹ An increased risk of pulmonary toxicity (4 of 12 patients, fatal in 3 of 4) was described in a small uncontrolled study of patients receiving G-CSF in combination with bleomycin-containing chemotherapy for non-Hodgkin's lymphoma.¹¹⁸

Long intervals between drug administration and onset of clinical toxicity have been described. Late-onset pulmonary fibrosis has been reported many years after cyclophosphamide and carmustine are discontinued.⁴¹

Signs and Symptoms

The cardinal symptom of drug-induced pulmonary toxicity is dyspnea; however, symptoms can range from nonproductive cough with low-grade fevers to overt respiratory failure. If bronchospasm occurs, shortness of breath is accompanied by wheeze. Fibrosis typically causes basilar crackles, although clubbing is not found. Increased fremitus and decreased breath sounds are signs of pleural effusion. Other characteristics of chemotherapy-induced pulmonary disease are outlined in Table 138.1. These findings can occur immediately following administration of the drug or over a treatment cycle. Fibrosis may take years to develop. Chest pain has been reported during infusion of bleomycin or immediately after therapy with methotrexate; however, it is an unusual manifestation

of toxicity.^{41,55} A syndrome of acute dyspnea, probably resulting from direct toxicity to the pulmonary vasculature, can occur during or shortly after vinca alkaloid infusion when given in combination with mitomycin for treatment of nonsmall-cell lung cancer.⁶¹ Because hemoptysis is an uncommon feature of drug-induced pulmonary toxicity unless treated with an anti-VEGF therapy, when it is present, other diagnoses should be considered.

Capillary leak syndrome can lead to a variety of symptoms. These include pulmonary edema that will manifest as tachypnea, low pulse oximetry readings, or in severe cases which lead to mechanical ventilation, cardiovascular symptoms that include tachycardia and hypotension or shock as well as renal insufficiency and hepatic insufficiency. For IL-2 therapy specifically, weight gain from loss of albumin can be seen after 3 to 4 days of administration of the drug and typically resolve after 2 weeks. However, manifestations can appear later and take longer to resolve as well.

All-trans-retinoic acid treatment of leukemias can induce the retinoic acid syndrome, which consists of fever, dyspnea, weight gain, pulmonary infiltrates, pleural or pericardial effusions, hypotension, renal dysfunction, and leukocytosis.¹¹⁹ The pulmonary disorder is thought to be mediated by newly differentiated leukemia cells marginating into the pulmonary circulation, increasing capillary permeability and releasing cytokines that induce neutrophil migration into the interstitium. High doses of corticosteroids are the most effective treatment, and steroid prophylaxis has been reported to be useful.

Diagnostic Imaging

The most common radiographic abnormality associated with drug-induced pulmonary toxicity is a reticulonodular or interstitial pattern with thickened septal lines or both, which may be basilar or diffuse. These changes can be seen with many different chemotherapies including antimetabolites, taxanes, and molecular-targeted therapies. Pleural effusions can be seen alone, as with tyrosine kinase inhibitors or thalidomide, or in the setting of heart failure or capillary leak syndrome, which is described with IL-2 therapy, G-CSF, and gemcitabine. Distinguishing capillary leak from heart failure is important as it will affect ongoing therapy and response to steroids. Effusions are also found with treatment from mitomycin, busulfan, methotrexate, and procarbazine toxicity.

EGFR inhibitors are associated with GGOs, which should be distinguished from tumor progression. They can cause dense consolidation with associated GGOs within 1 week to 1 month after initiation of therapy. Other CT patterns include patchy GGOs with interlobular septal thickening, or extensive bilateral GGOs with consolidation and traction bronchiectasis. The latter pattern carries the highest mortality rate.

Bleomycin pulmonary toxicity can have several patterns on chest CT, notably interstitial pneumonitis, cryptogenic organizing pneumonia, or fibrosis. Cavitating and noncavitating nodules, simulating metastatic disease, have been seen with bleomycin toxicity as well.⁴¹

Methotrexate toxicity often presents with bilateral interstitial and alveolar infiltrates along with pleural effusions. Hilar adenopathy is distinctly unusual in chemotherapy toxicity but has been reported with methotrexate toxicity.⁴¹ These changes can be seen with fever and eosinophilia and will usually not progress to fibrosis if the medication is stopped. These findings typically occur within the first year of therapy.

In some instances, the chest radiograph is normal, even in the presence of histologically proven pulmonary infiltration and fibrosis.⁴¹ Most commonly, methotrexate and carmustine toxicity have been reported, with normal chest radiographic findings. Finally, rituximab can cause interstitial infiltrates with cryptogenic organizing pneumonia in the setting of rapid onset of fever, dyspnea, and cough; however, this is a rare finding. Other CT findings of toxicity are GGO associated with vasculature that proves to be pulmonary hemorrhage. This is most often seen with bevacizumab.

Pulmonary Function Tests

The most common abnormalities associated with chemotherapy-induced pulmonary toxicity are a reduced diffusing capacity for carbon monoxide and a restrictive ventilatory defect.⁴¹ Isolated gas transport abnormalities manifested by a decrease in the diffusing capacity and/or arterial hypoxemia, especially with exercise, have been seen. Screening pulmonary function tests to predict which patients receiving chemotherapy are likely to develop toxicity would be helpful but have not been established. In bleomycin toxicity, changes in the diffusing capacity may be transient, whereas decreases in total lung capacity seem to correlate better with radiographic abnormalities.^{120,121}

Diagnosis

Lung biopsy is usually necessary for a definitive diagnosis and to rule out other causes of lung injury including infection, tumor progression, or diffuse alveolar hemorrhage. Acute respiratory distress syndrome is suggested by radiographic and physical examination, and lymphangitic spread is suggested by malignant cells within BAL fluid. Cardiogenic pulmonary edema is suggested by echocardiography as well as brain natriuretic peptide values and resolution with diuresis. Through the use of BAL, several studies reported the presence of a characteristic or predominant cell associated with particular drugs.^{56,63,106} Although these data might be of value in understanding the pathogenesis of drug-induced lung disorders, their usefulness in diagnosing drug toxicity is limited.

To date, biomarkers for chemotherapy-induced lung injury are research tools more than clinically applicable tests. No serum marker for drug-induced pulmonary toxicity currently exists. KL-6 may be helpful in diagnosis as it is elevated in 53% of patients with drug-induced pneumonitis.¹²² It will not be elevated in patients

with bacterial pneumonia, pulmonary aspergillosis, asthma, bronchiectasis, emphysema, eosinophilic pneumonia, or organizing pneumonia.¹²³ It lacks specificity, however, as it can also be elevated in patients with radiation pneumonitis, viral pneumonia, and *Pneumocystis* pneumonia in this patient population. Though elevated levels of TGF- β in plasma after high-dose chemotherapy for breast cancer predicted an increased risk of pulmonary toxicity after autologous bone marrow transplantation, its clinical applicability has been limited.¹²⁴

Treatment

The most effective way to manage pulmonary toxicity associated with chemotherapeutic agents is to prevent it. Animal studies of bleomycin toxicity showed a beneficial preventive effect of dietary supplementation with taurine and niacin; no comparable human studies have been reported.¹²⁵ G-CSF should be discontinued as soon as leukocytes reach over 1,000 cell/ μ L. Hypersensitivity reactions can be mitigated with the administration of steroids and H2 blockers prior to dosing.

If toxicity occurs, withdrawal of the offending agent is the cornerstone of therapy. Although no controlled studies in humans have systematically examined the efficacy of corticosteroids, a trial of these agents is probably warranted in most cases. The optimal dose and duration of therapy are not known; however, 1 mg/kg per day is usually initiated with a slow and careful tapering schedule because clinical deterioration after tapering has been reported. The use of lung transplant in the treatment of advanced drug-induced pulmonary fibrosis should be considered in appropriate patients. One report described the case of a 23-year-old male patient who underwent a single lung transplant because of presumed drug-induced pulmonary fibrosis 12 years after undergoing chemotherapy for acute lymphocytic leukemia.¹²⁶

139 Cardiac Toxicity

Joachim Yahalom and Matthew A. Lunning

INTRODUCTION

Chemotherapy, immunotherapy, and radiotherapy (RT) may have deleterious effects on the cardiovascular system.^{1,2} Within these categories exist agents that have well-described cardiotoxicity: chemotherapeutics (anthracyclines, alkylators, taxanes, fluoropyrimidines) and monoclonal antibodies. Each will be discussed in detail. A more comprehensive list is shown in Table 139.1. The effects of RT on the cardiovascular system are detailed in the latter section.

CHEMOTHERAPEUTICS

Anthracyclines

Reversible acute cardiotoxicity and delayed irreversible dilated cardiomyopathy (CM) are uncommonly seen with the use of anthracyclines. The reversible acute toxicity presents as a myocarditis and occasionally with evidence of pericarditis, and may lead to nonischemic CM (NICM) with or without concomitant arrhythmias. This acute toxicity is rarely a fatal complication of anthracycline therapy.

The delayed CM presents as fatigue, dyspnea on exertion, orthopnea with sinus tachycardia, S3 gallop, pedal edema, pleural effusions, and elevated jugular venous distention. Nevertheless, these classic clinical features of NICM are often late manifestations. In order to reduce the incidence and/or severity of delayed CM, keen clinical recognition of factors that may lead toward a NICM include monitoring cumulative dose (CD) of agent used, early detection strategies, limiting total cumulative dose, and the timely use of adjunctive cardioprotective agents or modified infusional or pegylated regimens/drugs are important.

The risk of anthracycline CM depends on CD received. Historically, a 5% risk is seen at 400 to 450 mg/m² for doxorubicin, 900 mg/m² for daunorubicin, 800 to 935 mg/m² for epirubicin, and 223 mg/m² for idarubicin.³ Cofactors for cardiotoxic risk include mediastinal irradiation, which includes the heart, older (particularly >70 years) or younger (<15 years) age, known coronary artery disease, antecedent valvular disease, and hypertension. Concurrent monoclonal antibodies (i.e., HER2 antibodies) appear to potentiate anthracycline-induced CM, whereas other chemotherapeutic agents may have independent or synergistic cardiac effects when used in combination.

The diagnosis of an NICM in the setting of a history of anthracycline exposure is generally made by comparing serial left ventricular function studies. Several modalities can be employed including multigated radionuclide imaging, two-dimensional transthoracic echocardiography, and cardiac magnetic resonance imaging (cMRI).⁴⁻⁶ Nevertheless, it is imperative that an ischemic CM be excluded. Regardless of the modality employed, a left ventricular ejection fraction (LVEF) of $\geq 50\%$ is considered within normal range. A threshold CD has not been identified below which left ventricular dysfunction is not seen.^{7,8} A low LVEF regardless of symptom burden remains a contraindication for anthracycline use.

Echocardiograms and cMRI can also evaluate other structural changes of the myocardium in the setting of CM. Typical progression on serial imaging includes left ventricular diastolic dysfunction and, later, left ventricular systolic dysfunction, particularly affecting septal wall motion. Initially, the left ventricle is not enlarged or only moderately enlarged; with complete development of CM, there is multisegment hypokinesis and evidence of muscle wall thinning. The electrocardiogram (ECG) findings associated with anthracycline-induced CM include sinus tachycardia, low voltage, poor R-wave progression, and nonspecific T-wave changes. Even sinus tachycardia alone is a relatively late finding, such that serial ECGs are of little value in early detection.

Early detection of anthracycline-induced CM may be important in preventing overt CM. As described above measurement of LVEF by multigated radionuclide imaging, transthoracic echocardiogram, cMRI can be utilized. In two small prospective studies of transthoracic echocardiogram and cMRI, both modalities reported that it was possible to distinguish patients who had developed CM from others by LVEF measures at baseline and at 200 to 300 mg/m² of doxorubicin.^{9,10} A fall of $\geq 10\%$ at 200 mg/m² had 72% specificity and 90% sensitivity in detecting later CD. At a dose of 300 mg/m², 50% had developed a change in LVEF $>10\%$ with 25% of patients with evidence of myocardial structure changes. Long-term follow-up data is lacking in the later publication. Others have examined the strategy of serial LVEF retrospectively and demonstrated that the overall costs of early detection were less than the medical costs of overt CM management.¹¹ Therefore, it is generally accepted that all patients prior to undergoing anthracycline-based regimens should have a baseline measure of LVEF; the modality employed is often left to the physician. Subsequent follow-up evaluation of the myocardium is often driven by symptoms as no large prospective studies have demonstrated an overall survival advantage to surveillance and are unlikely to given the low incidence of CM and high number needed to screen.

Additional serologic methods of CM detection include measurement of levels of brain natriuretic peptide, a peptide synthesized by the myocardium that reflects the degree of heart failure, and cardiac troponin T levels, a measure of active myocardial damage.¹² Brain natriuretic peptide and to a lesser extent troponin T levels are encouraging serologic markers and may correlate with subclinical left ventricular diastolic dysfunction; however, prospective sequential serologic and radiographic studies are lacking. Percutaneous endomyocardial biopsy of the right ventricle, the historic gold standard for anthracycline-induced CM, may demonstrate characteristic histologic features that include loss of myofibrils, distention of the sarcoplasmic reticulum, and vacuolization of the cytoplasm; however, with more conventional technologies, this modality is rarely used.

Aside from early detection, other strategies to reduce the incidence of CM are the use of low-dose or infusional drug schedules in an attempt to reduce peak drug dose delivery, and the use of liposomal formulations.^{13,14} Liposomal formulations have been shown to permit higher CD and lower CM at the same dose. Data remains limited, however, regarding tumor response and survival.

TABLE 139.1

Other Less Common Drugs Associated with Cardiovascular Toxicities

Drug	Incidence	Cardiovascular Effects	Onset
Arsenic trioxide	3%–24%	QT, VR	Acute
Busulfan	2%	CHF	Late
Carmustine	Rare	H, AR, CP	Acute
Cisplatin	Rare	H, AR, VR, CP	Acute
Cytarabine	Rare	AR, VR, CP, P, CHF	Acute, subacute
Etoposide	1%–2%	H	Acute
Gemcitabine	Rare	AR, CHF	Acute
Interferon	Rare	H, AR, CP, MI, CHF	Acute, subacute
Interleukin-2	Dose-dependent	H, AR, CP, MI	Acute, subacute
Mitomycin ^a	10%	CHF	—
Pentostatin	3%–10%	AR, VR, CP, MI, CHF	Subacute
Sunitinib	15%–28%; rare	HBP, CHF, MI	Acute, subacute
Sorafenib	20%; rare	HBP, CHF, MI	Acute, subacute
Teniposide	2%	H	Acute
Tretinoin ^a	14%–23%	H, AR	Acute, subacute
Vinca alkaloids	10%;	H	Acute, subacute

QT, prolonged QT; VR, ventricular arrhythmia; CHF, congestive heart failure; H, hypotension; AR, atrial arrhythmia; CP, chest pain; P, pericarditis; HBP, hypertension; MI, myocardial infarction.

^a Retinoic acid syndrome.

The iron-chelating cardioprotectant dexrazoxane decreases the risk of clinical CM in patients who have received doxorubicin doses of ≥ 300 mg/m².¹⁵ The American Society of Clinical Oncology recommends the use of dexrazoxane in this setting.¹⁶ However, American Society of Clinical Oncology guidelines do not advocate dexrazoxane in the several important situations including adjuvant regimens, CD < 300 mg/m², pediatric patients, or in high-risk disease patients. Clinical data are also insufficient to recommend dexrazoxane with other anthracyclines, except epirubicin in metastatic breast cancer. A pivotal study in pediatric acute lymphoblastic leukemia may serve to change these recommendations. With a median follow-up of 5.7 years, this prospective trial revealed no significant impact on 5-year event-free survival, whereas dexrazoxane reduced serial troponins during therapy.¹⁷

The management of anthracycline-induced CM is similar to other causes of NICM.¹ Angiotensin-converting enzyme inhibitors, β -blockers, and diuretics are commonly used. As pointed out in long-term pediatric studies, these agents do not cure or permanently control the CM. Rather, the CM may become progressive despite these agents after more than 5 years. The only curative therapy remains cardiac transplantation.

The mechanism of anthracycline CD is not fully elucidated, but there is emerging evidence that cardiomyocyte apoptosis may play a major role.¹⁸ The production of free radicals generated during cardiomyocyte metabolism of the anthracycline results in membrane lipid peroxidation, with the consequent activation of the extrinsic and intrinsic apoptotic pathways. It is thought that free radicals are generated by enzymatic reduction of the anthracycline quinone ring and by formation of iron-anthracycline complexes. The intrinsic antioxidant defense of the cardiomyocyte is more limited than other organs, leading to its apparent selective toxicity profile. In a knockout mouse model suggesting that a deficiency of the HFE gene (associated with hereditary hemochromatosis) confers increased susceptibility to doxorubicin CD.¹⁹ They studied wild-type, HFE (+/-), and HFE (-/-) mice that were chronically treated with doxorubicin. Survival was significantly decreased in the HFE-negative mice, and cardiac iron concentration was

significantly elevated. Moreover, cardiac ultrastructure changes demonstrated iron-associated mitochondrial damage. Interestingly, in rats the site of cardiac oxidative toxicity was also the mitochondria of the cardiac cell by gene expression profiling, and using cMRI in an anthracycline-exposed mouse model, these lesions demonstrate gadolinium enhancement.^{20,21}

Cyclophosphamide

The classic cardiac toxicity of cyclophosphamide (CTX) is an acute myopericarditis associated with high-dose therapy. In the era of stem cell transplantation and vigorous hydration, irreversible hemorrhagic myonecrosis is rare. More commonly, patients develop an acute or subacute congestive heart failure that is generally reversible with medical management.

Prospective monitoring of 16 patients during CTX high-dose administration (7 g/m²) and serial enzymes (CPK, CPK-MB, and troponin I) did not become elevated using a fractionated drug administration schedule during 13 hours.²² The only positive findings were four cases of transient, mild diastolic, and systolic left ventricular dysfunction. Moreover, others have reported on early and late cardiac toxicity in a combination regimen using a CTX used in doxorubicin-naïve patients.²³ A total of 6 of 100 patients developed transient NICM. There were no acute cardiotoxic fatalities; late cardiotoxicity was not seen except in those patients requiring anthracycline salvage. Thus, with current administration guidelines used with high-dose therapy, CTX cardiotoxicity is uncommon ($< 10\%$ of patients treated), generally transient, and reversible.²⁴

Ifosfamide

Ifosfamide is an alkylating agent with similar properties to CTX. As a result of possible chemical cystitis, it is always administered with mesna. However, there is no evidence that mesna has any cardioprotective effect for CTX or ifosfamide. Similar to CTX, ifosfamide may cause a dose-related NICM, which is generally transient and

reversible. In a small report, no episodes of NICM were seen at 10 g/m² (0 of 6 patients), but at ≥16 g/m², a NICM was more seen in 40% (6 of 15 patients).²⁵ Clinical symptoms were delayed and presented subacutely (mean, 12 days; range, 6 to 23 days). They often resolved with medical management. These doses are rarely encountered in current clinical practice. A larger study prospectively studied high-dose CTX or ifosfamide-based regimens in 211 patients with metastatic breast cancer.²⁶ The cardiac effects were similar with the two agents: troponin I became positive in 70 patients (33%) and remained negative in 141. LVEF fell significantly and continuously after the first month among the troponin I-positive patients, and the degree of dysfunction correlated with the troponin I level. Those who developed NICM had prior or concurrent exposure to anthracycline.

Taxanes (Paclitaxel and Docetaxel)

The taxanes (paclitaxel and docetaxel) are important antimicrotubule agents derived from the yew tree (paclitaxel, *Taxus brevifolia*; docetaxel, *Taxus baccata*). The yew tree is known to be poisonous, and the taxine alkaloid byproduct can affect cardiac conduction and automaticity. Although not fully proven, the mechanism of paclitaxel cardiotoxicity appears to be related to its taxane ring structural similarities to yew taxine.

The cardiovascular effects of paclitaxel are multiple: asymptomatic bradycardia may be documented in almost one-third of patients, hypersensitivity reactions associated with the Cremophor EL diluent (which can be ameliorated with corticosteroids, histamine H₁, and H₂ receptor antagonists), and most importantly, life-threatening atrial and/or ventricular rhythm disturbances and/or conduction abnormalities in approximately 0.5% of patients. Rare ischemic events have also been reported.

Life-threatening arrhythmias may occur acutely during infusion, or delayed up to 14 days after treatment. These tend to occur after two or more treatment exposures, rather than with initial therapy. There does not appear to be a cumulative dosing threshold or limit, unlike that with anthracyclines. The grade 4 and 5 adverse cardiac events, atrial arrhythmias (tachycardia, flutter, and/or fibrillation) occurred in 0.24%, ventricular arrhythmias (tachycardia/fibrillation) in 0.26%, heart block in 0.11%, and ischemia in 0.29%.²⁷ Paclitaxel does not appear to cause a NICM.

In metastatic breast cancer, the incidence of NICM in patients treated with a taxane and anthracycline in combination has been studied. Eighty-two doxorubicin/taxane-naïve patients received doxorubicin 60 mg/m² followed by a 1- or 3-hour paclitaxel 200 mg/m² infusion (AT) administered every 21 days for six to seven cycles.²⁸ The change in LVEF was a median of 10% (to 52.5%) at a CD of doxorubicin 310 to 360 mg/m². A later phase 3 trial compared AT, doxorubicin (60 mg/m²) followed by paclitaxel (175 mg/m² in 3-hour infusion) versus doxorubicin/CTX (60/600 mg/m²; AC) in 375 patients.²⁹ Similarly, treatment was repeated every 3 weeks for six cycles (maximum doxorubicin, 360 mg/m²). Overt NICM was not statistically different in the two study arms (3% versus 1%; *p* = 0.62). However, a fall in LVEF (≥10% fall from baseline or ≥5% drop below the normal range) was significantly more frequent for AT (27%) versus AC (14%). Moreover, the risk of LVEF decrease was significantly greater for AT than AC at every cumulative doxorubicin dose level >180 mg/m². Importantly, paclitaxel was administered within 30 minutes of preceding doxorubicin. It is now apparent that the enhanced cardiac toxicity of the doxorubicin-paclitaxel combinations is related to prolonged doxorubicin elimination, resulting in a plasma level of up to 30% greater when paclitaxel immediately precedes doxorubicin or follows it by <1 hour. This risk has been shown to be mitigated when the interval between doxorubicin and taxanes was 4 to 24 hours or longer and has remained minimal at 7-years of follow-up.³⁰⁻³²

It is known that paclitaxel appears to facilitate the metabolic conversion of doxorubicin to the toxic metabolite doxorubicinol in

a human heart in vitro model.³³ The taxane docetaxel has a similar effect on doxorubicinol generation and both are attributed to allosteric interactions with cytoplasmic aldehyde reductases.

Docetaxel has not been generally associated with clinical cardiac toxicity, NICM, or enhancement of doxorubicin cardiac dysfunction. However, data suggests this is due to a lower cumulative anthracycline level rather than a different mechanism of drug interaction than paclitaxel. Both docetaxel and paclitaxel increase toxic cardiomyocyte doxorubicinol production in vitro. Therefore, the lack of docetaxel effect on doxorubicin clearance and the relatively lower doses of the drug used when combined with doxorubicin are now thought to be the explanation for the prior differences.

Fluoropyrimidines

5-Fluorouracil (5-FU) is a synthetic pyrimidine antimetabolite and an important backbone agent in many common solid tumors regimens. Its cardiac toxicity is manifested as angina, atrial/ventricular arrhythmias, myocardial infarction (MI), and cardiogenic shock. A prior history of coronary artery disease significantly increases the risk of complication (15.1% versus 1.5%, with no coronary artery disease history). Other predisposing factors include prior mediastinal irradiation and prior/concurrent exposure to other cardiac toxic medications. The reported incidence of cardiac toxicity was low at 1.6% among 1,083 patients.³⁴ Using a continuous infusion of 5-FU noted a higher incidence of cardiac toxicity (6%) as compared with other daily schedules of administration.³⁵ The addition of leucovorin to the continuous infusion regimen appeared to further increase the cardiotoxicity risk, but this has not been conclusively reproduced.³⁶

The oral fluoropyrimidine capecitabine also appears to have similar frequency of cardiotoxicity. In a large retrospective study of the cardiac toxicities (grade 3 to 4) reported in four large metastatic cancer trials, it was demonstrated that in 593 patients who received bolus 5-FU-leucovorin (Mayo Clinic regimen) or capecitabine (596 patients), the incidence of cardiotoxic events was 3% and 1%, respectively.³⁷

The mechanism of fluoropyrimidine cardiotoxicity is not well understood. It is possibly related to vascular spasm in reaction to the parent drug and its catabolites (fluoro-beta-alanine and fluoroacetate). In an in vitro model, 5-FU causes vasoconstriction in smooth muscle rings, which is reversible with nitrates.^{38,39} On electron microscopy, the changes appear to be in the small arterial endothelium.³⁹ Although coronary angiography following the 5-FU-induced angina did not reveal ongoing cardiac spasm, and in fact on autopsy evaluation, patients were found to have myocarditis.⁴⁰ Brachial artery ultrasound was performed prospectively in 60 patients receiving regimens containing 5-FU (*n* = 30) versus regimens not containing 5-FU (*n* = 30).⁴¹ Fifty percent of the patients showed artery contraction with 5-FU and none with other therapy. Interestingly, arterial tone recovered within 30 minutes, but reoccurred with retreatment in a high proportion. Pretreatment with glyceroltrinitrate, a vasodilator, abrogated the contractions in five patients.

Nevertheless, there is no known prophylactic regimen that can be provided to prevent the cardiotoxicity, and despite evidence to the contrary vasodilators do not necessarily relieve the symptoms once apparent. As a result, the optimal treatment is discontinuation of the fluoropyrimidine infusion and supportive measures with keen attention toward likely myocardial damage, with available cardiac support.⁴²

Monoclonal Antibodies

Trastuzumab and Lapatinib

Trastuzumab and lapatinib are humanized monoclonal antibodies that target p185^{HER2} (ErbB2 or HER2 receptor), a transmembrane

receptor tyrosine kinase of the epidermal growth factor family. This receptor protein is overexpressed or amplified in 20% to 30% of breast cancer and is associated with a poor clinical outcome. These antibodies are important agents in the management of primary and metastatic breast cancer.⁴³

Cardiac HER-2 is essential for normal embryonic and adult cardiac development and function, respectively. Using cardiac HER2-deficient mutant mice, a dilated CM begins in the second postnatal month and extends into adulthood of affected mice.^{44,45} Moreover, HER2-deficient cardiomyocytes were more susceptible to anthracycline toxicity. However, it was subsequently discovered that no cardiac toxicity was seen when trastuzumab preceded anthracycline-based adjuvant therapy in a prospective study.⁴⁶

Currently, trastuzumab is generally given after an anthracycline-based regimen. Evidence that supported that conclusion came from an independent Cardiac Review and Evaluation Committee that retrospectively evaluated data from seven phase 2/3 clinical trials.⁴⁷ They identified 112 patients with a CM (as defined by the Cardiac Review and Evaluation Committee) among 1,219 treated patients. Three studies used trastuzumab alone: 383 patients, of whom 17 (4%) had a CM. Among 114 patients who received single-agent trastuzumab as first-line therapy for metastatic disease, 3% developed a CM. In contrast, concurrent trastuzumab with anthracycline-based regimens or paclitaxel had an increased incidence of CM (27% versus 13%, respectively) as compared to chemotherapy alone (11% versus 1%, respectively) or antibody alone (3%).

The degree of cardiac impairment (New York Heart Association class III or IV) among those with CM was greatest for patients receiving trastuzumab plus concurrent anthracycline (64%) as compared with 20% receiving trastuzumab plus paclitaxel. Moreover, all trastuzumab plus paclitaxel patients had functional cardiac recovery with treatment as compared with only half the trastuzumab plus concurrent anthracycline patients. Risk factors for CM included older age and cumulative doxorubicin 300 mg/m² or more. Concurrent anthracycline (doxorubicin or epirubicin) appeared to be more hazardous than temporally separated trastuzumab therapy.

The diagnosis of trastuzumab-induced CM is often made by the detection of an asymptomatic decrease in LVEF and now considered to be an “on-target” adverse event. Similarly to anthracycline-induced CM, tachycardia may be an early clinical indicator, and the late constellation of a dilated and hypokinetic myocardium is a late manifestation. Dissimilar to anthracyclines, trastuzumab-induced CM does not depend on the CD of the antibody and is often self-limited with supportive measure. For example, with echocardiography follow-up, the use of adjuvant trastuzumab had no additive adverse effect when used after anthracycline therapy.⁴⁸ To date, there remain no definitive predictive tests other than documenting a low LVEF prior to therapy and no preventive measures to ameliorate the development of trastuzumab-induced CM. Lastly, concurrent trastuzumab-anthracycline exposure is contraindicated. Guidelines have restricted eligibility to those with LVEF of $\geq 55\%$ and delay of initiation to 1 to 2 months if following anthracyclines.⁴⁵ In such criteria, trastuzumab was discontinued in only 4.3% of such patients for CM. In practice, active monitoring of LVEF is recommended every 4 months during therapy and every 6 months thereafter for up to 2 years.

Because of the previously described cardiac toxicity associated with trastuzumab, T-DM1, a recently approved antibody drug conjugate against HER-2 and used in HER-2-positive breast cancer while in development, was carefully assessed for CM by surveillance imaging. In 882 patients treated with T-DM1, defined cardiac-specific events were seen in only 1.5% (13 patients) with nearly all of the events being low grade.⁴⁹ Further clinical testing in combination strategies are ongoing, but lessons learned from the trastuzumab era will hopefully reduce the incidence of CM as the drug moves forward into the up-front setting.

Rituximab

Rituximab is a CD20 monoclonal antibody widely used in the management of non-Hodgkin's lymphoma (HL). In early development of the antibody, an initial concern for CM was seen that was felt to be related to the rate of infusion; however, those findings went unfounded when used in combination regimens.⁵⁰ There have been no long-term effects from rituximab; however, arrhythmias with cardiac death have been reported related to infusion reaction most commonly seen with the initial infusion but at a rate of $<0.07\%$.^{51,52}

Bevacizumab

Bevacizumab is a humanized monoclonal antibody that inhibits the vascular endothelial growth factor. Currently, bevacizumab is approved for use in combination with 5-FU-based chemotherapy in metastatic colon cancer. A recent US Food and Drug Administration black box warning was placed on bevacizumab after an increase in risk of MI, angina, and heart disease. The risk was greatest in those who are older than 65 with prior arterial events. The risk of grade 2 to 4 CM was 1.2% when used as a single agent, but increased to 3.8% in those with prior anthracycline exposure.

RADIOTHERAPY-ASSOCIATED CARDIAC SEQUELAE

In the past, cardiac complications resulting from mediastinal irradiation were considered rare and insignificant.⁵³ Since the mid-1960s, when follow-up information on a large number of patients who had been cured of HL with higher doses of radiation became available, the heart has no longer been considered radioresistant.⁵⁴ Radiation-associated heart disease has now been clinically described and the pathologic features of the damage have been described with regard to the coronary arteries and all three layers of the heart.

Pericarditis and pericardial effusion have been regarded as the most common side effects of cardiac irradiation.⁵⁵ However, modern techniques of irradiation, dose decrease, and reduction of the heart volume irradiated in most malignancies have substantially reduced the frequency of this complication. At the same time, evidence has accumulated to suggest that ischemic heart disease resulting from radiation-induced coronary heart disease (CHD) is the most concerning long-term risk of cardiac irradiation, particularly in patients at high-risk for ischemic disease.⁵⁶⁻⁶⁰

The clinical spectrum of radiation-induced heart disease involves most structures of the heart and is summarized as follows:

- Pericardial disease
- Acute pericarditis during irradiation
- Delayed acute pericarditis
- Pericardial effusion
- Constrictive pericarditis
- Myocardial dysfunction
- Valvular heart disease
- Electrical conduction abnormalities
- CHD

Although the pathologic and clinical manifestations of radiation-induced heart disease may overlap in many patients, they are discussed separately in the following paragraphs.

Pericardial Disease

Incidence

The risk of radiation-induced pericardial disease depends on the dose given and on the volume of the heart irradiated.^{61,62} Even

when a large volume of the heart ($\geq 60\%$) is irradiated ≤ 40 Gy, the risk for mild pericarditis is $< 5\%$, and severe pericarditis is rare.⁶³ Smaller heart volumes (20% to 30%) may tolerate up to 60 Gy, with an expected 2% risk of mild pericarditis. In the past, when the whole pericardium was irradiated, the pericarditis incidence was 20%, but when most of the left ventricle was excluded, it was reduced to 7%.⁶⁴ An updated analysis of these patients showed a sharp decrease in the risk of death from cardiac complications other than acute MI for patients who received mediastinal irradiation after 1972, reflecting the change in cardiac shielding.⁵⁹ Indeed, all series that showed a high risk of pericarditis are of patients treated with a radiation technique, energy, and total dose and fractionation that are no longer considered to be an acceptable standard of care in most centers.⁵⁸ With current RT techniques for HL and breast cancer, pericarditis is an infrequent event.

Acute Pericarditis During Radiation

Acute pericarditis during the course of RT is rare. It is almost always associated with massive mediastinal tumors adjacent to the heart. The signs and symptoms are of acute nonspecific pericarditis with chest pain, fever, and often ECG abnormalities. It does not lead to a significant risk of late pericardial damage and is not an indication for interrupting the radiation course.^{53,56}

Delayed Pericarditis

Radiation-induced pericarditis typically occurs within the first year after mediastinal irradiation. The common range is from 4 months to several years after treatment.^{53,65} Pericardial disease presents either as an acute pericarditis, as a pericardial effusion that may be asymptomatic, or as a combination of both. The symptoms of delayed acute pericarditis are indistinguishable from those of other types of pericarditis and usually consist of fever, pleuritic chest pain, pericardial friction rub, ST-T segment changes, and a decrease of the QRS voltage in the ECG. Pericardial effusion may be large and manifest as an enlarged cardiac silhouette.⁶⁶ Most cases of radiation-induced pericarditis and pericardial effusion resolve spontaneously, usually within 16 months. Approximately 20% of patients with delayed pericarditis progress within 5 to 10 years to develop symptomatic constriction requiring pericardiectomy. This is very rare in current practice. Radiation-induced hypothyroidism should also be considered in the etiology of pericardial effusion after mediastinal irradiation.⁶⁷

Treatment

Careful cardiac evaluation and monitoring with echocardiography and radionuclide ventriculography should be performed whenever radiation-induced heart disease is suspected.⁶⁶⁻⁶⁸ Patients with mild symptoms and no hemodynamic compromise can be followed without treatment or can receive symptomatic therapy with salicylates or other nonsteroidal anti-inflammatory agents. Symptomatic pericardial effusion or clinical evidence for hemodynamic compromise warrants a drainage procedure. Pericardiocentesis with or without percutaneous placement of an indwelling catheter is successful in the majority of patients. Failure to relieve tamponade with pericardiocentesis, recurrence of effusion, or the presence of symptomatic constrictive pericarditis requires pericardiectomy. This is rarely required with current RT practice.

Myocardial Dysfunction

When myocardial dysfunction is detected after standard-dose mediastinal irradiation, it is typically mild or subclinical.^{52,58,69} In patients who were studied 15 days after mediastinal irradiation, a transient decrease in LVEF was observed. Complete recovery of ejection fraction 2 months after irradiation and no additional change in patients who were also receiving doxorubicin were documented.⁷⁰ Noninvasive studies using echocardiographic and

radionuclide angiography detected subtle left ventricular dysfunction in patients with HL evaluated a few years after mediastinal irradiation.⁷⁰ A study of asymptomatic patients who were treated with mediastinal irradiation for HL at a young age showed reduced average left ventricular dimension and mass suggestive of restricted CM in 42% of patients.⁷¹ The majority of patients with abnormal ventricular function findings, however, do not have clinical heart failure.⁷¹ The magnitude of the potential contribution of cardiac irradiation to the risk of doxorubicin-induced CM is not well established. Some data suggest potentiation of anthracycline-induced cardiotoxicity when combined with RT. Yet the histopathologies of radiation heart disease and anthracycline heart disease are different, and the combined effects are probably additive rather than synergistic.⁷² It was reported that doxorubicin-induced decrease in LVEF was aggravated with concurrent mediastinal irradiation.^{73,74} In programs of combined modality therapy for HL that included relatively low doses of doxorubicin (up to 300 mg/m²) and mediastinal irradiation of 20 to 40 Gy, no significant clinical myocardial dysfunction was detected.⁷⁵

Symptomatic myocardial dysfunction after a radiation dose that does not exceed 60 Gy is rare. The few cases described with intractable heart failure had myocardial fibrosis as part of pancarditis, a generalized process with damage to all three layers of the heart. The hemodynamic pattern is usually of restrictive CM and is difficult to distinguish from constrictive pericarditis.

Valvular Disease

Clinically significant valvular heart disease resulting from mediastinal irradiation is relatively uncommon.⁷³ Analysis of 635 patients treated for HL before the age of 21 years revealed 29 patients in whom new murmurs of indeterminate significance developed. Of those, 14 received mediastinal doses of 44 Gy or more, and 2 patients who received high-dose irradiation died of valvular heart disease.^{53,54} When echocardiographic studies were performed in asymptomatic patients with HL > 7 years after mediastinal irradiation, valvular abnormalities were detected in 25% to 33% of the patients, although there was rarely any clinical significance. An echocardiographic study of 294 asymptomatic patients who received mediastinal irradiation disclosed moderate or severe regurgitation of the aortic valve in 5.0% of patients, of the mitral valve in 3.4%, and of the tricuspid valve in 1.4%. Four percent of the patients had aortic stenosis.⁷⁶ Valvular disease, particularly involving the aortic valve, increased with time after irradiation. Of 73 asymptomatic patients evaluated > 20 years after mediastinal irradiation, 60% had mild or more aortic regurgitation and 16% had aortic stenosis. It is important to note that radiation dose, volumes, and technique of radiation delivery have markedly changed during the last three decades, and the lower prevalence of valvular disease in patients treated at < 20 years may reflect those changes.⁷⁷ In a retrospective study of 415 patients that were irradiated from 1962 to 1998, 6.2% of patients developed clinically significant valvular dysfunction at a median of 22 years.⁷⁴ Of interest is a report from Norway that showed a significantly higher risk of cardiopulmonary complications for female subjects after radiation for HL.^{78,79} The mean interval from irradiation to detection of valvular disease in asymptomatic and symptomatic patients was 11.5 and 16.5 years, respectively.⁸⁰ Patients that received mediastinal RT and an anthracycline-containing chemotherapy had significantly more valvular disorders than patients receiving RT with no anthracyclines.⁵⁹

Electrical Abnormalities

Many ECG abnormalities were recorded years after mediastinal irradiation, the most common clinically significant abnormality being complete atrioventricular block.^{68,81} Slama et al.⁸² reported that radiation-related atrioventricular block was typically infranodal and occurred at long intervals (mean of 12 years), after radiation

doses above 40 Gy, most frequently in patients with abnormal conduction on ECG before the advent of complete block, and in those who had other radiation-related cardiac abnormalities.

Another aspect of RT and heart disease relates to the management of patients with implanted cardiac pacemakers.⁸³⁻⁸⁶ Although transient interference from electromagnetic noise (with the exception of betatrons) is not a problem in properly functioning RT equipment, pacemaker-dependent patients should be closely observed during the first treatment with a linear accelerator.⁸⁷⁻⁹⁰ Placing the pacemaker in an unshielded RT field may cause cumulative damage to the pacemaker components. The absorbed dose to the pacemaker should be estimated before treatment. If the total dose to the pacemaker might exceed 2 Gy, the pacemaker function should be checked weekly to detect any indicator of damage that may require replacement of the device.⁸⁷

Coronary Heart Disease

Experiments in laboratory animals,^{91,92} analysis of pathologic specimens,⁹³ clinical observations,⁹³⁻⁹⁵ and since the 1990s, long-term risk analysis in large series of patients treated for HL⁵⁷⁻⁵⁹ all indicate that mediastinal irradiation may facilitate the development of CHD.⁵³

Stenosis at the origin of the coronary arteries appears to be a common finding for radiation-associated CHD.^{57,90-95} After mediastinal irradiation, there is a greater likelihood for right coronary or left main or left anterior descending coronary artery lesions as opposed to circumflex lesions, which might be due to the fact that the former vessels, particularly at their origin, receive more radiation.^{95,96} Coronary spasm after RT has also been documented in patients in whom acute MI developed with patent coronary arteries.⁹⁴

Although only approximately 1% to 2% of patients with HL in series that analyzed death from MI after RT for HL actually died of MI, the observed risk in all series was higher than expected (Table 139.2).

Current involved field RT techniques, better fractionation schemes, and modern equipment deliver smaller doses of radiation to the coronary arteries and may have a lower risk of promoting CHD.⁷⁹ In a study by Boivin et al.,⁹⁷ the relative risk of acute MI was reduced from 6.33 for patients treated during the years 1940 to 1966 to 1.97 (with no significant difference from unity) for patients irradiated from 1967 to 1985.

Hancock et al.^{58,59} analyzed the risk of cardiac disease in patients with HL who were treated at Stanford University Medical Center from 1961 to 1991. In patients that were irradiated prior to age 21 years, the relative risk for death from acute MI was 41.5 and that the actuarial risk of fatal or nonfatal MI at 22 years was 8.1%.⁵⁸

Of note, all deaths in this study occurred in patients who received relatively high doses of radiation (42 to 45 Gy) to the mediastinum. When the Stanford analysis was extended to include 2,232 patients with HL (of all age groups), the relative risk for death from acute MI was 3.2.⁵³ This study showed that patients younger than 20 years who received high-dose irradiation had the highest relative risk, that the risk decreases with increasing age, and that patients older than 50 years had no increased risk. However, these results contrast with data published by other investigators,⁹³ suggesting an increased risk of acute MI for the older age groups. The small number of patients in the Stanford study who received radiation doses of <30 Gy did not allow an adequate analysis of the dose effect. The average interval between HL treatment and death from acute MI was 10.3 years, but risk was already significant during the first 5 years after treatment and remained elevated throughout the follow-up period (>20 years).⁵³

Two European studies analyzed the ischemic heart disease in patients with HL who received standard fractions and dose (30 to 42 Gy) of mediastinal irradiation.^{60,61} Both studies demonstrated an increase of ischemic heart disease after mediastinal irradiation. Of importance, a multivariate analysis of risk factors in the Rotterdam study showed that increasing age, gender (male), and a pretreatment cardiac medical history were significant for developing ischemic heart disease. Treatment-related parameters did not affect the risk.⁶⁰ In a study from Zurich, a detailed analysis of the effect of other CHD risk factors on the radiation-induced risk was performed. The study showed that, although the risk of CHD after irradiation increased by 4.2 for all patients, in irradiated female patients and in all irradiated patients without other cardiovascular risk factors (smoking, hypertension, obesity, hypercholesterolemia, diabetes), the risk remained as expected in the normal population.⁶⁰ In a recent study of 1,474 survivors of HL treated mostly with RT with or without chemotherapy, hypercholesterolemia was the most significant independent risk factor for developing CHD.⁵⁷ These data suggest that aggressive modification of CHD risk factors is warranted in patients who received mediastinal RT and/or anthracycline-containing chemotherapy.

Anthracycline-containing regimens like doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD), and rituximab, CTX, doxorubicin, vincristine, and prednisone, with or without RT, are the mainstay of current treatment of HL and non-HL, respectively. Yet, only recently, serious concerns regarding anthracycline-related risks (with or without RT) to the coronary arteries have been documented.⁹⁸ Aviles et al.⁹⁸ studied 476 patients with HL treated with anthracycline-containing chemotherapy and no RT. At a median follow-up of 11.5 years, 9% of patients who received ABVD had a clinical cardiac event and 7% had a cardiac-related death. The standard mortality ratio for cardiac death for patients who received

TABLE 139.2

Relative Risk of Mortality from Myocardial Infarction After Mediastinal Irradiation for Hodgkin's Lymphoma

Study (Ref.)	Center	No. of Patients	Lethal Myocardial Infarctions	Relative Risk	95% Confidence Interval
Boivin et al. ⁹⁷	Multiple	4,665	68	2.6	1.1-5.9

Swerdlow et al. ⁶⁴	Britain	7,033	168	2.5	2.1-2.9

^a Includes one patient who died of cardiomyopathy.

^b Myocardial infarction or sudden death.

doxorubicin was 46.4 (95% confidence interval = 28.9 to 70.1), and the absolute excess risk was 39.⁹⁸

Reduction of the radiation volume from even involved-field to the new concept of involved-site RT may have a significant impact on the risk as well the reduction in the recommended dose in HL.⁹⁹

The largest and most recent analysis of MI mortality risk after treatment for HL is a collaborative British cohort study of 7,033 patients.⁶⁴ This study included 3,590 patients who received RT without anthracyclines, 3,052 patients who received chemotherapy with supradiaphragmatic RT, and 1,744 patients received anthracycline regimens and no RT. For the whole group of survivors of HL, the death from MI was statistically significantly more than expected: standardized mortality ratio (SMR) of 2.5 with an absolute excess risk of 125.8. The risk was higher for male patients. The relative risk of death from MI decreased sharply with older age at first treatment, but as expected, the absolute excess risk increased with age. The 20-year cumulative risk of MI mortality for patients treated at age younger than 35 was 1.8%. The risk of death during the first year after treatment was four-fold compared with the general population, and it was higher for patients treated before 1980.¹⁰⁰

Of particular concern are the new data regarding chemotherapy alone.^{64,95} In the British study,⁶⁴ the risk of death from MI was statistically significantly increased for patients who had received anthracyclines (SMR of 2.9) and especially those treated with ABVD (SMR of 9.5). These data remained significantly elevated for patients who received those chemotherapy regimens and no RT (ABVD, no RT; SMR of 7.8). The authors suggest that the risk was particularly high for ABVD (compared with other doxorubicin-containing regimens) because ABVD alone was virtually always given for a full six cycles. The increased risk for patients treated with anthracyclines was primarily during the first year after treatment and the highest risk was in young patients (≤ 35 years). MI mortality risk was also significantly increased for treatment with vincristine with or without radiation.

Long-term mortality data from three trials, which randomized patients with breast cancer to receive postmastectomy RT as opposed to no additional treatment, demonstrated a higher incidence of cardiac death in the irradiated group.¹⁰¹⁻¹⁰³ The excess in mortality did not appear until after 10 years posttreatment.^{104,105} In one study, the increase in mortality risk was significant only in women who were irradiated for tumors in the left breast.¹⁰⁴ It was also increased in patients treated with orthovoltage irradiation, as opposed to those treated with more modern supervoltage equipment.¹⁰

A recent study from The Netherlands of 4,414 10-year survivors of breast cancer who were treated from 1970 through 1986 recorded both cardiovascular morbidity and mortality events.¹⁰⁶ It showed that radiation to the breast alone is not associated with increased risk of cardiovascular disease. Similar to other studies,^{107,108} it also documented that the increased risk of MI that was noted in patients treated prior to 1980 has disappeared with more recent RT techniques.

Prophylactic irradiation of the internal mammary nodes using a single anterior photon beam (hockey stick technique) or large tangents, which may deliver a high dosage to the heart,¹⁰⁹ is not indicated in most patients irradiated for breast conservation or postmastectomy.¹⁰¹ Techniques that reduce the risk of irradiating the coronary arteries have been developed; they include the

prone breast technique¹¹⁰ and use of three-dimensional computed tomography planning and intensity-modulated RT.¹¹¹ Patients with breast cancer irradiated with modern techniques are unlikely to receive a significant dose of radiation to the coronary arteries.¹⁰⁹⁻¹¹⁵ Proton therapy may also reduce the exposure of the heart in selected patients with breast cancer.¹¹⁶

In patients with breast cancer, conventional-dose doxorubicin-containing chemotherapy used as an adjuvant in combination with local-regional irradiation was not associated with a significant increase in the risk of cardiac events. However, higher doses of adjuvant doxorubicin were associated with a three- to four-fold increased risk of cardiac events. This appears to be especially true in patients treated with higher dose volumes of cardiac irradiation.¹¹⁷ Interestingly, in one recent large-scale study, patients with breast cancer who were treated with CTX, methotrexate, and 5-FU and RT had a significantly higher risk of congestive heart failure compared with patients treated with RT alone.

The radiation threshold for an increased risk of CHD has not been determined. Lederman et al.¹¹⁸ reported that patients with seminoma who received a relatively low dose of mediastinal irradiation (median, 24 Gy) had more ischemic heart disease than a similar group of patients whose mediastinums were not irradiated. It should be noted, however, that the observed cardiac risk in the irradiated group did not differ significantly from the expected risk of a comparable normal population.

Monitoring and reduction of other contributing CHD risk factors in patients who received mediastinal irradiation should be part of the follow-up of patients who underwent mediastinal irradiation.^{119,120} However, the value of routine noninvasive or invasive cardiac studies in asymptomatic patients has not been fully determined. In a recent screening study of 294 patients that received mediastinal radiation (median dose, 44 Gy) from 1960 to 1995, 21% of screened patients had abnormal ventricular images at rest.⁵⁹ During stress testing that included ECG and radionuclide perfusion, 14% showed abnormalities in one or both tests. Based on these tests, 40 patients underwent coronary angiography and 55% of them (7% of the screened population) had $\geq 50\%$ stenosis. The risk of a cardiac event in those patients was significantly related to abnormal stress testing, older age, RT given in early period, and higher RT dose given to the mediastinum.

Early detection of coronary artery disease should be encouraged, particularly in patients irradiated with high RT dose (practiced mostly in the past) and/or those with other CHD risk factors.^{56,121-123} because angioplastic or surgical intervention may be indicated in special anatomic or clinical situations. Successful treatment of radiation-induced coronary disease with bypass surgery and with stenting or angioplasty has been reported.¹²⁰ In some cases, surgery may be technically difficult because of mediastinal and pericardial fibrosis.⁸⁹

CONCLUSION

It is hoped that increased awareness and knowledge about potential cardiotoxicity from chemotherapy and RT will enable physicians to adequately monitor patients and modify therapy so as to minimize serious acute and chronic cardiac sequelae. The growing information about late cardiac effects should facilitate early diagnosis and therapeutic intervention for the benefit of previously treated patients.

140 Hair Loss

Joyson J. Karakunnel, Ibrahim M. Qazi, and Ann M. Berger

INTRODUCTION

Hair is an important aspect of a person's self-image. During many cancer treatments, hair is adversely affected and this can have a profound negative impact on patients. "The loss of hair is an extremely traumatic experience precisely because it is the symbolic precursor to the loss of self. This raises the psychological terror and consequent fear that the known self will no longer exist."¹ The incidence of alopecia is exceptionally high and is currently ranked third among the most common side effects of chemotherapy, directly behind nausea and vomiting.² In addition, cancer-related alopecia is not only due to chemotherapy but also to metastatic disease and the presentation of different malignancies. Also, with the introduction of biologic agents, chemotherapy-induced alopecia is no longer limited to cytotoxics, as anecdotal reports of biologic agents inducing alopecia are increasingly reported.³

Hair loss can be an immense burden both psychologically and physically. Currently, there are modalities to help alleviate the physical and emotional issues that are involved with alopecia. In addition, several experimental treatments are being explored. This chapter will focus on chemotherapy-induced alopecia.

ANATOMY AND PHYSIOLOGY

Normal hair is divided into three parts: the infundibulum, the isthmus, and the inferior segment (deepest area). Other structures attached to the hair follicle include the sebaceous gland and arrector pili muscle. The hair follicle consists of the outer and inner sheath, cuticle, hair shaft, hair matrix, dermal papilla, and follicular sheath.

Hair growth is cyclical in nature. The three phases during the hair life cycle are anagen, telogen, and catagen. The majority of the time, most hair is in the anagen phase. During this phase, hair undergoes mitotic changes and rapid cell growth. During telogen, hair is dormant and mitotic activity is arrested. This phase lasts from 3 to 6 months. During the catagen phase, the hair root is separated from the hair bulb, pigment storage is terminated, and the club-shaped root end is pushed out from the bulb. Less than 1% of hair is in this phase at any time.⁴ Chemotherapy-induced alopecia frequently occurs during anagen. Hair exposed to chemotherapy during this phase is much thinner and more brittle due to the suppression of cell proliferation.

Several types of alopecia are associated with problems in the transition from anagen to telogen. Hair lost during this period is called *telogen effluvium* or *hair breakage*. The five functional mechanisms of telogen effluvium are immediate anagen release, delayed anagen release, short anagen syndrome, immediate telogen release, and delayed telogen release.⁵ Immediate anagen release is the most important mechanism with respect to chemotherapy. Normally, hair bulbs are released 4 to 6 weeks after the onset of anagen. The mechanism consists of hair being prematurely forced into telogen, leading to a greater amount of shedding. This mechanism is seen during drug-induced alopecia and severe illness.

CLASSIFICATION

Classification for hair loss has been divided into several different categories. Telogen effluvium can be subdivided into three categories depending on the amount of time during which hair shedding occurs. These subcategories are acute telogen effluvium, chronic diffuse telogen effluvium, and chronic telogen effluvium. During acute telogen effluvium, hair loss begins to occur approximately 2 to 3 months after the insult. Some of the causes include fever, surgery, or hemorrhage. Hair growth resumes approximately 3 to 6 months after the insult has subsided. Chronic diffuse telogen effluvium is defined by shedding that is present for >6 months. Some of the causes are thyroid disease, acrodermatitis enteropathica, malnutrition, iron-deficiency anemia, pancreatic disease, zinc deficiency, and drug-induced alopecia. Hair loss associated with thyroid disease, zinc deficiency, and iron-deficiency anemia begins to resolve once therapy is initiated. Finally, chronic telogen effluvium is a diagnosis of exclusion once the possibilities for chronic diffuse telogen effluvium have been considered. When evaluating a patient with a possible chronic telogen effluvium, androgenetic alopecia should be excluded.

Chemically induced alopecia is due to immediate anagen release and destruction, known as *hair follicle dystrophy*. Intravenously administered chemotherapy usually leads to greater hair loss compared to orally administered chemotherapy. Hair loss generally begins approximately 2 to 4 weeks after treatment and hair usually begins to return 3 to 6 months later.² There are several causes for alopecia, some of which are listed in Table 140.1. In addition, multiple other animal models are being developed to characterize alopecia that is associated with different chemotherapeutic agents.⁶ Specifically, doxorubicin has been shown to inhibit angiogenesis in a mouse model, which may play a role in alopecia.

Some malignancies have been directly linked to alopecia. Mixed reports have appeared, indicating an association of prostate cancer with male pattern baldness. Some studies have shown that the risk of prostate cancer is as high as 50% in men who have male pattern baldness.⁷ Conversely, other studies have found no association between male pattern baldness and prostate cancer. In addition, follicular mycosis fungoides, a rare disease associated with a poor prognosis, should be differentiated from alopecia mucinosa when considered in the setting of alopecia. These illnesses should be carefully considered when a patient presents with hair loss.

DIAGNOSIS

The diagnosis of alopecia should begin with a thorough history and physical examination. Patients should be asked about the onset of alopecia. Drug-induced alopecia can be differentiated by considering the time elapsed since medication was initiated and alopecia started. In addition, the pattern of the hair loss should be considered as a physical finding that can help in etiology of the hair loss. Clinical examination revealing bitemporal recessions can help to narrow the diagnosis between telogen effluvium and androgenetic alopecia.

TABLE 140.1

Etiologic Classification of Alopecia

Telogen effluvium
Anagen effluvium
Follicular mucinosis (anecdotal reports)
Acute myeloid leukemia
Squamous cell cancer of tongue
T-cell lymphoma
Lung cancer
Alopecia neoplastica (anecdotal reports)
Breast cancer
Gastric cancer
Trophoblastic tumor
Androgenetic alopecia

Several tests can be conducted if a diagnosis of telogen effluvium is being considered. A blood workup should include, but not be limited to, blood count, thyroid function studies, rapid plasma reagin, Venereal Disease Research Laboratory, antinuclear antibody, and zinc or other nutritional deficiencies. In addition, clinical tests can determine whether the patient exhibits telogen effluvium such as hair-pull test and phototrichogram.

The most important test that helps to differentiate chronic telogen effluvium and androgenetic alopecia is the 4-mm punch biopsy. Biopsy is used to obtain a ratio of the amount of hair that is in anagen and telogen. This test has a diagnostic accuracy of 98%.⁵ In addition, a biopsy helps to differentiate between a follicular mycosis fungoides and metastatic tumor.

TREATMENT

Several treatments in varying stages of research and with varying efficacies can be used in the treatment of chemotherapy-induced alopecia (Table 140.2). They include scalp cooling, minoxidil, immunomodulator ammonium trichloro-9-dioxoethylene-O,O'-tellurate (AS101), scalp tourniquet, α -tocopherol, pulsed electrostatic fields (ETG), and various immunomodulating compounds. The therapies fall into three general modes: decreasing blood flow to the scalp, pharmacologically protecting the hair bulb, and inactivating the chemotherapeutic agent locally.

The amount of chemotherapy that reaches the scalp can be reduced in two ways: a scalp tourniquet or scalp hypothermia.

TABLE 140.2

Therapeutic Interventions in Alopecia

Decrease local delivery
Scalp tourniquet
Scalp hypothermia
Protection of the hair bulb
Topical minoxidil
AS101
α -Tocopherol
Inhibitors of cyclin-dependent kinase
Thiol solution
Inactivate chemotherapy locally
ImuVert
Epidermal growth factor and fibroblast growth factor
Topical cyclosporine
Interleukin-1
Topical calcitriol
Liposome-entrapped monoclonal antibody
Pulsed electrostatic field

Both methods induce vasoconstriction of superficial scalp vessels. For these methods to be effective, the chemotherapeutic agents must have short half-lives and rapid clearance of the drug and its metabolites.

Scalp tourniquets were first used in 1966. They are pneumatic devices placed around the hairline and inflated to a pressure greater than the systolic blood pressure while the patient is receiving the chemotherapy infusion. Several studies have been reported using scalp tourniquets that revealed their effectiveness in preventing hair loss; however, the studies are difficult to interpret due to inadequate sample size, inconsistent criteria of assessing alopecia, and differences in chemotherapy regimens. Side effects of the scalp tourniquet include nerve compression and headaches.⁴

Scalp hypothermia (i.e., scalp cooling), first used in 1978, decreases blood flow to the scalp and may slow uptake of the chemotherapeutic agent by the hair follicles. Several devices, such as bags of ice, molded gel packs, and thermocirculator devices, can be used to achieve scalp hypothermia; however, it is believed that the scalp temperature must be decreased to at least 24°C to effectively prevent alopecia. A common side effect is patient discomfort from heavy caps. Several concerns have been raised about the use of scalp hypothermia in those with liver dysfunction or in hematologic malignancies including leukemia and lymphoma, as well as a concern about the possibility of developing scalp metastases. More recent studies have found that hypothermia was effective, and several studies found no increased incidence of scalp metastases.^{8,9} A trial with 238 patients taking docetaxel found that scalp cooling reduced the risk of alopecia by 78%. The most common adverse event was sensation of cold.¹⁰ A study of 1,411 patients found that 50% of patients had good hair preservation. The study also showed positive benefits for almost all patients, except those using the taxotere, adriamycin, and cyclophosphamide regimen.¹¹

There are currently no approved or effective pharmacologic treatments for chemotherapy-induced alopecia. Several different medications may reduce or prevent alopecia by pharmacologically protecting the hair bulb from the damaging effects of chemotherapy. These medications include AS101, topical minoxidil, α -tocopherol, thiol, and inhibitors of cyclin-dependent kinase (CDK).

AS101 is a synthetic compound that is structurally similar to cisplatin. Studies initially done with mice revealed that AS101 works as an immunomodulator by stimulating production of interleukin (IL)-1, IL-2, IL-6, colony-stimulating factor, and tumor necrosis factor, thereby potentially being used to minimize cytotoxicity. The mechanism of AS101 may be due to IL-1 because there is an inverse correlation between IL-1 and alopecia.¹² An open-label prospective randomized trial with 44 patients who had unresectable or metastatic nonsmall-cell lung cancer and were receiving carboplatin and etoposide revealed a significant reduction in neutropenia and thrombocytopenia as well as chemotherapy-induced alopecia.¹³

Topical minoxidil has been used for the treatment of androgenetic alopecia and alopecia areata. Two randomized trials have been performed in patients with cancer. The first was in 48 patients with many different solid tumors who were receiving doxorubicin-containing regimens. Minoxidil 2% twice a day did not prevent alopecia as compared with placebo.¹⁴ A second randomized trial with 22 women being treated for breast cancer also found that topical minoxidil did not prevent alopecia; however, there was a statistically significant difference (favoring minoxidil) in the interval from maximal hair loss to first regrowth. Thus, the period of baldness was shortened in the minoxidil group.¹⁵

Oral α -tocopherol showed some degree of protection from doxorubicin-induced alopecia. α -Tocopherol was tested prospectively in two trials of patients with cancer who were receiving doxorubicin. In both trials, oral α -tocopherol did not prevent alopecia.^{16,17}

Several different immunomodulators have been studied for the treatment of alopecia by inactivating the chemotherapy locally.

These include ImuVert, epidermal growth factor (EGF) and fibroblast growth factor (FGF), IL-1, topical calcitriol, topical cyclosporine, and liposome-entrapped monoclonal antibodies. All of these agents have been studied only in vitro and in animal models, with no translation into clinical practice.

ImuVert is a biologic response modifier that was initially developed to perform immunomodulating or immunorestorative properties for malignancies and other diseases in which immune system dysfunction is implicated. It is produced by the bacterium *Serratia marcescens*. The mechanism of action is unclear; however, it induces many cytokines, including IL-1, tumor necrosis factor, interferon- α , IL-6, granulocyte macrophage-colony-stimulating factor, and platelet-derived growth factor. In rat studies, ImuVert showed almost complete protection against cytosine arabinoside and doxorubicin-induced alopecia, but offered no protection against cyclophosphamide-induced alopecia. Dose-limiting side effects were hypotension and flu-like symptoms. No human studies have been reported to date.¹⁸

Several studies in rat models have been done with other biologic response modifiers, including FGF, EGF, and IL-1. FGF given systemically provided relief only from cytarabine at the site of injection. Topical EGF provided protection in the treated area. EGF given systemically provided relief from cytarabine- but not cyclophosphamide-induced alopecia.⁴ Animal studies with IL-1 revealed that it is a potent inhibitor of cytarabine-induced alopecia, in a mechanism similar to that of ImuVert. There was no protective effect with IL-1 on cyclophosphamide-induced alopecia.¹⁸ These results led to the hypothesis that there may be different mechanisms for inducing alopecia, depending on whether the chemotherapeutic agent is cell-cycle specific or cell-cycle nonspecific.

Epidermal growth factor receptor inhibitors may also play a role in reducing the incidence of alopecia. A secondary analysis of nine clinical trials showed that patients taking gefitinib or erlotinib had a lower incidence of alopecia. However, this effect is only noted in small molecule inhibitors as epidermal growth factor receptor-neutralizing antibodies (cetuximab and panitumumab) did not show a similar effect.¹⁹

Cyclosporine A administered topically protected newborn rats from alopecia induced by cytarabine, etoposide, and a cyclophosphamide plus doxorubicin combination at the site of application. Cyclosporine is a potent inhibitor of P-glycoprotein, as well as a hypertrichotic agent. The mechanism of action is unknown; however, it is thought that it may protect the hair follicle keratinocytes from chemotherapy by the expression of P-glycoprotein.²⁰

A study done with a topical liposome-entrapped monoclonal antibody (MAD11) against doxorubicin-induced alopecia revealed

that in 31 of 45 rats, alopecia was completely prevented.²¹ No human studies have been done with this agent. In addition, this agent would have very little benefit in chemotherapy-induced alopecia from other agents.

Another area of interest that is being investigated is cell-cycle arrest by inhibition of CDK2. Several preclinical models have explored the role of topical small-molecule inhibitors of CDK2. In the neonatal rat chemotherapy-induced alopecia model, the application of the topical CDK2 inhibitor led to areas of less hair loss in 33% to 50% of the animals.²²

Topical calcitriol (1,25-dihydroxyvitamin D₃) has been evaluated in rat models and found to prevent alopecia from a cyclophosphamide-doxorubicin regimen or cyclophosphamide-etoposide regimen. At a dose of 0.2 mcg topical calcitriol, the protection was noted over the entire animal and not just at the site of topical application.²³ However, a phase 1 trial of topical calcitriol in 14 patients with breast cancer showed no efficacy in preventing alopecia.²⁴

A pilot project using ETGs was undertaken, with 13 women receiving chemotherapy with cyclophosphamide, methotrexate, and 5-fluorouracil for breast carcinoma. All patients were treated for 12 minutes twice weekly with an ETG. Twelve of the thirteen women had good hair retention throughout the chemotherapy period and afterward. No side effects were reported. The mechanism of ETG is unknown. Randomized, double-blind control studies should be developed using ETG for chemotherapy-induced alopecia.²⁵

Inhibition of apoptosis by p53 and caspase is another area of interest that is being explored. Unfortunately, there are drawbacks to each of these experimental theories. Inhibition of caspase has been tested only in etoposide animal models and p53 inhibition would not affect alopecia that is independent of p53. Further studies in this area may yield drugs that have a wider profile, which in the topical setting may be of greater benefit.²

Radiation-induced alopecia can be just as concerning for patients as chemotherapy-induced alopecia. One agent that is currently being explored for radiation-induced alopecia is tempol gel. This is a topical agent that has shown efficacy in animal models. Specifically, this agent is a nitroxide that has protective properties in vitro against free radical compounds. In addition, there was no decrease in tumor control in mice. The agent, applied prior to radiation treatments, has been shown to be well tolerated in a phase 1 trial in patients who were found to have metastatic lesions to the brain. Some of the patients in this study were found to have protection against radiation.²⁶ These results are being further evaluated by ongoing phase 2 trials.

141 Gonadal Dysfunction

George Patounakis, Alan H. DeCherney, and Alicia Y. Armstrong

INTRODUCTION

The increased survival associated with oncologic treatment has made the late-term effects, such as gonadal failure, increasingly important. When the cancer is controlled, quality of life, which often includes the ability to have a normal child, then becomes a major issue.^{1,2} Currently, the 5-year survival rate of childhood cancer is over 80%, and more than about 75% will have a 10-year survival.³ Furthermore, the number of women less than 45 years old, and thus likely premenopausal, who are estimated to be diagnosed with breast cancer in 2013 is 24,430.⁴ These statistics signify that gonadal dysfunction from the effects of treatment is becoming even more important.

Both neoplastic disease and its treatment can interfere with normal sexual and reproductive function (Table 141.1). Testicular and ovarian cancers directly involve the gonad and prostate, endometrial, and cervical cancers directly involve the reproductive tract. Surgical treatment for any of these diseases results in damage or loss of these important reproductive organs. Retroperitoneal lymph node dissection (RPLND) for testicular and colon cancer, prostatectomy, and surgery involving the bladder neck may result in loss of the ability to ejaculate. Primary and metastatic tumors in the hypothalamus and pituitary can directly affect gonadotropin secretion, resulting in secondary hypogonadism. Both chemotherapy and radiation cause toxic effects on the male and female gonads. Cytotoxic therapies delivered to women during pregnancy can have teratogenic effects on the fetus. If fertility is maintained or recovers, there remains the concern about the heritability of cancer and at least a theoretical risk of mutagenic alterations to germ cells caused by cytotoxic therapies. The literature on the safety of male reproduction just after and during treatment is still unclear largely because of methodologic differences and different end points assessed by studies.⁵ More well-controlled studies are needed in this area to address these concerns. A recent large study of 3,915 cancer survivors looked at adverse birth outcomes of congenital anomalies, preterm birth, perinatal death, and low birth weight.⁶ For the offspring of male cancer survivors, they did not find any differences versus controls. For female survivors, there was an increased risk of the preterm birth and low birth weight. They did not find a difference in major congenital abnormalities for either male or female survivors. Another recent retrospective study drawing data from the Childhood Cancer Survivor Study of 4,699 children of male and female cancer survivors showed a prevalence of 2.7% of congenital anomalies, which is similar to the 3% prevalence of congenital anomalies in the United States.⁷ Based on these two recent studies, patients receiving cancer treatments can be counseled that it will not affect their offspring in terms of congenital abnormalities.

The reproductive consequences of cancer potentially affect a large number of patients in the United States. Between the years 2006 and 2010, there were 175,214 people between the ages of birth and 45 years old that were diagnosed with cancer in the United States.⁸ Of these, 20,506 were diagnosed between the ages of birth and 19 years old. Both males and females share the burden

of cancer development from birth to 39 years of age, with males having a risk of cancer in that age group of 1 in 69, whereas females have a risk of 1 in 46.⁹ In women, the risk of developing breast cancer specifically within this age range is 1 in 202. The creation of patient advocacy groups such as RESOLVE and LIVESTRONG both underscore the importance of these issues. Furthermore, quality of life committees in professional oncology groups also support the importance of issues such as these to cancer patients.

This chapter will first review the effects of cytotoxic agents in men, women, and children. Next, the effects of cranial irradiation with respect to gonadal dysfunction will be addressed. Subsequently, the preservation of fertility in males and females will be reviewed in the context of both standard of clinical care and experimental technologies. Finally, the genetic and pregnancy outcome concerns after treatment will be addressed.

EFFECTS OF CYTOTOXIC AGENTS ON ADULT MEN

Biologic Considerations

The testis consists of the seminiferous (or germinal) epithelium arranged in tubules and endocrine components (testosterone-producing Leydig cells) in the interstitial region between the tubules. The seminiferous tubules contain the germ cells, which consist of stem and differentiating spermatogonia, spermatocytes, spermatids, sperm, and the Sertoli cells, which support and regulate germ cell differentiation. The testicular vasculature is permeable, and drugs can freely reach the Leydig and Sertoli cells and the spermatogonia, which are at the outer rim of the tubules. Many chemotherapeutic drugs may penetrate the Sertoli cell barrier, albeit at a lower intensity, and damage late-stage germ cells.¹⁰

Among the germ cells, the differentiating spermatogonia proliferate most actively and are extremely susceptible to cytotoxic agents. In contrast, the Leydig and Sertoli cells, which do not proliferate in adults, survive most cytotoxic therapies. These cells, however, may suffer functional damage. Frequently, after cytotoxic therapies, germ cells appear to be absent and the tubules contain only Sertoli cells, a state described as *germinal aplasia*. This could be a result of killing of the spermatogenic stem cells, the loss of the ability of the somatic cells to support the differentiation of a few surviving stem cells, or a combination of the two.

After cytotoxic treatment, sperm count diminishes with a time course that depends on the sensitivities of the different spermatogenic cells and their kinetics of maturation to sperm.¹¹ Because the later-stage germ cells (spermatocytes onward) are relatively insensitive to killing and progress through spermatogenesis, sperm count is not immediately affected. However, these later-stage cells are susceptible to the induction of mutagenic damage, and studies in rodents have shown they can transmit mutations induced in their DNA to the next generation.¹² The eventual recovery of

TABLE 141.1

Impact of Cancer and Cancer Therapy on the Reproductive System

Tumor	Direct gonadal involvement Reproductive tract involvement Hypothalamic and pituitary involvement Concern about heritability of cancer susceptibility
Surgery	Removal of gonad Genital mutilation Failure of emission and retrograde ejaculation Impotence and loss of orgasm
Radiotherapy or chemotherapy	Germ cell depletion Loss of gonadal hormones Mutagenic changes in germ cells Teratogenic effects on fetus
Chemotherapy	Seminal transmission of drug
Radiotherapy (cranial)	Loss of gonadotropic hormones

sperm production depends on the survival of the spermatogonial stem cells and their ability to differentiate. Surviving stem cells can remain in the testis but fail to differentiate to sperm for several years after cytotoxic insult.¹³ It is important to note that human studies have not necessarily shown an increased rate of congenital anomalies.^{6,7}

The loss of germ cells has secondary effects on the hypothalamic–pituitary–gonadal axis. Inhibin secretion by the Sertoli cells declines, and because inhibin limits follicle-stimulating hormone (FSH) secretion by the pituitary, serum FSH rises. Germinal aplasia reduces testis size, and testicular blood flow is consequently reduced, which results in the distribution of less testosterone into the circulation (Table 141.2).¹⁴ Because testosterone is a negative regulator of luteinizing hormone (LH) secretion by the pituitary, and LH is the primary stimulator of testosterone synthesis by the Leydig cells, LH increases to maintain constant serum testosterone levels.

Characteristics of Gonadal Toxicity

Although subnormal semen profiles, ejaculatory dysfunction, and low libido can often be results of cancer treatment, a thorough examination should be done to determine whether symptoms of these problems might have been present before treatment. A sexual and reproductive history should be taken, including information on developmental factors such as ages at testicular descent and puberty; surgery or injury to the genitals; diseases that might affect reproduction; drug, chemical, or heat exposure; and pretreatment fertility and libido status. A physical examination should consist of an examination of the testicles and secondary sexual

characteristics such as beard and hair distribution pattern. If there are indications, a semen analysis and a hormone profile should be done and results should be compared with normal values (see Table 141.2).

Cytotoxic therapies in the form of chemotherapy or radiation can have varying effects on the sperm quantity and quality. A recent study of testicular germ cell cancer patients looked at patients treated with less than or equal to two cycles of chemotherapy, more than two cycles of chemotherapy, and irradiation.¹⁵ For all three groups, the sperm count nadir was at 3 months posttreatment. This is expected because it is the time required for differentiating spermatogonia to become sperm. In the group of patients treated with two or less of bleomycin, etoposide, and cisplatin (BEP), the sperm counts returned to pretreatment levels by 12 months, whereas in the other two groups, it took 24 months to return to pretreatment levels. Another recent study shows similar results with the beginning of normalization of seminal parameters by approximately 18 months posttreatment.¹⁶

The induced azoospermia can be either temporary or prolonged, depending on the survival of stem spermatogonia and their ability to proliferate, differentiate, and produce spermatozoa, which in turn depends on the nature of the cytotoxic agent and dose (Table 141.3).^{17–20} If treatment is limited to the cytotoxic agents that do not kill stem spermatogonia or block their differentiation, normospermia is usually restored within 3 months after the cytotoxic therapy. However, if agents that kill stem spermatogonia or affect differentiation are used, longer periods of azoospermia ensue.^{13,21}

To evaluate the effects of cytotoxic therapy, one must consider the initial gonadal status. Men with testicular germ cell tumors have impaired semen quality even before cytotoxic therapy is instituted. Approximately 65% are oligospermic (counts <20 million/mL) and approximately 20% are azoospermic,²² whereas the values are 9% and 1%, respectively, in control populations. In half of the patients with reduced semen quality, this impaired testicular function is a result of abnormalities in the remaining gonad, such as carcinoma in situ or a history of cryptorchidism. In the other half, it may be a result of reversible factors such as chorionic gonadotropin production by the tumor with resulting increases in estradiol levels or the trauma of the recent orchiectomy.²³ In addition, emission and ejaculation may have been compromised by earlier RPLND so that the sperm density may not accurately reflect gonadal function.²⁴ In contrast to the severe dysfunction seen in cases of testicular cancer, in Hodgkin's lymphoma, between 16% and 50% of patients are oligospermic, only 2% to 8% are azoospermic, and the distribution of counts in the remainder is not significantly different from normal.^{25,26} Poor semen quality was more prevalent in patients with advanced than with early-stage Hodgkin's lymphoma, but specific risk factors have not been identified. In patients with other lymphomas and sarcomas, pretreatment sperm counts tend to be normal except for similar modest increases in the incidence of oligospermia.^{13,21}

The age at treatment is not a major factor in recovery from gonadal damage in men. Most studies have failed to show any age effect,^{13,21} but a few have indicated increased testicular damage after cytotoxic therapy in older men.²⁷

TABLE 141.2

Typical Clinical and Laboratory Features for Diagnosis of Male Reproductive Dysfunction

	Testis Size		Serum Hormone Levels			
	Length × Width (cm)	Volume (mL)	Sperm Count (Millions/mL)	Follicle-Stimulating Hormone (mIU/mL)	Hormone (mIU/mL)	Testosterone (ng/dL)
Normal men	5.0 × 3.0	15–25	20 to >100	1–12	2–12	300–1,200
Germinal aplasia	3.7 × 2.3	8–15	0	>20	>12	200–700

TABLE 141.3

Effects of Different Antitumor Agents on Sperm Production in Men

Agents (Cumulative Dose for Effect)	Effect
Radiation (2.5 Gy to testis)	Prolonged azoospermia
Chlorambucil (1.4 g/m ²)	
Cyclophosphamide (19 g/m ²)	
Procarbazine (4 g/m ²)	
Melphalan (140 mg/m ²)	
Cisplatin (500 mg/m ²)	
BCNU (1 g/m ²)	Azoospermia in adulthood after treatment before puberty
CCNU (500 mg/m ²)	
Busulfan (600 mg/kg)	Azoospermia likely, but always given with other highly sterilizing agents
Ifosfamide (42 g/m ²)	
BCNU (300 mg/m ²)	
Nitrogen mustard	
Actinomycin D	
Carboplatin (2 g/m ²)	Prolonged azoospermia not often observed at indicated dose
Doxorubicin (Adriamycin) (770 mg/m ²)	Can be additive with previous agents in causing prolonged azoospermia, but cause only temporary reductions in sperm count when not combined with previous agents
ThioTEPA (400 mg/m ²)	
Cytosine arabinoside (1 g/m ²)	
Vinblastine (50 g/m ²)	
Vincristine (8 g/m ²)	
Amsacrine, bleomycin, dacarbazine, daunorubicin, epirubicin, etoposide, fludarabine, 5-fluorouracil, 6-mercaptopurine, methotrexate, mitoxantrone, thioguanine	Only temporary reductions in sperm count at doses used in conventional regimens, but additive effects are possible
Prednisone	Unlikely to affect sperm production
Interferon- α	No effects on sperm production

BCNU, carmustine; CCNU, lomustine.

Individual Drugs

The most sterilizing drugs are the alkylating agents (with the exception of dacarbazine) and cisplatin. The cumulative dose appears to be more important than the dose rate in determining whether sperm production will recover (see Tables 141.3 and 141.4). Chlorambucil²⁸ and cyclophosphamide²⁹ induce prolonged azoospermia when given alone. The gonadal toxicities of other agents have generally been deduced from the effects of combination regimens; the doses given might be underestimates because there may be additive contributions from other drugs in the regimen. Procarbazine³⁰ and cisplatin in high doses³¹ are also highly sterilizing. Busulfan has an additive effect on the sterility resulting from cyclophosphamide treatment.³² The addition of high doses of ifosfamide (46 g/m²) to cisplatin-containing chemotherapy regimens significantly reduced the recovery of spermatogenic function.³³ Carboplatin, an analog of cisplatin, appeared in the same combination regimens to produce less sterility than cisplatin.²² The treatment of boys with carmustine (BCNU) and lomustine (CCNU) produced prolonged azoospermia,³⁴ and it is likely, but not proven, that the same would occur in adults. The agents that have only temporary effects were also identified from single-agent and combination chemotherapy regimens.

Radiation Therapy

The effects of radiation on the testes depend on the fractionation regimen. Whereas in all other organ systems, fractionation of radiation reduces the damage, radiation doses to the germinal epithelium of the testis given in 3- to 7-week fractionated courses cause more gonadal damage than single doses.³⁵ In the usual fractionated regimens, doses to the testes above 0.15 Gy are required to produce any reduction in sperm count. Doses between 0.15 and 0.5 Gy cause oligospermia.³⁶ Above 0.6 Gy, azoospermia occurs. The duration of azoospermia is dose dependent, and recovery can begin within 1 year after doses of less than 1 Gy, but not until more than 2 years after delivery of 2 Gy. Cumulative doses of fractionated radiotherapy of more than 2.5 Gy generally result in prolonged and likely permanent azoospermia. However, after a single dose of 8 Gy or fractionated doses of 10 to 13 Gy, given as total body irradiation in preparation for bone marrow transplantation, sometimes also with cyclophosphamide (4.5 g/m²), spermatogenesis eventually recovers in 15% of the patients.²⁰

Testicular androgen production is relatively resistant to irradiation: doses of over 18 Gy are required before an effect is evident,

TABLE 141.4

Probability of Germinal Aplasia in Men Treated with Different Combination Chemotherapy Regimens

Regimen	Disease	Courses or Dose	Patients with Prolonged Azoospermia (%)
<i>High-Dose or Moderately High-Dose Alkylating Agents</i>			
MOPPd or MVPPd	Hodgkin's lymphoma	≥6 courses	85
CyOPPd	Hodgkin's lymphoma	4–9 courses	100

and major damage does not occur until the dose exceeds 30 Gy.³⁷ The radiation-associated impotence after such treatments is likely a result of vascular damage.

Combination Regimens

The sterilizing potential of each combination chemotherapy or chemotherapy plus radiotherapy regimen is the additive effects of the doses of the individual agents given (see Table 141.3); there is no evidence for synergistic interactions between the agents. Although it is impossible to predict whether sperm production

in any given man will recover, the probability of prolonged azoospermia has been determined for many combinations (see Table 141.4). The sterilizing potential of new regimens can be predicted from the information in Table 141.3 and the results found with similar combinations. The additive effects of agents can be seen in the case of cyclophosphamide: When cyclophosphamide is given alone, 19 g/m² is required to produce prolonged sterility in half the men, but only 15 g/m² is required when cyclophosphamide is given with a median doxorubicin dose of 450 mg/m² in the cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) regimen, and only 11 mg/m² is required when it is given with a median doxorubicin dose of 880 mg/m² in the

cyclophosphamide, vincristine, doxorubicin, and dacarbazine (CY[V]ADIC) regimen.^{13,21}

EFFECTS OF CYTOTOXIC AGENTS ON ADULT WOMEN

Biologic Considerations

Gonadal cell kinetics in women are opposite to those in men: the germ cells are nonproliferative, whereas the somatic cells proliferate. Female germ cells only proliferate prenatally, and by birth, are arrested at the oocyte stage. At birth, there are 1 million oocytes, which are reduced to 300,000 at puberty and to fewer than 1,000 oocytes when menopause occurs at approximately age 50 years.³⁸

Before recruitment to the process leading to ovulation, oocytes are found in primordial follicles with few pregranulosa cells, surrounded by theca cells of the ovarian stroma. The stimulus for the initiation of follicular maturation depends on local growth factors, not the gonadotropic hormones. Once a follicle is recruited into growth, it develops until it either degenerates or ovulates. Follicular maturation is characterized by proliferation of granulosa cells and the development of steroidogenic potential of both the theca and granulosa cells. Estrogen production involves the stimulation of both these cell types by LH and FSH and causes the LH surge that triggers ovulation. The cyclic variations in FSH, LH, and estradiol are essential for menstrual cycles and reproduction.

Because the destruction of oocytes results in loss of follicles, germ cell loss leads directly to estrogen insufficiency. Radiation and chemotherapy appear to cause this germ cell loss by direct apoptotic action on the oocytes in mouse models.³⁹ Although the direct action on oocytes may be the dominant mechanism in the most gonadotoxic agents, other mechanisms such as effects on granulosa cells, surrounding stroma, and blood vessels may indirectly affect the oocyte.⁴⁰ When maturing follicles are destroyed by cytotoxic therapy, the result is oligomenorrhea or temporary amenorrhea. If the number of primordial follicles is reduced below the minimum necessary for menstrual cyclicity, irreversible

ovarian failure and menopause (>12 months without a menstrual period) occur.

Characteristics of Gonadal Toxicity

Because the size of the germ cell population in women cannot be determined, menstrual and reproductive histories are important in assessing the effects of cytotoxic therapy on ovarian function. Information on the patient's sexual function and menstrual histories during and after therapy is particularly useful (Table 141.5).⁴¹ Because the mechanisms of temporary and irreversible treatment-related amenorrhea are different, a posttreatment follow-up must be given to evaluate the significance of the outcome. To determine if effects are related to cytotoxic therapy, pretherapy ovarian function should be evaluated from the history of menarche, menses, pregnancies, and oral contraceptive use. The symptoms of recent primary ovarian failure, including hot flashes, night sweats, insomnia, mood swings, irritability, vaginal dryness, dyspareunia, decreased libido, and bladder infection, should be recorded. Laboratory measurements of hormone levels are most definitive in the diagnosis of primary ovarian failure. FSH level is the most sensitive, but LH and estradiol levels are also useful (Table 141.5). Antimüllerian hormone (AMH), a hormone produced by growing follicles from the primary to antral stage, is another hormone that can be used to determine ovarian reserve by inferring the number of primordial follicles present. AMH has been shown to be a useful marker of ovarian reserve in both prepubertal and postpubertal girls after gonadotoxic treatments.⁴² The physical symptoms and the changes in hormone levels associated with ovarian failure may be masked by oral contraceptive use or hormone replacement therapy.

Cytotoxic therapy often induces temporary amenorrhea, which may occasionally last several years.⁴³ Some patients with treatment-induced temporary amenorrhea do display menopausal symptoms. The permanent amenorrhea may begin during chemotherapy or, subsequently, after several years of oligomenorrhea.⁴⁴ Factors resulting in temporary amenorrhea during treatment appear to be age independent.⁴⁵ In contrast, the incidence of permanent treatment-induced amenorrhea (ovarian failure) dramatically and continuously increases with age at treatment (Tables 141.6 and 141.7), as expected from the decreasing number of follicles with increasing age.

Radiation (total body irradiation) (10 Gy)	40	75	100	100

Childhood cancer survivors who retain ovarian function after treatment have an increased relative risk of 13 for developing premature menopause.⁴⁶ When women aged 13 to 19 years are treated with alkylating agent chemotherapy and radiotherapy below the diaphragm, their median age at menopause is 32 years, compared with 44 years for women treated with either radiotherapy or chemotherapy alone and 49 years for controls.⁴⁷

Cytotoxic therapy–induced ovarian failure accelerates bone density loss. However, when only chemotherapy is used, some

residual ovarian function may be present despite the menopausal state, and the rate of bone density loss is less than when pelvic radiotherapy is used.⁴⁸

Individual Drugs

In women, as in men, alkylating agents appear to be the most likely to produce permanent gonadal failure (see Table 141.6).

TABLE 141.7**Probability of Ovarian Failure in Postmenarchal Women Treated with Combination Chemotherapy Regimens Containing Alkylating Agents**

Regimen	Disease	Courses or Doses	Permanent Age (Y)	Incidence of Ovarian Failure (%)
MOPPd or MVPPd	Hodgkin's lymphoma	Approximately 6 courses P = approximately 6 g/m ²	25 35	15 85

M, mechlorethamine (nitrogen mustard); O, vincristine (Oncovin); P, procarbazine; Pd, prednisone; V, vinblastine; A, doxorubicin (Adriamycin); B, bleomycin; D, dacarbazine; Cy, cyclophosphamide; Chl, chlorambucil; E, etoposide; HSCT, hematopoietic stem cell transplantation; Bu, busulfan; F, 5-fluorouracil; MI, melphalan; Mx, methotrexate.

The cumulative dose appears to be more important than the dose rate, as evidenced by similar incidences of ovarian failure in women who received similar total doses of cyclophosphamide, given either daily over several months⁴⁹ or within 4 days.⁵⁰ High doses of cisplatin (≥ 600 mg/m²) also produce permanent ovarian failure.⁵¹ Procarbazine is likely to be highly sterilizing inasmuch as permanent ovarian failure is observed after treatment with several different procarbazine-containing combinations (see Table 141.7).

Nonalkylating agents are thought to be far less likely to induce permanent ovarian failure. No ovarian failure was observed with 5-fluorouracil (30 g),⁴⁹ methotrexate (200 g) plus vincristine (40 g),⁵² etoposide (5 g),⁵³ or cisplatin (<450 mg/m²) plus doxorubicin (<400 mg/m²)⁵¹ in women aged 15 to 35 years. Doxorubicin (300 mg/m²), bleomycin, vincristine, and dacarbazine (ABVD) do not appear to induce ovarian failure because none was observed after this treatment of women up to age 41 years.⁵⁴

Radiation Therapy

Radiation therapy induces permanent ovarian failure with marked age dependence in sensitivity (see Table 141.6). Irradiation of the para-aortic nodes for Hodgkin's lymphoma results in cumulative ovarian doses of only 1.5 Gy and does not appear to interfere with menstruation in most patients.⁵⁵ Total nodal irradiation for Hodgkin's lymphoma or pelvic radiation for cervical cancer results in an ovarian dose of 4 to 5 Gy when proper transposition (oophoropexy) and shielding of the ovaries are performed, which preserves fertility in some younger women.⁵⁶ Total body irradiation in preparation for bone marrow transplantation delivers 8 to 12 Gy to the gonads, which destroys ovarian function in nearly all adult women.^{50,57} Ovarian damage from radiation appears to be independent of whether it is given in one or six fractions.³²

Combination Regimens

All combinations that include procarbazine and other alkylating agents (mechlorethamin, vincristine, procarbazine, prednisone [MOPP]; CHOP; mechlorethamine, vinblastine, procarbazine, and prednisone [MVPP]; and chlorambucil, vinblastine, procarbazine, and prednisone [ChlVPP]) induce ovarian failure in almost all older women and even in some younger ones (see Table 141.7). Ovarian function is maintained better by reducing the doses of these drugs through use of the MOPP/ABVD regimen.⁵⁸ Radiation and MOPP chemotherapy have additive, but not synergistic, effects, and the combination results in a higher incidence of ovarian failure than either modality alone.⁵⁹

Similarly, regimens containing cyclophosphamide also produce ovarian failure; however, the age dependence obscures any possible dose dependence. The treatments used for leukemia, which involve lower doses of cyclophosphamide and other agents that do not destroy primordial follicles, allow for the recovery of menses in women under the age of 35 years.⁶⁰ Combination chemotherapy regimens without alkylating agents do not produce ovarian failure.

EFFECTS OF CYTOTOXIC AGENTS ON CHILDREN

Extent of Gonadal Toxicity in Boys

The germinal epithelium in the prepubertal testis is not any more resistant to cytotoxic therapy than that in adults. When chemotherapy doses to boys are expressed appropriately on a per-meter-squared basis and radiation doses are calculated, the sterilizing effects of a variety of chemotherapy⁶¹ and radiotherapy⁶² regimens can be predicted on the basis of their effects on adult testes (see Tables 141.3 and 141.4).

As in adults, radiation; alkylating agents such as procarbazine, cyclophosphamide, chlorambucil, BCNU, and CCNU; and cisplatin are the most sterilizing and produce prolonged and sometimes permanent azoospermia.^{34,51} In addition, high doses of doxorubicin and cytosine arabinoside are additive with the aforementioned agents in producing gonadal damage.⁶³ Regimens lacking alkylating agents, such as some used for acute lymphocytic leukemia, can even allow pubertal progression of spermatogenesis during treatment.⁶⁴

Most chemotherapy regimens do not affect Leydig cell function, and hence, the timing of pubertal development and post-pubertal testosterone levels are generally normal.⁶⁵ However, busulfan plus cyclophosphamide, used in preparation for hematopoietic stem cell transplantation, appears to delay puberty in approximately 30% of boys.⁴³

Extent of Gonadal Toxicity in Girls

Prepubertal girls appear to be less susceptible than young post-pubertal women to cytotoxic therapy-induced ovarian failure (see Table 141.6). Furthermore, girls treated with radiation and alkylating agents after puberty have about a 10 times greater relative risk of developing early menopause versus those treated before puberty.⁶⁶ Exposure of the ovaries to high-dose radiation, alkylating agents, and procarbazine are significant risk factors for acute ovarian failure in childhood cancer survivors.⁶⁷ Radiation is the most damaging agent to the prepubertal ovary: 20 to 30 Gy induces permanent ovarian failure in nearly all girls.⁶⁸ Doses of 8 to 15 Gy, usually with cyclophosphamide or melphalan in preparation for bone marrow transplantation, cause failure of ovarian function and pubertal development in 50% of girls,⁶⁹ with younger girls being less sensitive than older ones.⁴³ Radiation doses of up to 7 Gy do not cause ovarian failure or inhibit puberty⁶² but can have additive effects if chemotherapy is also given.

Most chemotherapy regimens do not cause loss of primordial follicles or failure of pubertal development and menarche. This includes high doses of cyclophosphamide of up to 48 g,⁷⁰ various combination chemotherapy regimens used to treat leukemia, and the ABVD regimen for Hodgkin's lymphoma.⁷¹ Even MOPP or nitrosourea chemotherapy does not affect pubertal and menstrual function development in 90% of girls.^{62,72} However, ChlVPP produces ovarian failure in 25% of girls⁷³ and busulfan plus cyclophosphamide inhibits puberty in 50% of girls.⁴³

Besides causing ovarian damage, irradiation for solid tumors in the abdomen (20 Gy or more for Wilms' tumor) or in preparation for hematopoietic stem cell transplantation produces irreversible damage to uterine growth and blood flow in girls.⁷⁴ This damage affects achievement and outcome of pregnancy later in life.⁷⁵ If radiation doses are not too high (approximately 10 Gy, as in total body irradiation for transplantation), sex steroid replacement can improve uterine function.

GONADAL DYSFUNCTION AFTER CRANIAL IRRADIATION

Whereas gonadal irradiation causes primary hypogonadism, cranial irradiation is associated with secondary hypogonadism because of damage to the hypothalamus or the gonadotrophs in the pituitary, or both. In patients with pituitary or suprasellar lesions, gonadotropin deficiency is often present before antineoplastic therapy; however, patients with nasopharyngeal cancer or brain tumors have normal hypothalamic-pituitary-gonadal axes until they receive therapeutic irradiation with fields encompassing the hypothalamic-pituitary areas. In contrast, none of the cancer chemotherapeutic drugs directly impairs hypothalamic or anterior pituitary function.

TABLE 141.8

Reproductive Effects of Cranial Irradiation

Radiation Dose to Pituitary/Hypothalamus (Gy)	Disease	Reproductive Effects
<i>Childhood Cancers</i>		
18–24	Leukemia	Slightly early puberty (girls) Subtle ovulatory disorder (after puberty)
25–49	Retinoblastoma, brain tumors, face and neck cancers	Some with precocious puberty (both genders) Higher doses: delay of puberty, gonadotropin deficiency at later times, failure of puberty
>50	Brain tumors, optic glioma	Some show gonadotropin deficiency (failure to undergo puberty)
<i>Cancers In Adults</i>		
10–13	Leukemia	No deficiencies at <5 y
20	Pituitary tumors	LH/FSH deficiency: 30% at 5 y; 40% at 10 y
35–40	Pituitary tumors	LH/FSH deficiency: 65% at 5 y, 90% at 10 y
40–70	Brain tumors	LH/FSH deficiency: 60% at 7 y
40–70	Nasopharyngeal, paranasal sinus tumors	LH/FSH deficiency: 15%–30% at 5 y, 45% at >10 y

In children, prophylactic cranial irradiation with 24 Gy for leukemia does not affect LH or FSH pulsatile secretion in the first 6 years,⁷⁶ but it does produce subtle effects that appear after puberty (Table 141.8).⁷⁷ However, in the shorter term, they may indirectly increase LH and FSH levels and cause precocious puberty in both boys and girls.⁷⁸ Because irradiation also produces growth hormone deficiency, precocious puberty further exacerbates the risk of decreased adult stature. Treatment with a gonadotropin-releasing hormone (GnRH) analog to delay closure of the epiphyseal growth plates and, with growth hormone, can be given to avoid growth stunting.

In adults, LH and FSH secretion decreases after cranial irradiation, and the decline becomes more severe with increasing treatment dose and time since treatment. This results in oligomenorrhea in women and low testosterone levels in men. Hyperprolactinemia might mediate the observed gonadal dysfunction in some cases.⁷⁹

PRESERVATION OF FERTILITY, HORMONE LEVELS, AND SEXUAL FUNCTION

Choice of Regimens

It is sometimes possible to choose, among nearly equally curative regimens, one that minimizes the doses of the agents that are most sterilizing (see Tables 141.3 and 141.6). The use of ABVD instead of MOPP to treat Hodgkin's lymphoma has dramatically reduced gonadal toxicity in a large group of patients.⁸⁰ In the treatment of non-Hodgkin's lymphoma, regimens that minimize the dose of cyclophosphamide, such as doxorubicin, cyclophosphamide, etoposide, vincristine, bleomycin, prednisone (VAPEC-B), produce gonadal failure less often in men than does CHOP with bleomycin.⁸¹

Gonadal Shielding and Oophoropexy

Except when the gonads must be irradiated because of actual or potential neoplastic involvement, they must be outside the field or

shielded from the direct radiation beam. Nevertheless, an appreciable radiation dose from the accelerator head, collimator scatter, or internal lateral scatter may reach the gonads. Although moderately low radiation doses may be achieved, further reductions are desirable because of the possibilities of additive effects from chemotherapy and genetic damage to the sperm.

Gonadal dose depends on the distance from the field edge, field size, and photon energy. Pelvic radiation fields result in significant doses to the testis. Clamshell or other shields and beam blocking can reduce testicular doses two- to fivefold to 2 to 3 Gy for the inverted Y field used for Hodgkin's lymphoma and to 0.2 to 0.8 Gy for the hemipelvic field used for seminoma.⁸²

To reduce ovarian dose, an oophoropexy, in which the ovaries are surgically translocated away from the direct beam, can be performed. That region is further shielded using lead blocks. Some investigators report reductions in cumulative ovarian doses to 4 to 5 Gy during total nodal irradiation,⁶² which preserves fertility in younger women (see Table 141.6).⁵⁶ There is convincing evidence that moving the ovaries outside of the radiation field is beneficial in preserving ovarian function and future fertility in an adult population.^{83,84} There is also evidence that this technique can preserve fertility in girls treated with radiation for Hodgkin's lymphoma who were ultimately able to become pregnant.⁸⁵ With advancement in the field of endoscopic surgery, these procedures can now be performed laparoscopically^{86,87} or robotically,⁸⁸ allowing for a shortened hospital stay, earlier mobilization, and earlier return to normal activity.

Sperm Cryopreservation

Semen cryopreservation is an important procedure for preserving the fertility potential of men after cytotoxic treatment for cancer.⁸⁹ The significance of notifying the patient of the potential risk of iatrogenic sterility as early as possible cannot be overemphasized.⁹⁰ Physicians often are aware early during the diagnostic process that the patient will most likely need to receive potentially sterilizing cytotoxic therapy, although the exact diagnosis, stage, and treatment regimen may not have yet been decided. This time should be used to initiate and complete the cryopreservation procedure.

The number of samples to be banked may depend on how much time is available before starting therapy, sperm quality, and the cost of storing samples. A collection of three or four samples with approximately 48-hour periods of abstinence between sampling (a total of more than 5 days) is ideal. With current assisted reproductive technologies, however, success can be achieved with fewer samples, even with poor-quality semen. It is strongly advisable to complete sperm banking before starting therapy to avoid increased genetic damage in sperm collected after the start of therapy.¹² It is even possible to obtain semen with normal characteristics from 14- to 17-year-old boys by masturbation,⁹¹ penile vibratory stimulation, or electroejaculation.⁹² In addition, testicular sperm extraction is successful in 43% of pretreatment cancer patients who are azoospermic,⁹³ and the sperm obtained in this way can be cryopreserved and used in intracytoplasmic sperm injection (ICSI) procedures.⁹⁴ Testicular samples for sperm extraction can be obtained from orchiectomy or biopsy specimens that are routinely taken from testicular cancer patients if the surgeon is aware of the need and the processing procedures required for harvesting the sperm. Although a controversial topic, cryopreservation of immature testicular tissue in prepubertal boys with cancer may prove to be another suitable alternative, but the fear of reintroducing malignant cells through a graft is real, especially given the limitations of current technology.⁹⁵

The success of in vitro fertilization (IVF) and ICSI makes cryopreservation of all samples containing any live sperm worthwhile. Even though 100% of oncologists in a study by Zapzalka et al.⁹⁶ reported discussing fertility issues with their patients, Schover et al.⁸⁹ found that only 60% of 900 male cancer patients surveyed who replied stated that they were informed about fertility issues and that only 51% stated they had been notified about sperm banking. According to Kohler et al.,⁹⁷ only 36% of surveyed pediatric oncologists believe sperm banking is affordable, and the most likely reason to not offer it is poor survival prognosis.⁹⁷ The cost of sperm banking three samples, including analysis and storage for 5 years, is between \$1,200 (at a university medical school clinic) and \$2,500 (at some private sperm banks). Intrauterine insemination is the least expensive assisted reproductive technology method (cost per cycle: \$200 to \$500, plus \$1,200 for superovulation of the female partner, if necessary), but the sperm count and quality after thawing must be high, and conception rates are lower than with IVF. If sperm count or motility is impaired or sample amounts are limited, IVF is necessary. The average cost of IVF, including the medications used, is \$15,000 per cycle.

Optimization of Fertility after Treatment

If sperm count recovers after cancer therapy, it usually reaches normospermic levels. However, some men remain oligospermic for many years. Although controlled studies have not been done, men who have recovered sperm production appear to have normal fertility, and their incidence of infertility does not appear to be any higher than the 15% rate among couples in the general population. Furthermore, cancer patients with recovered sperm counts ranging from just below 1 million/mL to 10 million/mL are able to successfully father children.¹⁹ Infertile patients with oligospermia should be managed in the same way as are those in the general population with male factor infertility, including the use of IVF with or without ICSI.⁹⁸

Assisted Reproductive Technologies

Currently, the choices for preserving fertility in chemotherapy patients are limited (Table 141.9). Some are investigational, and all have demonstrated variable success. Fertility preservation can be attempted either with assisted reproductive technologies, gamete cryopreservation, or medical treatment. Assisted reproductive technology refers to in vitro handling of human oocytes and sperm or

TABLE 141.9

Options for Fertility Preservation

Males	Females
Sperm banking prior to chemotherapy Sperm collection via masturbation or surgical retrieval	Medical treatment GnRH analogs (agonists, antagonists)
Testicular cryopreservation and future transplantation	Ovarian cryopreservation and future transplantation Cortical strip Whole ovary
	Assisted reproductive technology Embryo banking (partner sperm or donor sperm) Oocyte banking (cryopreservation or vitrification)

embryos for the purpose of establishing a pregnancy. Techniques for gamete preservation include sperm cryopreservation, oocyte cryopreservation, ovarian cortical cryopreservation, or whole ovary cryopreservation. Medical therapy includes treatment with hormonal agents such as oral contraceptive pills, progesterone, and GnRH analogs.^{99–112}

Assisted reproductive technology is still undergoing rapid advances and provides new options for cancer survivors with gonadal damage to achieve fertility. Previously, intrauterine insemination following cryopreserved sperm had been the only fertility preservation method available, and only 30% of men who had stored high-quality semen samples were able to achieve pregnancy.¹¹³

Currently, IVF with ICSI is the most successful method for achieving pregnancy from banked sperm. ICSI makes it possible to use a single spermatozoa to achieve oocyte fertilization through IVF. This technology has revolutionized the treatment of male infertility.¹¹⁴ ICSI is also often used with frozen banked sperm. IVF can be performed to create embryos that can be frozen and stored for later use. Pregnancy outcomes vary by IVF center but are excellent overall with frozen embryo transfers. The downside of IVF is that a single cycle can take 2 to 3 weeks to complete and necessitates a delay in cancer treatment.

Women with estrogen-responsive tumors can undergo ovulation induction with an aromatase inhibitor either as a solo agent or as an adjunct to standard stimulation protocols.^{115,116} To avoid the potential risks of rising estradiol levels during ovarian stimulation (sometimes 10 to 20 times levels seen in natural cycles), an increasing number of fertility specialists are using aromatase inhibitors (letrozole or tamoxifen) for ovarian stimulation.¹¹⁷ To date, the recurrence and survival rates of breast cancer patients undergoing such protocols were comparable with those of unstimulated control breast cancer patients.¹¹⁸

Clinical pregnancy rates of 30% to 50% per cycle and live birth rates of 25% to 50% can be expected at most fertility clinics. Cumulative live birth rates after four cycles have been reported between 60% to 80% in patients with male factor infertility, ovulatory dysfunction, endometriosis, and unexplained infertility.¹¹⁹ Although fresh sperm is preferred to frozen sperm in intrauterine insemination and IVF cycles, studies have shown excellent outcomes using sperm that was frozen and banked prior to cancer treatment.¹²⁰ Although insemination with testicular sperm is an acceptable procedure, the use of nuclei from earlier stages (round spermatid nuclear injection) is not currently advisable.¹²¹ Overall, embryo banking is the most successful form of fertility preservation and should be offered to all women who are either in a serious

relationship, married, or who are open to the idea of using donor sperm.

Oocyte banking either via cryopreservation (slow freezing) or vitrification (rapid freezing) is an option for single women who are not interested in using donor sperm. Similar to IVF, this entails ovarian hyperstimulation followed by surgical oocyte retrieval and, similar to IVF, also necessitates a delay in treatment ranging from 2 to 6 weeks.¹²² Mature oocyte cryopreservation and vitrification were recently changed from experimental treatments to options that can be offered in routine clinical care.¹²³ There is no statistically significant difference in outcomes for fresh oocytes versus vitrified oocytes in oocyte donation programs.¹²⁴ Although oocyte vitrification appears to be a good option for the female cancer patient without a partner, the technology to achieve comparable pregnancy rates is not available at all IVF centers and, thus, may not be available to all patients. Furthermore, when embryo cryopreservation is a viable option, it should be used instead of oocyte preservation because of the greater experience with that method.

A recent meta-analysis¹²⁵ showed a 32% increase over baseline risk of birth defects in children born as a result of IVF/ICSI treatment, whereas another study¹²⁶ found no significant difference after controlling for confounders in its IVF population but still found an increased risk in its ICSI population. These results should be interpreted with caution in terms of counseling patients for fertility preservation. First, assuming the baseline risk of birth defects is approximately 5%, even a 30% increase risk results in an absolute risk of only 6.5%. Second, subfertile couples, who are the majority undergoing IVF/ICSI, already carry an increased risk of birth defects, which would not apply to the fertility preservation patient.¹²⁶ The increased risk of birth defects in ICSI treatment also has to be interpreted with caution in the setting of counseling the fertility preservation patient. There is an increased risk of approximately 3% for chromosomal abnormalities, mostly in the numbers of sex chromosomes, in offspring of ICSI procedures.¹²⁷ Most of the chromosome abnormalities were not caused by ICSI, but were already present in the sperm of the infertile male parent. These abnormalities, which are common in cases of primary male infertility, should not be present in cryopreserved sperm from cancer patients.

Female Germ Cell Cryopreservation and Development

In addition to cryopreservation of oocytes, cryopreservation of ovarian tissue can also be undertaken (see Table 141.9). One method entails the surgical removal of ovarian tissue containing numerous primordial follicles, cryopreservation of tissue slices, and subsequent grafting back to the site of the ovary. This was initially successful in restoring ovarian endocrine function and fertility in sheep.¹²⁸ There has been some reported success with ovarian tissue transplantation that has resulted in at least 12 patients with 28 subsequent live births in humans.^{129,130} These reports have included both fresh transplants from identical twins with discordant ovarian function and frozen transplants because of cancer. Some of the ovarian tissue grafts in these series have been functioning for over 7 years. A potential drawback of ovarian tissue cryopreservation and transplantation is the concern for reintroduction of malignant cells back into the host, particularly for patients treated for leukemia.¹³¹ Overall, this method of surgical conservation of ovarian tissue may prove to be more useful in the future as this concern for occult malignancy gets resolved.

Ovarian tissue cryopreservation is also an attractive alternative for fertility preservation and for restoring ovarian function in the pediatric population because ovarian stimulation is not required. Furthermore, patients do not need to have a partner at the time of treatment, there is no delay in treatment, and the tissue can remain frozen until the patient is ready for conception. Because

of the large numbers of immature oocytes in the ovarian cortex, this is an excellent emerging method suitable for premenarchal girls.¹³²⁻¹³⁴

Does It Work?

Results in various animal models have been encouraging in demonstrating the efficacy of ovarian cryopreservation and reimplantation.¹³⁵⁻¹³⁸ Silber and Gosden¹³⁹ published a case series describing seven pairs of monozygotic twins discordant for ovarian function who underwent ovarian transplantation. Four of seven conceived and one patient conceived twice. On average, the restoration of ovarian function ensued after 2 to 4 months after transplantation. Several other live births have been reported from ovarian cortical transplantation.¹⁴⁰⁻¹⁴²

The first case of heterotopic grafting of cryopreserved ovarian tissue following bilateral oophorectomy for a granulosa cell tumor resulting in an ongoing pregnancy at 26 weeks gestation has also recently been reported.¹⁴³ There are some advantages of heterotopic grafting of ovarian tissue to sites such as the abdominal wall, forearm, or breast. These advantages include potentially less invasive procedures for implantation, easy access to the graft, and avoidance of severe pelvic adhesions in the case of prior pelvic irradiation. A disadvantage is that the environment may not be optimal for follicle development in terms of temperature and other paracrine factors.

These cases are undoubtedly the first of many more to come. Ovarian cortical cryopreservation with subsequent reimplantation at this time is considered experimental and should only be performed in centers under institutional review board–approved protocols and necessary expertise. It can be anticipated that many more live births will occur as a result of this novel technique.

An alternate approach to ovarian preservation involves transplantation of the whole ovary as opposed to just cortical strips. The main obstacle facing ovarian cortical strip cryopreservation is the threat of ischemic damage prior to graft reimplantation.^{136,144} To combat this threat, maintenance of blood supply via whole-ovary cryopreservation with preservation of vascular pedicles might offer a potential advantage in reducing the large follicular loss. With the use of dimethyl sulfoxide as a cryoprotectant, improved follicular preservation has been noted compared with glycerol, which had been used in the past. Furthermore, recent microsurgical advances to enhance intact ovarian freezing and transplantation have been successful in rodents. Nine of 10 transplanted ovaries had successful restoration of ovarian function and 6 of 10 transplanted rats became pregnant.¹⁴⁵ In sheep, whose ovarian structure is more comparable to that of humans, intact ovaries with vascular pedicles were cryopreserved and later autotransplanted with microvascular anastomosis of the ovarian artery and vein to the branches of deep inferior epigastric vessels.¹⁴⁶ A recent study in sheep demonstrated ovarian function 6 years after transplantation of whole ovaries with the use of unidirectional solidification freezing technology.¹⁴⁷ The sheep underwent superovulation and the ovaries were found to have evidence of follicular growth and development.¹⁴⁷ More experience is needed with whole ovary transplantation for this to be a viable option for fertility preservation.

Another approach to oocyte preservation involves cryopreservation of immature oocytes in the germinal vesicle stage, followed by *in vitro* maturation (IVM) to meiotic metaphase II. These oocytes can then be fertilized *in vitro*. The first live birth from IVM was reported in 1991.¹⁴⁸ The application of IVM is becoming more widespread, ranging from the retrieval of immature oocytes in unstimulated or minimally stimulated cycles to reduce the cost of IVF to the retrieval of immature oocytes for fertility preservation.¹⁴⁹⁻¹⁵¹

It is possible that in the future stem cells may be used to repopulate the ovary. The derivation of oocytes from mouse embryonic stem cells in culture suggests the eventual power of stem cell technology and nuclear transplantation for the production of oocytes, perhaps even from somatic cell nuclei.¹⁵² Early animal

experiments involving human ovarian stem cells obtained from purified ovarian cortical tissue have been xenotransplanted into immunodeficient mice to yield what resemble oocytes.¹⁵³ This suggests that human ovarian stem cells may potentially be used for fertility preservation in the future. If this method proves to be successful, it would avoid the risks of reintroduction of malignant cells back into the patient. However, applications of such techniques to human fertility preservation are currently still under early investigation using animal models and should not be discussed with patients as options.

Most women who continue to have menstrual function after cytotoxic therapy for cancer but are infertile should be treated in the same way as similar women in the general population. One important exception is women who have uterine damage from receiving more than 10 Gy of abdominal radiation in childhood. These patients have increased rates of adverse pregnancy outcomes, including fetal or neonatal death, premature delivery, and low-birth-weight babies, and hence, their pregnancies must be closely monitored.⁷⁵

Immature Male Germ Cell Cryopreservation and Development

For the restoration of spermatogenesis, the harvest and cryopreservation of spermatogonial stem cells, which are capable of proliferation, self-renewal, and repopulation of the seminiferous tubules, are under investigation. Transplantation of cryopreserved testicular germ cells from a donor mouse into the seminiferous tubules of a recipient mouse, in which endogenous stem spermatogonia were killed with busulfan, restored spermatogenesis and fertility.¹⁵⁴ There are preliminary indications that this technique might restore spermatogenesis in irradiated macaques.¹⁵⁵ Testicular cells have been harvested from men before sterilizing cytotoxic therapy and later injected back into the testicular tubules after the completion of radiotherapy or chemotherapy. This technique would be most valuable for prepubertal boys, who are too young to produce sperm but have testes enriched in spermatogonia. Similar to female cancer patients, there exists concern that cancer cells may be reintroduced into the recipients. This possibility is a contraindication in cases of leukemia or testicular cancer, but the risks with other cancers may not be high.¹⁵⁶ To date, there has not yet been a report of successful transplantation of testicular tissue in a male patient, but this therapy is likely to first be applied to patients with nonmalignant disease then to those with cancer.⁹⁵

One way to circumvent the problem of the presence of tumor cells is to first transplant the tissue into a xenogeneic host. Human spermatogonial stem cells have been shown to survive and proliferate in seminiferous tubules of mice.¹⁵⁷ Also, subcutaneous transplantation of cryopreserved testicular tissue from immature pigs and goats into nude mice results in the production of functional sperm.¹⁵⁸ However, the risks of transfer of animal DNA or viruses (especially retroviruses) from the host to the human spermatogonial cells must be evaluated before such techniques could be applied.

New experimental approaches to germ cell development could potentially be applied to fertility preservation in men. The *in vitro* development of human round spermatids into elongated spermatids, which were used to produce normal embryos by ICSI, has been reported.¹⁵⁹ Development of an *in vitro* cell line derived from genetically modified mouse spermatogonia, which proliferates to produce more spermatogonia and can be stimulated to form haploid cells,¹⁶⁰ holds promise as a very useful resource for optimizing proliferation of spermatogonia and production of spermatids. Furthermore, the development of sperm from mouse embryonic stem cells by a combination of induction of differentiation *in vitro* and transplantation into host testes¹⁶¹ might eventually lead to methods for the development of sperm from other stem cell types obtained from a cancer patient.

PHARMACOLOGIC ATTEMPTS AT PRESERVING FERTILITY IN MEN

Hormone treatments have been investigated for their ability to enhance the survival of germ cells and promote recovery after cytotoxic treatments. Treatment of male rats with hormones that suppress testosterone levels or action (gonadal steroids, GnRH analogs, antiandrogens) before and during cytotoxic therapy with radiation or procarbazine enhances the subsequent recovery of spermatogenesis and fertility.¹⁶² The original proposal that these treatments would protect the spermatogonia from killing by suppressing their proliferation is incorrect; rather, the suppression of testosterone levels protects the subsequent ability of the somatic cells of the testis to support the recovery of spermatogenesis from surviving stem spermatogonia.¹⁶³ The hormonal treatment can even be given several months after exposure to radiation or procarbazine and still restore spermatogenesis and fertility.¹⁶²

Because stem spermatogonia are indeed present in regions of the testes of some cancer patients during prolonged periods of iatrogenic azoospermia, their recovery could possibly be stimulated. However, only one¹⁶⁴ of eight clinical trials has been able to demonstrate protection of spermatogenesis in humans by hormone treatment before and during cytotoxic therapy.¹⁶⁵ One attempt to restore spermatogenesis by steroid hormone treatment after cytotoxic therapy was unsuccessful¹⁶⁶; however, the doses of cytotoxic therapy were very high, and the hormonal suppression was given many years after the anticancer treatment. More discouraging was the failure of GnRH antagonist treatment to enhance spermatogenic recovery in a controlled primate study,¹⁶⁷ which suggests that there are important differences in this process in rats and in primates. Hence, pharmacologic preservation of male fertility is currently not effective.

PHARMACOLOGIC ATTEMPTS AT PRESERVING FERTILITY IN WOMEN

Although studies have been performed to assess the efficacy of oral contraceptive pills and GnRH analogs in girls, adolescents, and women, no comparative studies have been done using progestins in these age groups. Most studies do not support the use of hormonal therapy for the prevention of premature ovarian failure in girls and premenarchal adolescents receiving chemotherapy, because prior to the onset of menarche, the ovaries are thought to be quiescent and less likely to be subject to damage by cytotoxic agents. Therefore, there would be no additional benefit to giving hormonal therapy to an already suppressed hypothalamic–pituitary–ovarian axis. Furthermore, the use of estrogen may be associated with an increased risk of venous thrombosis. There is also concern regarding the side effect profile of hormonal therapy in premenarchal girls.

Longhi et al.⁹⁹ performed a small, observational study that examined the effects of oral contraceptive pills on ovarian function in premenarchal girls and postmenarchal women undergoing neoadjuvant chemotherapy treatment for osteosarcoma. They concluded that age and alkylant dose were the most predictive factors for early menopause, and that oral contraceptives during high-dose alkylant-based chemotherapy did not prevent chemotherapy-induced premature ovarian failure. The follow-up time of this study was too short to rule out any positive long-term effects on the preservation of ovarian function. In addition, this study did show greater risk than benefit because two patients in the group receiving chemotherapy plus oral contraceptive pills developed thrombophlebitis. Similar findings have been observed in other studies.¹⁰⁰ The majority of the evidence suggests that children and premenarchal adolescents do not benefit from hormonal suppression to preserve their ovarian function while undergoing chemotherapy.

The use of GnRH analogs to preserve fertility, although once thought to have promise, has failed to demonstrate consistent results in human studies. Preservation of ovarian function with the use of GnRH analogs, specifically agonists, prior to cancer treatment, in some studies has been shown to be beneficial.^{101,102} It has been proposed that GnRH agonist use prior to chemotherapy has a protective effect via two mechanisms. First, by downregulating the hypothalamic–pituitary–ovarian axis, it might reduce the number of primordial follicles destroyed by toxic agents. Second, it may reduce the blood flow to the ovary and decrease the delivery of toxic chemotherapeutic agents.^{103,104} This second theory may also explain the lack of a protective effect with GnRH analogs on ovarian function observed with increasing chemotherapeutic dosages and provide an explanation why this treatment has no effect with radiation therapy.^{103,105}

Animal studies have provided very convincing evidence regarding the efficacy of GnRH analogs. Ataya et al.¹⁰¹ conducted a prospective study looking at the effects of leuprolide on ovarian function in primates exposed to cyclophosphamide. Six adult female rhesus monkeys underwent unilateral oophorectomy and were divided into two groups. One group received cyclophosphamide and monthly injections of leuprolide, and the other received cyclophosphamide and placebo. At the end of treatment, the remaining ovary was removed and compared to the pretreated ovary. Ovarian follicle number and size were compared. As expected, there was a decline in follicle number with chemotherapy. Cyclophosphamide resulted in a significant reduction of nonprimordial follicles and primordial follicles compared to the leuprolide and cyclophosphamide group. The authors concluded that in rhesus monkeys, leuprolide protected the ovary against cyclophosphamide-induced damage.

Human studies have provided conflicting evidence for the efficacy of GnRH analogs. Two recent randomized studies from patients with breast cancer demonstrated some evidence of a protective effect of GnRH agonist treatment on the preservation of ovarian function.^{168,169} However, these studies have been questioned^{170–172} and will require larger study populations to definitively conclude the chemoprotective effects of GnRH analog therapy. A meta-analysis of this treatment showed an overall benefit of GnRH analog therapy.¹⁷³ This meta-analysis included the widely questioned study¹⁶⁸ and did not include the 24-month follow-up of the ZORO study¹⁷⁴; therefore, when reanalyzed, there is no difference in premature ovarian failure.¹⁷⁵

Although there is less evidence in the literature for the use of GnRH antagonists, the experience with ovulation induction and assisted reproductive technologies suggests it may have similar efficacy to GnRH agonists. On administration of GnRH agonists, there is an initial stimulatory *flare* effect prior to pituitary desensitization that ensues after 7 to 14 days. GnRH antagonists work via rapid inhibition of gonadotropin and sex steroids secretion and have an almost immediate downregulation of the pituitary gland. Because desensitization is so rapid, they have the advantage of not causing an initial flare effect. Gonadotropin deprivation halts follicular recruitment and decreases the size of the chemotherapy-sensitive pool.¹⁰³

GnRH antagonists are beginning to be studied further in both animals and humans. Using a mouse model, Meirou et al.¹⁰³ administered a GnRH antagonist, cetrorelix, prior to exposure to increasing doses of cyclophosphamide. The aim of the study was to assess the number of surviving primordial follicles in the ovaries of young mice. In each treatment group, half of the females were injected daily with cetrorelix starting 9 days before and 7 days posttreatment with cyclophosphamide. After treatment, ovarian sections were taken and the total number of primordial follicles in both ovaries was counted. A dose-response relationship was observed. Ovaries exposed to cyclophosphamide at dosages of 50 and 75 mg per kilogram had significantly fewer primordial follicles than those in the control group. In each of the cyclophosphamide groups that were pretreated with cetrorelix, there were higher

numbers of primordial follicles compared to controls. The administration of the GnRH antagonist cetrorelix to mice significantly decreased the extent of ovarian damage induced by the chemotherapeutic agent. A recent randomized trial in humans comparing a combination of GnRH agonist combined with antagonist to avoid the flare response in patients requiring early cyclophosphamide chemotherapy for hormone insensitive breast cancer (within 1 week of enrollment) versus GnRH agonist treatment for those with delayed chemotherapy (at least 10 days after enrollment) found no protective or harmful effects of the intervention.¹⁷⁶

Although some of the data seem promising with regard to GnRH analogs, the studies are plagued by low numbers and short follow-up periods. Thus, there is insufficient evidence to definitively recommend this therapy, and further study is needed. At this point, ovarian suppression should be considered and offered to all postmenarchal and reproductive-age women prior to initiating therapy if other, more well-proven options for female fertility preservation are not available or not feasible. Despite these conflicting results about the efficacy in terms of protecting ovarian function, both GnRH agonists and antagonists have the added advantage of menstrual suppression and, therefore, can be used to avoid heavy uterine bleeding often seen with hematologic malignancies.

FERTILITY PRESERVATION IN WOMEN WITH CERVICAL CANCER

Women with early-stage cervical cancer are most often treated with radical hysterectomy or radiotherapy to the pelvis. As women delay their childbearing and as screening programs have become more effective, an increasing number of patients with early-stage cervical cancer seek to preserve their future fertility.¹⁷⁷ Conservative surgery in the form of radical vaginal excision of the cervix (radical trachelectomy) to preserve the uterus in cases of cervical carcinoma has been reported with relatively good outcomes in terms of disease recurrence and pregnancy.^{177–180}

EVALUATION OF FERTILITY AFTER TREATMENT

Male and female cancer survivors should undergo timely evaluation when they are attempting conception. For males, it would be reasonable to obtain a semen analysis either before attempting conception or when conception fails to occur after 6 months of unprotected intercourse. Premature ovarian failure can be suspected based on a careful menstrual history. Shortening of the intermenstrual interval is an ominous sign that ovarian reserve is diminished. An evaluation of ovarian reserve with a gynecologist or reproductive endocrinologist is warranted for women who report amenorrhea, shortened menstrual cycles, irregular cycles, or for cancer survivors who have failed to conceive after 6 months of unprotected intercourse. There is no single best test available to measure ovarian reserve, but surrogate markers such as early follicular phase (cycle day 2 through 4) measures of antral follicles, ovarian volumes, FSH, estradiol, and antimüllerian hormone levels can be used. These tests, however, must be interpreted with caution, because the true utility is in predicting ovarian responsiveness and not reserve.

HORMONE REPLACEMENT THERAPY

Information that estrogen with or without progesterone given to postmenopausal women (aged 50 to 79 years) increases the cardiovascular risks¹⁸¹ has led to the view that the risks of hormone replacement therapy for normal postmenopausal women (cardiovascular disease and breast cancer) outweigh the benefits

(increased bone mineral density and reduced incidence of fracture). A further analysis of the Women's Health Initiative (WHI) and long-term follow-up essentially concluded that oral hormone replacement therapy, as given in the WHI, should not be used for the prevention of chronic disease, but this conclusion may be questioned in younger postmenopausal women and with other forms of hormone replacement.¹⁸² However, the physiologic replacement of ovarian hormones still remains appropriate for young, otherwise premenopausal girls who have developed premature ovarian failure as a result of their malignancy or cancer treatment. This is particularly true for adolescent girls and young women in whom bone mineral density is normally increasing.¹⁸³ In these cases, it is important to test for ovarian failure shortly after treatment and, if appropriate, to start hormone replacement therapy in a timely manner. If a woman has an intact uterus, estrogen should be combined with progesterone to prevent endometrial hyperplasia and cancer.¹⁸³ The use of hormone replacement therapy in survivors of breast cancer to alleviate debilitating postmenopausal symptoms that do not respond to nonhormonal treatments is controversial because of its unclear effects on breast cancer recurrence.¹⁸⁴

In males, germinal aplasia is often associated with testosterone levels in the low to normal range, and such individuals may experience reduced bone mineral density and a slight reduction in sexual function.¹⁸⁵ However, a controlled trial failed to show any benefit of testosterone treatment on bone mineral density or sexual function, which indicates that this mild hypogonadism is not of clinical importance in most men.¹⁸⁵ Testosterone replacement is, nevertheless, very important in cases of overt Leydig cell failure in prepubertal boys to promote secondary sexual characteristics, growth, and bone density.

PREVENTION AND MANAGEMENT OF ERECTILE AND EJACULATORY DYSFUNCTION

Ejaculation of semen first requires emission (the deposition of semen in the posterior urethra by contractions of the vas deferens, seminal vesicles, and prostate) and then antegrade ejaculation, which involves coordinated tightening of the bladder neck, relaxation of the external sphincter, and expulsion of semen. Most of these processes are controlled by trunks of nerve fibers forming the hypogastric plexus overlying the aorta and sacrum below the origin of the inferior mesenteric artery.¹⁸⁶ Surgery for testicular, prostate, and bladder cancers can produce neurologic dysfunction, resulting in failure of emission, retrograde ejaculation, impotence, and loss of orgasm. However, improvements in surgical techniques have reduced these adverse outcomes without diminishing the efficacy of treating the cancer.¹⁸⁷ Newer RPLND techniques used for nonseminomatous testicular germ cell tumors in addition to bilateral nerve-sparing modification for patients undergoing radical prostatectomies preserves ejaculatory function compared with controls.^{24,188} In cases in which the cavernous nerves cannot be spared, the technique of interposition sural nerve grafting has been shown to help preserve postoperative potency.¹⁸⁹

For men experiencing erectile dysfunction, phosphodiesterase type 5 inhibitors, such as sildenafil, vardenafil, and tadalafil, are clinically effective and safe treatments.¹⁹⁰ For patients who are not responsive to oral administration of these drugs, other treatment options for improving erectile function include intracorporeal injection therapy with a prostaglandin or a mixture of a prostaglandin, an alkaloid, and an α -adrenergic blocker, or penile prosthetic surgery. A penile prosthesis is usually not offered to patients until 2 years after a radical prostatectomy to allow for tissue healing and adequate monitoring of cancer control.

In patients who experience ejaculatory dysfunction after RPLND, the postmasturbation urine should be investigated for the presence of sperm cells.¹⁹¹ Use of sympathomimetic agents may enhance seminal emission and partially or completely convert the

patient to antegrade ejaculation.¹⁹² Although multiple therapies for retrograde ejaculation exist, a comparison of the therapies is difficult and must be tailored to the individual.¹⁹³ Natural pregnancies have been reported, but use of assisted reproductive technologies is often needed. Even when retrograde ejaculation is present, sperm may be recovered from the bladder by direct voiding into a buffering medium or by catheterization and irrigation with a somewhat alkaline solution.¹⁹⁴ When no ejaculation is present, electroejaculation, using a rectal probe under general anesthesia, has been successful in most patients.¹⁹⁵ Although patients will have some antegrade ejaculate, catheterization should always be done to collect the retrograde semen. Sperm obtained by these methods can be used with IVF/ICSI procedures to achieve 15% pregnancy rates per cycle.

GENETIC CONCERNS

Biologic Considerations

Many anticancer agents damage DNA and interfere with its replication and repair and with chromosome segregation in both animal and human cells. These agents induce both single-gene and chromosomal mutations in germ cells of animals,¹⁹⁶ both of which cause genetic disease in the offspring. Mutations induced in stem spermatogonia cause the continued production of mutation-carrying sperm for the lifetime of the male, whereas those induced in later stages of spermatogenesis result in the production of mutation-carrying sperm for only a few months. Radiation and several alkylating agents produce single-gene mutations in murine spermatogonia, whereas other tested chemotherapeutic drugs do not.¹⁹⁶ Radiation is the only agent that effectively induces stable reciprocal chromosomal translocations in stem spermatogonia that can be transmitted to offspring.¹⁹⁷

In male rodents, meiotic and postmeiotic germ cells are more sensitive to induction and transmission of mutations than are stem spermatogonia.¹² Therefore, mutational risks are highest when a pregnancy occurs within one spermatogenic cycle (time required for stem cells to become sperm) after the male is exposed to the damaging agent. Clinical reports of outcomes of pregnancies in which conception occurred while the man was undergoing cytotoxic therapy are too limited to evaluate the risks, but animal experiments and gamete genetic analyses show a higher risk.¹² In men, this higher risk period extends from the start of cytotoxic therapy until 3 months after the last course. Damage to sperm DNA for up to 2 years after the completion of therapy has been reported in a patient undergoing radiation therapy and chemotherapy for testicular cancer and systemic therapy for Hodgkin's lymphoma.^{198,199}

Fewer studies of the mutagenicity of cytotoxic agents have been done in female mice, but the limited results indicate induced mutation frequencies similar to those in male mice. Radiation induces single-gene and chromosomal mutations in developing oocytes.²⁰⁰ Most alkylating agents and a variety of other chemotherapeutic drugs induce chromosome aberrations or other mutations in developing oocytes that result in embryonic death.¹⁹⁶ There are insufficient data to determine whether primordial or growing oocytes are more sensitive to the induction of mutations.

Pregnancy Outcome

In humans, nearly all of the case reports, small series, and a few large retrospective case studies of the outcomes of pregnancies in, or produced by, survivors of cancer indicated no significant increase in birth defects or genetic disease in offspring conceived after cytotoxic treatment above the background level in the general population of approximately 4% to 5%.^{7,200,201} No increase in genetic disease was observed in 630 offspring of patients who were children or adolescents at the time of treatment and received

alkylating agents or radiation proximal to the gonads.²⁰² A study of 368 conceptions in adult women treated previously with methotrexate alone showed no significant adverse effects, as expected.²⁰³ In males, 70 offspring of testicular cancer patients treated with radiotherapy or chemotherapy (most received cisplatin), or both, revealed no apparent increase in congenital malformations.²⁰⁴ In a case-control study involving 45,000 children with congenital abnormalities, there was no higher incidence of parental exposure to alkylating agents or radiation proximal to the gonads in the parents of children with congenital abnormalities than in the parents of the control group of children.²⁰⁵ The results from the atomic bomb studies in Japan also show no significant increase in genetic damage in the offspring born to radiation-exposed parents.²⁰⁶

These observations should reassure those who wish to have children after treatment for cancer. However, the power of these studies can only rule out twofold or higher increases in abnormalities; the possibility remains of a small genetic risk that would increase genetic abnormalities less than twofold over background levels. Also, these long-term studies do not include as many patients receiving the newer chemotherapeutic agents.

There are significant teratogenic risks from cytotoxic therapy given to a woman during pregnancy. Radiation is highly damaging; doses as low as 0.1 to 0.2 Gy in the first trimester and doses higher than 0.7 Gy in the second trimester cause microcephaly.²⁰⁷ Almost all cytotoxic chemotherapeutic agents are considered teratogenic; however, some may be safely given in the second and third trimesters of pregnancy.²⁰⁸ Treatment with fluorouracil, doxorubicin, and cyclophosphamide during this period did not result in any adverse effects. Methotrexate, which is a documented teratogen in the first trimester, was excluded from the combination.

Gamete Genomic Analysis

Because epidemiologic studies of genetic damage in humans require large numbers of offspring, direct analyses of the genetic material of gametes have huge potential advantages for identifying heritable

mutations in humans. Such analyses are used only in the male because harvesting female gametes is impractical. These analyses can be used to detect both single-gene and chromosomal mutations.

Chromosomal abnormalities are measured by sperm karyotyping after fusion with hamster eggs or by fluorescence in situ hybridization. Structural chromosomal aberrations were present in sperm more than 5 years after the end of MOPP or radiation therapy, or both, which indicates that they are induced in stem cells.²⁰⁹ Numerical aberrations (aneuploidy) can show up to a fivefold increase during and shortly after chemotherapy with mitoxantrone, vincristine, vinblastine, prednisone (NOVP) or BEP and then return to baseline within 4 months or 2 years, depending on the study.^{210,211} These results demonstrate that there can be significant genetic risks if conception or storage of sperm occurs during cytotoxic therapy, but that this risk declines after the end of such therapy.

Cancer patients should be informed by their physicians about the possibilities of sterility and genetic risk from their disease and its treatment. The probability that sterility will result from the planned cytotoxic therapy should be calculated from the cumulative doses of agents and combinations that cause prolonged azoospermia, ovarian failure, or pituitary damage (see Tables 141.3, 141.4, 141.6, 141.7, and 141.8). They should also be told about psychological and physical effects on sexual desire, erectile function, and the ability to achieve orgasm. Now that a large percentage of reproductive-aged patients are surviving cancer, different methods of fertility preservation (see Table 141.9) should be discussed with both male and female patients, and they should be given information about different education resources. Pretreatment gonadal function testing and referral to a reproductive endocrinologist should be considered.

142 Fatigue

Sandra A. Mitchell and Ann M. Berger

INTRODUCTION

Fatigue is recognized as one of the most common symptoms in patients receiving treatment for cancer, often persisting beyond the conclusion of active treatment and at the end of life.^{1,2} Longitudinal and comparative studies indicate that fatigue may also be a significant problem for cancer survivors, with many survivors reporting fatigue scores higher than that of an age-matched general population.^{3–5} Prevalence estimates of fatigue vary from 25% to 99%, depending on how fatigue is defined and measured.^{6–10} Fatigue is often found to occur as a component of a cluster of symptoms such as depression, pain, sleep disturbance, and menopausal symptoms.^{11–14}

Cancer-related fatigue (CRF) is a multifaceted condition characterized by diminished energy and an increased need to rest, disproportionate to any recent change in activity level, and accompanied by a range of other characteristics, including generalized weakness, diminished mental concentration, insomnia or hypersomnia, and emotional reactivity.^{15–17} Consequences of CRF include decrements in physical, social, cognitive, and vocational functioning^{18–20}; mood^{21–23} and sleep disturbances^{24–26}; as well as emotional and spiritual distress for both the patient and the family members.^{27–29}

This chapter reviews the state of the science concerning CRF, and offers guidance for practice and continued research. Major content areas relative to CRF are addressed and include: (1) definition and etiology, (2) explanatory models, (3) screening and evaluation of the patient with CRF, and (4) evidence-based pharmacologic and nonpharmacologic interventions to prevent and manage fatigue during and following cancer and its treatment.

DEFINITION AND ETIOLOGY OF CANCER-RELATED FATIGUE

The etiology and clinical expression of CRF is multidimensional. An inherently subjective condition, fatigue may be experienced and reported differently by each individual. Qualitative studies of fatigue underscore the fact that the cancer fatigue experience is unlike any other fatigue patients have previously experienced,³⁰ and patients emphasize that its unpredictability and refractoriness to self-management strategies that were previously effective make fatigue a particularly distressing symptom.³¹ Personality and coping style may also influence the experience of CRF.^{32–34} Some patients complain of a loss of efficiency, mental foginess, inertia, and that sleep is not restorative; others describe an excessive need to rest, the inability to recover promptly from exertion, or muscle heaviness and weakness.^{31,35} Whether these are features of CRF, the cause, or sequelae of fatigue, remains a focus of continued study.^{17,36–38} Efforts continue to be directed toward clarifying what are the defining features of fatigue,³⁹ and determining how CRF may be distinguished from syndromes such as depression, cognitive dysfunction, or asthenia that have overlapping symptoms^{20,40–44} or may share neurophysiologic mechanisms.^{45,46}

Despite its complex etiology and varied features at presentation, fatigue may be defined quite simply as a distressing, persistent, subjective sense of physical, emotional, and/or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and that interferes with usual functioning.⁴⁷ The criteria for a diagnosis of CRF syndrome¹⁵ are provided in Table 142.1.

The relative contributions to CRF of treatment with radiation, chemotherapy, hematopoietic stem cell transplantation, and hormonal, biologic, and molecularly targeted agents have been explored.^{6,8,10,39,48–52} Fatigue symptoms are known to fluctuate across the cancer treatment course,⁵³ although few relationships between treatment-related variables such as dose-intensity, schedule, and time since treatment completion have been observed.² Comparatively less is known about the association between surgical treatments and CRF.⁵⁴ During a course of fractionated radiation therapy, fatigue is often cumulative and peak severity may occur after radiation is concluded.⁵⁵

Although the precise pathophysiology is poorly understood, studies suggest that fatigue may be related to anemia; mood disorder; concurrent symptoms such as pain, sleep disturbances, electrolyte disturbances, cardiopulmonary, hepatic or renal dysfunction, hypothyroidism, hypogonadism, adrenal insufficiency, infection, dehydration, protein-calorie malnutrition, cachexia, asthenia, and deconditioning; and the side effects of drugs such as opioid analgesics or anticonvulsants that act on a central nervous system.^{43,50,52,56–65} Altered energy metabolism within skeletal muscle has been postulated to cause CRF. Both the tumor itself and treatment with radiation or chemotherapy can produce anemia or cachexia, and both of these may contribute to altered skeletal muscle energy metabolism, disrupted mitochondrial synthesis of ATP, or diminished oxygen delivery to muscle cells.⁶⁶ Treatment with radiation or chemotherapy can produce anemia or cachexia, and both of these may contribute directly or indirectly to altered skeletal muscle energy. Accumulating evidence also suggests that gene polymorphisms, disruptions in the hypothalamic-pituitary-adrenal (HPA) axis, altered circadian rhythmicity, immune dysregulation, altered proteomic pathways, and pro-inflammatory cytokine activity may directly or indirectly contribute to CRF.^{46,67–73} Associations between the occurrence and severity of CRF and demographic variables such as gender, age, marital status, and employment status have not been consistently identified.² In any one individual, the etiology of CRF is likely to be multifactorial, and contributors across the disease trajectory may fluctuate.

CURRENT THEORIES OF CANCER-RELATED FATIGUE

Several different explanatory models of CRF have been proposed. Many of these models use similar constructs. Conceptual models can be organized into four thematic groups: (1) energy balance/energy analysis models, (2) fatigue as a stress response models, (3) neuroendocrine-based regulatory fatigue models, and (4) hybrid models.

TABLE 142.1

International Classification of Diseases, 10th Revision, Criteria for Cancer-Related Fatigue

Six (or more) of the following symptoms have been present every day or nearly every day during the same 2-week period in the past month, and at least one of the symptoms is (A1) significant fatigue.

- A1. Significant fatigue, diminished energy, or increased need to rest, disproportionate to any recent change in activity level
- A2. Complaints of generalized weakness or limb heaviness
- A3. Diminished concentration or attention
- A4. Decreased motivation or interest to engage in usual activities
- A5. Insomnia or hypersomnia
- A6. Experience of sleep as unrefreshing or nonrestorative
- A7. Perceived need to struggle to overcome inactivity
- A8. Marked emotional reactivity (e.g., sadness, frustration, irritability) to feeling fatigued
- A9. Difficulty completing daily tasks attributed to feeling fatigued
- A10. Perceived problems with short-term memory
- A11. Postexertional malaise lasting several hours
- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. There is evidence from the history, physical examination, or laboratory findings that the symptoms are a consequence of cancer or cancer therapy.
- D. The symptoms are not primarily a consequence of comorbid psychiatric disorders such as major depression, somatization disorder, somatoform disorder, or delirium.

Data derived Cella D, Peterman A, Passik S, et al. Progress toward guidelines for the management of fatigue. *Oncology (Williston Park, N.Y.)* 1998;12:369–377, with permission.

Energy balance/energy analysis models depict energy as the major variable in fatigue and alterations in the balance among intake, metabolism, and expenditure of energy as factors in producing fatigue. Examples of this thematic group of models include the integrated fatigue model of Piper et al.,⁷⁴ the energy analysis model of Irvine et al.,⁷⁵ and the psychobiologic-entropy model of Winningham.⁷⁶ *Fatigue as a stress response* models posit that tiredness, fatigue, and exhaustion form an adaptational continuum of response to stress. Each state along this continuum from tiredness to exhaustion may be distinguished by different behavioral and symptom patterns. Examples of models included in this thematic class include fatigue models proposed by Aistars,⁷⁷ Rhoten,⁷⁸ Glaus,⁷⁹ and Olson.⁸⁰ *Neuroendocrine-based regulatory fatigue* models hypothesize that the multiple dimensions of fatigue are explained by dysregulation in the function of neuroendocrine-based regulatory systems including the hypothalamic–pituitary axis, circadian rhythms, and neuroimmune system transmitter secretion and function.⁸¹ Examples of models based on neuroendocrine dysregulation include those that have been proposed by Lee et al.,⁸² Payne,⁸³ and Schubert et al.⁷¹ Models that represent *hybrid* conceptual approaches have also been proposed. Olson et al.⁸⁴ have recently proposed a model of CRF suggesting that stressors associated with cancer and its treatment trigger declines in four systems—cognitive function, sleep quality, nutrition, and muscle endurance—and that these declines reduce one's ability to adapt. Al Majid and Gray⁸⁵ have also proposed a hybrid model that incorporates biologic, psychobehavioral, and functional variables implicated in the induction of fatigue, and have illustrated the application of this model to define the mechanisms by which exercise may ameliorate CRF.

Models in all four thematic classes may be helpful in generating testable hypotheses for continued research into the problem of

CRF and in guiding the development and evaluation of interventions to limit and manage fatigue, and to reduce its deleterious impact on health-related quality of life.

EVALUATION OF THE PATIENT WITH CANCER-RELATED FATIGUE

Studies suggest that CRF is underdiagnosed, that the assessment of fatigue in patients with cancer is suboptimal, and that health-care professionals may not fully appreciate the degree of distress and functional loss that fatigue produces.^{86–90} Identified barriers to communication between patients and their clinicians about fatigue include a tendency to view fatigue as an inevitable consequence of illness, clinicians' failure to offer interventions, patients' lack of awareness of effective treatments for fatigue, a desire on the patient's part to treat fatigue without medications, and a tendency to be stoic about fatigue to avoid being labeled as a *complainer* and to avoid prompting a change in therapy toward less active/aggressive treatments.^{86,91–93} Instruments to evaluate patient-derived barriers to fatigue management,^{94,95} self-efficacy for fatigue management,⁹⁶ and the contributing factors to fatigue⁵⁸ have been proposed.

Identifying patients with CRF is the first key step in improving fatigue evaluation and management. Although there is currently no consensus concerning the optimal method or frequency to screen for CRF in the clinical or research setting,^{97–99} evidence of the widespread occurrence of CRF suggests that routine screening for CRF at regular intervals throughout treatment, follow-up, and long-term follow-up is warranted. Technologies that use electronic or Web-based assessment routines, including computer-adapted testing (CAT), can streamline screening procedures and integrate fatigue screening into workflow.^{100,101}

There is accumulating evidence that single-item measures to screen for fatigue are rapid and sensitive, and can be applied efficiently in the clinic to identify patients who would benefit from more systematic evaluation.¹⁰² Based on National Comprehensive Cancer Network (NCCN) guidelines,¹⁰³ fatigue should be assessed quantitatively on a 0 to 10 scale (0 = no fatigue and 10 = worst fatigue imaginable); those patients with a severity of more than 4 should be further evaluated by history and physical examination.

Although a single-item measure may provide for a rapid assessment of general fatigue or serve as a screening tool, evidence suggests that single-item measures do not fully capture all the dimensions of fatigue.^{104,105} There is good consensus in the literature that fatigue generally consists of a sensory dimension (fatigue severity, persistence), a physiologic dimension (e.g., leg weakness, diminished mental concentration), and a performance dimension (reduction in performance of needed or valued activities). More than 20 self-report measures (including single-item measures, multi-item unidimensional scales, and multidimensional inventories) have been developed to measure fatigue in patients with cancer.^{106–110} Consideration of the measurement properties and strengths and limitations of these instruments, including reliability, validity, specificity, sensitivity to change, recall period, respondent burden, translation in multiple languages, and the availability of normed values to aid interpretation, should be used to guide decisions about the utility of a measure for specific clinical or research purposes.^{97,111–113} Ecologic momentary assessment (a technique that offers real-time measurement of a phenomenon as it occurs in a naturalistic setting) may overcome some of the methodologic limitations of fatigue assessment, including recall bias and the influence of current context on the self-report of fatigue.¹¹⁴

A detailed history in patients with moderate or severe CRF includes the presence, intensity, and pervasiveness of fatigue, its course over time, the factors that exacerbate or relieve fatigue, and the impact of fatigue on functioning and level of distress. Clinicians can obtain valuable information about the consequences of CRF by exploring the effects of CRF on self-esteem, mood, and the ability to perform activities of daily living; fulfill important roles as parent, spouse, and worker; and relate to family and

TABLE 142.2**Dimensions to Include in an Assessment of Fatigue**

Fatigue is a common problem for patients with cancer. It is a feeling of weariness, tiredness, or exhaustion that can include a loss of physical and/or emotional energy. Many factors can contribute to the fatigue that a person with cancer experiences.

- On a scale of 0 to 10, where zero is no fatigue and 10 is the worst fatigue imaginable, how severe has your fatigue been in the past 7 days:
- Would you say that your fatigue is mild, moderate, or severe?
- When did the fatigue start? _____
- Duration of fatigue: _____ Days per week or hours per day: _____
- To what extent have you, because of fatigue, had to limit social activity, had difficulty getting things done, or thought that fatigue was making it difficult to maintain a positive outlook?
- To what extent does fatigue interfere with relationships or fulfilling responsibilities at work or in the home?
- What makes your fatigue better?
- What makes your fatigue worse?
- What do you do to help with fatigue or manage fatigue?
- Does rest relieve your fatigue?
- Do you have any trouble sleeping?
- Do you have other symptoms such as pain, difficulty breathing, nausea, and vomiting?
- Do you experience anxiety? If yes, how often?
- Do you feel discouraged, blue, or sad? If yes, how often?
- Have you discussed your fatigue with anyone on your health-care team?
- Have you ever been given any recommendations for managing your fatigue?

friends. Also important to the evaluation is an assessment of what interventions the patient is using to manage fatigue and the effectiveness of them. The dimensions of the fatigue experience that should be explored when evaluating a patient with CRF are listed in Table 142.2.

In evaluating the patient with CRF, it is important to screen for treatable etiologic or potentiating factors including hypothyroidism, hypogonadism, adrenal insufficiency, cardiomyopathy, pulmonary dysfunction, anemia, sleep disturbance, fluid and electrolyte imbalances, emotional distress, physical inactivity, deconditioning, and uncontrolled concurrent symptoms.^{10,57,115–118} The medication profile should also be reviewed to identify specific classes of medications such as opiates, antidepressants, anticonvulsants, antiemetics, antihistamines, and beta blockers, and drug-drug interactions that can also intensify fatigue.^{19,103,119,120}

INTERVENTIONS FOR FATIGUE

Because fatigue typically has several different causes in any one patient, the treatment plan needs to be individualized. It is helpful to work with the patient and family caregivers to improve the assessment of fatigue and identify management strategies. Open communication between the patient, family, and caregiving team will facilitate discussion about the experience of fatigue and its effects on daily life. General supportive care recommendations for patients with fatigue include encouraging a balanced diet with adequate intake of fluid, calories, protein, carbohydrates, fat, vitamins, ABD minerals and balancing rest with physical activity and attention-restoring activities such as exposure to natural environments and pleasant distractions such as music.¹⁰³

There have been more than 210 empiric studies of pharmacologic and nonpharmacologic interventions to reduce or manage CRF and a number of meta-analyses or systematic reviews.^{121–134} These are summarized in Table 142.3, and selected findings are

TABLE 142.3**Evidence-Based Interventions for Fatigue During and Following Cancer and Its Treatment****Interventions for Fatigue with Strong Evidence Supporting Effectiveness**

- Exercise
- Education/information provision and supportive counseling
- Measures to optimize sleep quality
- Energy conservation and activity management
- Structured rehabilitation
- Yoga
- Management of concurrent symptoms

Interventions for Fatigue with Some Evidence Supporting Effectiveness

- Acupuncture
- Massage
- Levocarnitine supplementation
- Corticosteroids
- Ginseng
- Bright light therapy
- Mindfulness-based stress reduction
- Healing touch, hypnosis, relaxation

Interventions for Fatigue for which Effectiveness Has Not Been Established

- Paroxetine, methylphenidate, donepezil, bupropion sustained release, modafinil, etanercept, infliximab, amisulpride, sertraline, venlafaxine
- Correction of anemia less than 10 g/dL with erythropoiesis-stimulating agents
- Essiac, Chinese medicinal herbs, ginseng, mistletoe extract
- High-dose vitamin C, multiple vitamin, omega-3 fatty acid supplementation
- Adenosine 5'-triphosphate infusion
- Beta-hydroxyl beta-methyl butyrate, glutamine, and arginine mixture
- Individual and group psychotherapy
- Animal-assisted therapy, art therapy, expressive writing
- Reiki, aromatherapy, qigong, distraction/virtual reality immersion
- Combination therapy: aromatherapy, foot soak, and reflexology
- Combination therapy: medroxyprogesterone, celecoxib, and enteral food supplementation
- Combination therapy: soy protein supplementation and nutrition counseling following discharge from hospital

Interventions for Fatigue Supported by Expert Opinion

- Work with patient and family to improve assessment of fatigue and identify management strategies
- Promote open communication between patient, family, and caregiving team to facilitate discussions about the experience of fatigue and its effects on daily life
- Consider attention restoring activities such as exposure to natural environments and pleasant distractions such as music
- Encourage a balanced diet with adequate intake of fluid, calories, protein, carbohydrates, fat, vitamins, and minerals

Data derived from Mitchell SA. Cancer-related fatigue: State of the science. *PMR* 2010;2:364–383; Mitchell SA, Beck SL, Eaton LH. ONS Putting Evidence Into Practice (PEP): Fatigue. In: Eaton LH, Tipton JM, eds. *Putting Evidence into Practice*. Pittsburgh: Oncology Nursing Society; 2009; and Mitchell S, Beck S, Hood L, et al. Putting evidence into practice (PEP): evidence-based interventions for fatigue during and following cancer and its treatment. *Clinical J Oncol Nurs* 2007;11:99.

discussed here. Guidelines for the management of cancer-related fatigue have been disseminated by NCCN¹⁰³ and the Oncology Nursing Society.¹³⁵

PHARMACOLOGIC MEASURES

Several pharmacologic agents (including paroxetine, venlafaxine, methylphenidate, donepezil, bupropion, and modafinil) have been evaluated for their effectiveness at reducing fatigue during and following cancer treatment.^{122,126,136} Four trials have examined the effectiveness of paroxetine in treating fatigue during and following cancer treatment with mixed results. In three multicenter, randomized, double-blind, placebo-controlled trials, paroxetine 20 mg by mouth daily did not demonstrate a beneficial effect on fatigue outcomes, although improvements in depression and overall mood were noted in the paroxetine treatment group.¹³⁷⁻¹³⁹ However, two small trials show a trend toward a possible benefit for either paroxetine¹⁴⁰ or venlafaxine¹⁴¹ in treating fatigue in women experiencing hot flashes.

Two recent meta-analyses and a systematic review concluded that there is preliminary evidence supporting the use of methylphenidate to treat CRF, although more study of efficacy and tolerability was warranted.^{127,142,143} Recent evidence from a meta-analysis across trials suggests that the D-isomer form of methylphenidate may be more effective than other forms, and that patients with more severe and those demonstrating an improvement in fatigue within the first few days of methylphenidate treatment are the most likely to derive benefit.¹⁴⁴

Two small trials also suggest that donepezil 5 to 10 mg per day^{145,146} or bupropion sustained release at a dose of 100 to 150 mg per day^{147,148} may be effective at limiting fatigue. However, in a controlled trial of donepezil, improvements in fatigue outcomes were not observed.¹⁴⁹ Several trials also suggest that modafinil at a dose of 100 mg twice a day may be effective at treating fatigue and improving daytime wakefulness and cognitive function in patients during and following cancer treatment.¹⁵⁰⁻¹⁵³ Additional rigorously designed trials of donepezil, bupropion, and modafinil for fatigue appear warranted.

Several nutritional supplements including coenzyme Q10, levocarnitine, lectin standardized mistletoe, omega-3 fatty acid supplements, ginseng, guarana, and valerian have been explored, either as single agents or as part of a combination therapy.^{130,154-156} Several trials suggest that levocarnitine supplementation is effective in patients who have low serum carnitine levels.¹⁵⁷⁻¹⁶¹ However a large double-blind, placebo-controlled trial failed to demonstrate an improvement in fatigue outcomes in patients with malignancy and good performance status, even in those study participants who were levocarnitine deficient.¹⁶² Guarana 50 mg twice daily has been shown to be safe and effective at treating CRF in women with breast cancer in a randomized placebo-controlled cross-over study (n = 75)¹⁶³; however, guarana 75 mg once daily was not effective at treating fatigue in women with breast cancer who were undergoing radiation therapy.¹⁶⁴ The primary active ingredient in guarana is caffeine. A week course of Wisconsin ginseng dosed at 2,000 mg daily was effective at improving fatigue outcomes in cancer survivors and was well-tolerated in a large (n = 364) double-blind, placebo-controlled trial.¹⁶⁵

Low-dose dexamethasone at a dose of 4 mg twice daily for 2 weeks improved fatigue outcomes in a randomized placebo-controlled trial in 84 patients with advanced cancers.¹⁶⁶ Although adverse events were comparable in the dexamethasone and placebo groups, systemic corticosteroids could be associated with a prominent adverse effects profile in particular subpopulations such as those at the end of life.¹⁶⁷ A pilot, randomized placebo-controlled cross-over study has also shown evidence for the effectiveness and tolerability of thyrotropin-releasing hormone in improving fatigue outcomes in a small sample of cancer patients with significant fatigue.¹⁶⁸ Although male hypogonadism

is hypothesized to adversely affect mood and well-being,¹⁶⁹ a recent blinded, placebo-controlled trial of testosterone replacement therapy in a small sample of men with advanced cancer did not demonstrate positive effectiveness on fatigue end points.¹⁷⁰

TREATMENT OF ANEMIA WITH ERYTHROPOIESIS-STIMULATING AGENTS

Although data from seven systematic reviews suggest that patients receiving erythropoiesis-stimulating agents (ESA) to correct severe anemia (hemoglobin less than 10 g/dL) may experience diminished fatigue and increased vigor,¹⁷¹ there is only limited evidence that ESAs improve fatigue when anemia is less severe.¹⁷²⁻¹⁷⁶ In addition, a recent systematic review concluded that in many of the trials, the improvement in fatigue outcomes did not exceed the minimally important clinical difference.¹⁷⁷ Importantly, the use of ESAs for fatigue must be considered in light of safety issues, including an increased risk of thrombotic events, hypertension, and pure red cell aplasia, and concerns that ESAs may decrease local-regional disease control and survival outcomes in particular tumor types.^{173,175,178}

National clinical practice guidelines¹⁷⁹⁻¹⁸¹ and product labeling from the U.S. Food and Drug Administration¹⁸² should direct individualized management of patients with cancer- or treatment-associated anemia, including an analysis of the risks and benefits of ESAs versus packed red blood cell transfusions based on cancer treatment goals, and decisions about patient monitoring, treatment thresholds, dose reductions, treatment discontinuation, and the use of supplemental iron in patients receiving ESAs. Particular caution is needed when using ESAs in patients who are not receiving chemotherapy because recent trials report increased thromboembolic risks and decreased survival in this subpopulation.^{176,183-185}

EXERCISE

Meta-analyses of randomized trials support the benefits of exercise in the management of fatigue during and following cancer treatment in patients with breast cancer or solid tumors, or who are undergoing hematopoietic stem cell transplantation, although effect sizes are generally small, and positive results for the outcome of fatigue have not been observed consistently across studies.^{132,186-189} The exercise modalities that have been applied differ in content (walking, cycling, swimming, resistive exercise, or combined exercise), frequency (ranging from two times per week to two times daily), intensity (with most programs at 50% to 90% of the estimated VO₂ maximum heart rate), degree of supervision (fully supervised group versus self-directed exercise), and duration (from 2 weeks up to 1 year). Knowledge about the type, intensity, and duration of physical exercise that is most beneficial for reducing fatigue at different stages of disease and treatment is not known,¹⁹⁰ and more research is needed to systematically assess the safety of exercise (both aerobic exercise and strength training) in cancer subpopulations.¹⁹¹

MANAGEMENT OF CONCURRENT SYMPTOMS

A recent large randomized trial demonstrated that effective management of concurrent symptoms including pain, shortness of breath, insomnia, and depression also produces improvements in CRF outcomes.^{38,118} Four other RCTs (n = 200 cancer patients with major depressive disorder¹⁹²; n = 83 cancer survivors with fatigue¹⁹³; n = 45 women with metastatic breast cancer who were depressed¹⁹⁴; n = 78 advanced cancer patients with fatigue¹¹⁸ and

a small case series ($n = 6$ women with metastatic breast cancer)¹⁹⁵ as well as a systematic review,¹²⁸ confirm that cognitive-behavioral therapy (CBT) interventions for symptoms may also alleviate CRF, including fatigue that occurs as a component of a symptom cluster along with pain and insomnia.

PSYCHOEDUCATIONAL INTERVENTIONS

Several adequately powered randomized controlled trials suggest that educational interventions; cognitive-behavioral treatment for fatigue, depression, and other symptoms; and psychological support have a role in supporting positive coping in patients with fatigue.^{121,124,196,197} Psychoeducational interventions that have been shown to be effective include anticipatory guidance about patterns of fatigue and recommendations for self-management, counseling, and supportive psychotherapy, and coordination of care. Energy conservation and activity management is a self-management intervention that teaches patients to apply the principles of energy conservation and activity management and provides coaching to integrate these activities into their daily lifestyle.

INTERVENTIONS TO IMPROVE SLEEP QUALITY

Studies indicate that cognitive-behavioral interventions designed to improve sleep quality also have a beneficial effect on fatigue.^{198–201} In contrast, the efficacy of pharmacologic therapies in treating fatigue by reducing insomnia has had very little systematic study.²⁰² Cognitive-behavioral interventions to improve sleep quality can be delivered individually or in a group setting, and include relaxation training along with sleep-consolidation strategies (e.g., avoiding long or late afternoon naps, limiting time in bed to actual sleep time), stimulus control therapy (e.g., go to bed only when sleepy, use bed/bedroom for sleep and sexual activities only, set a consistent time to lie down and get up, avoid caffeine and stimulating activity in the evening), and strategies to reduce cognitive-emotional arousal (e.g., keep at least an hour to relax before going to bed, establish a presleep routine to be used every night). Morning exposure to bright light has been shown in two small randomized trials to prevent deterioration in CRF during chemotherapy for breast cancer,^{203,204} potentially by protecting recipients from circadian rhythm desynchronization during cancer treatment.²⁰⁵

STRUCTURED REHABILITATION

Several trials^{206–211} and two systematic reviews^{212–214} support a conclusion that structured rehabilitation programs delivered formally by a multidisciplinary group result in statistically significant and sustained improvements in fatigue, particularly in patients who have completed treatment and are in the survivorship phase. However, because at least one study²¹⁵ suggests that programs that are

too intensive may actually worsen fatigue, tailoring based on the patient's current level of energy and stage along the treatment trajectory is important.

INTEGRATIVE THERAPIES

There is preliminary evidence to support the efficacy of integrative approaches to the treatment of fatigue, including yoga, relaxation, mindfulness-based stress reduction, acupuncture, medical qigong, massage, healing touch, and Reiki, and combined-modality interventions that include aromatherapy, lavender foot soaks, and reflexology.^{125,128} The design of these studies tend to be open label and/or uncontrolled, with no random assignment, and with sample sizes that were extremely small, making it difficult to draw firm conclusions about efficacy. Despite these limitations, and with acknowledgment that the inclusion of controls such as double-blinding presents methodologic challenges,²¹⁶ results suggest that these complementary therapies have potential in the treatment of fatigue in patients with cancer.

Yoga practices have shown particular effectiveness at improving fatigue outcomes in two rigorously conducted RCTs in breast cancer survivors.^{217,218} Yoga may also have beneficial effects in reducing fatigue in other populations.^{219–224} However, four systematic reviews^{223–226} have concluded that the effectiveness of yoga on fatigue outcomes has not been consistently established across a wide range of patient populations and at all points in the cancer trajectory. In addition, the high risk of bias across studies with respect to sample selection and blinding of participants and outcome assessors was also noted.

SUMMARY

A wide range of pharmacologic and nonpharmacologic interventions have been studied, although many have been tested only in uncontrolled or pilot studies. Interventions for fatigue that are supported by one or more well-designed randomized trials include exercise, psychoeducational interventions, measures to optimize sleep quality, as well as integrative and behavioral approaches such as relaxation, mindfulness-based stress reduction, massage, and healing touch. There is preliminary evidence or inconclusive evidence to suggest that pharmacologic agents, including paroxetine, methylphenidate, donepezil, bupropion sustained release, modafinil, and levocarnitine, have a role in the management of fatigue, although systematic drug development studies are needed to define the optimal dosing, gauge the toxicity profile, and determine the effectiveness of these agents in specific populations. Interventions for which there is preliminary evidence of effectiveness include individual and group psychotherapy and complementary therapies such as yoga and acupuncture. Rigorously designed and adequately powered randomized controlled trials of the therapies for fatigue that have shown initial promise are urgently needed.

143 Second Cancers

Lois B. Travis, Smita Bhatia, James M. Allan, Kevin C. Oeffinger, and Andrea Ng

INTRODUCTION

The occurrence of second primary cancers (SPC) in cancer survivors is one of the most serious and lethal complications of cancer and its therapy. Subsequent malignancies comprise about 18% of all incident cancers in the United States,¹ superseding first cancers of the breast, lung, and prostate. As such, second-order and higher order cancers are now the most common incident cancer and have been identified as one of the National Cancer Institute's (NCI's) Provocative Questions.² Increases in the prevalence of subsequent malignancies mirror advances in cancer survival, and thus reflect improvements in early detection, supportive care, and treatment. For all cancers combined, the 5-year relative survival rate has advanced steadily over the past few decades and is now approximately 66.1% for patients diagnosed between 1999 and 2006.¹ There are presently over 13.7 million cancer survivors in the United States, representing approximately 4% of the population,³ and this number continues to grow at a rate of about 2% per year.⁴ By 2022, it is anticipated that this population will expand to 18 million. Commensurately, it is expected that the number of patients with subsequent and higher order malignancies will increase.

In view of these rising numbers, it is important to recognize that SPC may not necessarily be due to the late sequelae of cytotoxic treatment, but rather reflect shared etiologic influences (including tobacco and excessive alcohol intake), environmental determinants, host factors, genetic predisposition, and combinations of influences including gene-environment interactions.^{5,6} Even though treatment can, in part, enable patients to live long enough to develop SPC, therapy in and of itself might not be solely responsible for their occurrence. A population-based survey of the U.S. Surveillance, Epidemiology and End Results (SEER) registries concluded that cancer treatment may cause only a minor proportion of all SPCs after all adult-onset cancers considered together, although it has a considerably larger role in survivors of childhood cancer.⁷ Nonetheless, among long-term survivors of selected adult-onset cancers such as Hodgkin lymphoma (HL), SPCs are one of the most common causes of death.⁸ Although the carcinogenicity of radiotherapy has long been recognized,^{9,10} an increasing body of research points to the importance of the role of chemotherapeutic agents, not only in the development of treatment-related leukemias, but also now in selected solid tumors including cancers of the lungs, sarcoma, thyroid, stomach, bladder, and kidney.^{9,10} Although in many patients, the development of SPC can be lethal, outcomes in patients after a SPC are being increasingly studied.¹⁰⁻¹⁶ Moreover, a number of patients may develop third and higher order cancers.¹⁷ The important role of genetic susceptibility in the development of SPC was reviewed in 2006 by Travis et al.,⁶ but major advances in genomics now underscore the importance of these factors. Shared genetic pathways for a number of different tumor types were recently highlighted by Sakoda et al.¹⁸ (Fig. 143.1). The focus of this chapter will be treatment-associated malignancies, taking into account new data on radiotherapy and chemotherapy carcinogenicity, genetic underpinnings, and outcomes.

CARCINOGENICITY OF INDIVIDUAL TREATMENT MODALITIES

Radiation Therapy

The leukemogenic and carcinogenic effects of ionizing radiation have long been recognized in atomic bomb survivors¹⁹⁻²⁵ and individuals exposed to low doses of radiation for diagnostic purposes or therapeutic radiation for benign conditions.²⁶⁻³⁰ The relation between radiation dose and cancer risk is well described in these low-dose ranges, with an approximately linear increase in risk with increasing radiation dose up to about 5 Gy for solid tumors,^{22,31,32} and up to 1.5 to 2 Gy for leukemia.^{10,23,33,34} The traditional view has been that increased cell killing occurs in the higher dose region and, therefore, results in a lowered cancer risk, whereas tissues exposed to intermediate doses are at highest risk for cancer development. A classic radiation dose-response curve plotting the incidence of cancer against the dose of radiation absorbed has a characteristic shape, with the incidence of malignancy increasing with a dose up to a maximum of about 3 to 10 Gy, followed by a decrease in cancer risk with a further increase in dose.^{34,35}

Much of the data on the leukemogenic and carcinogenic effects of radiation in the higher dose range were derived from cancer survivors who have received therapeutic radiation.^{9,10} In assessing radiation-related SPCs in these patients, it is important to take into consideration other potential contributing factors. These include exposure to cytotoxic drugs (see Chemotherapy section), genetic predisposition,³⁶⁻⁴⁰ immunosuppression,^{41,42} infections,⁴²⁻⁴⁴ environmental exposures,⁴⁵ and heightened surveillance in cancer survivors.⁴⁶ Additional factors can modify the effect of radiotherapy on SPC risk. Patients with certain cancer prone syndromes, including hereditary retinoblastoma (RB), nevoid basal cell carcinoma syndrome, and neurofibromatosis-1 are more susceptible to radiation-induced cancer.^{36,47-49} More recently, genome-wide association studies (GWAS) have identified single nucleotide polymorphisms (SNP) associated with sensitivity to radiation-related cancers.⁵⁰⁻⁵² Tobacco history increases the risk of treatment-related lung cancer in a multiplicative manner as demonstrated in a case-control study of HL survivors.⁵³ Younger age at irradiation is associated with a significantly increased risk of breast cancer⁵⁴⁻⁵⁹ and thyroid cancer,^{54,60} as shown in survivors of HL, breast cancer, and childhood cancer. On the other hand, early menopause has a protective effect on breast cancer after radiotherapy in HL survivors,^{61,62} suggesting that ovarian hormones play an important role in promoting tumorigenesis once an initiating event has been induced by radiation.

More recent studies have addressed the effect of radiation dose in the therapeutic range on SPC risk by estimation of radiation dose at the site of SPC development. The risk of radiation-related cancer has been shown to increase with increasing dose for cancers of the breast,^{59,61-63} esophagus,⁶⁴ lungs,^{53,65} stomach,⁶⁶ meningioma,⁶⁷ and sarcoma,⁶⁸⁻⁷⁰ with no evidence of a downturn in risk at high doses within the therapeutic range. Preliminary data also

Figure 143.2 Treatment plans with three-dimensional (3D-CRT) (left), VMAT (middle, left), proton therapy (PT) (middle, right), and MF (right) treatment for two different patients with mediastinal HL are shown in dose color wash. The top panels show the treatment plans for patient 1; the lower panels are for patient 2. (With permission from Maraldo MV, Brodin NP, Aznar MC, et al. Estimated risk of cardiovascular disease and secondary cancers with modern highly conformal radiotherapy for early-stage mediastinal Hodgkin lymphoma. *Ann Oncol* 2013;24:2113–2118.)

promise for reducing SPC risk as a result of low neutron contamination.^{83,85} This technique utilizes magnetically scanned pencil beams over the target volume, does not require scattering devices, collimation, or compensation, and therefore, is associated with reduced secondary neutron production from the treatment head.

There has been a growing literature on the estimation of SPC risks using radiobiologic modeling of SPC risk with these new radiotherapy techniques and delivery systems,^{80,86} some of which focused on specific disease sites, including prostate cancer,^{87–90} HL,^{91,92} gynecologic malignancies,⁹³ lung cancer, and childhood malignancies.^{90,94} The estimated risks vary considerably depending on the model assumptions.^{88,89,92} Several studies estimated the lowest SPC risk with the scanning proton beam technique.^{91,94,95} Epidemiologic data for SPC risks in patients treated with modern techniques are currently lacking. Preliminary epidemiologic data on SPC risks following proton beam therapy for 503 patients treated at the Harvard Cyclotron with proton radiotherapy with passive scattering were reported.⁹⁶ Compared to a matched cohort of 1,591 photon-treated patients identified in the SEER database,⁹⁶ treatment with photon therapy was associated with a significantly increased risk of SPC (hazard ratio, 2.73; $p < 0.0001$) after adjusting for age and gender. The median duration of follow-up was 6.1 and 7.7 years, respectively, in the photon and proton cohorts. Additional observation time may be needed to fully assess the long-term SPC risks following proton therapy. In a recent report issued by the National Council on Radiation Protection and Measurements (NCRP),⁹ recommendations with regard to future research on treatment-associated SPCs were outlined and are summarized in Table 143.1.

Chemotherapy

The association between alkylating agents and acute myeloid leukemia (AML) has long been recognized. Alkylating agents with known or suspected leukemogenic effects include mechlorethamine, chlorambucil, cyclophosphamide, melphalan, semustine, lomustine, carmustine, procarbazine, prednimustine, busulfan, dihydroxybusulfan, and the platinating agents.^{97–100} Of these, the platinating agents are the most commonly used group of cytotoxic drugs worldwide, and the most recently identified class of drugs for which highly significant dose-response relationships with therapy-associated leukemia have been observed.^{101,102} Chemotherapeutic topoisomerase II poisons, such as the epipodophyllotoxins (e.g., etoposide), the anthracyclines (e.g., epirubicin), and anthracenediones (e.g., mitoxantrone), are associated with a clinically and cytogenetically distinct type of AML, which show a relatively short induction period (median 2 to 3 years) and typically present without preceding myelodysplastic syndrome (MDS).^{105–105}

Although the risk of treatment-related leukemias following chemotherapy has long been established, the induction of solid tumors is less well understood. Elevated risks of cancers of the bladder,¹⁰⁶ bone,¹⁰⁷ the lungs,⁵³ gastrointestinal sites,^{66,108} and the thyroid¹⁰⁹ following chemotherapy have been reported. There are also suggestions of associations between anthracyclines and excess sarcomas and thyroid cancers.^{108,109} Wilson et al.¹¹⁰ reported a 3.5-fold increased risk of renal cell carcinoma, albeit based on four cases, after cisplatin exposure in childhood cancer survivors. More recently, Fung et al.¹¹¹ found a significant threefold (standardized incidence ratio [SIR] 3.37; 95% confidence interval [CI], 1.798 to 5.77; $n = 13$ cases) risk of renal cell carcinoma

TABLE 143.1

Summary of Conclusions and Research Recommendations of the NCRP 1-17 Report on Second Malignant Neoplasms after Radiotherapy

Conclusions

- Second malignant neoplasm (SMN) after radiotherapy (RT) are experienced by an ever growing number of cancer survivors.
- Quantitative estimates of RT-induced SMN are: (1) derived from studies incorporating comprehensive dose reconstructions, (2) although based on past regimens, are applicable to risk assessment following current RT in terms of organ-specific doses and dose-response relationship.
- Newer RT modalities and treated techniques, which include intensity-modulated radiation therapy (IMRT) and protons, result in different organ dose distributions.
- Computational models are useful for SMN risk assessment and comparisons with other RT modalities.
- Few reports describe survival after SMN.
- For individual and epidemiologic risk assessment, the effective dose (a construct for radiation protection purposes) should not be used. Instead, the organ-specific absorbed dose coupled with the appropriate relative biologic effectiveness for end point of interest and radiation type (e.g. electrons, protons, neutrons) should be used for the risk assessment.

Research Recommendations

- Overarching recommendations:
 - a) Long-term large-scale follow-up of extant cancer survivors to characterize the risks of SMNs and to evaluate role of comorbidities and effect modifiers
 - b) Follow-up of prospective cohorts of cancer patients to evaluate the life-long risks of SMNs, including:
 - Populations treated with newer RT modalities (including IMRT, tomotherapy, stereotactic RT, CyberKnife, gamma knife, and protons)
 - Cancer sites for which a reduction in field size and radiation dose have been implemented (e.g., HL, testis cancer), and cancer populations not treated with radiation (e.g., testes cancer patients treated with surgery) to define natural history and baseline risks
 - Collect biologic specimen for an evaluation of genetic factors in survival and development of SMNs
- Specific recommendations:
 - a) Given the differing dose-response relationships for various SMNs, analytic studies should continue to address the relationship between dose and risk.
 - b) Compare the risks of SMN after different RT modalities.
 - c) Address interactions between RT and other risk factors for SMNs.
 - d) Particular attention should be given to adolescents and young adult cancer survivors, given the scarcity of data.
 - e) Molecular and genetics underpinnings:
 - Investigate genetic contributions of RT associated SMNs.
 - Intensively study patients who develop two or more primary cancers likely associated with RT.
 - f) Risk prediction models:
 - Develop comprehensive risk prediction models for SMNs to stratify patients into risk groups to customize follow-up strategies and develop evidence-based interventions.

in a population-based study of 6,013 testicular cancer survivors treated in the modern cisplatin-based era (also see Testicular Cancer section). Just as the study of chemotherapy-induced leukemia has yielded considerable insight into the molecular mechanisms underlying SPC etiology, it will also be important to determine whether these or other mechanisms might be operant in second solid tumors.

Other agents used in cancer therapy may also have leukemogenic and carcinogenic effects. Immunosuppressants, including azathioprine, a thiopurine pro-drug related to 6-mercaptopurine and 6-thioguanine, is associated with significant excesses of AML,¹¹² where risk is modified by host genetics (discussed in the Genetics section). In addition, azathioprine is also linked to the development of non-Hodgkin lymphoma (NHL),¹¹³ skin cancer,¹¹⁴ and brain tumors.¹¹⁵ There is evidence that granulocyte colony-stimulating factors, which are used in the treatment of lymphoblastic leukemia, breast, and other conditions, may also be associated with an increased risk of therapy-related AML.¹¹⁶⁻¹¹⁹ Similarly, the tyrosine-kinase inhibitors, such as imatinib, which is used to treat Philadelphia chromosome-positive cancers, including leukemia and gastrointestinal stromal tumors, might also be leukemogenic.¹²⁰⁻¹²³

Cancer after Bone Marrow Transplantation

Cancer after bone marrow transplantation is reviewed in Chapter 101. In brief, in survivors of high-dose therapy with bone marrow or stem cell transplantation, the estimated 10-year incidence of MDS/AML is 5% to 20%.¹²⁴⁻¹²⁶ Risk factors include the use of total body irradiation (TBI) in the conditioning regimen, prior radiotherapy, extent and type of prior chemotherapy, peripheral stem cell source, and low stem cell dose. Increased solid tumor risks are also evident after bone marrow or stem cell transplantation.¹²⁷⁻¹²⁹ Friedman et al.¹³⁰ reported a 25-year cumulative incidence of breast cancer of 11% among 3,337 female 5-year survivors of allogeneic hematopoietic stem cell transplantation. In a multivariable analysis, risk factors included time since transplantation, use of TBI, and age <18 years at transplant. Rizzo et al.¹³¹ found a 3.3% 20-year cumulative risk of solid tumors in 28,874 recipients of allogeneic stem cell transplantation. The use of TBI as conditioning was significantly associated with solid tumor risk, but was restricted to patients age <30 years at transplant. The risk of invasive solid cancers among 4,318 allogeneic hematopoietic cell transplant (HCT) recipients given high-dose busulfan-cyclophosphamide without total body irradiation was 1.4-fold (95% CI,

1.08 to 1.79).¹³² Chronic graft-versus-host disease was an independent risk factor for all solid cancers, especially those of oral cavity.

GENETIC SUSCEPTIBILITY TO SECOND PRIMARY CANCERS

The role of chemotherapy and radiation in the development of SPC is well-established,^{9,10} although the existence of considerable interindividual variability suggests a role for genetic variation. Proposed mechanisms for susceptibility to the development of SPC after exposure to genotoxic therapy are summarized in Figure 143.3. SPC risk could potentially be modified by mutations in high-penetrance genes that lead to serious genetic diseases such as Li-Fraumeni syndrome,¹³³ Fanconi anemia,^{134–137} and RB (see Pediatric Malignancy section). In fact, clues to the identification of loci important in affecting the risk of SPCs were initially suggested from studies of constitutional human cancer susceptibility syndromes (e.g., neurofibromatosis [NF]), many of which confer acute sensitivity to the mutagenic and cytotoxic effects of chemotherapy and radiotherapy, and where elevated risks of SPC are known or suspected.^{47,138} Consistent with this hypothesis, whole-genome sequencing of a patient with therapy-related AML identified a novel constitutional heterozygous deletion of *TP53*, affecting exons 7 through 9 encoding the DNA-binding domain of the protein. This likely represents a founder mutation in this patient with first primary breast and ovarian cancers and is consistent with a

Li-Fraumeni syndrome–like phenotype.¹³⁹ However, because of their low frequency, these alleles appear to contribute to only a small fraction of SPC risk at the population level. Nevertheless, this case highlights the possibility that *TP53* and other established cancer susceptibility genes might harbor other novel low-frequency alleles conferring susceptibility to therapy-induced SPC, either with or without associated familial susceptibility to disease.

Evidence suggests that outside the context of familial cancer susceptibility syndromes, the genetic contribution to chemotherapy and radiotherapy-related cancer risk is multigenic, and likely related to the coinheritance of common low-penetrance polymorphisms in genes that regulate the availability of active drug metabolites, or those responsible for DNA damage signaling and repair. In the multigenic model, penetrance for SPC is predicted to be modulated by gene exposure and gene–gene interactions. For example, Ellis et al.¹⁴⁰ utilized a case-control study design (171 cases) to examine the association of t-MDS/AML with two common functional p53-pathway variants—the mouse double minute 2 homolog (MDM2) SNP309 and the TP53 codon 72 polymorphism.¹⁴⁰ Although neither polymorphism demonstrated a significant association, an interaction was detected such that patients with both *MDM2* G and *TP53* pro alleles were at increased risk of chemotherapy-related t-MDS/AML (interaction term $p = 0.009$). MDM2 is an E3 ubiquitin-protein ligase that recognizes the N-terminal transactivation domain of TP53 and negatively regulates its transcriptional activity in response to DNA damage. As such, interaction at the genetic level to modify SPC risk is plausible.

Figure 143.3 Proposed mechanisms of susceptibility to single nucleotide polymorphism (SPC) development after exposure to genotoxic chemotherapy and translational potential for patient care (preemptive pharmacogenomics). Similar principles could be applied for preemptive radiogenomics (refer to text). (Figure adapted and modified from Seedhouse C, Russell N. Advances in the understanding of susceptibility to treatment-related acute myeloid leukemia. *Br J Haematol* 2007;137:513.)

Strengths of this study included the utilization of discovery ($n = 80$) and replication ($n = 91$) case sets. However, the investigators utilized healthy controls as a comparison group, thus precluding the ability to assess whether case-control differences reflected differences in susceptibility to primary disease or t-MDS/AML.

Genetic variation contributes 20% to 95% of the variability in cytotoxic drug disposition.¹⁴¹ Polymorphisms in genes involved in drug metabolism and transport are relevant in determining both disease-free survival and drug toxicity.¹⁴² Variation in DNA damage signaling and repair also plays a role in susceptibility to de novo cancer,¹⁴³⁻¹⁴⁵ and likely modifies SPC risk after exposure to DNA-damaging agents. Just as the pharmacology of cancer chemotherapy is impacted by underlying principles of pharmacokinetics, pharmacodynamics, and pharmacogenomics, these influences likely also contribute to SPC risk. Many loci that affect SPC risk encode proteins that metabolize and detoxify human carcinogens in an exposure-specific manner.¹⁴⁶⁻¹⁴⁹

Drug-Metabolizing Enzymes—Activation/ Detoxification Pathways

The metabolism of genotoxic agents occurs in two phases. Phase I involves activation of substrates into highly reactive electrophilic intermediates that can damage DNA, a reaction principally performed by the cytochrome P-450 family of enzymes. Phase II enzymes (conjugation) function to inactivate genotoxic substrates, and include glutathione S-transferase (GST), NAD(P)H:quinone oxidoreductase-1, and others. The high activity of a phase I enzyme and the low activity of a phase II enzyme can result in DNA damage from excess harmful products (see Fig. 143.3).

Cytochrome P-450 Enzymes

The chemotherapeutic substrates of cytochrome P-450 proteins include cyclophosphamide, ifosfamide, thioTEPA, doxorubicin, and dacarbazine.¹⁵⁰ The expression of these enzymes is highly variable among individuals because of several functionally relevant genetic polymorphisms, some of which are suspected to impact on SPC risk in patients treated with DNA damaging chemotherapy for a first primary cancer.^{146,147}

Glutathione S-Transferases

Polymorphisms exist in cytosolic subfamilies such as μ [M], π [P], and θ [T]. GSTs detoxify doxorubicin, lomustine, busulfan, chlorambucil, cisplatin, cyclophosphamide, melphalan, and others.¹⁵¹ A common functional polymorphism in GSTP1 is associated with a significantly increased risk of developing therapy-related AML after exposure to chemotherapy that includes a leukemogenic GSTP1 substrate (chlorambucil, cyclophosphamide, melphalan, or doxorubicin) (odds ratio [OR], 4.34; 95% CI, 1.43 to 13.20), but does not influence the risk of radiogenic leukemia.¹⁵² Fabiani and colleagues¹⁵³ also report an association with therapy-related myeloid neoplasia ($n = 94$ case) in carriers of the GSTP1 codon 105 risk allele (OR, 1.60; 95% CI, 0.95 to 2.69; $p = 0.08$), although findings were not stratified by treatment modality or exposure to a GSTP1 substrate.

DNA Repair

Variants in pathways that mediate cellular response to genotoxic damage are also likely to influence the risk of chemotherapy and radiotherapy-induced cancer, such as cell death signaling, cell proliferation, and DNA repair (*MLH1*,¹⁵⁴ *MSH2*,¹⁵⁵ *XPB*,¹⁵⁶ *XRCC1*,¹⁵⁷ *XRCC3*,¹⁵⁸ *NBN*,¹⁵⁸ *RAD51*,¹⁵⁹⁻¹⁶¹ and *P73*¹⁶²). DNA repair mechanisms protect cells from mutations in tumor suppressor genes and oncogenes that can lead to cancer initiation and

progression, with an individual's DNA repair capacity largely genetically determined.¹⁶³ A number of DNA repair genes contain polymorphic variants, resulting in large interindividual variation in repair capacity, which could affect SPC risk.¹⁶³ In support of this, a study of HL survivors suggested that those who developed a SPC had higher baseline levels of DNA damage than those who remained cancer free.¹⁶⁴

Mismatch Repair

Mismatch repair (MMR) functions to correct mismatched DNA base pairs that arise as a result of misincorporation errors that avoided polymerase proofreading during DNA replication.¹⁶⁵ Defects in this pathway result in genetic instability or a mutator phenotype, manifested by an elevated rate of microsatellite instability. Up to 90% of therapy-related AML patients have microsatellite instability, associated with methylation of the MMR family member *MLH1*,^{166,167} low expression of *MSH2*,¹⁶⁸ or polymorphisms in *MSH2*.^{155,169}

Double-Strand Break Repair

High levels of double-strand breaks follow ionizing radiation and chemotherapy exposures. Cellular pathways available to repair double-strand breaks include homologous recombination, non-homologous end joining, and single-strand annealing.¹⁷⁰ *RAD51* is one of the central proteins in the homologous recombination pathway,¹⁷¹ and a common variant in the *RAD51* gene (*G-135C*) is significantly overrepresented in patients with therapy-related AML compared with controls (C allele: OR, 2.7; 95% CI, 1.17 to 6.02).¹⁵⁹ *XRCC3* also functions in the homologous recombination double-strand break repair pathway by directly interacting with and stabilizing *RAD51*,¹⁷² and functions to maintain genetic stability.^{173,174} A polymorphism at codon 241 in the *XRCC3* gene results in a Thr→Met amino acid substitution.¹⁷⁵ The variant Met-encoding allele has been associated with a higher level of DNA damage, and has also been associated with increased levels of chromosome deletions in lymphocytes after radiation exposure,¹⁷⁶ implying aberrant repair.¹⁷⁷ Although the *XRCC3* Thr241Met variant was not an independent risk factor for t-MDS/AML, a synergistic interaction with the *RAD51*-135C variant resulted in an eightfold increased risk of therapy-related AML (OR, 8.1; 95% CI, 2.2 to 29.7).¹⁵⁹ Genes encoding proteins responsible for signaling DNA strand breaks are also predicted to carry risk alleles for therapy-induced SPCs. Prime candidates include those encoding components of the MRE11/*RAD50*/*NBS1* (MRN) heterotrimeric complex responsible for recognition of DNA double-strand breaks in mammalian cells. Consistent with this hypothesis, the Women's Environmental, Cancer, and Radiation Epidemiology (WECARE) study (a population-based, multicenter, case-control study of 708 women with asynchronous bilateral breast cancer and 1,395 women with unilateral breast cancer) identified a haplotype encompassing the *RAD50* gene associated with the risk of contralateral breast cancer.¹⁷⁸ The report identified an interaction with radiation dose (interaction term $p = 0.006$), where carriers of the *RAD50* risk haplotype exposed to ≥ 1 Gy had an increased risk of contralateral breast cancer compared to unexposed carriers (rate ratio 4.31; 95% CI, 1.93 to 9.62). Taken together, these studies highlight the importance of gene-gene and gene exposure interactions in studies of SPC.

Base Excision Repair

Base excision repair corrects individually damaged bases that result from ionizing radiation and exogenous xenobiotic exposure. A common variant at codon 399 of the *XRCC1* protein, which is central to the base excision repair pathway and functions as a scaffold for other repair components,^{179,180} was associated with an increased risk of developing t-AML,¹⁵⁷ and has also been implicated as a risk factor in numerous other cancers.

Nucleotide Excision Repair

Nucleotide excision repair removes structurally unrelated *bulky* DNA lesions induced by radiation and chemotherapy. The nucleotide excision repair pathway is linked to transcription, and components of the pathway comprise the basal transcription factor IIH complex, which is required for transcription initiation by RNA polymerase II. Polymorphic variation in ERCC2, a component of the transcription factor IIH complex, has been associated with an increased risk of therapy-related AML.¹⁵⁶

Hypothesis-Generating Genome-wide Association Studies

The associations reported previously were identified based on known gene-exposure interactions and analysis of loci in relevant pathways. Unfortunately, stratification by exposure is not always possible, particularly when a biological role has not been defined or when gene-exposure interactions are speculative. In this case, the application of high-density single nucleotide polymorphism arrays or next-generation sequencing can prove useful in identifying genetic variants and cellular pathways potentially important in causing chemotherapy- and radiotherapy-related cancer,^{139,140,181,182} as have genome-wide and whole transcriptome-based studies in laboratory animals.^{183,184}

Knight et al.¹⁸¹ utilized a case-control study design to conduct a GWAS in patients who developed therapy-related leukemia (cases) and healthy controls. The discovery set included 80 cases and 150 controls. The relevant findings were replicated in an independent set of 70 cases and 95 controls. The investigators identified three SNPs (rs1394384 [OR, 0.29; 95% CI, 0.15 to 0.56], rs1381392 [OR, 2.08; 95% CI, 1.29 to 3.35], and rs1199098 [OR, 0.46; 95% CI, 0.27 to 0.79]) to be associated with t-MDS/AML with chromosome 5/7 abnormalities. The SNP rs1394384 is intronic to *ACCN1*, a gene encoding an amiloride-sensitive cation channel that is a member of the degenerin/epithelial sodium channel; rs1199098 is in linkage disequilibrium with *IPMK*, which encodes a multikinase that positively regulates the pro-survival protein kinase B (AKT) kinase and may modulate WNT/beta-catenin signaling; rs1381392 is not located near any annotated genes, miRNAs, or regulatory elements, although it lies in a region recurrently deleted in lung cancer. Although the investigators were able to confirm findings in an independent replication cohort, the utilization of a noncancer healthy control group raises concerns about any case-control differences being generated by the genetics of the primary cancer, rather than t-MDS/AML. Nevertheless, this study highlights the potential of GWAS to reveal novel risk alleles for SPC. Moreover, the identification of risk alleles unique to t-MDS/t-AML with somatic chromosome 5/7 abnormalities suggests that some risk alleles for SPCs may be subtype specific. Indeed, subtype-specific risk alleles have been identified for some first primary cancers. For example, Papaemmanuil and colleagues¹⁸⁵ identified a risk allele at the *ARID5B* gene for pediatric B-cell precursor acute lymphoblastic leukemia that appears to be selective for disease with somatic hyperdiploidy. Likewise, there is compelling evidence that estrogen receptor-positive and estrogen receptor-negative breast cancers have different genetic components to their etiology.^{186,187} These data highlight the importance of appropriate stratification to identify the context (e.g., gender, exposure, disease subtype) in which risk alleles for SPCs are operating and where penetrance for SPC is highest, an approach that will facilitate translation into the clinic for patient benefit.

Considering this model, Best et al.⁵² performed a GWAS to identify genetic variants associated with radiation-associated solid malignancies in HL survivors. They identified two variants at chromosome 6q21 associated with SPC, but which only modified risk in patients who were exposed to radiation in childhood and had no penetrance for SPC when exposure occurred in adulthood. The variants comprise a risk locus associated with decreased basal

expression of *PRDM1* and impaired protein induction after radiation exposure. These data suggest a novel gene-exposure interaction implicating *PRDM1* in the etiology of radiation therapy-induced SPC, with evidence that age at radiation therapy exposure modifies the association between variants in this gene and SPC risk. Hosking and colleagues⁵¹ also conducted a GWAS for inherited susceptibility to radiation-associated malignancy—specifically, meningioma in patients previously treated for tinea capitis. Although the average radiation dose to the brain was relatively low (~1.5 Gy), there was a significant increase in the risk of meningioma in exposed individuals (excess relative risk [ERR]/Gy 4.63; 95% CI, 2.4 to 9.1).¹⁸⁸ The high level of natural linkage disequilibrium in the exposed population allowed the authors to identify putative risk haplotypes associated with radiation-induced meningioma at 18q21.1 ($p = 7.5 \times 10^{-5}$), 18q21.32 ($p = 2.8 \times 10^{-5}$), and 10q21.3 ($p = 1.6 \times 10^{-4}$), although none reached GWAS significance and they require validation in independent cohorts with the inclusion of appropriate control groups to exclude an association with meningioma without a radiation etiology. To the extent that carcinogenic pathways operant at very low doses of radiotherapy may also be functional at the high doses given in cancer treatment, these genomic regions may also harbor risk alleles predisposing to meningioma in cancer survivors who were administered cranial radiotherapy.

Although most candidate gene association studies for SPC have focused on pathways involved in regulating cell death or maintaining genetic stability in response to genotoxic therapies, genome-wide approaches also have the potential to uncover risk alleles in novel pathways influencing the risk of therapy-induced malignancy. By conducting a genome-wide linkage study using inbred mice, Boulton et al.¹⁸⁹ identified genomic regions harboring putative risk loci for radiogenic AML. One such locus on chromosome 1 encompassed *Scfr1*, a gene encoding a key regulator of stem cell frequency, suggesting that the size of the stem cell pool at risk of transformation is genetically defined and a determinant of radiation-induced AML. If validated in human disease, these data would add another dimension to risk models of therapy-induced SPC.

Preemptive Pharmacogenomics and Preemptive Radiogenomics

Regardless of whether identified via candidate gene, genome-wide, or systems biology approaches, accurate estimates of the contribution of single gene variants will require large studies with sufficient power such that specific gene-gene or gene exposure can be identified. Indeed, the identification of the context in which penetrance for a genetic variant for SPC is greatest will facilitate the identification of patients at largest risk. Moreover, precise estimates of the magnitude of the effect(s) are required in order to develop personalized risk-adapted clinical strategies, including dose modification, alternative treatments, and posttherapy surveillance. Risk management could prove particularly important in children or young adults with primary cancers in whom cure rates are high and the risk of a subsequent cancer is associated with substantial morbidity or premature mortality.

In several instances, such as the relation between constitutional thiopurine methyltransferase (TPMT) activity and SPC risk, the goal of clinical translation has already been achieved. For example, children with acute lymphoblastic leukemia (ALL) who received combined-modality therapy that included 6-mercaptopurine at a dose of 75 mg/m² and who had high TPMT activity (conferred by constitutional polymorphism in the *TPMT* gene) had an 8.3% cumulative risk of subsequently developing a brain tumor, whereas children with low TPMT activity had a 42% risk of a posttherapy brain tumor ($p = 0.0077$).¹¹⁵ It was hypothesized that the deficient TPMT activity resulted in higher exposures to thio-guanine nucleotide metabolites of 6-mercaptopurine during the period of radiation. Likewise, patients with lower TPMT activity also had an increased risk of developing AML and other SPC after high-dose thioguanine chemotherapy.¹⁹⁰⁻¹⁹² However, a reduction

in 6-mercaptopurine dose (50 mg/m²), along with other changes adopted as part of the Berlin-Frankfurt-Munster protocol for the treatment of childhood ALL, appeared to attenuate the effect of *TPMT* status on risk of AML after thioguanine-containing chemotherapy.¹⁹³

The gene-exposure interaction between *TPMT* and chemotherapeutic thioguanine nucleotides is well-established and strongly associated with several life-threatening toxicities (bone marrow, hepatotoxicity) in cancer patients inadvertently *overtreated* with these agents as a consequence of genotype. Indeed, convincing evidence of acute toxicity in *TPMT*-compromised patients prompted the U.S. Food and Drug Administration (FDA) to add a warning to the drug along with information on genotype frequencies and a recommendation for *TPMT* genetic testing following the administration of 6-mercaptopurine for patients with clinical or laboratory evidence of severe bone marrow toxicity, particularly myelosuppression.¹⁹⁴ Evidence of elevated SPC risk in carriers of *TPMT* null alleles^{115,190–192} also underscores the importance of preemptive genotyping within this context, rather than posttherapy response-mode genotyping, particularly because there is now convincing evidence that toxicity and SPC risk can both be ameliorated with appropriate dose modification.¹⁹³ Preemptive testing for *TPMT* genotype and/or phenotype status is recommended by the Clinical Pharmacogenetics Implementation Consortium and others prior to initiating therapy that includes thioguanine nucleotides, including 6-mercaptopurine.^{192,195–201}

Although it remains to be determined whether the *TPMT* model can be extended to other gene exposure interactions involving therapeutic agents, dose, and/or regimen modification has the potential to reduce the risk of SPCs in genetically susceptible individuals. Indeed, this principle has also been applied to other populations at risk of therapy-induced SPC, such as patients with NF1. Neurofibromatosis (NF) (caused by mutations in the *NF1* gene) is an autosomal dominantly inherited disorder characterized by a predisposition to benign tumors of the nerve sheath. There is evidence from studies of both laboratory animals²⁰² and humans²⁰³ that constitutional heterozygosity for *NF1* pathogenic mutations confers susceptibility to radiogenic cancer, such that many investigators now recommend avoidance of radiotherapy whenever possible to treat tumors in NF patients.^{204,205}

Preemptive testing of either genotype or phenotype status, such that appropriate dose modification or alternative treatment approaches can be implemented at first treatment, is critical to reducing therapy-induced SPC risk in patients with a strong genetic predisposition. Although not routinely yet considered in the context of SPC risk, preemptive testing based on gene-exposure interactions could potentially be applied in other clinical settings, and the value of this approach as a mechanism to reduce acute adverse drug events is already evident.^{206,207} *TPMT* and *NF1* represent two examples where dose/regimen modification can ameliorate the risk of therapy-induced SPC in affected individuals, providing proof of principle of the potential value of preemptive genomics to reduce the risk of therapy-induced malignancy in selected cancer survivors (see Fig. 143.3). Moreover, as additional data are accrued with regard to molecular mechanisms that underlie radiotherapy-associated carcinogenesis,^{9,10,52,208} the principles previously outlined can also be expanded to introduce a new field of preemptive radiogenomics.

RISK OF SECOND MALIGNANCY IN PATIENTS WITH SELECTED PRIMARY CANCERS

Lymphoma

The use of combined-modality therapy in patients with both HL and NHL has resulted in significant improvements in survival, but with the attendant risk of SPCs, including leukemia and a number of solid tumors.²⁰⁹

Hodgkin Lymphoma

Reports from large, well-characterized cohorts of HL survivors show that the risk of SPC is 2 to 18 times higher than in the general population.^{55,56,210–218} Dores et al.²¹⁶ reported an analysis of 32,591 HL survivors (1935 to 1994) in 16 population-based registries. A total of 2,153 SPCs (relative risk [RR] = 2.3) was observed, including 1,726 solid tumors (RR = 2.0). The 25-year cumulative incidence of a solid tumor was 21.9%. Temporal trends for cancers of the female breast, thyroid, esophagus, stomach, rectum, bladder, and bone/connective tissue were suggestive of a radiogenic effect.

Hodgson et al.⁵⁴ reported on 18,862 5-year survivors of HL in 13 population-based registries from North America and Europe, treated between 1970 and 2001, and identified 1,490 cases of solid tumors (RR = 2.38). Cancers of the lung, breast, and gastrointestinal sites comprised the three most common diagnoses accounting for 21%, 19%, and 17% of the cases, respectively. The RRs of lung and breast cancers were 6.7 and 6.1, respectively, and the RR of gastrointestinal cancers ranged from 1.8 for anorectal cancer to 9.5 for stomach cancer. Other solid tumors with significantly increased risks included cancers of the head and neck, kidney, thyroid, gynecologic organs, soft tissue, bone, and brain.

It is important to recognize that radiation therapy for HL has undergone substantial changes in 4 decades with fields decreasing from total nodal irradiation to involved-field radiation therapy and, most recently, to involved site therapy. Prescribed dose has also decreased from 40 to 44 Gy to as low as 20 Gy in selected early-stage patients as part of combined modality therapy. Modeling studies show significant reduction in SPC with lower dose and smaller fields and with modern radiation therapy techniques. Many currently available epidemiologic studies of SPC after HL were based on patients treated in the earlier era, and long-term follow-up of patients treated with modern techniques will be needed to accurately assess SPC risk.

Non-Hodgkin Lymphoma

Several population-based studies have provided estimates of the risk of SPCs following NHL.^{91–95,219–223} In a study by Dores et al.,²²³ 5,490 subsequent cancers were observed among 73,958 2-month survivors of NHL, reflecting an overall elevated risk of 14% compared with the general population (observed-to-expected ratio [O/E] = 1.14; 95% CI, 1.11 to 1.7; excess absolute risk [EAR] = 19). The cumulative risk of SPC reached 12.3% within 25 years. Lung cancer accounted for the largest excess of SPCs after NHL. Results from the SEER program²²³ corroborated findings in previous surveys of NHL, which reported significant excesses of cutaneous melanoma, Kaposi's sarcoma, HL, AML, and cancers of the buccal cavity, lip, lungs, urinary bladder, and kidneys.^{219–221,224}

Radiotherapy for NHL appeared related to the increased risks for bladder cancer, bone sarcoma, and mesothelioma.²²³ Chemotherapy for NHL has been associated with an increased risk for leukemia²²⁵ as well as several solid tumors, including bladder cancer¹⁰⁶ with dose-dependent relationships. The immunosuppressive state associated with NHL²²⁶ may contribute to excesses reported for cutaneous melanoma, HL, and lip cancer.^{223,224,227,228} Most recently, analyses of the SEER program data reported SPC risk by major histologic groups of NHL,²²⁹ akin to studies of SPC after ovarian cancer.²³⁰ Among patients without known HIV/AIDS, the SIR of SPC after chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), diffuse large B-cell lymphoma (DLBCL) and follicular lymphoma (FL) were 1.19 (95% CI, 1.13 to 1.25), 1.11 (95% CI, 1.04 to 1.19), and 1.03 (95% CI, 0.96 to 1.11), respectively. Risks of lung cancer and melanoma were significantly increased in survivors of CLL/SLL and FL, but not DLBCL. Moreover, an elevated risk was observed regardless of whether radiation therapy was given as part of the initial treatment. An increased risk of acute nonlymphocytic leukemia was seen after FL and DLBCL, with a SIR of 4.96 (95% CI, 3.87 to 6.87)

and 5.96 (95% CI, 4.15 to 8.29), respectively, but not after CLL/SLL. The increased leukemia risk was restricted to survivors who received chemotherapy initially.

In summary, NHL survivors are at increased risk for a number of SPCs, although to a considerably lesser degree than HL patients. The persistent increase in the risk of all SPCs for more than 20 years after NHL treatment alerts clinicians to the importance of long-term surveillance.

Selected Second Primary Cancers Following Hodgkin Lymphoma or Non-Hodgkin Lymphoma

Breast Cancer

Breast cancer is one of the most common solid tumors after HL. Studies have consistently shown that young age at radiotherapy is associated with a significantly higher risk of breast cancer.^{54-57,231} In a population-based cohort study,⁵⁴ the absolute risks of breast cancer in women diagnosed with HL at ages 15 through 25 years were higher than the absolute risks of women in the general population between 50 and 54 years, a standard age when mammography screening is recommended. Travis et al.²³² developed estimates of the cumulative absolute risk of breast cancer, taking into account age and calendar year of HL diagnosis, current age, radiation dose, and competing causes of mortality. Thus, for a HL survivor who received a chest radiation dose of ≥ 40 Gy at age 25 years, the cumulative absolute risks of breast cancer at 10, 20, and 30 years were estimated to be 1.4%, 11% and 29%, respectively. A report from the Childhood Cancer Survivor Study (CCSS) estimated the risk of breast cancer in a cohort of 1,268 female 5-year childhood cancer survivors given chest radiation therapy. The overall cumulative incidence of breast cancer by age 50 years among HL survivors was 30% (95% CI, 25% to 35%).

There is a clear radiation dose-response relation for breast cancer risk after HL. In an international case-control study of breast cancer after HL that included 105 cases of breast cancer and 266 matched controls,⁶¹ radiation dose to the area of the breast where the tumor developed in the case (and a comparable area in controls) was estimated. Breast cancer risk increased significantly with increasing radiation dose to reach eightfold for the highest category (median dose 42 Gy) compared to the lowest dose group (<4 Gy) (p-trend for dose <0.001) (Table 143.2).

A significant radiation dose-response relation was similarly demonstrated in a Dutch study that was included in the previous international investigation.⁶² The CCSS also published a case-control study of 120 cases of breast cancer (65% in survivors of HL) matched to 464 controls.⁶³ Again, a significant linear radiation dose-response was observed (p-trend <0.0001), with an estimated relative risk of breast cancer of 6.4 at 20 Gy and 11.8 at 40 Gy (see Table 143.2). Radiation field size for HL also affects breast cancer risk. A cohort study of 1,122 5-year female HL survivors showed that mantle field irradiation (inclusion of mediastinum, bilateral axillae and neck) was associated with a 2.7-fold increased risk (95% CI: 1.1 to 6.9) of breast cancer compared with mediastinal irradiation alone.⁷⁴ A meta-analysis of SPC after HL found that extended-field radiotherapy was associated with a significantly higher breast cancer risk than involved-field radiotherapy (OR = 3.25; $p = 0.04$).⁷⁵ A study from Yale University evaluated solid tumor risks in 404 HL survivors and observed 10 cases of breast cancer in women who received radiation treatments that included the axillae, but no cases when the axillae were omitted from the field.

Early menopause has been shown to be protective against breast cancer in HL survivors treated with radiotherapy. In particular, the Dutch study clearly documented that breast cancer risk reduction associated with chemotherapy was due to premature menopause.⁶² In a more recent HL cohort study from the same group,⁷⁴ among women age <41 years at treatment, those women with >20 years of ovarian function post-treatment had a significantly higher risk

of breast cancer compared to patients with 10 to 20 years of intact ovarian function after therapy (hazard ratio = 5.3; 95% CI, 2.9 to 9.9).

Several studies have shown a reduced risk of breast cancer among NHL survivors compared to the general population, likely due to chemotherapy-related early menopause.^{233,234} Although breast cancer risk after mediastinal irradiation for NHL has not been specifically assessed, indirect data suggested an increased risk with younger age at irradiation. In a SEER-based study of 77,876 NHL patients,²²² the relative risk of breast cancer was significantly increased among women irradiated at age <25 years (RR = 5.05; $p < 0.05$), whereas breast cancer excesses were not observed in the entire irradiated cohort. Similarly, in a Swedish Cancer Registry-based study of 29,134 patients with NHL,²³⁵ the relative risk of breast cancer was significantly increased only among women diagnosed between age 20 to 39 years (RR = 3.29; 95% CI, 1.91 to 5.67) and not in older patients. The increased breast cancer risk in these young women may have been due to chest radiotherapy, although this cannot be confirmed because the sites of irradiation were not described.

Lung Cancer

Significantly elevated three- to sevenfold relative risks of lung cancer have been reported after HL,^{53-56,65,216,217,236} with a dose-dependent relationship documented for antecedent alkylating agent chemotherapy^{53,236} and for radiation dose to the area of the lungs in which the cancer developed.⁵³ The modifying effect of smoking history on treatment-related lung cancer in HL survivors was investigated in a case-control study by Travis et al.⁵³ Using patients who had minimal radiation or alkylating chemotherapy exposure and who were nonsmokers as the reference group, exposure to >5 Gy of radiotherapy and/or alkylating agent chemotherapy was associated with a 4.3- to 7.2-fold increased risk of lung cancer. The relative risk increased to 16.8 and 20.2, respectively, in patients who had either one of the treatment exposures and who used tobacco. Moreover, the relative risk was 49.1 in patients who had >5 Gy of radiotherapy, received alkylating chemotherapy, and who used tobacco, consistent with a multiplicative effect of tobacco use on the risk of treatment-related lung cancer.

The risk of lung cancer is modestly increased after NHL, with most studies reporting a risk of less than twofold compared to the general population.^{219,220,222,233-235,237,238} The increased risk appears to be associated with both chemotherapy and radiotherapy, with significantly increasing risk following higher cumulative doses of chemotherapy.²³⁷ Increased risks for malignant mesothelioma have been reported in survivors of both HL and NHL, although the excesses appear limited to irradiated patients.^{236,239,240}

Gastrointestinal Malignancies

Population-based and multi-institutional cohort studies have consistently reported an increased risk, compared to the general population, for cancers of the esophagus, the stomach, the colon, and the rectum among HL survivors.^{55,56,215,216,241,242} Van den Belt-Dusebout et al.⁶⁶ conducted a nested case-control study of 5,142 Dutch testicular cancer and HL survivors to examine the role of radiation dose and chemotherapy in the etiology of gastric cancer. Because age characteristics of the testicular cancer and HL patients were generally similar, these populations were pooled, although it should be kept in mind that the underlying cancers are distinctly different and that only males were represented in the former group. A 3.4-fold increased risk of gastric cancer was observed compared with the general population. Risk increased with increasing mean radiation dose to the stomach, with an ERR of 0.84 per Gy. Adjusted for radiation, higher doses of procarbazine ($\geq 13,000$ mg versus <10,000 mg) were associated with a 5.4-fold increased risk. Smoking more than 10 cigarettes per day was associated with a 1.6-fold increased risk compared with survivors who did not smoke.

TABLE 143.2

Relative Risk of Breast Cancer after Chest Radiotherapy According to Radiation Dose to Affected Site in Breast and Alkylating Chemotherapy Exposure

National Cancer Institute-International Study ^a				Childhood Cancer Survivor Study ^b			
Radiation Exposure							
Radiation Dose to Affected Site in Breast (Gy)	Cases/Controls	Relative Risk	95% Confidence Interval	Radiation Dose to Affected Site in Breast (Gy)	Cases/Controls	Relative Risk	95% Confidence Interval
0–3.9	15/76	1.0	(Referent)	0	13/127	1.0	(referent)

^a Population included women who were diagnosed with HL at age 30 years or younger and who survived 1 or more years. (Adapted from Travis LB, Hill DA, Dores GM, et al. Breast cancer following radiotherapy and chemotherapy among young women with Hodgkin disease. *JAMA* 2003;290:465–475.)

^b Population included patients diagnosed with the following primary cancers at age younger than 21 years and who survived 5 or more years: HL (65%), soft tissue sarcoma (7.5%), leukemia (5.8%), non-Hodgkin lymphoma (3.3%), central nervous system tumors (2.5%), kidney tumors (2.5%), and neuroblastoma (0.8%). (Adapted from Inskip PD, Robison LL, Stovall M, et al. Radiation dose and breast cancer risk in the Childhood Cancer Survivor Study. *J Clin Oncol* 2009;27:3901–3907.)

^c Dose scores were assigned to individual alkylating agents on the basis of the distribution of dose (mg/m²) of each agent, with scores then summed across agents.

In a nested case-control study of stomach cancer risk in 19,882 HL survivors,²⁴³ 89 cases and 190 matched controls were included, with 19 of the cases and 69 controls previously reported.⁶⁶ Risk was significantly associated with radiation dose to the stomach (excess OR, 0.09/Gy; p-trend <0.001) and number of cycles of alkylating chemotherapy (p-trend = 0.02). Patients who received gastric radiation doses of 25 Gy or more to the stomach and cumulative doses of procarbazine of 5,600 mg/m² or higher had an OR of 77.5 (95% CI, 14.7 to 1,452). Exposure to dacarbazine was also associated with an increased stomach cancer risk (OR, 8.8; 95% CI, 2.1 to 46.6), after adjustment for radiation and procarbazine dose.

Breast Cancer

Women with breast cancer are at significantly elevated risk for developing SPCs. The largest amount of data have accrued on the

risk of contralateral breast cancer (CBC), which is estimated to be increased two- to fivefold. Factors that may modify the increased risk include preexisting breast cancer risk factors such as genetic predisposition, reproductive factors and health habits, as well as treatment exposures.^{244–247}

Conflicting data exist on the contribution of radiotherapy to excess risks of CBC.^{248–251} In a case-control study by Boice et al.,²⁵⁰ the overall relative risk of CBC was not significantly increased after radiotherapy (RR, 1.19; 95% CI, 0.94 to 1.15). Among women age <45 years at the time of irradiation, however, the relative risk was significantly elevated at 1.59 (95% CI, 1.07 to 2.36). Hooning et al.⁵⁸ assessed the long-term risk of CBC in 7,221 breast cancer survivors, and found a 2.91-fold (95% CI, 2.66 to 3.18) increased risk compared with the general female population (absolute excess risk [AER] = 46.1 out of 10,000 person-years). The risk of radiotherapy-related CBC also increased significantly with decreasing age at treatment; among women who received radiotherapy at age <35 years,

the hazard ratio for CBC was 1.78 (95% CI, 0.85 to 3.72), whereas for women irradiated at age ≥ 45 years, risk decreased to 1.09 (95% CI, 0.82 to 1.45). The Early Breast Cancer Trialists' Collaborative Group reported a significantly increased risk of CBC with radiotherapy, mainly during the period 5 to 14 years after randomization (RR, 1.43; $p = 0.00001$), and the increased risk was significant even among women aged ≥ 50 years when randomized (RR, 1.25; $p = 0.002$).²⁵² In a report from the WECARE group,⁵⁹ where absorbed doses to quadrants of the contralateral breast were estimated, women < 40 years of age who received > 1.0 Gy of absorbed dose to the specific quadrant of the contralateral breast had a significantly increased 2.5-fold greater risk for CBC than unexposed women. No excess risk was observed in women > 40 years of age. In contrast, in an earlier case-control study from Denmark, a significant difference in CBC risk was not observed in women who did and did not receive radiotherapy, regardless of age at treatment.²⁵³ A study from the Institut Curie, which included 13,472 women also similarly showed no increased risk of CBC when comparing women who did or did not receive radiotherapy (RR, 1.1; 95% CI, 0.96 to 1.27). Currently available data, therefore, support a modest risk of CBC after radiotherapy, mostly limited to younger women at the time of treatment.

Several other solid tumors have been linked to radiotherapy for breast cancer, including lung cancer, sarcoma, and esophageal cancers. Compared to women who did not receive radiotherapy, women given radiotherapy have a 1.5- to 3-fold increased risk of developing lung cancer.^{248,254,255} In a case control study by Kaufman et al.,²⁵⁶ 113 breast cancer patients who developed lung cancer were matched to 364 controls without lung cancer; excess risks of lung cancer following postmastectomy radiotherapy were limited to ever-smokers. Compared with nonsmoking women who did not receive postmastectomy radiotherapy, the adjusted OR for lung cancer among nonirradiated ever-smokers was 5.9 (95% CI, 2.7 to 12.8) and the adjusted odds ratio among ever-smokers who also received postmastectomy radiotherapy was 18.9 (95% CI, 7.9 to 45.4). Others have shown that the increased risks of lung cancer appeared more related to postmastectomy radiotherapy, in which the radiation target volume often also includes the supraclavicular, axillary, and/or internal mammary nodal regions, thus exposing a larger volume of lung tissue, whereas the risk after postlumpectomy radiotherapy is less clear.^{76,77} Similarly, in a population-based study by Zablotska et al.⁷⁷ of squamous cell esophageal cancer after adjuvant radiotherapy for breast cancer, the relative risk was significantly increased only among women who received postmastectomy radiotherapy, but not among those who received postlumpectomy radiotherapy. In a recent international population-based nested case-control study of esophageal cancer in breast cancer survivors that included 252 cases and 488 controls, the esophageal cancer risk was 8.3-fold (95% CI, 2.7 to 28) higher in women who received doses of 35 Gy or higher, compared with women who received no radiation dose to the site of esophageal tumor.⁶⁴

Although the occurrence of sarcoma after breast cancer is a rare event, with a 15-year incidence rate of $< 0.5\%$, the relative risk has been estimated to be as high as sevenfold, given the low background incidence in the general population.^{248,257,258} In a study by Rubino et al.,⁷⁰ all sarcomas occurred among women initially given radiotherapy, and in all cases, the sarcomas were located in the irradiated fields or in the upper extremity of the arm ipsilateral to the treated breast. Further, a significant dose-response relationship was demonstrated. In a SEER-based study of 563,155 breast cancer patients, women who received radiotherapy had a 1.5-fold risk (95% CI, 1.3 to 1.8) of all types of sarcomas, and a 7.6-fold risk (95% CI, 4.9 to 11.9) of angiosarcoma, compared to women who did not receive radiotherapy.²⁵⁹ In addition to radiotherapy, partial mastectomies and lymph node dissections were also independent risk factors for the development of angiosarcoma. Unlike other radiation-related soft tissue sarcomas, angiosarcoma has a short latency and can occur in the first 5 years after therapy.

Endometrial cancer after breast cancer can be linked with both shared etiologic factors and antecedent therapy—in particular, tamoxifen therapy. Several large studies have demonstrated a two- to fourfold increased risk of endometrial cancer after tamoxifen therapy.³⁰ Earlier studies indicated that endometrial cancer after tamoxifen use may have a more favorable prognosis, although recent data have raised the concern that tamoxifen-related endometrial cancers may have a more aggressive behavior.^{260–262} In a study that included 732 women with endometrial carcinoma, 59 patients (8%) had a previous diagnosis of breast cancer, of whom 29 (49%) had used tamoxifen.²⁶³ A longer duration of tamoxifen use (60 versus 46 months; $p = 0.034$) was significantly associated with high-risk histologic type. A Dutch study, which examined endometrial cancer after tamoxifen treatment for breast cancer, found that long-term tamoxifen use was associated with a higher proportion of nonendometrioid tumors than nonusers (32.7% versus 17.4%; $p = 0.004$), especially serous adenocarcinomas and carcinosarcomas; a higher proportion of International Federation of Gynecology and Obstetrics (FIGO) stage III and IV tumors was also observed (20.0% versus 11.3%; $p = 0.049$).²⁶¹ The differences in histologic and stage distributions translated to a significantly lower 3-year endometrial cancer-specific survival among long-term tamoxifen users (82% versus 93%; $p = 0.001$).

Testicular Cancer

Significant excesses of solid tumors, leukemia, and contralateral testicular cancer (CTC) have been documented in testicular cancer survivors (TCS).^{102,264–275} In an international population-based survey of 40,576 TCS,²⁶⁴ significantly elevated 1.5- to 4-fold relative risks were noted for malignant melanoma and cancers of the lungs, thyroid, esophagus, pleura, stomach, pancreas, colon, rectum, kidneys, bladder, and connective tissue among 10-year survivors (Table 143.3). By age 75 years, men who were diagnosed with seminomas or nonseminomatous tumors at age 35 years experienced cumulative risks of solid cancer of 36% and 31%, respectively. Among TCS treated with radiotherapy alone, relative risks of SPC at sites included in typical infradiaphragmatic radiotherapy fields were significantly larger than risks at nonexposed sites (RR, 2.7 versus RR, 1.6; $p < 0.05$) and remained elevated for ≥ 35 years. No decrease in the risk of postradiotherapy in-site SPC was observed for seminoma patients diagnosed between 1975 and 2001, although a lowered risk was noted among nonseminoma patients. In a case-control investigation of 23 stomach cancers among TCS,⁶⁶ a significant relation with increasing radiation dose was observed. In the international series,²⁶⁴ the relative risk (RR = 1.8) of solid tumors was significantly elevated after chemotherapy alone, although information on specific cytotoxic drugs was not available. A subsequent investigation²⁶⁵ showed that cisplatin-based chemotherapy was associated with a significantly elevated twofold risk of solid tumors, confirming other reports.²⁷⁵

In a study exploring cause-specific mortality in patients with stage I seminoma using data from the SEER program, with 121,037 person-years of follow-up, the standardized mortality ratio (SMR) of SPC was 1.81 (95% CI, 1.61 to 2.03).²⁷⁶ The risk was higher among irradiated patients, with an estimated 15-year cumulative risk of 2.64%.

Cytotoxic drugs used to treat testicular cancer (TC) that have been related with excess secondary leukemias include etoposide and cisplatin.^{102,271,273,274} Kollmannsberger et al.²⁷⁴ estimated that the cumulative risk of leukemia for TCS given etoposide at total doses of $< 2,000$ mg/m² and $> 2,000$ mg/m² was 0.5% and 2%, respectively. A strong dose-response relation ($p < 0.001$) between cumulative dose of cisplatin and subsequent leukemia risk was reported by Travis et al.,¹⁰² who also noted a nonsignificant threefold risk following involved-field radiotherapy. Fung et al.¹¹¹ recently examined solid tumor risk after surgery and chemotherapy in 12,691 testicular nonseminoma survivors in the SEER program (1980 to 2008). A significantly increased RR of solid tumor of 1.43 (95% CI,

Obs., observed number of cases; RR, relative risk; CI, confidence interval.

^a The table is restricted to those sites for which significantly increased RR were observed in 10-year survivors of testicular cancer. The RR is a decreasing function of age at testicular cancer diagnosis; results are presented for age 35 years, which is the mean age of the cohort.

^b Percentage contribution to the total excess is shown within the parentheses; percentages may not sum to 100 due to rounding.

^c P trend (negative) = .007

^d Obtained as sum of site-specific excesses.

^e P trend (negative) <0.001

^f P trend (positive) = 0.02

^g Includes 172 tumors for which site was specified and 105 tumors of unknown or ill-defined primary site.

^h P trend (negative) = 0.013

ⁱ Restricted to those sites that are included in typical infradiaphragmatic radiotherapy fields for testicular cancer: stomach, small intestine, colon, rectum, liver, gallbladder and ducts, pancreas, kidneys, and bladder.

^j P trend (negative) = 0.005.

Modified from Travis LB, Fossa SD, Schonfeld SJ, et al. Second cancers among 40,576 testicular cancer patients: focus on long-term survivors. *J Natl Cancer Inst* 2005;97:1354–1365.

1.18 to 1.73) was found (median latency period: 12.5 years), with significantly increased site-specific risks for cancers of the kidney (SIR, 3.37; 95% CI, 1.79 to 5.77), thyroid (SIR, 4.40; 95% CI, 2.19 to 7.88), and soft tissue (SIR, 7.49; 95% CI, 3.59 to 13.78).

In a population-based study of 29,515 TCS, the 15-year cumulative risk of CTC was 1.9%, representing a 12.4-fold higher risk than expected in the general population.²⁷² Chemotherapy may reduce the risk of CTC,^{277,278} although the delaying effect and duration of cisplatin-based chemotherapy on CTC incidence should be examined further.

In the future, it will be important to determine whether the decrease in radiation dose and field size in the 1990s,^{279,280} along with the use of carboplatin as adjuvant therapy in seminoma patients,²⁸¹ will be associated with a reduction in excess SPCs. The long-term influence of cisplatin-based chemotherapy on the site-specific risk of solid tumors, temporal patterns, and the effect of age at exposure and attained age should also be addressed in analytic investigations that control for lifestyle factors, shared etiologic influences, and host determinants.^{5,6} Screening strategies for selected SPCs should be considered.²⁸² The risk of SPCs in TCS initially treated with radiotherapy or chemotherapy should be compared to the risk in patients managed with surgery alone, because the development of cancer at a young age may itself indicate an underlying susceptibility for subsequent malignancy. Similarly, the incidence of SPC among TCS managed with surgery only should be contrasted with cancer incidence in the general male population in order to understand the evolution of cured TC, given its origin from a pluripotent stem cell and the presence of non-germ-cell elements in nonseminomatous TC and its metastases.^{283,284} Future research strategies for testicular cancer survivors, including detailed recommendations for the study of SPC, were recently published.²⁸⁵ These included an evaluation of the role of genetic variants in the development of SPC after testicular cancer and the development of site-specific risk prediction models.

Prevention and Risk Reduction for Second Primary Cancers

Given the increased SPC risk in survivors of adult-onset cancer, screening and early detection strategies have been suggested for this population.²⁸² In general, survivors should follow applicable national guidelines for cancer screening. Further, earlier or additional screening may be indicated in survivors deemed at high risk due to genetic predisposition, previous treatment history, and/or health habits. Site-specific recommendations regarding screening and prevention are summarized in Table 143.4.

In survivors with a family history suggestive of hereditary non-polyposis colon cancer (HNPCC), colonoscopy screening starting at age 20 to 30 years, and endometrial sampling in women annually starting at age 35 years, should be considered.²⁸⁶ For survivors with a strong family history and/or personal or family history of *BRCA1* and *BRCA2*, screening breast magnetic resonance imaging (MRI) as an adjunct to mammograms starting at age 25 years, and serum cancer antigen 125 (CA-125) and transvaginal ultrasound every 6 to 12 months are recommended in women, and serum prostate specific antigen (PSA) with or without digital rectal examination every 1 to 2 years, starting at age 45 years, are recommended in men.²⁸⁷ Screening breast MRI scans in addition to mammograms are also recommended in female survivors with a history of chest irradiation at a young age, 8 to 10 years after treatment (further discussed in the following paragraphs), and colonoscopy screening is recommended in survivors with a history of pelvic irradiation, starting 10 years after treatment.²⁸⁸ In survivors with a history of chest irradiation and/or tobacco history, annual low-dose chest computed tomography should be considered.^{289,290} Finally, survivors with a family history of early melanoma may benefit from annual skin examination and monthly skin self-examinations.²⁹¹

Data on chemoprevention strategies specifically for SPCs are limited. At this time, there are data to support the use of tamoxifen in pre- and postmenopausal women, and raloxifene in postmenopausal women, as primary breast cancer prevention in high-risk women.^{292,293} The role of low-dose tamoxifen as breast cancer chemoprevention in HL survivors is currently being addressed in an ongoing clinical trial.²⁹⁴ Observational studies have demonstrated a reduction in colon cancer risk with aspirin, which might be considered for high-risk cancer survivors.^{295,296} Although preclinical and early clinical studies have shown that retinoids have chemopreventive effects against lung cancer and squamous cell cancer of the head and neck,²⁹⁷ currently, insufficient data exist to support their use as chemoprevention in high-risk cancer survivors.²⁹⁸⁻³⁰⁰

PEDIATRIC MALIGNANCIES

Survival rates for children with cancer have increased substantially over the past 3 decades, with this rapidly growing population at lifelong risk for the late effects of cancer treatment. In a British population-based study of 17,981 5-year survivors of childhood cancer diagnosed prior to age 15 years and followed for a median of 24.3 years, 1,354 SPCs were ascertained, yielding an overall fourfold risk (SIR, 3.9; 95% CI, 3.6 to 4.2). The cumulative percentage of survivors developing an SPC by age 60 years was 13.8% (95% CI, 12.3% to 15.5%). The AER for attained ages older than 40 years was highest for digestive and genitourinary SPCs; 36% of the total AER was attributable to these two SPCs.³⁰¹ In a recent update of 14,359 5-year survivors (diagnosed prior to age 21 years) in the CCSS,³⁰² the 30-year cumulative incidence was 7.9% for invasive SPC, 9.1% for nonmelanoma skin cancers (NMSC), and 3.1% for meningiomas, with an overall 30-year incidence for all SPCs of 20% (Fig. 143.4). Childhood cancer survivors have a three- to sixfold increased risk of developing an SPC compared with the general population, translating into an EAR ranging from 1 (in early life) to 6 per 1,000 patient-years of observation.³⁰²⁻³⁰⁴ Furthermore, survivors of childhood cancer have a persistent excess risk of an SPC throughout life, accompanied by continuous changes in the risk of cancers at specific sites.³⁰²⁻³⁰⁴ The incidence and type of SPC differs with the primary diagnosis, type of therapy received, and presence of genetic conditions.

Influence of Primary Cancer

Among 5-year survivors in the CCSS, the 30-year cumulative incidence of SPC by primary cancer diagnosis was as follows: HL, 18.4%; Ewing sarcoma, 10.1%; soft tissue sarcoma, 8.8%; osteosarcoma, 6.0%; neuroblastoma, 5.9%; NHL, 5.8%; leukemia, 5.6%; central nervous system (CNS) tumor, 5.5%; and kidney tumor, 4.0%. In multiple studies, it is evident that hereditary RB, HL, and soft tissue sarcomas are overrepresented among patients who develop an SPC relative to their incidence in the general population.^{48,210,302,305,306} The 40- to 50-year cumulative incidence of a SPC following RB ranged from 28% to 36%,^{48,306} reflecting an interaction between genetic predisposition in patients with hereditary RB and radiotherapy,^{47,305,307} as observed in familial soft tissue sarcoma. In individuals with other primary malignancies such as HL, the extent to which the primary cancer type may serve as an independent risk factor for SPC in addition to the well-established role of treatment requires further study.

Host-Related Risk Factors

Younger age at diagnosis of a primary cancer is associated with a higher risk of radiation-associated solid tumors.^{210,211,308} Conversely for t-MDS/AML, which is strongly linked with specific chemotherapeutic agents, risk appears to increase with age at treatment of primary cancer.^{125,309} Female sex is associated with a higher risk

TABLE 143.4

Second Malignant Neoplasm (SMN) Screening and Prevention Recommendations in Cancer Survivors at Moderate to High Risk

SMN Site	Risk Level	Screening Recommendation	Chemoprevention Agents
Breast	Moderate risk: Family history of breast cancer High risk: Personal or family history of <i>BRCA1</i> , <i>BRCA2</i> , <i>TP53</i> , or <i>PTEN</i> mutation History of radiation to chest between age 10 and 30 years	Mammogram starting 5 to 10 years before earliest case of cancer in the family; CBE twice yearly; BSE monthly Screening breast MRI, starting at age 25 years (or for women with a history of chest radiation, 5 to 10 years after radiation); annual mammogram; CBE twice yearly, BSE monthly	<ul style="list-style-type: none"> ■ Tamoxifen, raloxifene: Recommended for those at increased risk of first primary breast cancer; recommendations for second tumors are not established ■ Other SERMs (e.g., lasofoxafine): No recommendation ■ Aromatase inhibitors: No recommendation for SMN
Colon	Moderate risk: FDR with colon cancer younger than age 60 years or two SDRs with colon cancer at any age Radiation in which colon/rectum were included in treatment fields High risk: Family history suggestive of HNPCC	Colonoscopy at age 40 years or 10 years before the earliest case of cancer in the family Colonoscopy at age 35 years or 10 years after radiation Colonoscopy every 1 to 2 years, starting at age 20 to 30 years (depending on syndrome)	<ul style="list-style-type: none"> ■ NSAIDs, COX-2 inhibitors, curcumin, difluoromethylornithine, aspirin, isothiocyanates (including sulforaphane), or resveratrol: Not recommended for secondary or tertiary prevention
Ovary	High risk: Family history of ovarian cancer; personal history or family member with mutation in <i>BRCA1</i> or <i>BRCA2</i> or mismatch repair gene (<i>MLH1</i> , <i>MSH2</i> , <i>MSH6</i> , <i>PMS2</i>)	Serum CA-125 and TVUS every 6 to 12 months starting at age 35 years	—
Endometrium	High risk: Family history suggestive of HNPCC	Endometrial sampling annually starting at age 35 years	—
Skin	High risk: Family history of early melanoma	Annual skin examination and monthly skin self-examination	—
Lung	Increased risk: Prior radiation to chest with or without chemotherapy High risk: Current smokers (>30 pack years); former smokers (>30 pack years and quit <15 years ago)	Smoking cessation Annual low-dose spiral CT	<ul style="list-style-type: none"> ■ Isotretinoin, etretinate, vitamin E, retinoids, N-acetylcysteine, or aspirin: Not recommended ■ Budesonide, COX-2 inhibitors, 5-LOX inhibitors, and prostacyclin analogs: Not recommended for individuals who have a history of lung cancer
Prostate	High risk: Family history of early prostate cancer (onset younger than age 65 years); personal or family member with mutation in <i>BRCA1</i> or <i>BRCA2</i>	Serum PSA with or without DRE every 1 to 2 years, starting at age 45 years	—
Head and neck (upper aerodigestive tract)			<ul style="list-style-type: none"> ■ Isotretinoin, β-carotene: Not recommended

of SPC, primarily contributed to the excess occurrence of secondary breast cancers among female cancer survivors. Moreover, some studies indicate a greater susceptibility of women to known carcinogens such as cigarette smoke, which has been postulated to account for differences in the risk of first primary lung cancers.³¹⁰ Possible mechanisms that underlie this greater susceptibility include greater activity of cytochrome P-450 enzymes, enhanced formation of DNA adducts, and the effects of hormones such as estrogen on tumor promotion.³¹⁰

Radiation

Radiation is associated with the majority of excess SPC following therapy for childhood cancer, with a two- to threefold increased risk among irradiated patients compared with those treated with chemotherapy alone.^{302,311–313} In order of decreasing incidence, radiation-associated SPCs include NMSC, breast cancer, CNS tumors, thyroid cancer, bone and soft tissue sarcomas, and other carcinomas.^{302,312}

Multiple Subsequent Cancers in Long-term Childhood Cancer Survivors

Long-term childhood cancer survivors are at increased risk for multiple SPCs. The cumulative incidence of a third neoplasm was 38.8% at 15 years after a diagnosis of an SPC in the CCSS study and varied by type of first primary cancer (Fig. 143.5). Among

survivors given radiotherapy for a first primary cancer, the cumulative incidence of a third neoplasm was 41.3% at 15 years compared with 25.7% for those not treated with radiation. As noted by Armstrong et al.,¹⁷ limited data with regard to the treatment of SPCs restricted risk factor analyses to primary therapy only.

Secondary Breast Cancer

Breast cancer following treatment for HL and NHL with chest irradiation during adulthood is discussed previously. In addition, an excess risk of breast cancer has been noted following other chest radiation fields used in the treatment of childhood cancer, including whole lung and chest wall radiation.³¹⁴ The cumulative incidence of breast cancer by 40 to 45 years of age is 13% to 20% among childhood cancer survivors treated with moderate- to high-dose radiation to the chest.^{74,241,315,316} Although overall survival in women with localized breast cancer following chest radiation for childhood cancer may not be as favorable as for women with de novo breast cancer, an early cancer stage still appears associated with favorable outcomes.^{15,317,318} Furthermore, second breast cancers can be detected by mammography, although sensitivity is limited. Based on this information, the Children's Oncology Group (COG) recommends annual surveillance mammography and breast MRI, starting at age 25 or 8 years after the completion of radiotherapy, whichever occurs last.^{288,314} These recommendations are consistent with those of the American Cancer Society,³¹⁹ the United Kingdom Children's Cancer Study Group (UKCCSG),³²⁰ and the Netherlands Cancer Institute.³²¹

To characterize breast cancer surveillance practices among female childhood cancer survivors treated with chest radiation, 675 women in the CCSS were queried. Almost half of women between the ages of 25 and 39 years had never had any breast imaging study and only 53% of women aged 40 to 50 years were undergoing regular mammography, and less than 3% reported a breast MRI. The primary barrier was lack of physician recommendation for screening.³²²

Secondary Thyroid Cancer

Childhood cancer survivors are at 11.3- to 18-fold increased risk of developing thyroid cancer when compared with the general population, with an EAR of 1.4 per 10,000 person-years.^{211,312,323,324} Risk begins to increase about 8 to 10 years following radiation, and the excess risk does not appear to plateau with age.^{71,324} The histology of thyroid cancers is similar to that of the general population, with the vast majority of tumors either papillary or follicular carcinomas. Radiation-associated thyroid cancers do not appear to be more aggressive than thyroid cancer in the general population, and 5-year survival rates exceed 95%.^{325,326} The most common primary diagnoses treated with radiotherapy to the neck/thyroid region include HL, ALL, CNS tumors, NHL, and soft tissue sarcoma.^{71,323,324}

In contrast to the linear dose-response relationship observed between radiation and breast cancer risks (Fig. 143.6A)⁶³ or CNS tumors (Fig. 143.6B),⁶⁷ there is a linear exponential relation for the risk of thyroid cancer consistent with a cell-killing effect at higher doses (Fig. 143.6C).⁷¹ As illustrated in a nested case-control study (n = 69 cases) conducted in the CCSS, Sigurdson et al.⁷¹ reported a peak risk of thyroid cancer between 10 and 29 Gy with a decrease in the dose-response relation at doses greater than 30 Gy. An update of the CCSS study with 119 pathologically confirmed second thyroid cancers among 12,547 5-year survivors of childhood cancer demonstrated a linear increase in risk with radiation dose up to ~20 Gy, where the relative risk peaked at 14.6-fold (95% CI, 6.8 to 31.5). At thyroid radiation doses >20 Gy, a downturn in the dose-response relationship was observed. Female sex, younger age at exposure, and time since exposure were significant modifiers of radiation-related risk.⁷² A pooled analysis of 16,757 childhood cancer survivors with 187 second thyroid cancers also demonstrated a dose-related linear increase in risk for exposures <10 Gy and a leveling off of the risk from 10 to 30 Gy, followed by a decline thereafter. However, the risk remained elevated for doses >50 Gy.³²⁷ Risk was modified by age at first cancer diagnosis, with those

treated before age 10 years at highest risk.^{71,324} Although some studies report no relationship with chemotherapy,^{71,324} others reported an association with anthracyclines (RR = 4.5; 95% CI, 1.4 to 17.8).³²⁷ Although the majority of thyroid cancers occur in females, this reflects the same sex distribution of first thyroid cancers in the general population. Taylor et al.³²⁴ reported a higher SIR for males (26.2) than females (15.1; $p = 0.05$); however, the AER was higher for females (1.9 per 10,000 person-years) than in males (1.0 per 10,000 person-years). In an effort to reduce the incidence of serious late effects, including breast cancer and coronary artery disease, the dose of radiation has been lowered or omitted in contemporary risk-adapted therapy.^{257,328} Although this may achieve these primary goals, the use of reduced radiation doses may in fact lead to an increased incidence of thyroid cancer among certain groups. Based on a small cohort of survivors of childhood HL who were treated with low-dose involved field radiation (15 to 25.5 Gy), O'Brien et al.³²⁹ reported an SIR of 53.2 and an AER of 22.9 thyroid cancers per 10,000 person-years.

Given the indolent nature and excellent long-term survival rates associated with a radiation-related thyroid cancer, the high incidence of thyroid nodules following radiation, and the high rate of false-positive findings with ultrasonography, neither the COG²⁸⁸ nor the UKCCSG³²⁰ recommend a screening thyroid ultrasound in the follow-up of asymptomatic survivors of pediatric or young adult cancer. Instead, both groups recommend a yearly neck examination. If a thyroid nodule is palpated, it should be further evaluated with an ultrasound and fine-needle aspiration.

Secondary Osteosarcoma and Soft Tissue Sarcoma

In a French–British cohort of 4,400 3-year survivors of a childhood solid tumor (including RB), the 20-year cumulative incidence of a secondary osteosarcoma and soft tissue sarcoma was 1% and 0.6%, respectively.^{69,330} In an analysis of 5-year survivors in the CCSS (excluding RB), Henderson et al.³³¹ reported a 30-year cumulative incidence of 1.1% for secondary sarcoma among those treated with radiation (any location) and 0.5% among those who did not receive radiation. An overall ninefold increased risk existed compared with the general population, with an EAR of 3.3 cases per 10,000 person-years. Risk among survivors who received radiation therapy (SIR = 11.4) was higher than among survivors who did not receive radiotherapy (SIR = 2.7). In general, increased risks for secondary osteosarcoma and soft tissue sarcoma emerge 5 to 8 years after radiotherapy and appear to remain consistently elevated thereafter.^{68,69,107,330,331}

Although increased risks of both secondary osteosarcoma and soft tissue sarcoma are associated with radiation, patterns of risk appear somewhat different according to radiation dose. In a nested case-control study set within the French–British cohort (32 cases and 160 controls), the excess risk of secondary osteosarcoma was 1.8 per Gy, with increased risks beginning at low doses (1 to 10 Gy).³³⁰ In two other case-control studies, with 59 and 64 cases (both including RB), no increased risk was associated with lower radiation doses (<10 Gy),^{68,107} but an increased risk was observed at higher doses and reached 40-fold after doses to the bone of more than 60 Gy.⁶⁸ In another case-control study in the French–British cohort, the excess risk of a soft tissue sarcoma was very low until 10 Gy, with most sarcomas developing after exposure to very high doses of radiation; a quadratic model of the dose-response relationship provided the best fit to the data.⁶⁹ In multiple studies, alkylating agent exposure has been independently associated with excess secondary sarcomas in a dose-response fashion.^{68,69,107,330,331} However, there do not appear to be interactions between radiation and alkylating agent chemotherapy in terms of risk. Gender, race/ethnicity, and age at primary cancer diagnosis did not modify risk in any of the previous studies.^{68,69,107,330,331}

There are few data on the long-term prognosis of childhood cancer survivors with secondary sarcoma; however, 5-year survival rates have been less than 50% among other populations with radiation-associated sarcomas.³³² Routine screening with MRI or computed tomography scans of the irradiated field is not recommended.^{288,320}

Secondary Central Nervous System Tumors

Secondary gliomas and meningiomas are well-recognized late effects after cranial radiation. In a recent review, childhood cancer survivors were found to be at an 8.1- to 52.3-fold increased risk of secondary CNS tumors. Nearly all cancer survivors who develop CNS neoplasms have been exposed to cranial radiation. Gliomas have a shorter latency than meningiomas. Further, the dose-response relationship between radiation and risk of CNS tumors is steeper for meningiomas.³³³ Secondary gliomas occur relatively soon after completion of treatment for the first cancer. Neglia et al.⁶⁷ reported that over 50% of secondary gliomas in the CCSS occurred between 5 and 9 years after the first cancer and over 90% occurred before 15 years. The ERR dropped to nearly zero among persons followed past 25 years. There was a linear relationship between radiation dose and glioma risk. Although there was not a difference in risk between males and females, those who were diagnosed at a younger age (<5 years) had a higher risk than those treated in later childhood. Subsequent survival following a secondary glioma is poor: the British CCSS reported 19.5% 5-year survival, with 4.9% for high-grade gliomas and 38.9% for low-grade gliomas.³³⁴

Secondary meningiomas tend to appear later after radiotherapy and are associated with generally good outcomes. Taylor et al.³³⁴ reported an 83% 5-year survival rate for patients in the British CCSS with a secondary meningioma. Most secondary meningiomas are benign,³⁰² but may be large or cause significant morbidity depending on location (e.g., seizures, hearing loss). Neglia et al.⁶⁷ reported that over 70% of the meningiomas occurring among CCSS survivors were diagnosed 15 years or more after the primary cancer. As with secondary gliomas, there was a strong radiation dose-response relationship for meningioma risk with an excess relative risk per Gy of 1.06, translating to substantial excesses for the majority of CNS tumor survivors treated with 30 Gy or more to the whole brain. The British CCSS also demonstrated a strong linear and independent relationship with radiation dose and intrathecal methotrexate. Those whose meningeal tissue received 0.01 to 9.99 Gy, 10.00 to 19.99 Gy, 20.00 to 29.99 Gy, 30.00 to 39.99 Gy, and ≥ 40 Gy had risks that were 2-fold, 8-fold, 52-fold, 568-fold, and 479-fold, respectively, compared to those whose meningeal tissue was unexposed.³³⁵ Gender did not modify risk. In contrast to the risk for secondary gliomas, children irradiated after the age of 5 years had a higher risk than those irradiated before 5 years. Genetic susceptibility may also increase the risk of radiation-induced meningiomas.³³⁶

Five-year survival ranged from zero to 19.5% for subsequent high-grade gliomas and 57.3% to 100% for meningiomas; these rates are similar to those observed in patients with primary gliomas or meningiomas. Despite the poor outcomes associated with secondary gliomas and high frequency of secondary meningiomas following cranial irradiation, there is no evidence that surveillance improves outcomes. Consequently, neither the COG²⁸⁸ nor the UKCCSG³²⁰ recommend screening brain MRI for asymptomatic patients. However, clinicians should have a heightened index of suspicion for childhood cancer survivors treated with cranial irradiation and who experience new neurologic signs or symptoms.

Secondary Melanoma and Nonmelanoma Skin Cancer

Among the CCSS cohort, the risk of melanoma was 3.3-fold higher than the general population, with a median interval from

primary cancer to melanoma of 18.9 years.³⁰² Similarly, in a Nordic population-based study, the risk of melanoma was 2.6-fold higher than the general population. A systematic review included 151,575 childhood cancer survivors, of whom 212 developed melanoma.³³⁷ Melanomas were most frequently observed after HL, hereditary RB, soft tissue sarcoma, and gonadal tumors. This review identified exposure to radiation as well as the combination of alkylating agents and antimetabolic drugs to be associated with an increased risk of melanoma. Although many of these cases of melanoma occurred among patients who received irradiation, to date and to our knowledge, there has not been a study assessing the radiation dose-relation or potentially modifying factors. Moreover, for patients such as those with HL, underlying immunosuppression may also be a factor in excess risks of malignant melanoma.

NMSC is common among childhood cancer survivors following irradiation, exceeding the incidence of all other SPCs combined.^{302,304} Indeed, in the recent CCSS update, among 14,359 survivors, there were 1,574 cases of NMSC and 802 cases of invasive or in situ cancer.³⁰² The 30-year cumulative incidence of NMSC was 9.1%.³⁰² The vast majority of NMSC was basal cell carcinoma (97%), with a median age of 31 years at occurrence.³³⁸ Radiotherapy was associated with a sixfold increase in risk, and 90% of the tumors occurred within the radiation field. Gender did not appear to modify risk.^{302,338} However, older age at radiation exposure (10 to 20 years of age) appeared to be associated with increased risk.³⁰² Among childhood cancer survivors who received hematopoietic cell transplantation, Leisenring et al.³³⁹ reported that patients given either total-body irradiation or who were light skinned had an increased risk of basal cell carcinoma. Acute graft-versus-host disease was associated with an increased risk of squamous cell carcinoma; chronic graft-versus-host disease was associated with an increased risk of both basal and squamous cell carcinoma. The COG²⁸⁸ and the UKCCSG³²⁰ recommend annual examination of the skin in irradiated fields.

Other Secondary Carcinomas

The risk of other carcinomas (besides breast, thyroid, and skin) appears to increase with age among childhood cancer survivors. Using CCSS data, Bassal et al.³⁴⁰ reported that radiation was associated with a significantly increased risk for carcinomas of the head and neck, the colorectum, other gastrointestinal sites, the kidneys, the bladder, and the lungs. The risk for an SPC (excluding breast, thyroid, and skin) was fivefold higher for survivors treated with radiation compared with the general population. In the CCSS update,³⁰² the number of these other carcinomas increased by 28% in just 4 years. As survivors in the CCSS and similar cohorts (e.g., British CCSS, Dutch LATER³⁴¹) enter mid adulthood, this is an area that warrants further study to better understand modifying risk factors, to quantify radiation dose-response relations, and to identify surveillance approaches. In the following paragraphs, we describe some of the more recent reports of carcinomas among the aging childhood cancer survivor population.

Secondary Tumors of the Digestive Tract

Excess cancers of digestive tract sites have been reported among childhood cancer survivors. A French and British cohort found a 9.7-fold increased risk of SPCs of digestive tract sites compared with the general population.³⁴² These included esophageal cancer, gastric carcinoma, pancreatic cancer, hepatocellular carcinoma, and colorectal cancer. A strong dose-response relation was identified; compared with those who had not received radiation, survivors with a history of exposure to radiation between 10 and 29 Gy were at 5.2-fold increased risk, and those exposed to doses ≥ 30 Gy were at 9.6-fold increased risk. The CCSS reported a 4.6-fold increased risk of gastrointestinal cancers among childhood cancer survivors when compared with the US population.¹⁰⁸ The highest

risk was associated with abdominal radiation. In addition, exposure to procarbazine (RR = 3.2) and platinum (RR = 7.6) were identified to be associated with increased risks.

Colorectal cancer has been described as an SPC after successful treatment of childhood cancer. A single institution study found the 40-year cumulative incidence of secondary colorectal cancer to be 1.4%.³⁴³ The cohort was at 10.9-fold increased risk when compared with the general US population. Colorectal carcinomas were more likely to develop in an irradiated colon; the risk increased by 70% with each 10-Gy increase in radiation dose. Increasing radiation volume also increased colorectal cancer risk. Finally, alkylating agent exposure was associated with an 8.8-fold increased risk of secondary colorectal cancer. The population-based British CCSS found the cumulative incidence of colorectal cancer for survivors treated with direct abdominopelvic irradiation to be 1.4% (95% CI, 0.7% to 2.6%) by age 50 years, comparable with the 1.2% risk in individuals with at least two first-degree relatives affected by colorectal cancer.³⁰¹ Similarly, the CCSS reported a cumulative incidence of colorectal cancer following abdominal radiation to be 1.2% by 30 years following radiotherapy.¹⁰⁸

The COG recommends a screening colonoscopy every 5 years in childhood, adolescent, and young adult cancer survivors treated with more than 30 Gy of radiation to the abdomen or pelvis, starting at age 35 years or 10 years after radiation, whichever occurs last.³⁴⁴ Nathan et al.³⁴⁵ reported that only 17% of long-term childhood cancer survivors at risk for colorectal cancer reported ever having a colonoscopy.

Renal Cell Carcinoma

An eightfold increased risk of renal cell carcinoma compared with the general population was reported in the CCSS cohort.¹¹⁰ The highest risk was observed among neuroblastoma survivors. Exposure of the renal bed to radiation as well as exposure to platinum chemotherapy increased the risk.

Salivary Gland Cancer

The incidence of salivary gland cancer among childhood cancer survivors has been reported to be 39-fold that of the general population.³⁴⁶ Of the 23 salivary gland tumors, 14 were mucopidermoid carcinomas, 3 were adenocarcinomas, 3 were acinar cell carcinomas, and 3 were miscellaneous other types. The risk increased linearly with radiation dose and remained elevated for 20 years. Exposure to chemotherapeutic agents, tobacco, or alcohol did not appear to increase the risk.

Genetic Conditions

RB is the prototype malignancy in which genetic factors are responsible for a substantial proportion of SPC. Familial RB is caused by inherited mutations of the *RB1* tumor suppressor gene, which has been localized to the long arm of chromosome 13q14.³⁴⁷ Approximately 90% of hereditary RB patients have bilateral disease. In a large cohort of 1,601 RB survivors in Boston and New York, the risk of SPC was increased 19-fold in hereditary RB survivors; risk was not elevated in nonhereditary patients.⁴⁸ The 50-year cumulative incidence of an SPC was 36% and 5.7% for hereditary and nonhereditary patients, respectively. Among the hereditary patients, radiotherapy increased the 50-year cumulative incidence of an SPC to 38.2%, whereas the cumulative incidence was 21.0% for nonirradiated patients. Similar risks among hereditary RB survivors have been reported in the Dutch³⁰⁶ and British³⁴⁸ nationwide cohorts. The 50-year cumulative mortality from any SPC for hereditary RB survivors ranged from 17.3 to 25.5%.^{349,350}

The majority of SPCs are bone and soft tissue sarcomas occurring in the most heavily irradiated areas (head and neck region). A radiation dose-response relationship exists for sarcomas, with an

almost 11-fold risk increase at doses of 60 Gy or greater.³⁰⁵ Osteosarcomas and soft tissue sarcomas that develop after hereditary RB harbor similar *RBI* mutations as found in RB. Radiation is thus likely to cause the somatic mutations needed to result in sarcomas in carriers of germ-line *RBI* mutations.

Importantly, hereditary RB survivors also have an increased risk in comparison with the general population of second (and third and fourth) cancers in sites distal to the radiation field, suggesting a genetic predisposition independent of radiation exposure.^{48,305,306,323,351} Sites for distal cancers include the breast, lung, colon, bladder, uterus, and long bones. In particular, there are excess risks of distal soft tissue sarcomas (leiomyosarcoma, fibrosarcoma, and rhabdomyosarcoma) and osteosarcomas (especially in the lower extremities), suggesting that *RBI* mutation carriers may be inherently predisposed to soft tissue sarcomas and osteosarcomas.^{306,351,352} Moreover, the Boston–New York cohort recently reported an increased risk of secondary uterine leiomyosarcomas in hereditary RB survivors.³⁵³ Risk increased from 20 to 27 per 10,000 females for those age 30 to 39 years and 40 or more years, respectively; risk was unrelated to radiation dose for primary RB treatment (ocular radiotherapy). With contemporary therapy largely excluding external beam radiotherapy, it is anticipated that hereditary RB survivors may now live longer without radiation-associated SPC, but with treatment-associated tumors possibly supplanted by increasing uterine leiomyosarcomas in older women.

Childhood sarcoma survivors also have an excess risk of non-radiation-related SPCs, such as breast cancer.^{302,315,354} Although many of these patients likely have a *p53* germ-line mutation and are thus classified with Li-Fraumeni syndrome,³⁵⁵ there may be other genetic factors affecting risk. These issues are discussed in detail elsewhere in the chapter.

Outcomes after Second Primary Cancers

Outcomes among patients who survive SPCs are being increasingly studied.^{10–16,356} A comprehensive systematic investigation of factors that affect survival after an SPC diagnosis were recommended as a research priority in the recent NCRP report.^{9,10} One large population-based analysis¹⁶ compared mortality after 621 SPCs in testicular cancer survivors with mortality after 12,420 matched first cancers, and found no overall difference between the two groups. Rate ratios for cancer-specific and all-cause mortality were 1.05 (95% CI, 0.90 to 1.23) and 1.09 (95% CI, 0.96 to 1.23), respectively. The exception was among those TC patients treated from 1973 to 1979, during an era when chest irradiation was routinely given and before reductions in infradiaphragmatic radiation fields and doses were implemented; for these patients, all-cause mortality after either a second primary lung cancer or a cancer below the diaphragm (likely to be included in irradiated fields) was significantly higher than in patients with matched first cancers.

Other large population-based studies have systematically evaluated survival after second primary cancers of the breast,¹⁵ the lung,¹³ or gastrointestinal sites¹⁴ after HL. In each survey, survival after a second cancer at one of these sites among HL survivors was significantly reduced compared with first primary cancers at the same site. Each of these SPCs has, in part, been linked to antecedent HL treatment.

Solomon et al.¹¹ evaluated overall and cancer-specific survival after second cancers of the breast, colorectum, lungs, and prostate in patients with and without CLL. Although, to date, these cancers have not been associated with CLL treatment, Solomon and colleagues¹¹ hypothesized that CLL patients who develop these cancers could experience less favorable cancer-specific outcomes, due either to more aggressive biologic characteristics of the second cancers or to less effective immune surveillance and control. Overall, among CLL patients, 892 developed colorectal cancer, almost 1,300 were diagnosed with lung cancer, 608 with female breast cancer, and over 1,200 men later developed prostate cancer. After taking into account age,

gender, and disease stage, the overall age-specific survival for CLL patients was significantly inferior to patients who developed a first primary cancer at one of these sites. Cancer-specific survival was significantly inferior for CLL patients who developed cancers of the breast (HR, 1.41), lung (HR 1.3), and colorectal sites (HR 1.64), but not prostate (HR, 1.40). These findings have important implications for CLL patients, because cancers of the breast, lung, and colorectal sites represent the three most common cancers in US women and two of the three most common cancers in US men.¹² These data suggest that CLL patients who develop these common cancers experience a more aggressive clinical course and are more likely to die from these cancers, even after adjusting for age, race, and disease stage. Limitations of the SEER data set (a lack of detailed data with regard to initial therapy, other patient-specific factors that may affect prognosis, and a lack of information on subsequent therapy) precluded Solomon et al.¹¹ from an in-depth probe of various hypotheses. Nonetheless, this study heightens awareness of the importance of the further investigation of outcomes after a SPC diagnosis.^{15,16,356} Even if risks, per se, for some of the more common cancers (e.g., cancers of the breast, colorectum, prostate, lungs) are not elevated after a selected first primary cancer, nonetheless these cancers remain common.

At a minimum, all cancer survivors should be encouraged to follow guidelines for cancer screening recommended for the general population, as recently reviewed.²⁸² The identification of individuals at increased risk for additional primaries due to genetic predisposition, treatment, and other factors can also pinpoint patients who should have earlier and more frequent screening and/or who might be candidates for prevention strategies.²⁸² Furthermore, it will also now be important to determine optimal *management* strategies for second cancers. Many times, cancer survivors are limited with regard to treatment options, because they have already received large amounts of cytotoxic therapies.^{15,16} Further research is needed to understand how to optimize the treatment of not only those SPCs that indeed may reflect the carcinogenic effects of prior therapy, but also those SPCs that represent the operation of other factors.

COMMENTS

Future SPC research areas of importance to cancer survivors include those of etiopathogenesis, optimal management, and subsequent outcomes.^{6,9,10,12,282,356,357} Overarching research recommendations in the 2012 NCRP report (see Table 143.1)^{9,10} included the long-term, large-scale follow-up of extant cancer survivors and the construction of prospective cohorts of patients given new treatment modalities. One identified need involved the long-term follow-up of survivors successfully treated for tumors at sites for which reductions in field size and radiotherapy dose have been implemented, and the follow-up of populations successfully managed without any type of cytotoxic treatment to define baseline risks. For carcinogenic drugs, pharmacogenomic and pharmacoepidemiologic studies should be carefully considered.^{6,356,358,359} It will also be important to follow survivors of adolescent and young adult cancer,³⁶⁰ given the sparseness of information for this population.

Groups of cancer survivors for whom detailed treatment data information are collected will also be important in providing new insights into a wide range of outcomes,^{6,356} including other possible late sequelae, such as cardiovascular disease, neuropathies, and endocrine dysfunction.^{9,10,285,356} Furthermore, an enhancement of the understanding of genetic and other influences that contribute to one late effect of cancer and its treatment might inform our understanding not only of other untoward sequelae, but also factors that impact survival. Thus, future investments in research infrastructure should also include the collection of biologic samples to better evaluate the role of genetic factors in not only SPC development,^{6,52} but also the occurrence of other outcomes.³⁵⁶ In addition, future investment

should be directed to the application of animal models in unraveling the genetic underpinnings of SPC risk.^{356,361} The elucidation of functional genetic variants will also enhance risk assessment²⁸² and the development of risk-stratification in terms of a cost-effective framework for patient follow-up. Comprehensive SPC risk prediction models could also stratify patients into risk groups to personalize follow-up strategies and develop evidence-based interventions.^{6,362}

The database to support various lifestyle recommendations in reducing SPC occurrence is grounded in only a few observational studies and randomized clinical trials conducted in cancer survivors,^{363,364} and rests largely on inference from studies conducted in other diseases, such as cardiovascular disease. Therefore, additional research is needed among cancer survivors to understand the relative contribution and interaction of lifestyle factors with the patient's genetic profile and exposure to treatment and environmental factors. Furthermore, additional efforts should be directed to determine the efficacy of different SPC screening approaches in survivors of adult-onset cancer. Many of the strategies applied to childhood cancer survivors serve as a potential paradigm for future work.^{344,365}

As additional information is generated with regard to SPCs,^{17,357} it should be recognized that the time of cancer diagnosis and the period that follows are opportune times for health-care providers to counsel patients about health promotion to not only reduce the risk of cancer recurrence, but also to minimize comorbidities. Health-care providers can play an important role in this process by recommending genetic counseling for selected patients (and family members), and by referring patients to nutrition counselors, exercise trainers, and clinical psychologists to assist with lifestyle change interventions. In particular, the importance of smoking cessation, weight control, physical activity, and other factors consistent with a healthy lifestyle should be consistently conveyed to patients. Given the current investment in cancer survivorship research, further study of the late effects of cancer and its treatment is critical.³⁵⁶ It will be important to continue to add to our understanding of genetic variants and etiologic influences that increase not only SPC risk, but also factors that influence subsequent management and survival.^{6,9,10,12,15,282,356,357}

144 Neurocognitive Effects

Paul D. Brown, Sanne B. Schagen, and Jeffrey S. Wefel

INTRODUCTION

Patients with central nervous system (CNS) tumors frequently suffer from a number of adverse symptoms, including cognitive impairment. Cognitive dysfunction occurs in most patients with brain tumors, often at presentation, and is frequently progressive even after aggressive treatment. In addition, recent advances in multimodality therapy have led to improvement in survival, raising concerns regarding the long-term effects of these interventions on cognitive function. Treatment options for cognitive deficits remain quite limited; therefore, a thorough understanding of the impacts of brain tumor interventions and an awareness of the cognitive function of patients with adult brain tumors at presentation and over time is necessary to help guide treatment decisions. Finally, in non-CNS cancers, there is a growing understanding of the cognitive impact of the cancer process itself and non-CNS-directed therapies.

ASSESSMENT OF COGNITIVE FUNCTION

Cognitive impairment in patients with primary brain tumors is extremely common at presentation before any interventions have been performed. Several studies report cognitive dysfunction in over 90% of patients with primary brain tumors prior to surgical intervention.^{1,2} Memory and executive function are most commonly impaired, which is consistent with the tendency for primary brain tumors to arise in the frontal or temporal regions. Studies of patients suffering from stroke or epilepsy have demonstrated that the nature of the cognitive impairments often relates to the location of a lesion. Although tumor patients have shown typical lateralizing patterns of cognitive impairment (e.g., left hemisphere lesions frequently cause difficulties with verbal learning and memory and language functions),³ these impairments are often more subtle and diffuse in patients with tumors than are those observed in sudden-onset neurologic conditions such as a stroke.⁴ Differences in the pathophysiology of these lesions are believed to underlie these observations; whereas a cerebrovascular accident may rapidly result in tissue destruction, tumors diffusely and often more slowly infiltrate the brain, thereby disrupting normal brain function in networks that are proximal to the visible tumor as well as more distant from the site through mechanisms such as diaschisis. Using magnetoencephalography and functional magnetic resonance imaging (MRI), the abnormal organization of widespread brain networks has been demonstrated in cognitively impaired brain tumor patients.^{5,6} Prior to surgery, differences in tumor histology are associated with differences in network organization, which may reflect the adverse effects of seizure and anticonvulsant use on brain organization or the effects of neuroplasticity.⁷

Cognitive impairment is associated with difficulty in daily life more often than physical impairments, and caregivers cite cognitive problems as the most difficult problems to manage.³ These cognitive deficits cause significant difficulties, such as decreased independence, interference in academic or vocational pursuits, and increased caregiver distress and burden. Even subtle cognitive

deficits can significantly limit a patient's ability to perform usual activities, but may not be evident on casual observation or detectable via routine medical examinations. If unrecognized, these cognitive deficits can lead to inaccurate judgment on the part of the medical team regarding the patient's ability for self-care and in the believed safety of the treatments themselves.

A neuropsychological assessment provides quantitative, objective measurement of potentially subtle, yet clinically significant, changes in a patient's cognitive function. Cognitive testing involves the administration of standardized psychometric instruments (i.e., tests) that evaluate various aspects of brain function such as attention, learning and memory, information processing speed, expressive and receptive language function, executive function (e.g., abstract reasoning, planning, decision making), visual perception and construction, and mood and personality. Test results are integrated with the patient's clinical history, observations of the patient's behavior, patient report, and reports of family members and/or caregivers. Interpreting these psychometric instruments and assessments requires a trained neuropsychologist. A brief evaluation with screening instruments such as the Mini-Mental Status Examination are not recommended because these were not developed to assess cognition in brain tumor patients and they provide limited information about domains of cognitive function frequently affected by brain tumors and their treatment (e.g., learning and memory, executive function, processing speed, fine motor control).⁸ Similarly, a patient self-report does not routinely correlate with objectively measured cognitive function⁹ or functional outcomes.¹⁰

The neuropsychological assessment may be used to identify and guide interventions for impaired patients, including compensatory strategy training (cognitive rehabilitation), pharmacotherapy, or psychotherapy. This information is critical in designing realistic goals and future plans for patients with cognitive deficits. In addition, repeated assessments can track the patient's response to primary therapy, allowing for careful evaluation of the costs and benefits of a given treatment regimen or supportive therapy (e.g., deterioration of cognitive function predicts tumor progression) and to targeted interventions for cognitive dysfunction.¹¹

IMPACT OF TUMOR

Whether the *predominant* cause of cognitive decline in patients with brain tumors is the treatment or the tumor itself is an important question and has a significant impact on treatment recommendations. Older studies have emphasized the late neurotoxicity of treatment, especially radiotherapy.¹² However, these studies have suffered from deficiencies, but most importantly, have lacked baseline cognitive testing because the brain tumor itself is often the primary cause of cognitive difficulties. The importance of baseline testing cannot be overemphasized because, for example, large prospective studies with baseline evaluations have found more than 90% of patients with brain metastases have significant cognitive impairment in one or more cognitive domains at the time of diagnosis (i.e., before whole-brain radiotherapy [WBRT]).¹³

More recent studies that have included prospective baseline and serial cognitive testing have found the tumor to be the dominant cause of cognitive decline in brain metastases,^{13,14} patients with low-grade gliomas,¹⁵ and patients with high-grade gliomas.¹⁶ For example, Li et al.¹⁴ divided 135 patients with brain metastases into poor responders and good responders based on the response of their brain metastases on MRI 2 months after WBRT. For all tests, the median time to cognitive deterioration was longer in good than in poor responders and was statistically significant in a number of domains. In long-term survivors, tumor shrinkage was significantly correlated with the preservation of executive function and fine motor coordination.

There is also mounting evidence that cognitive decline in brain tumor patients after therapy may frequently reflect subclinical tumor progression rather than neurotoxicity resulting from treatment. In a North Central Cancer Treatment Group study of 1,244 patients with high-grade gliomas prospectively treated with radiation and nitrosourea-based chemotherapy, cognitive deterioration was noted at evaluations prior to radiographic failure; in contrast, patients without tumor progression had stable cognitive function.¹⁶ In an M.D. Anderson Cancer Center study of 56 patients with recurrent high-grade gliomas treated on phase 1 and phase 2 trials, cognitive deterioration occurred 6 weeks prior to radiographic failure, highlighting the sensitivity and predictive value of cognitive assessments.¹⁷ Similarly, a large randomized phase 3 glioblastoma (GBM) trial studying the effects of standard- versus a dose-dense regimen of temozolomide found cognitive dysfunction at baseline and cognitive decline after concurrent chemoradiation (in progression-free patients) was prognostic for progression-free and overall survival time.¹⁸

IMPACT OF TREATMENT

Surgery

Nonbrain surgery is known to cause postoperative cognitive impairments, especially in the elderly. The deficits, particularly for memory, may be present for weeks or months.¹⁹ Risk factors besides age includes duration of anesthesia and postoperative complications. In contrast to nonbrain surgery, surgery for brain tumors may lead to focal cognitive deficits.³ However, relief of mass effect and increased intracranial pressure frequently results in improvement in cognitive function. Variability in frequency of cognitive improvement or decline have been reported, with 24% to 84% demonstrating cognitive improvement and 36% to 38% demonstrating cognitive decline.^{1,20,21} There is some preliminary evidence that better preoperative cognitive function (i.e., memory, language) is associated with increased risk for postoperative cognitive dysfunction in patients with high-grade gliomas.^{20,21} Potential adverse effects of surgery can be seen in patients with benign tumors, such as pituitary adenomas. Neuropsychological tests performed on a cohort of 69 pituitary tumor patients treated found that a transfrontal approach was associated with greater frequency and severity of cognitive impairment (44% impaired) when compared to the transphenoidal approach (30% impaired) and even more so when compared to a nonsurgical control group with pituitary tumors.²²

The balance between attaining a maximal resection and, at the same time, preserving function has been difficult, especially because gliomas are infiltrative and invasive. However, that goal has been advanced by comprehensive evaluations, including neuropsychological assessments and technologic advances such as intraoperative MRI, functional neuroimaging techniques, white matter pathway mapping, and intraoperative stimulation.²³ Recent studies indicate that as many as 80% of patients with low-grade gliomas will experience postoperative cognitive deficits even when using intraoperative-guided imaging and functional mapping in patients

with tumors in eloquent brain locations. However, most of these deficits resolve within a few months. In a report by Duffau,²³ 94% of patients returned to their preoperative functioning by 3 months, presumably owing to the plasticity of the normal brain and recovery from the acute effects of surgery.²⁴

Radiotherapy

Radiation therapy plays an important role in the treatment of primary and metastatic tumors located in the CNS. As more effective treatments for intracranial lesions have become available and long-term survival has increased, more attention has been placed on identifying and quantifying the adverse effects of radiation on cognitive function in adult patients. The mechanisms for these adverse effects are not fully understood but include neuroinflammation, alterations in neurogenesis, and direct vascular injury.^{25,26}

Because of their relatively long progression-free and overall survival, patients with low-grade brain tumors are an ideal population to study when analyzing the potential cognitive deficits of radiotherapy because cognitive deficits can take years to develop. In addition, patients with low-grade brain tumors are often young and do not have underlying medical comorbidities that may confound the cognitive analysis. A number of retrospective studies have found increased cognitive difficulties after cranial radiotherapy for low-grade brain neoplasms. However, these studies have suffered from many deficiencies such as an absence of baseline cognitive testing because the brain tumor itself is often the primary cause of cognitive difficulties.¹² A retrospective study of patients with low-grade gliomas followed longitudinally highlights some of these shortcomings.²⁷ With a median follow-up of 12 years, there were declines in attentional functioning in the patients who received radiotherapy, whereas the patients who were observed retained stable cognitive functioning. Although these data are valuable in that they provide long-term follow-up on patients with low-grade gliomas, the study has been criticized for a lack of baseline testing, the inherent selection bias of patients who received radiotherapy having a more aggressive disease, and outdated techniques such as WBRT.²⁸

In sharp contrast, a number of studies have prospectively performed extensive neuropsychological testing on adult patients with low-grade neoplasms before (baseline) and after radiotherapy (up to 6 years after radiotherapy) (Table 144.1) and have not found significant cognitive deterioration when compared to either baseline²⁹⁻³³ or to a cohort of patients with low-grade brain neoplasms not treated with radiotherapy.^{15,34} For example, a subset of 20 of the 203 patients with adult low-grade gliomas enrolled on an Intergroup prospective phase 3 trial that randomized patients to 50.4 or 64.8 Gy underwent cognitive testing before and up to 5 years after localized radiation therapy.³² No significant losses in general intellectual function, new learning function, or memory function were seen. The groups' mean test scores were higher at follow-up evaluations than their initial performances on all psychometric measures, although the improvement was not statistically significant. However, four patients, all in the 64.8-Gy arm, had a mild decline in one or more of the domains assessed. The results of this study are consistent with the weight of evidence that indicates a low incidence of cognitive difficulties after *focal*, conventionally fractionated (i.e., 1.8 to 2 Gy) radiotherapy using modern techniques to deliver moderate doses (i.e., 45 to 54 Gy) in adults.^{12,35}

An extreme form of *focal* radiotherapy used to treat many benign and neoplastic cranial conditions is stereotactic radiosurgery (SRS). SRS uses multiple radiation beams and is able to encompass treatment volumes in the high-dose region with small margins because of the stereotactic imaging and immobilization. This results in rapid dose falloff, allowing greater sparing of normal brain tissues, and therefore minimizes risk to the surrounding structures. The cognitive impact of SRS was evaluated in a prospective trial assessing 95 patients with cerebral arteriovenous malformations

TABLE 144.1

Prospective Trials for Low-Grade Neoplasms with Baseline and Serial Neurocognitive Testing

Study (Reference)	Number of Patients	Radiation Total Dose/ Fraction Size (Gy)	Mean Follow-up (Years)	Extensive Neurocognitive Assessment	Neurotoxicity After RT
Glosser ³⁰	17	Proton RT median 68.4 CGE/1.8	4	Yes	No; mild decline in psychomotor speed with high doses
Vigliani ³⁴	17	Focal RT 54/1.8	4	Yes	No; transient decline in reaction time
Armstrong ²⁹	26	Focal RT mean 54.6/1.8–2.0	3	Yes	No; mild decline in visual memory after 5 years
Brown ⁸⁸	203	Focal RT 50.4/1.8 or 64.8/1.8	7.4 (median)	No (MMSE and NFS)	5.3% with MMSE decline at 5 years
Torres ¹⁵	15	Focal RT mean 54/1.8	2	Yes	No; decline in memory and attention only if tumor progression
Laack ³²	20	Focal RT 50.4/1.8 or 64.8/1.8	3	Yes	No
Steinvoth ³³	40	SRT median 57.6/1.8	1	Yes	No
Jalali ³¹	22	SRT median 54/1.8	2	Yes	No

RT, radiotherapy; CGE, centigray equivalent; MMSE, Folstein Mini-Mental State Examination; NFS, neurologic function scores; SRT, stereotactic radiotherapy.

with extensive neuropsychometric testing before and after SRS (median dose: 20 Gy in one fraction) and found all measures of cognitive function were stable or improved 3 years after SRS.³⁶

The impact of WBRT on cognitive function is best addressed by prophylactic cranial irradiation (PCI) trials because, by definition, these patients should not have brain metastases (and, therefore, tumor progression is less of a confounding variable). PCI has been shown to decrease the development of brain metastases and improve cure rates and survival for small-cell lung cancer patients because of the propensity of these patients to develop brain metastases. Similar to low-grade brain tumors, a number of retrospective studies have raised concerns of neurotoxicity after PCI, but these studies have been compromised by the use of large, unconventional fraction sizes, comorbid conditions (known brain metastasis), high total doses (up to 50 Gy), concomitant use of chemotherapy, and, most importantly, lack of baseline neuropsychological testing (prospective cognitive studies have shown up to 97% of limited stage small-cell lung cancer patients have evidence of cognitive dysfunction prior to PCI).^{37,38} Two of the largest randomized trials of PCI did incorporate prospective neuropsychometric testing and both found a significant proportion of patients had cognitive dysfunction at baseline, but found no differences in cognitive performance between the randomization arms of PCI or no PCI.^{39,40} However, higher doses of PCI are associated with worse cognitive outcomes; a randomized trial of different radiation schedules found greater rates of cognitive decline in patients treated with 36 Gy compared to patients treated with 25 Gy.⁴¹ Finally, in patient populations with a low incidence of brain metastases, the risk-benefit ratio of PCI shifts and is less favorable. A phase 3 trial of PCI for patients with non-small-cell lung cancer found worse function on some measures of cognitive function in those patients treated with PCI compared to the observation arm. However, the 1-year rate of brain metastases was only 18% in the observation arm—much lower than would be expected with small-cell lung cancer, where 50 to 60% of patients develop brain metastases if they do not receive PCI.^{42,43} Therefore, it should be recognized that PCI does have a risk, but in high-risk populations such as those with small-cell lung cancer, the risk of brain metastases and associated decline with growing intracranial lesions outweighs the cognitive risk of PCI.

More recently, there have also been prospective trials with extensive cognitive testing for patients with brain metastases treated with WBRT. One of these studies, an international phase 3 trial, prospectively evaluated cognitive function in 135 patients with brain metastases before and after WBRT and found tumor progres-

sion was the predominant cause of cognitive decline, with stable or improving cognitive function in long-term (i.e., 15-month) survivors.¹⁴ A smaller German trial assessed 15 patients with brain metastases with a 90-minute battery of cognitive tests before and after WBRT (40 Gy in 2-Gy daily fractions) and found stable cognitive function in long-term survivors.⁴⁴ On the other hand, in a recent study comparing SRS alone to SRS and WBRT for 58 patients with up to three brain metastases, 49% of patients in the WBRT group experienced declines in learning and memory at 4 months compared to only 23% in the SRS group.⁴⁵ Critics note the small size of the single-institutional study and a substantial difference in survival in the two groups, suggesting that the patients may not have been well-matched for prognostic factors.⁴⁶ Additionally, at 4 months, cognitive function after radiotherapy is at a nadir due to subacute or early-delayed effects of radiotherapy that gradually resolve over time.⁴⁷ Recognizing the limitations of this trial, it does suggest that for patients undergoing radiosurgery for a relatively small burden of intracranial disease followed closely with MRI, delay or avoidance of WBRT may be reasonable and may result in better cognitive function over time.

Radiotherapy techniques may impact the cognitive risk of WBRT. For example, large fraction sizes, as delivered in many historical studies, have been associated with dementia and cognitive decline in long-term survivors after WBRT; therefore, dose-fractionation schedules should be determined by the patient's estimated prognosis, with more protracted schedules used for patients with the possibility of long-term survival.³⁸ Another approach is to modify the WBRT to avoid sensitive regions of the brain. It has been suggested that hippocampal neural stem cell injury from WBRT may play a role in memory decline.⁴⁸ Intensity-modulated radiotherapy can be used to conformally avoid the hippocampal neural stem cell compartment during WBRT (HA-WBRT). The Radiation Therapy Oncology Group (RTOG) conducted a single-arm phase 2 study of HA-WBRT for 113 patients with brain metastases.⁴⁹ Only 4.5% of patients experienced progression within the hippocampal avoidance region consistent with prior retrospective studies.⁵⁰ The mean relative decline in verbal memory at 4 months was 7%, which was significantly lower in comparison to the historical control of 30% at 4 months ($p = 0.0003$).

In summary, although WBRT and PCI prospective trials suggest that, on the whole, any detrimental effects on cognitive function from radiotherapy seem to be balanced by the beneficial cognitive effects of improved tumor control in the brain, this must be balanced with selecting the proper patient population

and weighing out the risk–benefit ratio. Modification of WBRT techniques such as hippocampal avoidance presents an intriguing treatment approach, although further study is needed.

Chemotherapy

The last decade has seen a surge in research on cognitive functioning following diagnosis and treatment of non-CNS cancer. An emerging body of data show that a subgroup of cancer patients is vulnerable to posttreatment (mostly but not exclusively chemotherapy related) cognitive decline, which has a significant impact on quality of life and daily function.^{51–55} Chemotherapy is widely used in patients with non-CNS cancer and is known to be harmful to multiple organ systems. Traditionally, the CNS has been considered to be less vulnerable to the toxic effects of chemotherapy; however, acute and delayed neurologic complications are being identified with increasing frequency. Human and preclinical studies into the occurrence and determinants of cognitive decline in non-CNS cancer patients have led to a growing consensus that many chemotherapeutic agents for non-CNS cancer can interfere with various neurobiologic processes and can induce cognitive impairment.^{56,57}

Incidence and Pattern of Cognitive Decline

Cognitive dysfunction has been particularly well studied in breast cancer patients undergoing adjuvant systemic therapy. The majority of the prospective studies in this patient population have indicated that 20% to 60% of patients have cognitive decline after chemotherapy compared to pretreatment cognitive performance.^{54,55} In addition, several neuropsychological studies have demonstrated that cognitive impairment may already be present in cancer patients before the start of treatment.^{58–61} Psychological distress, fatigue, or surgical factors (in case the assessment took place postsurgery) do not completely explain the possible link between cancer and cognitive dysfunction. Proposed causes for pretreatment cognitive dysfunction include not only the biology of cancer (inflammatory responses triggering neurotoxic cytokines) and common risk factors for the development of cancer and cognitive decline (e.g., poor DNA repair mechanisms linked to cancer and neurodegenerative disorders), but also methodologic considerations (patients participating in cognitive studies may not represent a random sample of individuals confronted with cancer).^{62,63}

Patients show changes from pre- to posttreatment on a wide range of standardized neuropsychological tests. On the basis of studies with comprehensive neuropsychological examinations, a pattern of cognitive impairment can be described. Patients frequently demonstrate learning and memory deficits possibly secondary to impairment of encoding or initial processing of information and the retrieval of stored information, and diminished speed of information processing and reduced executive functioning. These changes in cognitive function have been associated with adverse impacts in cancer survivors' daily life (e.g., work-related disabilities).⁶⁴

Trajectory of Cognitive Decline

The majority of prospective studies have demonstrated cognitive dysfunction up to 1 to 2 years postchemotherapy.⁶⁵ Cross-sectional studies with long-term cancer survivors show the presence of cognitive differences between chemotherapy-treated patients and noncancer controls up to 20 years posttherapy, suggesting the persistence of cognitive impairment over the years.^{66,67} But, mature follow-up data from prospective studies are lacking to ascertain these changes from the baseline state and to determine the slope of cognitive changes over the course of years. This is relevant, because current insights into the mechanisms of chemotherapy-induced neurologic complications raise the possibility of chemotherapy-associated premature and accelerated cognitive aging.⁶⁸ Whether

patients treated with chemotherapy are at risk for developing new late-onset cognitive dysfunction or dementia is not known. Several retrospective studies have been published examining the risk of dementia in breast cancer survivors who completed cytotoxic treatment up to 15 years previously using data from the linked Surveillance, Epidemiology and End Results (SEER)–Medicare database. None of these studies showed clear evidence for the existence of such a relationship, but several important methodologic issues limit the validity and interpretation of the studies.⁶⁶

Risk Factors

The finding that subgroups of patients experience posttreatment cognitive decline has led to the examination of patient- and disease/treatment-related risk factors for cognitive change.⁶⁹ There are some indications for a dose-response relationship based on a study that observed more patients with cognitive decline following high-dose chemotherapy compared to conventional dose chemotherapy and on a study showing a linear decline in cognitive performance after each cycle of chemotherapy.^{70,71} Also, several studies have pointed to a higher frequency of cognitive dysfunction in breast cancer patients receiving both chemotherapy and endocrine therapy compared to breast cancer patients treated solely with chemotherapy or endocrine treatment.⁵⁵ Plausible patient-related risk factors such as age, intelligence quotient (IQ), baseline cognitive function, presence of comorbid conditions, and a host of other factors such as depression, anxiety, stress, fatigue, and treatment-induced menopause have not been identified as strong contributors to the impact of chemotherapy on cognitive function. A limited number of studies also looked at genetic factors (e.g., vulnerable alleles of genes such as APOE and COMT allele) as an explanation for why only a subgroup of patients seem to be more vulnerable for treatment-associated cognitive decline. In a study among lymphoma and breast cancer survivors, it was shown that survivors with at least one E4 allele scored lower on several cognitive tasks as compared to survivors who did not carry an E4 allele.⁷² Another study found that breast cancer patients who had the COMT-Val allele and were treated with chemotherapy performed more poorly on several neuropsychological tests as compared to those with the COMT-Met allele.⁷³

Based on experimental animal studies, other blood-based biomarkers that may mediate chemotherapy-associated cognitive decline are circulating proinflammatory cytokines. Up to now, studies in cancer patients show only weak correlations between interleukin 1B (IL-1B), IL-6, and tumor necrosis factor alpha (TNF- α) levels and cognitive impairment and suggests that the role of cytokines in postchemotherapy cognitive decline is not well understood and requires further evaluation.⁶³

Neural Substrate

Structural, functional, and molecular imaging studies in non-CNS cancer patients are helping to clarify the neural basis and have started to shed light on the brain alterations that may be part of the mechanisms underlying the observed cognitive dysfunction.^{74–77} White matter pathology has been observed within months and after 10 years posttreatment, both following high-dose and standard-dose regimens. Studies using voxel-based morphometry have reported volume reductions of white and grey matter 1 year and also at 20 years after the completion of chemotherapy.^{78,79} A prospective study observed a decrease in focal gray matter volume 1 month after cessation of chemotherapy, which recovered in some but not in all regions at 1 year posttreatment.⁸⁰ The cerebral white matter seems particularly vulnerable to the effects of chemotherapy. Prospective studies investigating cerebral white matter integrity using diffusion tensor imaging reported lower fractional anisotropy (FA) in the genu of the corpus callosum, lower FA in the frontal and temporal white matter, and higher mean diffusivity in the frontal white matter of breast cancer patients who received standard-dose anthracycline-based regimens compared to breast cancer controls

and healthy controls.⁸¹ In cross-sectional studies conducted, on average, 10 and 20 years after the completion of chemotherapy, comparable indications for affected white matter tracts in breast cancer patients who received chemotherapy compared to subjects without a history of cancer or breast cancer patients who never received chemotherapy were observed.^{78,79} Importantly, several studies have demonstrated a link between the abnormal microstructural properties in white matter regions and the cognitive impairments seen in breast cancer patients treated with chemotherapeutic agents.⁸¹ The observed changes in diffusion tensor imaging (DTI) parameters may be related to demyelination of white matter axons or axonal injury after chemotherapy. Functional MRI (fMRI) studies have demonstrated postchemotherapy changes in brain activation and in resting brain connectivity pattern. The prospective fMRI studies show a complex picture with both hyper- and hypoactivation patterns and inconsistent findings with regard to accompanying changes in fMRI task performance.⁷⁶

Underlying Mechanisms

A large number of studies in rodent models have extended our understanding of the cell biology and molecular basis underlying chemotherapy-associated CNS toxicity. Moreover, patterns of behavioral performance in animals seem to correspond to a significant extent with cognitive patterns in patients, supporting the important role for preclinical research in understanding the cognitive effects of cancer treatments in humans. Using detailed cell lineage-based approaches, it has been shown that neural progenitor cells, which are the direct ancestors of all differentiated cell types in the CNS, and mature postmitotic oligodendrocytes are the most vulnerable cell populations to the effects of multiple chemotherapeutic agents.^{48,56,57,82,83} It has been hypothesized that long-term cognitive decline in cancer survivors is the result of a combination of decreased proliferation of neural progenitor cells, impaired hippocampal neurogenesis, and damage to oligodendroglial cells and white matter tracts.

As many different chemotherapeutic agents seems to have similar effects on the CNS, studies are also exploring common indirect mechanisms as etiologic factors of chemotherapy-associated neurotoxicity, such as pro-oxidative effects, toxic neurotransmitters/monoamine release, disruption of blood vessel density and supply, and inflammation.⁵⁷ Unraveling the precise mechanisms underlying chemotherapy-related cognitive side effects is necessary to enable the identification of novel treatment strategies. Several animal studies have shown promising interventions such as the prevention of oxidative stress associated with chemotherapy using as N-acetyl cysteine or melatonin, strategies that stimulate neurogenesis using insulin-like growth factor 1 or fluoxetine, and treatments with glutamate receptor antagonists such as dextromethorphan, which ameliorate negative chemotherapy-induced cognitive outcomes.⁸⁴⁻⁸⁷

TREATMENT OF COGNITIVE DYSFUNCTION

If cognitive impairment is identified in a patient, it is essential to evaluate for reversible causes such as depression, medications (e.g., changing or, if possible, discontinuing antiepileptics), or endocrine disturbances (i.e., hypothyroidism). For patients with a brain tumor, the most common reversible cause of cognitive dysfunction is tumor progression because a number of studies have shown effective treatment of the tumor can result in improvement in cognitive function.⁸⁸

There are few proven therapies for cognitive dysfunction in patients with a brain tumor, although there are a number of small trials with interesting findings.⁸⁹ Methylphenidate is a psychostimulant that has generated clinical and research interest for some time, and several small studies have suggested a benefit for patients with psychomotor slowing, a decline in executive functioning, or

general apathy.⁹⁰ Unfortunately, a phase 3, placebo-controlled trial did not confirm a benefit in cognitive function or quality of life in patients receiving radiotherapy for brain tumors.^{91,92} Similarly a phase 3 trial of donepezil, an acetyl cholinesterase inhibitor used in the treatment of symptoms of Alzheimer's disease, was no better than placebo at improving overall cognitive function in brain tumor survivors.⁹³ However, on a subgroup analysis, among patients with more cognitive problems at baseline, there was a significant benefit in verbal memory for patients on donepezil.

Patients with a brain tumor actually represent an ideal population for research in neuroprotection because, unlike stroke patients, patients with a brain tumor typically have *planned* injurious events (i.e., surgery, chemotherapy, radiotherapy) to their brain, providing a golden opportunity for prophylactic treatment. A phase 3 trial of 554 adult patients with brain metastases evaluated the potential neuroprotective properties of memantine, an N-methyl-D-aspartate (NMDA) receptor antagonist that has been shown to be effective and well tolerated in vascular dementia patients.⁹⁴ All patients received WBRT and were randomized to either placebo or memantine at the start of radiotherapy and were treated for a total of 24 weeks. Memantine was well tolerated and had a toxicity profile very similar to placebo. Although there was less decline in the primary endpoint of delayed recall at 24 weeks, this lacked statistical significance ($p = 0.059$), possibly due to significant patient loss over time due to disease progression and death. The memantine arm had significantly longer time to cognitive decline ($p = 0.01$), and the probability of cognitive function failure at 24 weeks was 53.8% in the memantine arm and 64.9% in the placebo arm. Superior results were also seen in the memantine arm for specific tests of executive function, processing speed, and memory.

Another treatment option is brain injury rehabilitation, using methods developed for traumatic brain injury survivors. Gehring et al.⁹⁵ conducted a phase 3 trial of 140 patients with adult brain tumors. Patients were randomly assigned to an intervention group or to a waiting list control group.⁹⁵ The intervention involved six weekly 2-hour sessions, self-study for reinforcement, and at 3 months, a telephone-based booster session. The sessions incorporated both computer-based attention retraining and compensatory skills training of attention, memory, and executive functioning. At the 6-month follow-up, the intervention group performed significantly better with attention and verbal memory than the control group and reported less mental fatigue.

Pharmacologic interventions to prevent or intervene against cognitive symptoms in non-CNS cancer patients are still in an early stage of development. Some agents are promising, but rigorous testing with appropriate study designs and sufficient sample sizes necessary to translate and implement these agents in daily practice are either absent or have generated disappointing results. For example, several studies found positive effects of erythropoietin (EPO) on cognitive functioning during or shortly after chemotherapy, but randomized controlled studies at longer follow-ups failed to show positive effects of EPO on cognition. Psychostimulants like methylphenidate and modafinil have been tested in several studies, but the effectiveness of methylphenidate to treat cancer therapy-associated cognitive dysfunction is, at present, not established. Initial small studies with modafinil are slightly more hopeful, but larger studies with longer follow-ups are needed before conclusions about effectiveness can be drawn. Another example of an agent that received attention following initial interesting preclinical findings but for which convincing data from phase 3 studies on the efficacy are lacking is donepezil.^{89,96}

Nonpharmacologic interventions like mindfulness-based stress reduction and exercise interventions are gaining increasing attention as potential effective interventions for cancer- and cancer-treatment related cognitive effects, and several large trials are underway that should clarify the value of these behavioral interventions. Multiple behavioral-based studies have proven successful in improving daily life functioning using intact cognitive abilities and strategies together with psychoeducation.⁹⁷⁻¹⁰¹ Finally, interventions focusing

on mental stimulation, collectively known as brain training, are frequently accessed by cancer survivors, but limited evidence supports their efficacy,¹⁰² and recent reviews of the current brain training literature indicate that most programs still fail to display fundamental transfer (i.e., generalization of trained skills).¹⁰³

CONCLUSION

Just as recent technologic advances in neurosurgery and radiotherapy have enabled physicians to perform surgery and administer radiation more safely than in prior eras, it is expected that future technologic advances will further improve the therapeutic ratio. Current radiation and chemotherapy doses and regimens are based on populations of patients and not the individual sensitivity

of the patient or the tumor. As more research is conducted in this arena, it is likely that, in the future, treatments will be individualized for each unique patient and tumor.

Recent cellular, molecular, and biochemical work has also been instrumental in elucidating the mechanism of the CNS response to injury, and this should lead to the rational development of selective neuroprotective and therapeutic agents. In the meantime, larger prospective, longitudinal studies with well-validated quality of life instruments and neuropsychological batteries are needed to determine the impact of (especially novel) treatment regimens on cognitive function. And, finally, because lack of tumor control remains the predominant cause of cognitive dysfunction and deterioration in brain tumors, it is imperative that the neuro-oncology community continues to focus their scientific endeavors on the ultimate goal of durable tumor control.

145 Cancer Survivorship

Wendy Landier, Craig C. Earle, Smita Bhatia, Melissa M. Hudson,
Kevin C. Oeffinger, Patricia A. Ganz, and Louis S. Constine

INTRODUCTION

Living beyond cancer into long-term survivorship is now a reality for most children and many adults who are diagnosed with cancer today. However, as the numbers of long-term cancer survivors continue to increase, oncologists and other clinicians must understand and address the complex interplay of their biologic, psychological, and socioeconomic needs. Biologic sequelae disrupt organ function and cause tissue-specific and systemic comorbidities, which can compromise quality of life (e.g., fatigue, infertility) or cause death (e.g., cardiovascular disease, second malignancies). Psychological sequelae, including depression and distress from fear of cancer recurrence, and failure to work effectively and to socially engage with others, are clear detriments to life satisfaction. Socioeconomic consequences such as insufficient income and high costs of medical care and medical bankruptcies may exacerbate the difficulties associated with daily living.

The multifaceted needs of survivors demand a spectrum of actions from clinicians in order to provide them with quality survival. It is necessary that clinicians diagnose and treat the chronic physical effects of cancer and its therapy, promote adaptive and rehabilitative lifestyle changes, and campaign for fair socioeconomic treatment by society. The process begins with communication between the clinician and patient regarding details of the treatment, potential sequelae in all the various domains, and guidance for ongoing care. Table 145.1 outlines the essential components of survivorship care as discerned by the Committee on Cancer Survivorship from the Institute of Medicine (IOM), and Table 145.2 states their 10 recommendations.¹ In this seminal report, specific goals were defined to ensure optimal outcomes for cancer survivors as follows:

- Raise awareness of the medical and psychosocial problems faced by cancer survivors and establish cancer survivorship as a distinct phase of the cancer trajectory during which specific clinical interventions are needed.
- Define quality health care for cancer survivors and identify strategies to achieve it.
- Improve quality of life through policies to ensure cancer survivors' access to psychosocial services, fair employment practices, and health insurance.

There are many unanswered questions about surveillance strategies, models of health-care delivery, research strategies, and education of both patients and health-care providers. This chapter is designed to serve as an introduction to understanding the scope of the survivorship problem.

DEFINITION OF SURVIVORSHIP AND SCOPE OF THE PROBLEM

Cancer survivorship is an evolving concept with multiple definitions. Prior to the recent evolution of curative cancer therapy, *cancer survivors* were defined as family members left behind after a loved one had succumbed to the disease.² In the latter half of the

20th century, as survival rates increased, the dramatic impact of life-saving but potentially toxic therapies began to emerge. Izsak and Medalie³ are credited with first describing the “costs” of cancer survivorship: “Survival rates . . . do not relate to how the patient survives, at what cost to his physical functioning, how he adapted to his condition from a psychological point of view, and how he is fulfilling his roles in his family, at work, among friends, and in the wider society.” Three decades ago, Fitzhugh Mullan,⁴ a young physician and cancer survivor, challenged the binary concept of illness versus cure and suggested that survivorship was a process with predictable stages, ranging from the acute diagnosis and treatment phase, through the post-therapy phase of watchful waiting, and finally to the phase of permanent survival, when the focus shifts from concerns about risk of recurrence to those impacting long-term quality of survival. Soon after, the National Coalition for Cancer Survivorship (NCCS) was founded, raising awareness of the importance of the survivorship experience and setting the stage for recognition of survivorship as a distinct phase along the cancer control continuum.⁵ In the mid 1990s, the National Cancer Institute established the Office of Cancer Survivorship, which was charged with directing and supporting research, training, and education regarding issues relating to cancer survivorship. Over the past decade, many influential groups, including the IOM,¹ the President’s Cancer Panel,⁶ and the American Society of Clinical Oncology (ASCO),⁷ have released reports highlighting issues relating to cancer survivorship. For the purposes of this chapter, the IOM’s definition of cancer survivorship will be used, which focuses on the phases of cancer care following the completion of primary treatment and lasting until cancer recurrence or the end of life.¹

The number of cancer survivors has increased more than three-fold since 1975 as a result of improvements in early detection and therapeutic successes (Fig. 145.1).⁸ There are currently nearly 14 million cancer survivors in the United States⁸ and more than 25 million worldwide.⁹ The 5-year relative survival rate has also continued to increase steadily, and has now reached 68% for adults and 83% for children.¹⁰ The number of cancer survivors is expected to increase in the United States by 31% to almost 18 million over the next decade,⁸ because of the general population growth and the increasing proportion of older adults in the population for whom cancer prevalence rates are the highest. More than 8 million cancer survivors in the United States are age 65 or older, representing 59% of all cancer survivors.¹¹ Among survivors, the most common diagnoses are breast cancer (22%) and prostate cancer (20%); survivors of colorectal cancer, hematologic malignancies, gynecologic, urinary, melanoma, lung, and other cancers each represent less than 10% of the population of cancer survivors (Fig. 145.2).¹¹ Dramatic improvements in childhood cancer survival has resulted in a growing population that now exceeds 379,000 in the United States alone,¹² and multiple studies regarding the impact of cancer therapy on health-related outcomes in this population have been published.¹³ In a retrospective cohort of 10,397 childhood cancer survivors diagnosed between 1970 and 1986 (the Childhood Cancer Survivor Study), Oeffinger et al.¹⁴ reported that 62.3% experienced

Essential Components of Survivorship Care

- Education** of the cancer survivor, family, health-care providers
 - A plan for care based on the treatment administered and future health risks
 - Promotion of healthy lifestyles
 - Information to assist health-care providers in understanding future risks and to foster an effective interaction with the oncology team
- Surveillance** for cancer spread, recurrence, or second cancers and for long-term adverse physical, psychosocial, socioeconomic effects
- Intervention** to prevent or treat consequences of cancer or its therapy
- Communication** between specialists and primary care providers to ensure that the survivor's health needs are met and detailed records are kept about treatment history
- Research** focused on understanding, preventing, and treating adverse consequences of cancer or its therapy
- Patient advocacy** to address problems related to employment, insurance, and disability

Modified from Hewitt M, Greenfield S, Stovall E. *From Cancer Patient to Cancer Survivor: Lost in Transition*. Washington, D.C.: National Academies Press; 2006.

at least one treatment-related late effect, 37.6% developed multiple late effects, and 27.5% developed a late effect that was severe or life-threatening. The impact of cancer therapy on health-related outcomes in the rapidly growing population of adult cancer survivors is largely unknown, but the need for ongoing follow-up care and late effects surveillance for all cancer survivors is clear.¹

GOALS OF SURVIVORSHIP HEALTH CARE

Identifying Late Effects of Cancer Therapy

The modern era of cancer therapy is predicated on the safe intensification of radiation, chemotherapy, and biologic therapies. Malignancies resistant to therapy have demanded an aggressive treatment approach that often resides on the edge of normal tissue tolerance, or even exceeds tolerance to some “acceptable” degree. The potential to ameliorate or prevent such normal tissue damage, or to manage and rehabilitate affected patients, requires an understanding of these persistent long-term or late-onset chronic effects. Because late effects can manifest months or years after the cessation of treatment, therapeutic decisions intended to obviate such effects can be based only on the probability, not the certainty, that such effects will develop.

Determining the frequency and pathogenesis of late effects is difficult for several reasons: (1) Patients must survive long enough for tissue injury to develop, (2) the number of patients both affected and unaffected by therapy must be known, and (3) the latent period to the manifestation of damage compromises discernment of the responsible component of multimodality therapy. Further complicating our understanding of organ tolerance to therapy is that cancer and host factors interact with therapy in the causation of late effects. Cancer factors include direct tissue effects (e.g., from organ invasion such as the lung), systemic effects of cancer-induced organ damage or loss (e.g., hepatic dysfunction or loss of a kidney), and indirect mechanical effects (e.g., renal or airway obstruction). Host factors include genetic (e.g., ataxia-telangiectasia) and comorbid (e.g., vascular disease, diabetes) conditions, the developmental age at treatment, and underlying structural abnormalities (e.g., cardiac). The previously mentioned report by Oeffinger et al.¹⁴ documents the high frequency of chronic health conditions in adult survivors of childhood cancer, many of which

TABLE 145.2

Ten Recommendations for Cancer Survivorship Care

- Health-care providers, patient advocates, and other stakeholders should work to raise awareness of the needs of cancer survivors, establish cancer survivorship as a distinct phase of cancer care, and act to ensure the delivery of appropriate survivorship care.
- Patients completing primary treatment should be provided with a comprehensive care summary and a follow-up plan that is clearly and effectively explained. This Survivorship Care Plan should be written by the principal provider(s) who coordinated the oncology treatment. This service should be reimbursed by third-party payors of health care.
- Health-care providers should use systematically developed evidence-based clinical practice guidelines, assessment tools, and screening instruments to help identify and manage the late effects of cancer and its treatment. Existing guidelines should be refined, and new evidence-based guidelines should be developed through public and private sector efforts.
- Quality of survivorship care measures should be developed through public/private partnerships and quality assurance programs implemented by health systems to monitor and improve the care that all survivors receive.
- The Centers for Medicare and Medicaid Services (CMS), the National Cancer Institute (NCI), the Agency for Healthcare Research and Quality (AHRQ), the Department of Veterans Affairs (VA), and other qualified organizations should support demonstration programs to test models of coordinated, interdisciplinary survivorship care in diverse communities and across systems of care.
- Congress should support the Centers for Disease Control and Prevention (CDC), other collaborating institutions, and states in developing comprehensive cancer control plans that include the consideration of survivorship care and promoting the implementation, evaluation, and refinement of existing state cancer control plans.
- The NCI, professional associations, and voluntary organizations should expand and coordinate their efforts to provide educational opportunities to health-care providers to equip them to address the health care and quality of life issues facing cancer survivors.
- Employers, legal advocates, health-care providers, sponsors of support services, and government agencies should act to eliminate discrimination and minimize adverse effects of cancer on employment while supporting cancer survivors with short-term and long-term limitations in their ability to work.
- Federal and state policy makers should act to ensure that all cancer survivors have access to adequate and affordable health insurance. Insurers and payors of health care should recognize survivorship care as an essential part of cancer care and should design benefits, payment policies, and reimbursement mechanisms to facilitate coverage for evidence-based aspects of care.
- The NCI, CDC, AHRQ, CMS, VA, private voluntary organizations such as the American Cancer Society (ACS), and private health insurers and plans should increase their support of survivorship research and expand mechanisms for its conduct. New research initiatives focused on cancer patient follow-up are urgently needed to guide effective survivorship care.

Figure 145.1 Estimated number of cancer survivors in the United States over time as of January 1, 2012. (Data from <http://cancercontrol.cancer.gov/ocs/prevalence/prevalence.html#survivor>, based on modeling provided by Angela Mariotto, PhD as described in Mariotto AB, Yabroff KR, Shao Y, et al. Projections of the cost of cancer care in the United States: 2010-2020. *J Natl Cancer Inst* 2011;103:117-128. Accessed November 5, 2013.)

are severe or life-threatening. At 30 years, almost three-fourths of survivors had a chronic health condition, more than 40% had a serious health problem, and one-third had multiple conditions. Additionally, Yeh et al.¹⁵ have recently developed a model based on Childhood Cancer Survivor Study data to estimate cumulative excess mortality in a simulated cohort of 5-year survivors of childhood cancer. These investigators predict a substantial decrement in life expectancy of 10.4 years (range: 4 to 17.8 years) for

the childhood cancer survivors, compared with the general population.^{15,16} Moreover, the model estimates that the reduction in life expectancy is up to 28%, and that approximately one in four survivors will die of either a late recurrence or late effects related to secondary cancer and cardiopulmonary conditions. These data underscore the importance of understanding the toxic effects of our therapy. Several chapters in this text provide detailed information on the long-term physical effects of cancer therapy for each organ system.

Surveillance/Guidelines for Late Effects

Treatment-related sequelae can manifest at any time during or after therapy, and may be clinically silent at times when a diagnosis might lead to effective interventions. Some chronic or late effects can evolve during normal development or aging. Health-care providers need to anticipate these effects as well as evaluate those that are overt in order to optimize measures that can enhance quality of life. The need for standardized guidelines to direct follow-up care after cancer treatment and surveillance for late effects of therapy has been recognized as an important component of cancer care for over a decade.^{1,5,17,18} However, the development of evidence-based long-term follow-up guidelines has proven to be a challenging endeavor. The Children's Oncology Group (COG) developed the *Children's Oncology Group Long-term Follow-up Guidelines for Survivors of Childhood, Adolescent, and Young Adult Cancers*, a set of risk-based, exposure-related screening recommendations to guide the long-term follow-up care of pediatric cancer survivors with the goals of improving quality of life and decreasing complication-related health-care costs.¹⁹

The COG guidelines (available at www.survivorshipguidelines.org)²⁰ exemplify a hybrid of evidence-based and consensus-driven approaches to guideline development. The strength of the evidence linking specific therapeutic exposures with adverse outcomes is considered for the inclusion of a therapeutic agent or modality. Screening recommendations in these guidelines were initially determined by consensus from a panel of experts in the late effects of pediatric cancer treatment; evidence is now emerging

regarding the yield and utility of these recommendations, and further guideline refinement is in process.^{21,22} The screening recommendations outlined in the COG guidelines are organized by therapeutic exposure and are appropriate for asymptomatic survivors presenting for routine exposure-based medical follow-up 2 or more years following the completion of therapy for a pediatric malignancy, and can be customized for individual patients based on age, gender, and treatment history. Multidisciplinary task forces continue to monitor the literature to ensure that guideline recommendations reflect emerging knowledge about late effects; version 1.0 of the COG guidelines was published in 2003, and version 4.0 was released in 2014.

Guidelines for follow-up of pediatric cancer survivors have also been developed by the Scottish Intercollegiate Guidelines Network (SIGN),²³ the United Kingdom Children's Cancer and Leukemia Group (CCLG),²⁴ and the Dutch Childhood Oncology Group (DCOG).²⁵ An international effort is currently underway to harmonize these guidelines.²⁶ Joint European–American guidelines for follow-up after hematopoietic cell transplantation were released in 2006^{27,28} and updated in 2012.^{29–31}

The lack of standardized guidelines to direct the care of adult cancer survivors with regard to health promotion and the early detection of treatment-related complications is an ongoing focus of concern, particularly given the IOM's recommendation for the development of such guidelines in their 2006 report.¹ In 2011, ASCO formed a Cancer Survivorship Committee, which has recently partnered with ASCO's Clinical Practice Guidelines Committee to develop consensus-based guidance documents, informed by evidence, to address long-term effects in cancer survivors.⁷ Two ASCO guidance documents have now been released.^{32,33}

Intervention to Prevent Potential Late Effects

In the past decade, a growing number of studies have been designed and conducted with the intent of treating health conditions that are identified during or after the completion of therapy as well as preventing later occurring conditions. Randomized clinical trials have tested the effectiveness of a wide range of interventions, including ones aimed at increasing levels of physical activity, promoting healthy diets and smoking cessation, and reducing adverse psychosocial outcomes.

To illustrate the evolution of survivor-focused intervention studies, one can look at studies of breast cancer survivors. In the general population, it has been well documented that physical inactivity and obesity are associated with an increased risk of all-cause mortality, several cancers, cardiovascular disease, insulin resistance, hypertension, osteoporosis, and diminished quality of life. Women with pre- or postmenopausal breast cancer who are obese and physically inactive usually experience lower 5-year survival rates, increased rates of recurrence, and increased all-cause and cancer-related mortalities. Several randomized clinical trials conducted in breast cancer survivors have demonstrated that increasing levels of physical activity are associated with improved cardiorespiratory fitness, weight management, decreased fatigue, and quality of life.³⁴ A prospective trial now in progress is designed to assess the feasibility of a cognitive–behavioral intervention on achieving sustained weight loss in overweight/obese women with early stage breast cancer and to examine the impact of weight loss on comorbidities and quality of life.³⁵ Similar interventions designed to promote physical activity and weight management are also being tested in other populations of cancer survivors.^{36,37}

Although many interventions have been found to be effective at reducing psychosocial morbidities such as depression and anxiety in patients undergoing therapy for cancer, Stanton³⁸ notes that relatively few studies have focused on long-term survivors. Kazak et al.,³⁹ Pai and Kazak,⁴⁰ and Alderfer et al.⁴¹ have published an elegant series of studies describing post-traumatic stress symptoms

experienced by childhood and adolescent cancer survivors and testing interventions to reduce these symptoms.

With this experience in survivor intervention studies, a growing survivor-based data set and increased sophistication in study design, it is becoming more feasible to compare outcomes across trials. Important challenges remain, including the ability to test specific interventions in survivor populations that are relatively small in number, and to recruit and retain long-term survivors in these studies.⁴² Several potentially helpful interventions have yet to be studied, such as the use of statins to reduce the progression of radiation-associated atherosclerosis or chemoprevention to reduce the incidence of breast cancer in women who were treated with chest radiation.

Promotion of Adjustment and Healthy Lifestyles

The importance of providing appropriate support to facilitate positive psychosocial adjustment following treatment for cancer has been a central facet of the survivorship movement since its inception.¹⁸ The rates of depression and other types of psychosocial distress in cancer survivors (such as anxiety, anger, and feelings of isolation) have been found to exceed those in the general population, and unmet psychosocial needs often persist following the completion of cancer treatment.³⁸ The oncology health-care provider should play a key role in screening for psychosocial distress in cancer survivors, and appropriate referrals to psychosocial professionals or other resources should be provided. Numerous print and online materials are available to address patient concerns, including: *Facing Forward: Life after Cancer Treatment*, from the National Cancer Institute (www.cancer.gov/cancertopics/life-after-treatment.pdf); the Cancer Survivor Toolbox, from the NCCS (www.canceradvocacy.org/resources/cancer-survival-toolbox/); and online resources from the Office of Cancer Survivorship (<http://cancercontrol.cancer.gov/ocs/>) and the American Cancer Society's (ACS) Cancer Survivors Network (<http://csn.cancer.org/>).

The potential for positive modification of lifestyle behaviors following a cancer diagnosis and treatment in adulthood has been recognized as a window of opportunity during which cancer survivors may be open to making significant changes in their health habits oriented toward decreasing the likelihood of cancer recurrence and enhancing their overall health status.⁴³ In a study of more than 1.2 million records from the Surveillance, Epidemiology, and End Results Program, cancer-specific death rates were found to underestimate the mortality associated with a cancer diagnosis; death rates from non-cancer-related causes were noted to be higher among persons with a history of cancer than among the general population.⁴⁴ Taking advantage of the *teachable moment*, which occurs when patients transit from active cancer therapy to follow-up care, is an important role for oncology health-care professionals who are poised to serve as powerful catalysts in promoting behavioral change and modifying adverse health risks.⁴⁵ Although a substantial proportion of cancer survivors may be willing to initiate positive lifestyle changes at this juncture, there are known groups of survivors who are less likely to adopt healthy lifestyle changes, including males, those with lower educational levels, and those who live in urban areas.⁴⁶ Additional support and intervention may be required in order to achieve positive lifestyle modification in these subgroups.

Survivors of childhood cancer often lack a distinct teachable moment for lifestyle modification such as that experienced by survivors of adult-onset cancers, given the wide range of ages and developmental stages of patients treated for pediatric malignancies. They are known to be at increased risk for multiple chronic health conditions such as obesity and cardiovascular disease.¹⁴ Several suboptimal health behaviors, including smoking and unhealthy dietary and exercise habits, have been observed in subsets of these survivors.⁴⁶ The importance of health promotion

in this population should be emphasized, and attention should be given to providing targeted health counseling appropriate to each patient's cancer history, therapeutic exposures, age, gender, and developmental stage.

CARE PLANS

Providing high-quality care for cancer survivors presents several challenges. Cancer care is often fragmented among many different specialists, and traditionally, there has been inadequate communication between physicians about the diagnosis and treatments a patient received. Primary care providers (PCP) often have limited contact with patients undergoing active cancer treatment and lack details regarding their experience at its completion. Furthermore, there is limited information about the types and severity of potential long-term and late effects from cancer treatments, and a paucity of guidelines for surveillance for both recurrence and late effects. Most nononcology physicians will only have a handful of cancer survivors in their practice, and each survivor will likely have had a different disease and exposures. Consequently, it is not reasonable to expect PCPs to have knowledge of all of the potential survivorship scenarios these patients could face in the future.

The IOM¹ recommended that "upon discharge from cancer treatment . . . every patient should be given a record of all care received and important disease characteristics" and went on to assert that every patient should receive "a follow-up plan that is clearly and effectively explained." (See Table 145.3 for details regarding the IOM recommendations for survivorship treatment summary and care plan content.) These documents are intended to communicate the survivor's treatment history, to delineate a plan to ensure that the survivor receives appropriate follow-up care, and to specify which caregivers will provide which services.^{1,7} To date,

only two randomized controlled trials have evaluated outcomes related to use of survivorship care plans in clinical practice. One trial reported no effect,⁴⁷ and the other reported a decrease in self-reported health worry in the group receiving care plans.⁴⁸ This has sparked lively dialogue, particularly with regard to the patient-reported outcome variables measured,⁴⁹ as well as the appropriateness of focusing on the care plan document, rather than on the process of care planning.⁵⁰

Several organizations have developed standardized treatment summaries and survivorship care plans to guide post-therapy follow-up care. Important components include surveillance for the recurrence of the primary cancer, the identification of potential long-term complications resulting from specific therapies employed during treatment of the primary cancer, and a plan for psychosocial support and coordination of cancer survivorship care.¹ Downloadable survivorship care plan templates are available from ASCO (www.asco.org/treatmentsummary), COG (www.survivorshipguidelines.org), Journey Forward (www.journeyforward.org), and the LIVESTRONG Survivorship Network (www.livestrongcareplan.org).

Creating a survivorship care plan as outlined here requires time and energy.⁵¹ Despite the barriers this presents, leading groups such as the IOM, LIVESTRONG, COG, and ASCO are promoting the idea that treatment summaries and survivorship care plans should be the standard of care in oncology. This is now a specific quality metric in the ASCO quality of care certification program (Quality Oncology Practice Initiative),^{52,53} and was also recently adopted as an American College of Surgeons Commission on Cancer Program Standard, with required implementation by 2015.⁵⁴ The information contained within well-developed care plans is intended to facilitate necessary communication between the patient and their oncology, primary care, and specialty providers, thereby maximizing the likelihood that high-quality survivor care can occur.

TABLE 145.3

The Institute of Medicine Survivorship Care Plan

On discharge from cancer treatment, every patient should be given a record including:

1. Contact information for each treating institution and key individual providers
2. Dates of treatment initiation and completion
3. Diagnostic tests and results
4. Tumor characteristics
5. Surgery or other therapies provided, including specific agents, regimens, dosage, number and title of clinical trials (if any), treatment response, and toxicities experienced
6. Psychosocial and nutritional services provided
7. Identification of a coordinator of continuing care

On discharge from cancer treatment, every patient and his or her primary health-care provider should receive a written follow-up care plan including:

1. The likely course of recovery from treatment
2. Recommended periodic testing and examinations by whom and on what schedule
3. Possible late and long-term effects of treatment and symptoms
4. Possible signs of recurrence and second tumors
5. Possible effects of cancer on daily life (personal relationships, work, mental health) and available resources for support
6. Potential insurance, employment, and financial consequences of cancer and referrals to counseling, legal aid, and financial assistance if needed
7. Recommendations for healthy behaviors that should also be shared with first-degree relatives to minimize their potential risk of cancer
8. As appropriate, information on genetic counseling and testing to identify high-risk individuals who could benefit from more comprehensive cancer surveillance
9. As appropriate, information on known effective chemoprevention strategies for secondary prevention (e.g., tamoxifen for breast cancer, aspirin for colorectal cancer)
10. Referrals to specific follow-up care providers
11. A listing of cancer-related print or online information resources and support organizations

Modified from Hewitt M, Greenfield S, Stovall E. *From Cancer Patient to Cancer Survivor: Lost in Transition*. Washington, D.C.: National Academies Press; 2006.

DELIVERY OF FOLLOW-UP CARE AND BEST PRACTICE MODELS

There is no consensus on the best strategy for providing follow-up care to the growing number of cancer survivors. Most children with cancer are treated at pediatric oncology referral centers where, on termination of cancer therapy, they are seen in a follow-up clinic or program.⁵⁵ Because of the diverse ages at diagnosis (infancy to adolescence), childhood cancer survivors may be under the care of pediatric oncologists for a decade or more. However, once they become young adults and leave home for college or work, they may need to transition to care outside of the pediatric referral center.⁵⁶ This poses a substantial challenge, because few PCPs will be knowledgeable about the exposures and risks from prior cancer therapy.^{57,58} Thus, arming the young adult survivor with a treatment summary and care plan with specific surveillance recommendations can facilitate subsequent care with generalist physicians.⁵⁵

Delivery of high-quality care to survivors is not without challenges.⁵⁹ Although PCPs given explicit instructions about the necessary components of surveillance and follow-up have been shown to produce the same outcomes as specialist follow-ups,⁶⁰ they have also expressed concerns about the lack of adequate training to provide survivorship care and report being more likely than oncologists to order tests/treatments as malpractice protection.⁶¹ Although oncologists are able to provide primary noncancer care to patients,⁴³ many report uncertainty regarding responsibility for general preventive care,⁶¹ and only a minority appear to want to regularly assume this role.⁶² Most survivors experience some form of shared care, in which PCPs collaborate with cancer specialists. The role of oncologists in a shared care model is to provide or guide periodic surveillance and to be available to evaluate patients when potential cancer-related concerns arise, and the PCP continues to carry out routine prevention and health maintenance interventions and manage comorbid conditions.⁶²⁻⁶⁵

Based on the IOM report, better coordination is needed and direct communication among providers is critical to ensure that appropriate follow-up care is provided. Current adult survivorship care models include tertiary care centers with consultative services, free-standing cancer centers that integrate survivorship care within their disease-oriented teams using advanced practice nurses and/or PCPs, hybrid models, and community-based models.^{65,66} A recent systematic review of models of care for post-treatment follow-up for adult cancer survivors identified a global consensus among cancer-focused organizations that the oncologist/cancer center-based follow-up model is not sustainable and that, given the burgeoning survivor population, a reconfiguration of care models is needed.⁶⁷

EDUCATIONAL CONSIDERATIONS

Educating the cancer survivor, health-care provider, and family is critical to promoting cancer survivorship. Studies evaluating health knowledge among childhood cancer survivors have revealed significant knowledge deficits and misconceptions regarding diagnosis, treatment, and therapy-related health risks.⁶⁸ Studies of survivors of adult cancers report similar knowledge deficits regarding risks of and surveillance for disease recurrence or therapy-related late effects, such as risks for infertility or second malignancies.^{1,69} Many health-care professionals are also ill-equipped to provide cancer survivorship care, primarily because of the lack of experience in caring for cancer survivors and a deficit of relevant information in professional and/or continuing education curricula.^{1,7}

COG has developed a set of health education materials specifically targeted to childhood cancer survivors.⁷⁰ These materials, known as Health Links, address 43 key topics within the *COG Long-term Follow-up Guidelines* and are designed to enhance health knowledge and improve compliance with guideline-specific recommendations. Each Health Link provides an overview of the

potential therapy-related complication, a review of relevant risk factors, recommendations for screening, and an explanation of applicable health-protective behaviors. They are designed to be used in conjunction with the *COG Long-term Follow-up Guidelines* and are available to download from www.survivorshipguidelines.org.

COG, working collaboratively with Baylor College of Medicine, developed an Internet-based decision support system for COG institutions that provides up-to-date screening and health information from the COG guidelines that can be individually tailored to each patient's specific treatment exposures.⁷¹ This technology-driven system, known as Passport for Care, will also empower survivors to assume greater control of their own health care via a planned survivor portal that will allow direct access to information that will assist in making decisions regarding individual lifestyle behaviors and follow-up care. When comprehensive guidelines for follow-up care are available for adult cancer survivors, similar Internet-based systems may prove valuable in disseminating this information to survivors and their health-care providers. In addition to providing education to cancer survivors, the incorporation of cancer survivorship care into the objectives for medical school core curricula, along with development and dissemination of continuing education programs for practicing health-care professionals, are imperative in order to optimize care for survivors.^{1,7}

ENHANCING RESEARCH

The growing and rather heterogeneous population of cancer survivors provides novel opportunities for research in many domains, including the etiopathogenesis, screening, and early detection of adverse outcomes and their impact on quality of life. This population lends itself to research regarding these issues because of the ability to assess therapeutic exposures accurately, both in terms of the type of exposure and its timing, and to examine the role of host characteristics.

Reports demonstrating the risks of adverse outcomes in childhood cancer survivors were published beginning more than 4 decades ago and have subsequently proliferated.⁷²⁻⁸⁴ Outcomes include premature death, second neoplasms, organ dysfunction, impaired growth and development, decreased fertility, impaired intellectual function, and overall reduced quality of life. Extended follow-ups of large cohorts of survivors has demonstrated the emergence of adverse outcomes at a younger age than would be expected in the general population. There remains a critical need for systematic follow-ups of large cohorts of adult cancer survivors to identify the role of host and clinical characteristics along with comorbidities in the health and well-being of this rapidly growing population.

The focus of investigation thus far has been on the magnitude of risk and the identification of demographic and treatment-related risk factors. Attention needs to be devoted to understanding the underlying etiopathogenesis, such as the role of genetic susceptibility, or the mechanism of action of specific therapeutic exposures associated with the development of the adverse event. In addition, specific research initiatives focusing on the utility of surveillance and interventional strategies need to be mounted. These include the efficacy of agents designed to protect normal tissues from the toxic effects of specific therapeutic agents (e.g., dexrazoxane and anthracycline-induced cardiomyopathy), the use of chemopreventive agents for the prevention of second malignancies, the use of afterload-reducing agents for the prevention of further progression of myocardial dysfunction, lifestyle and behavior modifications, and education to increase awareness of the need for screening. Follow-ups for extended periods of time are required to assess the efficacy of these strategies. The efficiency and cost-effectiveness of competing models of survivorship care and community-based services also require study.

Several challenges persist in the conduct of survivorship research. The multiple etiologies that can influence long-term sequelae often demand large sample sizes in order to address the

research questions effectively. Incompleteness of follow-up of cancer survivors results in surveillance bias, which can significantly compromise the quality of research; this may be particularly problematic in younger survivors due to the mobility of this population. Resources are therefore needed to establish the necessary infrastructure to conduct cancer survivorship research effectively.

SURVIVORSHIP ADVOCACY

Employment

Cancer survivors face challenges that go beyond medical issues. Work and ongoing access to health care are primary areas of difficulty, and not just in the United States. A study based on the 2000 National Health Interview Survey found that 18% of cancer survivors were unable to work because of residual health problems, compared with only 10% of matched controls.⁸⁵ A further 27% were limited in the amount or kind of work they could do. Such employment problems can impact many other people if the survivor was the main breadwinner. A recent prospective cohort study similarly showed that long-term labor force departures attributable to cancer occurred in 17% of lung and colorectal cancer survivors who were employed at diagnosis.⁸⁶ Even among those who are able to return to work, there may be discrimination that is either overt or an unstated undercurrent based on a perception by others that the cancer survivor is not well enough to perform his or her job at the highest level or would be unable to tolerate the added responsibilities entailed by a promotion. The situation has definitely improved over the years because of federal laws like the Americans with Disabilities Act (1990) and the Family and Medical Leave Act (1993) and several state regulations that have done much to protect the rights of workers such as those with a history of cancer.

Insurance

To be effective, health insurance options must be available, affordable, and adequate in coverage.¹ Historically, health insurance options for cancer survivors in the United States have often been deficient on one or more of these criteria. The implementation of the Patient Protection and Affordable Care Act (ACA) in the United States promises to remove restrictions, such as lifetime limits and denial of coverage for preexisting conditions, for those with a history of cancer.⁸⁷ Additionally, this new health-care law provides coverage for preventive care and certain services of particular relevance to survivors, such treatment of infertility, that have not been consistently covered previously. Cancer survivors over the age of 65 years have almost all been covered by Medicare and this will not change, but provisions in the ACA will now address gaps in outpatient medication coverage for Medicare recipients. Despite the increased access to coverage that will occur with full

implementation of the ACA, there are nevertheless unanswered questions of potential concern for cancer survivors, such as the scope of coverage for screenings beyond those typically offered for the general population, and coverage for other specialized post-treatment needs. An analysis by the American Cancer Society has identified 160 provisions within the ACA that have significant implications for those affected by cancer.⁸⁸ Life insurance applications by people with a personal history of cancer are often rejected or the plans come with very high premiums unless it is part of an employer-based group insurance.

Advocacy

Several nonprofit organizations have formed to provide advocacy for the issues that affect cancer survivors. Some, like the ACS and CancerCare, are not exclusively for survivors of cancer but have survivorship as one of their main areas of interest, whereas the NCCS and LIVESTRONG clearly make survivorship their focus. In addition to advocating for more research funds and resources for survivor care, several of these organizations provide education, counseling, links to legal contacts, and other types of assistance to help survivors with employment, insurance, or economic issues. They also provide assistance in navigating the Social Security Disability system. The ACS reports that about 13% of the calls to an information line it operates are about employment concerns.¹

There are a few programs of limited financial assistance run through government and charitable organizations that assist with expenses incurred during cancer treatment or transportation to medical appointments. Programs are also offered by several pharmaceutical companies to help provide expensive long-term outpatient medications to cancer patients and survivors. Providing information about resources available to cancer survivors to help them deal with these nonmedical issues is a recommended component of the survivorship care plans discussed earlier in this chapter.

CONCLUSION

The English word “cure” derives from the Latin *cura*, which means “care.” Survivorship care is a young science, although substantial progress has been made over the past decade in our understanding of the multifaceted needs of our ever growing and vulnerable population of cancer survivors. The sobering physical, psychosocial, and socioeconomic correlates of successful therapy are their long-term consequences that can compromise quality and quantity of life for our patients and their families, friends, and society. It is the obligation of health-care providers to critically assess and study these adverse effects, intervening when possible. We must also advocate for societal adjustment to our patients’ needs in order to provide care in the broadest sense. Celebrating cancer survival is no longer sufficient, and we are fortunate to embrace the associated challenges with our patients.

Palliative and Alternative Care

146 Management of Cancer Pain

Thomas W. LeBlanc and Amy P. Abernethy

INTRODUCTION

Advances in the diagnosis and treatment of cancer, coupled with advances in understanding the anatomy, physiology, pharmacology, and psychology of pain perception, have led to improved care of the patient with pain of malignant origin. Specialized methods of cancer diagnosis and treatment provide the most direct approach to treating cancer pain by facilitating the treatment of its underlying cause. However, prior to the initiation of antitumor therapy, when primary cancer treatment has failed, or when injury to bone, soft tissue, or nerve has occurred as a result of therapy, appropriate pain management remains essential. Patients with cancer are managed most effectively through a multidisciplinary approach that draws on the expertise of a wide range of health-care professionals.¹⁻³ The goal of pain therapy for patients receiving active treatment is to provide them with sufficient relief to tolerate the diagnostic and therapeutic approaches required to treat their cancer and to improve or maintain quality of life. For patients with advanced disease, pain control should be sufficient to allow them to function at an achievable level of their choosing and to die in relative comfort.

Effective pain management is only one component of a broad palliative care approach for cancer patients.⁴⁻⁸ The American Society of Clinical Oncology now recommends palliative care as an essential component of comprehensive cancer care for all patients with advanced solid tumors.⁹ Early palliative care, along with high-quality comprehensive cancer care, may even prolong patients' survival, while improving quality of life.¹⁰ Control of other symptoms, treatment of psychological distress, and attention to the religious, spiritual, and existential dimensions of the patient's illness experience should be concurrently addressed to maintain the patient's quality of life throughout the cancer illness course from diagnosis to death. Palliative care interdisciplinary teams specialize in providing this type of care. The World Health Organization (WHO) has published international guidelines for cancer pain relief and palliative care.⁶⁻⁸ In the United States, the National Comprehensive Cancer Network has published specific guidelines that provide a best practice approach for both the provision of pain treatment and palliative care; the American Pain Society, the British Pain Society, and the European Society of Medical Oncology (ESMO) have also published specific pain guidelines.¹¹⁻¹⁶

EPIDEMIOLOGY

Numerous national and international surveys, supplemented by WHO estimates, suggest that moderate to severe pain is experienced by one-third of cancer patients who receive active therapy, and by 60% to 90% of patients with advanced disease.¹⁷ There are over 19 million new cases of cancer diagnosed worldwide each year and more than 7 million cancer deaths, many of whom suffer from cancer pain.¹⁸ Pain related to direct tumor involvement is

the most common cause, occurring in as many as 85% of patients according to one pain service study, or in 65% of cases, as demonstrated through an outpatient cancer center pain clinic survey.¹⁹⁻²¹ Bone pain is the most common type, with tumor infiltration of nerve and hollow viscera as the second and third most common pain sources. Cancer therapy causes pain in 15% to 25% of patients receiving chemotherapy, surgery, or radiation therapy. Up to 10% of patients with cancer have pain caused by non-cancer-related problems, with pain syndromes reflecting the common causes of pain in the general population. Chronic pain is also prevalent in cancer survivors, with prevalence rates ranging from 5% to 40% of patients, varying by tumor and treatment type.^{22,23}

Patients with cancer often have multiple causes of pain, involving multiple sites.²⁴⁻³¹ Based on a variety of survey data, up to one-third of patients have more than one type of pain, and 81% of patients report two or more distinct pain complaints; 34% report three types of pain.

Studies to date have explored not only the prevalence of pain, but also its intensity, the degree of pain relief, and its effect on quality of life in patients with various malignancies, including the lungs, colon, and ovarian cancers.^{25,26,28-30} These studies highlight that pain is prevalent in both ambulatory patients and those who are hospitalized, and that it compromises function in approximately one-half of those who experience it.

A series of studies have focused on the seriously ill and nursing home cancer population and have identified a high prevalence of pain in these groups as well. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) showed that 50% of adults who die in the hospital experience moderate to severe pain in their last 3 days of life.³¹ A study of 4,000 elderly nursing home residents with cancer revealed that 24%, 29%, and 38% of those over age 85 years, 75 to 84 years, and 65 to 74 years, respectively, reported daily pain.²⁴ Twenty-six percent of these elderly in daily pain did not receive any medication. Those older than 85 years who reported pain were most likely to receive no analgesic. Similar studies of children report that 54% to 85% of pediatric inpatients and 26% to 35% of pediatric outpatients experience pain. Up to 62% to 90% of children experience pain at the end of life.²⁷

Such studies have led to an assessment of the factors that influence the prevalence of cancer pain. Primary tumor type is one factor. Tumors that commonly metastasize to bone such as breast or prostate tumors are associated with a higher incidence of pain (60% to 80%) than lymphoma and leukemia.¹⁹ Stage of disease is a contributing factor, with pain prevalence increasing as disease progresses. For example, fewer than 15% of patients with nonmetastatic disease report pain, whereas pain is the most common symptom in patients in the last months of life.^{32,33} Tumors that occur in close proximity to neural structures also produce a higher incidence of pain. Patient variables such as anxiety, depression, and history of previous substance abuse also influence the patient's report and experience of pain.^{34,35}

DEFINITION OF PAIN

The definition of pain, as proposed by the International Association for the Study of Pain, is as follows: “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.”³⁶ Because pain is a subjective experience, there is no definitive way to distinguish pain that occurs in the absence of tissue damage from pain that results from such damage. Pain as a somatic delusion or masked depression is rare in cancer patients; the presence of pain usually implies a pathologic process.

Types of Pain

Three major categories of pain have been described based on the neuroanatomy and neurophysiology of pain pathways: (1) somatic, (2) visceral, and (3) neuropathic. Each type results from the activation and sensitization of nociceptors and mechanoreceptors in the periphery by either mechanical stimuli (e.g., tumor compression, infiltration) or chemical stimuli (e.g., epinephrine, serotonin, bradykinin, prostaglandin, histamine).

Somatic Pain

When nociceptors are activated in cutaneous or deep tissues, somatic pain results, typically characterized by a dull or aching but well-localized pain. Metastatic bone pain, postsurgical incisional pain, and myofascial and musculoskeletal pain are common examples of somatic pain.

Visceral Pain

Visceral pain results from the activation of nociceptors due to infiltration, compression, extension, or stretching of the thoracic, abdominal, or pelvic viscera. This typically occurs in patients with intraperitoneal metastases and is common with pancreatic cancer. This type of pain is poorly localized; is often described as deep, squeezing, and pressure like; and, when acute, it is often associated with significant autonomic dysfunction, including nausea, vomiting, and diaphoresis. Visceral pain is often referred to cutaneous sites that may be remote from the location of the lesion itself (e.g., shoulder pain with diaphragmatic irritation). It may also be associated with tenderness in the referred cutaneous site. Recent data demonstrate the role of kappa-opioid receptors in modulating visceral pain.³⁷

Neuropathic Pain

Neuropathic pain results from injury to the peripheral or central nervous system as a consequence of tumor compression or infiltration of peripheral nerves or the spinal cord, or from chemical injury to the peripheral nerve or spinal cord caused by surgery, radiation therapy, or chemotherapy. Examples of neuropathic pain include both metastatic and radiation-induced brachial and lumbosacral plexopathies, chemotherapy-induced peripheral neuropathies, paraneoplastic peripheral neuropathies, and postmastectomy, postthoracotomy, and phantom limb pain.³⁸ Pain from nerve injury is often severe and is described as burning or dysesthetic, with a viselike quality. The pain is typically most common in the site of sensory loss and may be associated with hypersensitivity to nonnoxious (*allodynia*) and noxious stimuli. Intermittently, patients complain of paroxysms of burning or electric shock–like sensations. The latter symptoms result from the phenomenon of central sensitization.

These three types of pain may occur alone or together in the same patient. Experimental models of bone and nerve pain provide

great insight into the mechanisms underlying these clinical pain states. Clohisy and Mantyh,³⁹ Lindsay et al.,⁴⁰ and Peters et al.⁴¹ have developed both a bone tumor model and a chemotherapy-induced peripheral neuropathy model in animals that have helped to elucidate the mechanisms of pain and their biologic correlates. These correlative studies with animal models provide the opportunity to test both bone and nerve pain model responses to clinical treatments. For example, opioids, gabapentin, and nonsteroidal anti-inflammatory agents produce analgesic efficacy in the bone tumor model.³⁹

Temporal Aspects of Pain

Acute Pain

Acute pain is characterized by a well-defined temporal pattern of pain onset, generally associated with subjective and objective physical signs and with hyperactivity of the autonomic nervous system. These signs provide the physician with objective evidence that substantiates the patient's complaint of pain. Acute pain is usually self-limited and responds to treatment with analgesic drug therapy and to treatment of its precipitating cause. This type of pain can be further subdivided into subacute and episodic categories. Subacute pain arises over several days, often with increasing intensity, and represents a pattern of progressive symptomatology. Episodic or intermittent pain occurs during confined periods of time on a regular or irregular basis. Subacute pain is also generally accompanied by autonomic hyperactivity.

Chronic Pain

Chronic pain is pain that persists for more than 3 months, with a less well-defined temporal onset. The autonomic nervous system adapts, and chronic pain patients lack the objective signs common to those with acute pain. Chronic pain often leads to significant changes in personality, lifestyle, and functional ability. Treatment of chronic pain in the cancer patient is especially challenging because it requires a careful assessment of not only the intensity of the pain, but also its broad multidimensional aspects. Evidence suggests that the persistence of pain has a major negative effect on patients' quality of life.

Investigators have developed a nomenclature to describe a series of specific pains in cancer patients with both acute and chronic pain states. *Baseline pain* is the average pain intensity experienced for 12 or more hours during a 24-hour period. *Breakthrough pain* is a transient increase in pain to greater than moderate intensity that occurs on a baseline pain of moderate intensity or less. Various epidemiologic studies provide a range of prevalence of breakthrough pain from 23% to as high as 90% of cancer patients.^{42–45} Breakthrough pain has a diversity of characteristics. In this and other series, the transitory increase in pain marks the onset or worsening of pain at the end of the dosing interval or the regularly scheduled analgesic. In other patients, it is caused by an action of the patient, referred to as *incident pain*. Sometimes the incident pain has a nonvolitional precipitant, such as flatulence. Clinical trials have focused attention on the clinical management of breakthrough pain and dosing guidelines.⁴²

Intensity of Pain

Pain may also be defined on the basis of intensity, but there are limitations to a concept of pain based solely on intensity. Specific categorical scales of pain intensity have been used in which patients are asked to describe their pain as mild, moderate, severe, or excruciating. Visual analog scales (VAS) have also been used. These are presented on a 10-cm line anchored at either end by two points, signifying *no pain* and *worst possible pain*. The patient is asked to mark the intensity of the pain on the line. Numeric scales

are also commonly used, and patients are asked to rate their pain between 1 (no pain) and 10 (worst possible pain). These scales have their limitations, but they are part of a series of validated instruments that include a measure of pain intensity as one of the components of the pain experience to be defined.

Measurement of Pain

The multidimensional pain assessment is the recommended approach to the study of pain prevalence and pain intervention. Several validated instruments for pain measurement attempt to look at it in a multidimensional way. The use of such methods can provide a rapid evaluation in clinical settings of the major aspects of the pain experienced by cancer patients. The Joint Commission for the Accreditation of Healthcare Organizations require the use of pain scales in routine care.⁴⁶

Brief Pain Inventory

The Wisconsin Brief Pain Inventory (BPI) is a self-administered, easily understood, brief method to assess pain.⁴⁷ It addresses the relevant aspects of pain (history, intensity, location, and quality) and the ability of the pain to interfere with the patient's activities, and helps to provide an understanding of its cause. The history of pain and its relation to the patient's disease are assessed initially. If the patient admits to pain in the past month, he or she answers questions about current manifestations of pain. If the patient has no pain, he or she skips to the end of the questionnaire to complete the demographic information. For patients with pain, a human figure drawing is provided on which the patients shade the area corresponding to the pain. Patients are asked to rate their pain at its worst, their usual pain, and their pain at the time they are completing the questionnaire. The pain scales consist of numbers from 0 to 10; 0 is labeled *no pain* and 10 is labeled *pain as bad as you can imagine*. Patients are asked to report the medications or treatments they receive for pain, the percentage relief that these medications or treatment provide, and their belief about the cause of their pain. Finally, they are asked to rate how much the pain interferes with their mood, relations with other people, and functional ability (walking, sleeping, working, enjoying life). All patients, including those without pain, are asked for basic demographic information about marital status, education, occupation, spouse's occupation, and months since diagnosis. This inventory has been translated into numerous languages and has been used to assess pain in cancer patients in various settings.

McGill Pain Questionnaire

The McGill Pain Questionnaire (MPQ) is an extensively used pain assessment instrument that produces scores on four empirically derived dimensions, as well as several summary scores.⁴⁸ The instrument consists of 78 adjectives that cluster in 20 categories. Within each category, the adjectives are arranged in order of intensity from low to high. The categories are divided into four dimensions: sensory, affective, evaluative, and miscellaneous. The patient is asked to choose one adjective from each applicable category that describes an aspect of his or her current pain, and the score for each dimension is obtained by adding the rank values of the selected adjectives. Adding the scores across the four dimensions derives a total summary score, and a total word count is also obtained. Finally, a rating of present pain intensity is made on a five-point scale. Studies with this instrument have demonstrated that the factors derived reflect specific sensory qualities and combined emotional and sensory dimensions. This tool has also been used to assess distinct score profiles according to the nature of pain. For instance, patients with acute pain tend to use more sensory words, but patients with chronic pain tend to use more affective and reaction word subgroups. The MPQ offers a methodological approach to assessing the sensory, affective, and evaluative

components of pain, but it may be more difficult and cumbersome for patients to understand and complete than some other pain assessment tools and may also be limited by its language constraints.

Patient-Reported Outcome Measures

Assessing symptoms by direct patient self-report is an increasingly common and desirable method for collecting data on important patient-centered outcomes like pain.⁴⁹ These so-called *patient-reported outcome* (PRO) measures avoid clinicians' bias in their assessments and allow for reproducible collecting and trending of self-reported items over time. A growing body of literature demonstrates that electronic methods for data collection are quite robust and at least equivalent if not superior to paper options. PROs are increasingly included as outcome measures in oncology clinical trials, and several instruments have been directly developed as PROs, including the M. D. Anderson Symptom Inventory (MDASI) and the Patient Care Monitor (PCM).^{50,51} Others include the following.

Memorial Symptom Assessment Scale

The Memorial Symptom Assessment Scale (MSAS) is a validated, patient-rated measure that provides multidimensional information about a diverse group of common symptoms. Thirty-two physical and psychological symptoms are characterized in terms of intensity, frequency, and distress. The MSAS provides a Global Distress Index (MSAS-GDI), a 10-item subscale that reflects global symptom distress and separate subscales that measure physical (MSAS-Phys) and psychological (MSAS-Psych) symptom distress. Ongoing studies have confirmed its value in patients with various types of cancer, and studies of its reliability and validity with repeated administration are currently under way. The use of the MSAS allows the concurrent measurement of pain and various other symptoms, psychological distress, and psychological factors; overall, it represents a useful, patient-accepted method to measure the multidimensional issues facing cancer patients with pain.⁵² Newer studies have identified the usefulness of a short form for a rapid assessment.⁵³

Functional Assessment of Cancer Therapy – General

The Functional Assessment of Cancer Therapy – General (FACT-G) is a 27-item PRO that assesses cancer-related symptoms across four major domains: physical, social, emotional, and functional. Patients are asked to rate each item as it applies to the past 7 days. Each question is anchored to a five-point scale from zero to four (*not at all, a little bit, somewhat, quite a bit, very much*). It includes a specific question on pain, and also explores the impact of pain and other symptoms on the patient's overall well-being.

European Organization for Research and Treatment of Cancer Quality of Life Questionnaire-C30

The European Organization for Research and Treatment of Cancer has included specific pain questions in its Quality of Life Questionnaire-C30 (QLQ-C30) scale. The pain scale measures pain intensity and interference with function. The pain scale has a four-level verbal rating scale (*not at all, a little, quite a bit, very much*), measuring the presence of pain and pain interference with daily activities. The responses are summed to a composite score and transformed to a 0 to 100 pain scale of severity. The pain severity composite score better represents the cancer pain experience than the intensity score alone. In published studies, it has been shown to reliably predict functional status, toxicity, and chemotherapy response. Because of their multiple scales, the QLQ-C30 and the FACT-G require more time, attention, and cooperation on the part of patients, which makes them less useful as routine measurement tools, and more useful in the context of research.⁵⁴

TABLE 146.1

Tumor-Related Chronic Pain Syndromes**Bone Pain**

Multifocal or generalized bone pain
 Multiple bony metastases
 Marrow expansion
 Vertebral syndromes
 Atlantoaxial destruction and odontoid fractures
 C7 to T1 syndrome
 T12 to L1 syndrome
 Sacral syndrome
 Back pain and epidural compression
 Pain syndromes of the bony pelvis and hip
 Hip joint syndrome
 Acrometastases
 Arthrides
 Hypertrophic pulmonary osteoarthropathy
 Other polyarthritides
 Muscle pain
 Muscle cramps
 Skeletal muscle tumors

Headache and Facial Pain

Intracerebral tumor
 Leptomeningeal metastases
 Base of skull metastases
 Orbital syndrome
 Parasellar syndrome
 Middle cranial fossa syndrome
 Jugular foramen syndrome
 Clivus syndrome
 Sphenoid sinus syndrome
 Painful cranial neuralgias
 Glossopharyngeal neuralgia
 Trigeminal neuralgia
 Eye and Ear syndromes
 Otagia
 Eye pain

Tumor Involvement of the Peripheral Nervous System

Tumor-related radiculopathy
 Post therapeutic neuralgia
 Cervical plexopathy
 Brachial plexopathy
 Malignant brachial plexopathy
 Idiopathic brachial plexopathy associated with Hodgkin's lymphoma
 Malignant lumbosacral plexopathy
 Tumor-related mononeuropathy
 Paraneoplastic painful peripheral neuropathy
 Subacute sensory neuropathy
 Sensorimotor peripheral neuropathy

Pain Syndromes of the Viscera and Miscellaneous

Tumor-Related Syndromes
 Hepatic distention syndrome
 Midline retroperitoneal syndrome
 Chronic intestinal obstruction
 Peritoneal carcinomatosis
 Malignant perineal pain
 Malignant pelvic floor myalgia
 Adrenal Pain Syndrome
 Ureteric obstruction
 Ovarian cancer pain
 Lung cancer pain

Paraneoplastic Nociceptive Pain Syndromes

Tumor-related gynecomastia

Edmonton Symptom Assessment Scale

The Edmonton Symptom Assessment Scale (ESAS) is a nine-item patient-reported symptom visual analog scale developed to assess symptoms in patients who receive palliative care. The scale has been validated in cancer patients and correlated closely with the MSAS and BPI measurement tools.⁵⁵

COMMON PAIN SYNDROMES

Pain in the cancer patient results from direct tumor infiltration and from the various cancer treatments and can occur unrelated to the cancer and cancer therapy. Tables 146.1 and 146.2 list the common wide range of both acute and chronic pain syndromes in patients with cancer. These lists are a compendium of various sources and serve to summarize the broad and now well-recognized pain syndromes that occur often uniquely in this population of patients.^{1,5,19-21,25}

Clinical Assessment of Pain

Certain general principles should be followed in evaluating cancer patients with pain.⁵⁶ Lack of attention to these general principles is the major cause for misdiagnosis of a specific pain syndrome. Adequate assessment is a critical component for defining the appropriate therapeutic strategy for each patient. The general principles are the following:

- Believe the patient's complaint of pain.
- Take a careful history of the patient's pain complaint.
- Evaluate the patient's psychological state.
- Perform careful medical and neurologic examinations.
- Order the appropriate diagnostic studies and personally review the results.

TABLE 146.2

Treatment-Related Chronic Pain Syndromes**Postchemotherapy Pain Syndromes**

Chronic painful peripheral neuropathy
 Avascular necrosis of femoral or humeral head
 Plexopathy associated with intra-arterial infusion
 Raynaud's Phenomenon

Chronic Pain Associated with Hormonal Therapy

Gynecomastia with hormonal therapy for prostate cancer

Chronic Postsurgical Pain Syndromes

Postmastectomy pain syndrome
 Postradical neck dissection pain
 Postthoracotomy pain
 Postoperative frozen shoulder
 Phantom pain syndromes
 Phantom limb pain
 Phantom breast pain
 Phantom anus pain
 Phantom bladder pain
 Stump pain
 Postsurgical pelvic floor myalgia

Chronic Post Radiation Pain Syndromes

Plexopathies
 Radiation-induced brachial and lumbosacral plexopathies
 Radiation-induced peripheral nerve tumors
 Chronic radiation myelopathy
 Chronic radiation enteritis and proctitis
 Burning perineum syndrome
 Osteoradionecrosis

From Cherny NI, Portenoy RK. Cancer pain: principles of assessment and syndromes. In: Wall PK, Melzack R, eds. *Textbook of Pain*. London: Churchill Livingstone; 1994:787, with permission.

Adapted from Cherny NI, Portenoy RK. Cancer pain: principles of assessment and syndromes. In: Wall PK, Melzack R, eds. *Textbook of Pain*. London: Churchill Livingstone; 1994:787.

- Treat the pain to facilitate the appropriate workup.
- Reassess the patient's response to therapy.
- Individualize the diagnostic and therapeutic approaches.
- Discuss advance directives with the patient and family.

Critical to the management of the patient with cancer pain is the establishment of a trusting relationship with the physician. The complaint of pain is a symptom, not a diagnosis. Pain perception is not simply a function of the amount of physical injury sustained by the patient but is a complex state determined by multiple factors. The diagnosis of a specific pain syndrome and a complete understanding of the patient's psychological state are not always accomplished during the initial evaluation. In fact, it may take several weeks to define its nature because of the lack of radiologic or pathologic verification. It may take a similar period to fully comprehend each patient's psychological makeup.

Take a Careful History of the Patient's Pain Complaint

A careful history of the patient's pain complaint should include the patient's description of site of pain, quality of pain, exacerbating and relieving factors, temporal pattern, exact onset, associated symptoms and signs, interference with activities of daily living, effect on the patient's psychological state, and response to previous and current analgesic therapies.⁵⁶ Patients should be asked to describe the intensity, frequency, and severity of their baseline pain and episodes of breakthrough pain. Routine pain assessment tools should be provided to patients and families to record the patient's pain experience and provide easy recording of analgesic drug use and the use of rescue medications. Multiple pain complaints are common in patients with advanced disease and must be ranked, classified, and recorded.

Evaluate the Patient's Psychological State

The patient's current level of anxiety and depression must be clarified and his or her past history of such symptoms must be defined. Knowledge of the patient's previous psychiatric history and need for past hospitalization for psychiatric care helps to clarify the patient's potential psychological risk. Information on how the patient has handled previous painful events may provide insight into whether the patient has demonstrated chronic illness behavior or has a past history of a chronic pain syndrome. It is important to know about a personal or family history of alcohol or drug dependence to understand why the patient may be fearful of taking or refuses to take opioid drugs.

Because each patient has his or her own understanding of the meaning of pain, it is useful to have the patient elaborate this meaning.⁵⁷⁻⁶⁰ Does he or she think it represents a recurrent tumor, or is he or she convinced it is simply arthritis? Evidence suggests that when patients have a clear understanding of the meaning of their pain as representing a recurrent tumor, they have increased psychological distress.

The importance of defining the psychological makeup of the patient with pain is supported by a variety of studies that have focused on the effect of suffering in patients with pain.⁵⁷⁻⁶² Psychological factors play a significant role in accounting for the differences in pain experiences in cancer patients. A series of psychiatric syndromes have been described for cancer patients, with depression occurring in as many as 25% of patients.^{57,62} The depression presents either as an acute stress response or as a major depression. Awareness of the common psychiatric syndromes when evaluating the pain complaint expands the physician's understanding of such a complaint.

Although it is critical to know as much as possible about each patient with pain, some information may not be readily available in the first interview; in some instances, it may never be available because of some patients' inability to clearly define the various components of their pain. It is often necessary to verify the history by consulting a family member who may provide additional information. The family may be more objective in assessing a disability of a patient who underreports symptoms. Similarly, in a patient who is a poor historian, family may be able to provide essential information that may alter the diagnostic approach. All attempts should be made to compile a careful

history and define the medical, neurologic, and psychological profile of the pain complaint. In geriatric patients with compromised cognitive function, geriatric pain and symptom scales should be used.²⁴

It is critical to define the goals of any pain treatment. Some patients harbor unreasonable expectations, whereas others fail to critically consider the various options available to them. Complete relief is typically impossible, and the degree of relief must be balanced with any treatment's adverse effects. Before starting any intervention, review carefully with patients the risks and benefits to provide them with a reasonable expectation of the potential outcome of this approach. As patients become more active in defining advance directives and as they focus on the quality of life, it is critical to ask them to define what they would do if the pain were intractable or intolerable.⁶² Did the patient have a family member who died a painful death? In the authors' experience, patients who have had such an experience are particularly fearful of their own deaths. Does the patient have suicidal thoughts or a pact with a family member? Does the patient have a family history of suicide? Does the patient have drugs in reserve or a gun in the house that he or she might use in desperation? In a study by Chochinov et al.,⁶² pain alone did not correlate with patients' suicidal ideation. Significant depression appeared to be the major correlating factor, although pain clearly played a role in the development of depression in some patients. This series of questions allows patients to discuss openly their fears of death and their intention to take matters into their own hands rather than trust the health-care professional. Such open discussions can allow the physician to better define for the patient the options for care and to reassure the patient of the physician's commitment to care. Because patients rarely offer this information unless requested, it is critical to develop specific questions that can be readily integrated into the initial history taking by the physician. Discussing with the patient how he or she would die and engaging the patient in a discussion of his or her concerns and desires can address the commonly heard comment of patients, "I have never died before, how do I do it?"

Perform Careful Medical and Neurologic Examinations

Medical and neurologic examinations help provide the necessary data to substantiate the history. They also provide a direct assessment of the cognitive status of the patient. Knowledge of the referral patterns of pain and the common cancer pain syndromes can direct the examinations. For example, the commonly described pain syndromes associated with postmastectomy states can readily be defined as separate from tumor infiltration of the brachial plexus.⁶³

The physical and neurologic examinations allow a physician to visually inspect and palpate the site of pain and to look for the associated physical and neurologic signs that might help to better define the nature of the pain symptom. Defining the degree of motor or sensory changes can help identify the specific site in the nervous system that may be involved. Similarly, in patients with sensory loss, the presence of allodynia and hyperesthesia can further identify the nature of the sensory problem and define a neuropathic pain syndrome. Moreover, the degree of muscle spasm, gait instability, and impaired coordination can only be fully assessed by such an evaluation. In patients with neuropathic pain, the use of quantitative sensory testing can help define the underlying mechanism and determine selection of drug therapy.

Order the Appropriate Diagnostic Studies and Personally Review the Results

Diagnostic studies confirm the diagnosis and define the site and extent of tumor infiltration, when applicable. Computed tomography (CT) and magnetic resonance imaging (MRI) are the most useful diagnostic procedures for evaluating cancer patients with pain. Positron-emission tomography (PET) helps to further define the tumor and differentiate the tumor from radiation injury and postsurgical injury. The bone scan is a useful screening device and is more sensitive for demonstrating abnormalities in the bone before changes appear on a plain radiograph. However, a negative finding on bone scan does not rule out bony metastatic disease, nor does a positive finding on

bone scan confirm the diagnosis of metastatic tumor. In patients with collapsed vertebral bodies, an MRI can distinguish osteoporotic from tumor-induced bony changes. The physician should review the results personally with the radiologist to correlate any pathologic change with the site of pain. Also, the measurement of tumor markers such as carcinoembryonic antigen (CEA), cancer antigen 125 (CA-125), and prostate-specific antigen, among others, can be useful in a patient in whom a recurrent tumor is suspected. In certain pain syndromes, the presence of recurrent disease is closely associated with the onset of pain (e.g., the appearance of late postthoracotomy pain syndrome in a patient after initial resolution of the postoperative pain).¹⁹

Treat the Pain to Facilitate the Appropriate Workup

Inadequate evaluations sometimes occur in the setting of severe pain. Early aggressive pain management while the source is investigated markedly improves the patient's ability to participate in any necessary diagnostic procedures. During the initial evaluation, early consideration of the use of alternative methods of pain control, including anesthetic and neurosurgical approaches, should be considered (e.g., the temporary use of a local anesthetic via an epidural catheter to manage sacral pain).

Reassess the Patient's Response to Therapy

A continual reassessment of the patient's response to the prescribed therapy provides the best method to validate the initial diagnosis as correct. If relief is less than predicted or if the pain worsens, a reassessment of the treatment approach or a search for a new cause of the pain should be considered. Ideally, use the same assessment instrument at each time point; for example, if you are monitoring pain using a 0 to 10 numerical rating scale, continue to use that for each follow-up visit.

Individualize the Diagnostic and Therapeutic Approaches

An evaluation of the patient must be closely linked to the patient's level of function, ability to participate in the diagnostic workup, willingness to undergo the necessary diagnostic approaches, objective evidence that treatment approaches may be beneficial, and life expectancy. Careful judgment is required to select diagnostic approaches that will have a direct effect on the choice of the therapeutic strategy or will answer a specific question. The random use of diagnostic procedures in these patients, particularly those with advanced cancer and significant pain, is inappropriate and costly. Open discussion with the patient about the need for assessment as well as the therapeutic options is critical to allow the patient to be part of the decision-making process. For some patients, diagnostic procedures such as an MRI are inappropriate because they simply confirm the existence of a disease for which no treatment is available, or for which the treatment would be a major surgical procedure (e.g., vertebral body resection) that would be inappropriate for a dying patient. Patient refusal of an evaluation or treatment must be respected when the physician has fully explained the options and is convinced that the patient has an accurate understanding of the implications of undertaking no further workup or treatment.

Discuss Advance Directives with the Patient and Family

When treatment approaches are being developed, there must be an open discussion about advance directives so that the physician has a clear understanding of the patient's goal for therapy. The physician must have unconditional positive regard for the patient, placing the control of symptoms of pain and treatment of psychological distress in the highest regard. Knowledge of the patient's decisions about resuscitation, living wills, and symptom management should he or she become incapacitated improves the physician's ability to appropriately and humanely care for the dying patient with advanced disease.⁵⁹

MANAGEMENT OF CANCER PAIN

Evidence-based cancer pain management follows a systematic strategy of applying demonstrated interventions in the context of individual needs, circumstances, and preferences. The basic approach employs three categories of agents: opioid analgesics, non-opioid analgesics, and adjuvant therapies. The foundation of this approach is an individualized combination of opioid and nonopioid drugs; to this foundation is added tailored care that selects from a broad array of adjuvant interventions to achieve maximum comfort for the individual patient. Guidelines are available to assist the clinician in determining a foundation treatment plan (the reader is referred to the National Comprehensive Cancer Network, the American Pain Society guidelines, ESMO guidelines, and the British Pain Society as excellent sources of cancer pain management guidelines).^{8,11-16} To enhance the effectiveness of this foundation, many pharmacologic and nonpharmacologic options exist for tailoring adjuvant care to individual exigencies.

The sections that follow will emphasize the principles of pharmacologic, nonpharmacologic, procedural, and manual management of cancer pain and briefly describe anesthesia and neurosurgical approaches to pain management to which the oncologist might refer a patient for specialized procedures.

Pharmacologic Management of Cancer Pain

Analgesic Drug Therapy: The Mainstay of Cancer Pain Management

Cancer pain management combines treatment of the primary disease with (1) analgesic drug therapy and (2) specific approaches that may include anesthetic, neurosurgical, rehabilitative, psychological (cognitive-behavioral), psychiatric, or complementary and alternative methods. The clinician begins with determining a patient-specific appropriate analgesic drug plan. Titration to effective pain relief and individualization of treatment represent hallmarks at this stage in the therapeutic approach. In recent years, standard analgesic drug therapy has become more effective due to increased sophistication in the use of analgesic drugs, coupled with research to understand the underlying mechanisms of pain. These new and more effective analgesic practices include the use of novel means of drug administration, particularly transdermal and transmucosal delivery; novel methods, such as the use of bisphosphonates and calcitonin for bone pain, radiopharmaceuticals, and novel approaches to neuropathic pain, such as antidepressants and anticonvulsants; and anesthetic, neurosurgical, psychological, and psychiatric approaches concurrently applied in the overall continuum of care.

As noted previously, numerous guidelines for the management of cancer pain have been issued by various organizations and researchers.^{8,11-16} These guidelines have each defined analgesic drug therapy as the mainstay of treatment and have articulated the aims of drug therapy as the achievement of adequate pain relief safely within an acceptable time frame, minimization of side effects of treatment, and ongoing analgesia by the most convenient and least noxious means available. Yet, despite available guidelines and an agreed upon approach to cancer pain management, determination of the best treatment path for the individual patient remains a complex, individualized process.

The World Health Organization Cancer Pain Guidelines

Although frequently debated, the WHO guidelines on cancer pain continue to provide a framework approach for pharmacologic management of cancer pain management. Field testing of these guidelines, as well as clinical experience, has shown that 70% to 90% of cancer patients' pain can be controlled using a simple and inexpensive method described as the *three-step analgesic ladder*.^{64,65}

The ladder describes a process for combining nonopioid, opioid, and adjuvant drugs, titrated to meet the individual needs of the patient according to the severity of pain and its pathophysiology. A randomized controlled trial of an algorithm based on the WHO ladder demonstrated that a standardized approach to cancer pain management using the algorithm provided more effective analgesia than routine oncology care.⁶⁶ These new studies suggest that a two-step ladder is equally effective for cancer pain management, and the WHO is beginning a process of guideline revision and updates.⁶⁷

Step 1 of the WHO ladder focuses on analgesic drug therapy for patients with mild-to-moderate cancer pain. Such patients should be treated with a nonopioid analgesic that may or may not be combined with an adjuvant drug, depending on the specific pain pathophysiology. For example, in a patient with mild pain from a peripheral neuropathy, the combination of a nonopioid with a tricyclic antidepressant or an anticonvulsant drug would be appropriate.

Step 2 of the WHO ladder focuses on patients with moderate pain who do not experience adequate pain relief from a nonopioid analgesic. These patients are candidates for a combination of a nonopioid, such as aspirin, acetaminophen, cyclooxygenase 2 (COX-2) inhibitors, or other nonsteroidal anti-inflammatory drug (NSAID), and low doses of opioid analgesics, such as codeine, oxycodone, or morphine, usually dosed at less than 60 mg oral morphine equivalents (OME) daily. These patients often require adjuvant drugs, depending on the pain pathophysiology.

Step 3 pertains to patients who report either severe pain (often gauged as greater than 7 on a 0 to 10 scale) or moderate pain that is inadequately managed after appropriate administration of drugs at the second step of the WHO ladder. For these patients, nonopioids are often used in combination with more potent doses of opioids to mitigate the opioid effect, and adjuvants are administered depending on the pain pathophysiology or need to control other concurrent symptoms in the individual patient. Opioid doses on step 3 are commonly greater than 60 mg OME daily.

In short, the analgesic drug ladder of the WHO defines a method for using drug combinations in three categories: nonopioids, opioids, and adjuvants; it is based on previously well-tested pharmacologic principles. However, controversy in the application of the WHO ladder continues to surround the choice of analgesic drug for the individual patient.⁶³⁻⁶⁶ For example, one meta-analysis of the role of NSAIDs in bone pain found them to be no more or less effective than opioids, although they are commonly used.⁶⁸

Cancer Pain Management Using the World Health Organization Three-Step Analgesic Ladder

Nonopioid Analgesics for Cancer Pain Management. The nonopioid analgesics include acetaminophen and the NSAIDs, of which aspirin is the prototypic agent. These compounds are most commonly administered orally. Their analgesia is limited by a ceiling effect, such that increasing the dose beyond a certain level (900 to 1,300 mg per dose of aspirin) produces no increase in peak effect. Tolerance and physical dependence do not occur with repeated administration. Aspirin and the other NSAIDs have analgesic, antipyretic, anti-inflammatory, and antiplatelet actions. Some NSAIDs, such as choline magnesium trisilicylate, lack the antiplatelet effects of aspirin and may have less collateral toxicity in cancer patients already at risk of bleeding. Others (e.g., ibuprofen) appear to produce fewer gastrointestinal side effects than aspirin. The COX-2 inhibitors potentially offer less gastrointestinal (GI) toxicity and without affecting platelet function. However, the drug currently marketed as a COX-2 inhibitor—celecoxib—has not been systematically studied in cancer patients to define its particular role in pain management; concerns regarding cardiovascular side effects have limited use of this class of agents.⁶⁹ More recently, cardiovascular effects have been recognized across even nonselective COX inhibitors, including ibuprofen; naproxen

may pose a slightly lower risk.⁷⁰ Acetaminophen, an analgesic and antipyretic agent equipotent to aspirin, is much less effective as an anti-inflammatory agent but does not interfere with platelet function or pose cardiovascular risk.

The nonopioid analgesics are generally thought to produce analgesia by inhibiting activation of peripheral nociceptors through their prevention of the formation of prostaglandin E₂, a known sensitizer of peripheral receptors to nociceptive stimulation from tissue injury. The NSAIDs differ from one another both in duration of their analgesic action and in their pharmacokinetic profile. Ibuprofen and fenoprofen have short half-lives and the same duration of action as aspirin, whereas diflunisal and naproxen have longer half-lives and are longer acting. Because clinical experience has found that some patients respond better to one NSAID than to another, each patient should be given an adequate trial of one drug on a regular basis before switching to another. Survey data from the WHO demonstration projects suggest that 20% to 40% of patients obtain pain relief with the use of nonopioid analgesics alone.⁷¹

These drugs are thought to play a special role in the management of bone pain because numerous studies have shown that aspirin inhibits tumor growth in an animal model of metastatic bone tumor. A meta-analysis of studies using NSAIDs to treat bone pain did not demonstrate them to be more effective than weak opioids such as codeine, oxycodone, and propoxyphene.⁶⁸ Recent data that detail cancer-related bone pain as a neuropathic pain model have challenged the dogma of NSAIDs for bone pain.³⁹

Numerous studies have elucidated the major risk factors for GI toxicity, particularly ulcerative complications, associated with NSAIDs. These risk factors include advanced age, higher doses, concomitant administration of corticosteroids, and history of either ulcer disease or previous GI complications from NSAIDs. Various prophylactic therapies are administered to prevent GI complications. Misoprostol is the only U.S. Food and Drug Administration (FDA)-approved medication for this indication; a Cochrane systematic review supports its use for the prevention of NSAID-induced GI complications.⁷² More commonly, proton-pump inhibitors are prescribed, which have been associated with significantly decreased frequency of NSAID-related dyspepsia and fewer ulcers diagnosed by endoscopy.⁷³ Whether this leads to fewer GI bleeds and reduced health-care utilization is still being debated. An empiric approach at this time is to administer misoprostol or a proton-pump inhibitor to all patients who are receiving NSAIDs with significant risk factors for GI complications.⁷⁴

Nonopioid drugs represent the front-line approach for cancer pain management, but the choice and use of nonopioids must be individualized. Although several NSAIDs are FDA approved for use as analgesics for mild to moderate pain (Table 146.3), guidelines for the use of NSAIDs in patients with cancer are largely empirical. According to a 2004 Cochrane systematic review of 42 trials involving cancer pain patients, the evidence demonstrated at best a nonstatistically significant trend toward improvements when NSAIDs and opioids were combined; conclusions were limited by the short duration of the studies.⁷⁵ The clinician must select an agent based on evidence, individual patient history, and patient-specific considerations, and then must give the patient an adequate trial of that nonopioid analgesic before switching to an alternative one. Such a trial should include the administration of the drug to maximum levels at regular intervals. Because there is a great variability among patient responses to different drugs, patients may require trials with several NSAIDs before finding an effective drug and dose regimen. If pain relief is not obtained, adding an opioid to a nonopioid provides additive analgesia.

Combinations containing codeine, oxycodone, and propoxyphene are available, but these combinations often contain less than the full dose of 650 mg of aspirin or acetaminophen. Prescribing each drug separately provides a better method for individualizing pain control; this is particularly important when the patient requires escalation of the combination to provide analgesia,

TABLE 146.3

Nonopioid Analgesics for Mild to Moderate Pain

Class	Generic Name	Half-Life (h)	Dosing Schedule	Recommended Starting Dose (mg)	Maximum Starting Dose (mg)
Salicylates	Aspirin	3–12	q4–6h	2,600	6,000
	Choline magnesium trisalicylate	9–17	q12h	200	600
	Diflunisal	8–12	q12h	1,500 × 1, then 1,000 q12h	4,000
p-Aminophenol derivative	Acetaminophen (paracetamol)	2–4	q4–6h	2,600	4,000
Propionic acids	Ibuprofen	1.8–2	q4–8h	1,200	3,200
	Fenoprofen	2–3	q4–6h	800	3,200
	Ketoprofen	2–3	q6–8h	150	300
	Naproxen	13	q12h	550	1,100
	Naproxen sodium	13	q12h	550	1,100
Acetic acids	Etodolac	7	q6–8h	600	1,200
	Ketorolac	4–7	q6h	15–30 q6h IV, IM	120 IV, IM
				10 q6h PO	40 PO
Fenamates	Meclofenamic acid	1.3	q6–8h	150	400
	Mefenamic acid	2	q6h	500 × 1, then 250 q6h	1,000
COX-2 inhibitor	Celecoxib	11	qd–q12	100	200

IV, intravenous; IM, intramuscular; PO, by mouth.

in which case the additional amount of the NSAID or acetaminophen may become excessive.

Opioid Drugs for Cancer Pain Management. The opioid analgesics, of which morphine is the prototype, vary in potency, efficacy, and adverse effects. These drugs produce their analgesic effects by binding to discrete opiate receptors in the peripheral and central nervous systems. In contrast to the nonopioid analgesics, opioid analgesics, at least the opioid pure agonists, do not appear to have a ceiling effect (i.e., as the dose is escalated on a log scale, the increment in analgesia is linear to the point of loss of consciousness). There are also series of drugs that are pure antagonists (i.e., they block the effect of morphine at the receptor). The antagonist drug most commonly used in clinical practice is naloxone, which is administered to reverse respiratory depression and other complications associated with opioid overdose.

Effective use of opioids requires the balancing of the most desirable effects of pain relief with the undesirable effects of nausea, vomiting, mental clouding, sedation, constipation, tolerance, and physical dependence. These undesirable effects impose a practical limit on the dose useful for a particular patient and have led to the concept of opioid responsiveness.

The use of opioids in the management of cancer pain remains controversial.^{5,76–90} Some of the controversies include their role in the management of neuropathic pain, which has been suggested to be *opioid resistant*, the specific choice of opioid drug, the use of sequential trials of opioids, routes of administration, the development of tolerance, risk of addiction, economic factors influencing these controversies, and the concern that opioids are agents of physician-assisted suicide and euthanasia. The following principles take into account these controversies while laying out a basic approach to the use of opioids in cancer pain management (Table 146.4).

1. *Start with a specific drug for a specific type of pain.* As defined by the WHO three-step analgesic ladder, the specific drug chosen depends in part on the degree of pain intensity and the

type of pain. Cancer patients commonly have multiple sites and types of pain. A continuum of opioid responsiveness, rather than an all-or-none phenomenon, has been clearly observed. *Opioid responsiveness* is defined as the degree of analgesia achieved during dose escalation to either intolerable side effects or adequate analgesia. Patient characteristics and pain-related factors, as well as drug-selective effects, influence this variable response.⁸⁹

It has been suggested that neuropathic pain, which accounts for 15% to 20% of pain problems that are difficult to manage, is opioid resistant and that opioid drugs should not be used in this patient population.⁸² In fact, studies that explored reasons for inadequate pain treatment have identified that up to two-thirds of cancer pain patients have some contribution of neuropathic pain to their global pain syndrome⁶⁶; when the concept of bone pain as a neuropathic pain syndrome is included, this number increases.³⁹ Studies of cancer patients with both nociceptive and neuropathic pain, as well as controlled studies of nonmalignant neuropathic pain, demonstrate the variable responsiveness of neuropathic pain to opioid analgesics. Hence, the contribution of neuropathic pain must be considered when assessing opioid responsiveness.

A wide range of adjuvant analgesics has been suggested to provide analgesia alone or in combination with opioid drug therapy, and there are specific adjuvants for bone pain and neuropathic pain. The choice of a specific drug is dictated not only by pain intensity and type of pain, but also by the patient's prior opioid exposure and history of allergy or side effects.

The WHO's Cancer Pain Relief Program has developed cancer pain guidelines that designate morphine as the drug of choice based on practical, not scientific, considerations. The introduction of the WHO program rapidly demonstrated the limited availability of morphine worldwide for the oral treatment of chronic cancer pain.^{6,17} Morphine consumption worldwide is now used as an indicator of the success of the WHO Cancer Pain Relief Program.¹⁸ Controlled-release oral morphine is currently available in a wide range of doses from 15 to 200 mg; differing products provide options for every 8-, 12-, and 24-hour administration. These preparations

TABLE 146.4

Guidelines for the Rational Use of Analgesics in the Management of Cancer Pain

Start with a Specific Drug for a Specific Type of Pain

Know the pharmacology of the drug prescribed.
 Know the relative potency of the drug.
 Know the duration of the analgesic effect.
 Know the pharmacokinetics of the drug.
 Know the equianalgesic doses for the drug and its route of administration.

Administer Analgesic on a Regular Basis

Gear the route of administration to the patient's needs

Oral
 Buccal
 Rectal
 Subcutaneous
 Intrathecal
 Sublingual
 Transmucosal
 Transdermal
 Intravenous
 Intraventricular

Use a Combination of Drugs to Provide Additive Analgesia

Narcotic plus nonnarcotic (aspirin, acetaminophen, nonsteroidal anti-inflammatory drugs)
 Narcotic plus adjuvants

Anticipate and Treat Side Effects

Sedation
 Respiratory depression
 Nausea and vomiting
 Constipation
 Multifocal myoclonus and seizures

Management of the Tolerant Patient

Use combinations of nonopioid and opioid drugs.
 Use combinations of drug therapy, anesthetic, and neurosurgical procedures.
 Switch to an alternative opioid analgesic, starting with one-half the equianalgesic dose.
 Use epidural local anesthetics.
 Reassess the nature of the pain.

Prevent and Treat Acute Withdrawal

Taper drugs slowly.

Anticipate Complications

Overdose
 Psychological dependence

provide analgesia comparable to that of immediate-release forms and offer increased convenience, improved compliance, and a reduction in the duration of pain. Historically, the dogma was to titrate patients to adequate pain relief using 4-hourly doses and then combine into sustained-release doses that provide an equal amount of opioid in 24 hours. In a recent randomized clinical trial, it was demonstrated that for cancer pain patients receiving greater than 60 mg OMEs daily, titration with a sustained release product was equally efficacious and yielded fewer side effects.⁹¹

The clinician's armamentarium for managing cancer pain now encompasses a series of opioid alternatives to morphine, including congeners of morphine—hydromorphone, oxycodone, and oxymorphone—as well as methadone, levorphanol, fentanyl, and buprenorphine. The choice of agent depends on the clinician's knowledge about how to use the drug, patient factors such as age and renal function, route of delivery, opioid availability, and cost (Tables 146.5 and 146.6). Recently, new formulations of these drugs have been marketed with various combinations to deter tampering and to reduce their diversion.⁹²

Hydromorphone has poor oral availability and a short half-life. Its high solubility and availability in high-potency parenteral form (10 mg per milliliter) make it a useful choice for chronic subcutaneous administration. Because of its short half-life, it is commonly used in the elderly patient. Myoclonus has been reported after high doses, possibly due to an accumulation of its metabolites (3-O methyl-glucuronide and hydromorphone-6-glucuronide).⁹³ When compared in a double-blind trial of patient-controlled analgesia, no differences in analgesia or side effects were noted between morphine and hydromorphone; these findings have been confirmed in several settings.^{94,95} Although cognitive performance was poor in the hydromorphone group, patients reported better mood than those who received morphine. A slow-release 24-hour formulation was recently released, but clinical experience thus far remains limited, and its cost is high.

Oxycodone, which is commonly administered in a 5-mg dose at the second step of the WHO analgesic ladder, can also be used in the third step at higher doses. It is available in a slow-release preparation.⁹⁶ Its half-life is 3 to 4 hours. Oxymorphone is its active metabolite. Oxymorphone is currently available in oral sustained

release, intravenous, and rectal preparations and serves as an alternative to morphine and its other congeners. Oxymorphone has a reduced histamine effect and may be of use in patients who complain of headache or itch after the administration of other opioids.

Levorphanol has high bioavailability but a long plasma half-life (12 to 16 hours). It should be used cautiously because, with repeated administration, accumulation may occur.

The role of methadone in managing cancer pain also remains controversial.^{5,76,87,88,90} Methadone represents a second-line drug for cancer pain patients who have had prior exposure to opioids. It is a relatively inexpensive oral analgesic, but its name has negative connotations for cancer patients, who view methadone as a

TABLE 146.5

Relative Single-Dose Potencies of Commonly Used Opioid Drugs for Pain and Their Oral-Intravenous Ratios

Drug	Equianalgesic Intravenous or Intramuscular Dose (mg)	Oral-Intravenous Ratios
Morphine	10	3
Oxycodone	Not available	Not available
Oxymorphone	1	10–15
Hydromorphone	1.5	5
Methadone ^a	10	1–2
Levorphanol	2	2
Fentanyl	100 µg	1 (transdermal intravenous)

This table should be used as a guide only. Individual dosing and drug selection depend on each patient's particular situation and comprehensive assessment.

^a Refer to Table 146.6 for rotation to methadone for long-term administration.

TABLE 146.6

Variability in Dose Ratios When Switching Oral Morphine, Oral Hydromorphone, and Transdermal Fentanyl to Methadone

Dose	Morphine–Methadone Ratio
Morphine (mg/24 h)	
30–90	4:1
91–300	9:1
≥300	12:1
Hydromorphone (mg/24 h)	Hydromorphone–methadone ratio
<330	0.95:1
≥330	1.6:1
Fentanyl	Fentanyl–methadone ratio
50–2,500 [μg]/h	250 [μg]/h:1 mg/h

Based on direct morphine to methadone, hydromorphone to methadone, and fentanyl to methadone conversion studies, when the clinician needs to rotate to methadone convert all opioids first to intravenous (IV) morphine (see Table 146.5 for equianalgesic dose ratios) and then convert the IV morphine dose to an IV methadone dose using a 10:1 ratio. The resulting methadone dose may be higher in less opioid-tolerant patients and lower in highly opioid-tolerant patients (see Moryl et al.⁵).

drug used to treat addicts. The bioavailability of methadone is higher than that of morphine (85% versus 35%, respectively). Its analgesic potency also differs, with a parenteral to oral ratio of 1:2 in contrast to 1:6 for morphine. Moreover, the plasma half-life of methadone is 17 to 24 hours, with reports of up to 50 hours in some cancer patients, but with an analgesic duration of only 4 to 8 hours. Significant adverse effects have been reported in cancer patients receiving methadone by various routes. Most notably, reports of drug-induced long QT syndrome have increased concern, especially in cancer patients who may be on multiple agents that can prolong the QT interval.^{97–99} The discrepancy between the analgesic duration and plasma half-life of methadone has made it a difficult drug to use in the naïve patient because of the need for careful titration. In a randomized trial, the initial treatment of cancer pain with morphine versus methadone provided equal analgesic efficacy.¹⁰⁰

A number of case reports have highlighted the possibly greater analgesic potency of methadone than the often quoted 1:1 equivalency with morphine.^{76,87,88,90} Studies of interindividual differences in response to opioid analgesics have demonstrated that dramatically reduced dosages of methadone are required to produce analgesia in patients chronically taking morphine or hydromorphone. Several authors have shown marked reductions in the equianalgesic dose of methadone when patients with either uncontrolled pain or extreme side effects were switched to methadone.^{5,90} These clinical survey studies suggested up to a 75% reduction in the methadone equianalgesic dose when switching from hydromorphone to methadone (see Table 146.6).

In a prospective study, Ripamonti et al.⁹⁰ developed a specific dose ratio based on the patients' morphine doses. For patients taking 30 to 90 mg of morphine, the dose ratio is 4:1; for those taking 90 to 300 mg daily, the dose ratio is 6:1; and for those taking 300 mg or more, the dose ratio is 8:1. Bruera et al.⁷⁶ developed a similar ratio for hydromorphone based on survey data. In patients who received more than 330 mg of hydromorphone, the dose ratio is 1.6:1.0; and in those who received less than 300 mg, the dose ratio is 0.95:1.0.

Studies of the use of methadone by experienced clinicians in caring for advanced cancer patients at home report fewer dose escalations and good pain control, which supports the use of methadone in home settings.⁸⁷ Methadone can be administered

by a variety of routes, but the subcutaneous route is associated with adverse effects, including cutaneous hypersensitivity.¹⁰¹ Due to its long half-life, some offer the suggestion that methadone be administered every 8 to 12 hours, whereas others have demonstrated analgesic efficacy and safety in acute 3- to 4-hour dosing intervals.¹⁰² Ongoing studies are attempting to better elucidate the clinical pharmacology of methadone to facilitate its broader use.

Meperidine is a drug that should not be used chronically in the management of patients with cancer pain. Meperidine has a poor parenteral to oral ratio (1:4). It is available in oral and intramuscular preparations, but repetitive intramuscular administration is associated with local tissue fibrosis and sterile abscess. Repetitive dosing of meperidine (more than 250 mg per day) can lead to the accumulation of normeperidine, an active metabolite that can produce central nervous system hyperexcitability.¹⁰³ This hyperirritability is characterized by subtle mood effects followed by tremors, multifocal myoclonus, and occasional seizures. It occurs most commonly in patients with renal disease but can also occur after the repeated administration in patients with normal renal function. Naloxone does not reverse meperidine-induced seizures, and its use in meperidine toxicity is controversial. There have been some case reports that the use of naloxone has precipitated generalized seizures in individual patients. In rare instances, central nervous system toxicity characterized by hyperpyrexia, muscle rigidity, and seizure has been reported after the administration of a single dose of meperidine to patients receiving treatment with monoamine oxidase inhibitors. Recent reports of potentially fatal serotonin syndromes due to concurrent use of meperidine with selective serotonin reuptake inhibitors (SSRI) or with the antimicrobial linezolid raise further concern about the safety profile of this medication.^{104–106}

The availability of transdermal patches and various transmucosal preparations facilitates the use of fentanyl for the management of both acute and chronic pain.¹⁰⁷ The half-life of fentanyl is 1 to 2 hours. Published guidelines for fentanyl use summarize available data.⁸⁵ In chronic cancer pain management, relative potency comparisons have not been fully established, but the common dosing guideline is that 10 mg of intravenous morphine is equivalent to 100 μg of intravenous fentanyl (see <http://www.aahpm.org/pdf/equianalgesictable.pdf>). The uniqueness of the available fentanyl preparations facilitates the management of patients who are unable to take drugs by mouth by providing them with continuous opioid analgesia. Patches are currently available in 12.5 to 100 μg per hour doses and are changed every 72 hours. When a patient is started on the fentanyl patch, there is up to a 12- to 15-hour delay in the onset of analgesia, and a 24- to 72-hour equilibration period; alternate approaches must be used to maintain pain control during this early period. Patients should be cautioned about factors that can impact the absorption rate of the drug from the patch, such as heating pads, sweating, or fever; deaths likely relating to these issues led to an FDA advisory. Proper disposal is also paramount, given the risk posed by unintentional exposure to caregivers or children. Of note, reliable drug absorption requires adequate subcutaneous fat to be present; topical fentanyl may not be appropriate in the setting of cachexia. Specific guidelines for switching to the fentanyl patch after an intravenous infusion of fentanyl have been developed and are based on use of a 1:1 conversion ratio.⁸⁵ Fentanyl can also be used as an anesthetic premedication, as well as intravenously for pain control. Oral transmucosal and sublingual formulations have demonstrated effectiveness in treating breakthrough pain in cancer patients.^{85,108,109}

Buprenorphine, a mixed agonist/antagonist opioid drug, is used to treat chronic noncancer pain and drug addiction and is also available in a transdermal preparation for cancer pain management. It is reported to be a useful agent in patients with moderate to severe pain, and it does not accumulate in patients with renal dysfunction. Its place in the management of cancer pain among the other opioids is not yet fully clarified.¹¹⁰

2. *Know the equianalgesic dose of the drug and its route of administration.* Knowing the equianalgesic dose (i.e., the dose of one analgesic drug that is equivalent in the pain-relieving potential of another analgesic drug) can ensure more appropriate drug use. The equianalgesic dose guides the recommended starting dose, with the optimal dose for each patient determined by dose adjustment. *Relative potency* is the ratio of the doses of two analgesics required to produce the same effect. Estimates of relative potency allow for a calculation of the equianalgesic dose, which provides the basis for selecting the appropriate dose when switching drugs or changing the route of administration of the same drug. The values in Table 146.5 are based on studies using 10 mg of morphine as the standard dose.¹¹¹ There is now evidence to suggest that relative potency may differ in single-dose and repeated-dose studies. For example, for morphine, a 1:6 relative analgesic potency ratio should be used for patients with acute pain, whereas a 1:2 or 1:3 ratio is more appropriate in patients treated with repeated doses on a chronic basis. Lack of attention to differences in drug dose is the most common cause of undermedication of pain.

3. *Administer analgesics regularly after initial titration.* Medication should be given regularly to maintain the plasma level of the drug above the minimum effective concentration for pain relief. In the initial titration, patients should be advised to take their medication as needed to determine their total 24-hour requirements. During this time, the patient should reach the steady-state level of drug, which depends on the drug's half-life. For morphine, a steady state can be reached in 24 hours; with methadone, it may take up to 5 to 7 days to reach a steady state. In patients on a fixed schedule, rescue medications equivalent to one-half of the standing dose should be available for breakthrough pain.

Continuous intravenous and subcutaneous opioid infusions to manage both acute and chronic cancer pain are commonly administered using a patient-controlled analgesic pump programmed to the patient's need with a set *lock-out time* to prevent overdosing. This method of drug administration is especially useful in managing patients with breakthrough pain. It is a significant advance in facilitating adequate titration of analgesics in chronic cancer patients, allowing discharge to home and hospice settings.

4. *Gear the route of administration to the patient's needs.* Various methods of opioid drug delivery have been developed in order to maximize pharmacologic effects and minimize side effects. Most patients require at least two routes of drug administration, and 20% need up to four approaches during the course of their cancer pain treatment.

The oral route is preferable and easy. Orally administered drugs have a slower onset of action, delayed peak time, and longer duration of effect. Drugs given parenterally have a rapid onset of action but a shorter duration of effect. Slow-release preparations of morphine, hydromorphone, and oxycodone allow more convenient dosing every 8 to 12 hours, or every 24 hours.

For cancer pain management by the sublingual route, well-absorbed drugs include fentanyl and methadone.¹¹² Oral transmucosal fentanyl citrate preparations and intranasal sprays have been widely studied for the management of breakthrough pain and are increasingly available.

For the rectal route, oxymorphone, hydromorphone, and morphine are available in suppository form. Oxymorphone suppositories produce analgesia equivalent to 10 mg of parenteral morphine. Slow-release oxycodone and morphine preparations have also been demonstrated to be effective rectally, and ongoing studies with rectal methadone suggest that this drug is well absorbed by the rectal route.

The transdermal route is a convenient way to deliver a potent short-acting opioid on a continuous basis. Drug is released through the skin patch at a nearly constant amount per unit time with a concentration gradient from patch to skin. Serum fentanyl concentrations increase and steady-state levels are approached at 12 to 24 hours.¹⁰⁹ After patch removal, the drug persists in the skin, with falling blood levels over 24 hours. Innovative transdermal

delivery systems are in phase 3 testing, which include systems for immediate-dose delivery using iontophoresis and drug reservoirs. Iontophoresis is the transfer of ionic solutes through biologic membranes under the influence of an electric field. It offers an alternative system for parenteral administration and has been shown to allow for comparatively rapid achievement of fentanyl dose levels using a transdermal system.

Various parenteral routes include intermittent and continuous subcutaneous, intravenous, epidural, intraventricular, and intrathecal infusions. The use of intermittent and continuous subcutaneous infusions is most appropriate for patients who cannot tolerate oral analgesics because of GI obstruction or intractable nausea and vomiting, and for those who do not have intravenous access. The utility of this technique has been demonstrated using morphine, heroin, hydromorphone, levorphanol, and fentanyl. The administration of methadone by this route is associated with the development of a cutaneous hypersensitivity syndrome.¹⁰¹

Patient-controlled analgesic pumps designed to infuse continuously but with options for bolus administration are connected to a 27-gauge butterfly needle that the patient can insert into a new subcutaneous site every 3rd to 6th day. Limited pharmacokinetic studies have demonstrated that, for example, systemic absorption of the drug at a steady state reaches 87% bioavailability from subcutaneous infusion of hydromorphone.⁹⁵ Intermittent and continuous intravenous infusions are used if intravenous access is available and more commonly in patients who are hospitalized. Specific guidelines for the use of continuous infusions have been developed.^{5,113}

The use of intermittent and continuous epidural and intrathecal opioid infusions is based on the demonstration of opioid receptors in the dorsal horn of the spinal cord and the availability of opioid drugs to suppress noxious stimuli at the spinal cord level. Localized selective analgesia is produced without motor or sensory blockade. An analysis of the pharmacokinetics of epidural opioid administration demonstrates that there is significant systemic uptake after epidural injection, comparable with that after an intramuscular injection of the same drug and dose. However, distribution of the drug directly into the cerebrospinal fluid is 10 to 100 times greater. Existing studies demonstrate that this approach is used with approximately 10% of cancer patients to maximize analgesia and minimize side effects. This technique is commonly used in patients who have mixed nociceptive neuropathic pain syndromes and in whom combinations of local anesthetics and opioids are administered epidurally. A 3-year retrospective outcome study of the use of epidural catheters in the management of chronic cancer pain identified the occurrence of technical problems and infection, including epidural abscesses, in a significant number of patients. The study suggests that epidural catheters be used in patients with limited life expectancy.¹¹⁴

Smith et al.¹¹⁵ completed a randomized clinical trial in which an implantable drug delivery system was compared to comprehensive medical management of refractory cancer pain. The patients using the implantable system reported better pain relief with fewer drug side effects and improved survival. Cost-effectiveness studies have not been done, but there is clearly the added cost of the pump, and the costs of the system need to be compared to the costs of nonpump medicines, with the potential savings from prevention of hospitalizations for pain management analyzed. Rarely, intraventricular opioid infusion has been used to manage patients with pain in the cervical and craniofacial region from tumor infiltration.¹¹⁶ Doses between 1.0 and 7.5 mg per 24 hours have been used, and excellent results have been reported in 70% of patients. At present, there is not a clear indication that this intraventricular route offers special advantages over systemic approaches.

5. *Use a combination of drugs.* By using a combination of drugs, the physician can increase analgesic effects without escalating the opioid dose. Combinations that produce additive analgesic effects include an opioid plus a nonopioid, an opioid plus an antihistamine (100 mg of intramuscular hydroxyzine),

and an opioid plus an amphetamine (10 mg of intramuscular dextroamphetamine).¹¹⁷⁻¹¹⁹

6. Anticipate and treat side effects. The side effects of the opioid analgesics often limit their effective use. The most common side effects are sedation, respiratory depression, nausea, vomiting, constipation, and multifocal myoclonus and seizures.

Sedation and drowsiness vary with the drug and dose and may occur after both single and repeated administration. They are mediated through activation of opiate receptors in the reticular formation and diffusely throughout the cortex. Management of these effects includes reducing the individual drug dose while giving the drug more frequently, or switching to an analgesic with a shorter plasma half-life. In controlled trials, amphetamine, methylphenidate, and caffeine have been demonstrated to counteract opioid-induced sedative effects. It is important to discontinue all other drugs that might exacerbate the sedative effects of opioid analgesics, including a wide variety of medications such as cimetidine, barbiturates, and other anxiolytics.

Respiratory depression is the most serious adverse effect of the opioid drugs. It occurs most commonly after short-term administration of an opioid and is usually associated with other signs of central nervous system depression, including sedation and drowsiness. The opioid agonist drugs act on brain stem respiratory centers to produce, as a function of dose, increasing respiratory depression to the point of apnea. Tolerance to this effect develops rapidly with repeated drug administration, which allows for prolonged use without significant risk of respiratory depression. Respiratory depression can be reversed by giving the short-acting opioid antagonist naloxone (suggested dose: 0.4 mg per milliliter). Repeated administration, including an intravenous drip, may be necessary to prevent respiratory arrest in such patients. In patients receiving opioids for prolonged periods who develop respiratory depression, diluted doses of naloxone (0.4 mg in 10 mL of saline) should be titrated carefully to prevent the precipitation of severe withdrawal symptoms while reversing the respiratory depression. A useful dosing nomogram for continuous intravenous infusion of naloxone has been developed in which two-thirds of the initial bolus is started on an hourly basis and titrated against the patient's symptoms.¹²⁰

In some patients, the use of naloxone to reverse drug-induced respiratory depression can be dangerous. An endotracheal tube should be placed in the comatose patient before giving naloxone to prevent aspiration from excessive salivation and bronchial spasm induced by naloxone administration. In patients receiving meperidine over a longer period, naloxone may precipitate seizures by lowering the seizure threshold and by allowing the convulsant activity of the active metabolite, normeperidine, to become evident. In this instance, special attention must be given to the potential seizure effect of naloxone. If naloxone is used, diluted doses, slow titration, and appropriate seizure precautions are advised. There is insufficient clinical evidence to make more specific recommendations. If respiratory support can be affected by other means (i.e., continuous stimulation to maintain the patient's wakefulness), such an approach may place the patient at less risk and clearly in less discomfort.

The opioid analgesics produce nausea and vomiting by an action limited to the medullary chemoreceptor trigger zone. The incidence of nausea and vomiting is markedly increased in ambulatory patients. Tolerance develops to these side effects with repeated administration. The occurrence of nausea with one drug does not mean that all drugs will produce it. Switching to alternative opioid analgesics and using an antiemetic together with the opioid analgesic are ways to obviate this effect. Lack of controlled trials to identify a specific first-line agent has supported the practice of using sequential trials of agents, beginning with prochlorperazine concurrently with the opioid, to clarify a useful regimen. Droperidol has also been noted to be effective against opioid-induced nausea and vomiting.¹²¹ Low doses of haloperidol may also be effective.

Constipation results from the action of these drugs at multiple sites in the GI tract and in the spinal cord to produce a decrease in the intestinal secretions and peristalsis, which leads to dry stools and constipation. When opioid analgesics are started, a regular bowel regimen, including use of cathartics and stool softeners, should also be instituted. Laxative bowel regimens have been suggested because of their specific ability to counteract the effects of the opioid drugs, but none has been studied in a controlled way. Anecdotal surveys suggest that doses far above those used for routine bowel management are needed, that senna derivatives are effective, and that careful attention to dietary factors along with the use of a bowel regimen can reduce patient complaints dramatically. Tolerance to this effect develops over time, but relatively slowly. Oral naloxone has been shown to be effective in treating constipation, but its use is variable depending on the degree of opioid exposure of the patient; oral naloxone may reverse the analgesic effect of the opioid.¹²² Clinical trials of two peripherally acting opioid antagonists, methylnaltrexone and alvimopan, have proved the concept that these drugs prevent opioid-induced constipation by targeting mu opioid receptors in the gut without interfering with analgesia and are available for clinical use in selected patients; only methylnaltrexone is FDA-approved for the indication of opioid-induced constipation.^{122,123}

Multifocal myoclonus may occur with high doses of all of the opioid drugs. Multifocal myoclonus and seizures have been reported in patients receiving multiple doses of meperidine (250 mg or more per day), although signs and symptoms of central nervous system hyperirritability may occur with toxic doses of all the opioid analgesics. In a series of cancer patients receiving meperidine, accumulation of the active metabolite normeperidine was associated with these neurologic signs and symptoms. However, in a similar group of cancer patients with pain, subtle mood effects were noted after meperidine administration, which suggests a spectrum of central nervous system effects. Management of this hyperirritability includes discontinuing the meperidine, using intravenous diazepam if seizures occur, and substituting morphine to control the persistent pain. Because the half-life of normeperidine is 16 hours, it may take 2 or 3 days for the signs of central nervous system hyperirritability to clear completely. As previously, meperidine may also result in a fatal serotonin syndrome when used in conjunction with monoamine oxidase inhibitor (MAOI) drugs or possible even SSRIs. Its use is contraindicated in patients with chronic renal disease, but these complications as noted in cancer pain treatment occurred in patients with normal renal function.¹⁰⁵ Morphine and hydromorphone at high doses produce myoclonus, which has not been directly associated with their known active metabolite such as M6G and hydromorphone-6-glucuronide. In dying patients with myoclonus, the use of benzodiazepines or barbiturates has been reported anecdotally to suppress this sign, improving the patient's comfort.

Opioid hyperexcitability has been reported with the use of increasing opioid doses by the parenteral and epidural routes. They have most often been observed in patients on high doses of morphine and hydromorphone and are characterized by uncontrolled pain, hypervigilance, total body hyperalgesia, and allodynia. They are best managed by rapid dose reduction and substitution with an alternative opioid such as methadone. The mechanism of action is unclear.

7. Manage tolerance. The earliest sign of developing tolerance is the patient's complaint that the duration of effective analgesia has decreased. For reasons not yet understood, cancer patients develop tolerance at vastly different rates. Some demonstrate tolerance within days of initiating opioid therapy; others experience pain control for many months on the same dosage. Studies in an outpatient clinic population, a hospitalized population, and a home care population revealed three patterns of drug use: a rapid increase in opioid requirements, stabilization at one dose for several weeks or months, and a decrease or elimination of opioids.¹²⁴ Increased opioid requirements are most commonly associated with

disease progression rather than with tolerance alone. With the development of tolerance, increases in the frequency of the dose of the opioid are required to provide continued pain relief. Because the analgesic effect is a logarithmic function of the dose of opioid, a doubling of the dose may be needed to restore full analgesia. There appears to be no limit to the development of tolerance, and with appropriate dose adjustments patients can continue to obtain pain relief. Tolerance to the respiratory effects of opioid doses occurs. This degree of tolerance makes it safe for patients to increase their opioid doses for analgesia.

Tolerance to one opioid does not lead to complete tolerance to another opioid. This phenomenon of so-called *incomplete cross-tolerance* is best exemplified in the dramatic reduction in dosages needed to provide analgesia when patients are switched from, for example, morphine or hydromorphone to methadone, as previously discussed.^{76,87,88,90} Further data elucidating the mechanism of opioid tolerance demonstrate that the N-methyl-D-aspartate (NMDA) receptor plays a critical role in opioid tolerance and analgesia.¹²⁵ These findings have focused new attention on methadone's opioid and nonopioid mechanisms of action and its potential role in the management of neuropathic pain. The use of analgesic combinations can reduce the amount of opioid required. Similarly, the use of bolus or continuous epidural local anesthetics in patients with perineal pain can dramatically reduce the need for systemic opioids and reverse tolerance.

8. *Taper drugs slowly.* The long-term administration of opioid analgesics is associated with the development of physical dependence; thereafter, the sudden cessation of the opioid analgesic produces signs and symptoms of withdrawal: agitation, tremors, insomnia, fear, marked autonomic nervous system hyperexcitability, and exacerbation of pain. Slowly tapering the dose of the opioid analgesic prevents such symptoms. The appearance of abstinence symptoms from the time of drug withdrawal is related to the elimination half-life for the particular drug. For example, with morphine, withdrawal symptoms occur within 6 to 12 hours after drug cessation. Reinstating the drug in doses of approximately 25% of the previous daily dose suppresses these symptoms.

9. *Anticipate complications.* An overdose with opioid analgesics occurs either intentionally, when a patient takes an excessive amount of drug in a suicide attempt, or unintentionally, when the recommended dose accidentally produces excessive sedation and respiratory depression. In both instances, the complication can be treated effectively with naloxone. Intentional overdose in cancer patients occurs rarely, and concern for this is overemphasized. An overdose in patients previously stabilized on an opioid regimen for cancer pain rarely is caused by drug intake alone. More commonly, the cause is the medical deterioration of the patient with a superimposed metabolic encephalopathy. Reducing the opioid drug dosage and carefully assessing the patient's metabolic status usually provide the differential diagnosis.

Psychological dependence or addiction is characterized by a concomitant behavioral pattern of drug abuse evidenced by craving a drug for other than pain relief and overwhelming involvement in the use and procurement of the drug. This is a state distinct from tolerance and physical dependence, which are responses to the pharmacologic effects of long-term opioid administration. The profound fear of causing psychological dependence plays a major role in a physician's reluctance to prescribe opioid analgesics, particularly in cancer patients in the early phase of their disease. Patients may share this fear, consistently taking less analgesic drug than is effective to control their pain. Increasing evidence suggests that cancer patients with pain can take opioid analgesics for prolonged periods but can discontinue such drugs when adequate pain relief is achieved using other approaches. In almost all instances, a dramatic escalation of drug intake is associated with the progression of disease and subsequent death. Few patients with cancer and pain become psychologically dependent on the drugs and participate in drug seeking and illicit drug use. A careful evaluation of patients who might be at risk for

this complication is necessary, but such concern should not be punitive to the patient with severe cancer pain.

Out-of-control, aberrant drug taking among oncology patients with or without a prior history of substance abuse represents a serious and complex clinical occurrence. Passik and Portenoy³⁵ have developed guidelines for the management of such patients. The most difficult situations present themselves in the patient who is actively abusing illicit or prescription drugs or alcohol while concurrently receiving medical therapies. Such patients need a multidisciplinary approach usually focused on a harm-reduction concept that attempts to enhance social support for the patient to maximize treatment compliance. Passik and Portenoy have outlined a series of approaches to maximize the effectiveness of strategies for promoting compliance, including the consideration of a written contract between the team and patient, the inclusion of spot urine toxicology screens to assess compliance, set expectations regarding attendance at the clinic, and the patient's management of medication supplies. It is often most useful to see the patient on a regular basis, often every several days, and to limit prescribing opioids on that basis until the patient has demonstrated his or her willingness to be compliant and to follow an appropriate drug regimen. In an inpatient setting when patients demonstrate manipulative behaviors in the inappropriate use of medication, directing discussion with the patient about the drug use in an open manner is a first step. Providing the patient with a private room near the nurses' station to monitor the patient, discouraging attempts to leave the hospital for the purchase of illicit drugs, and requiring visitors to check in with the nursing staff before visitation are additional steps. Underlying all of this is the attempt to provide the patient with a supportive environment that respects the patient's pain symptomatology and serious medical illness and attempts to limit harm to the patient or others by the aberrant drug use and behaviors.

Adjuvant Drugs

Adjuvant drugs are used to enhance opioid analgesia, provide analgesia for certain types of pain (e.g., neuropathic pain, bone pain, visceral pain), and treat opioid side effects or other symptoms associated with pain.¹²⁶ They are an integral part of the WHO three-step analgesic ladder. Because of the lack of well-defined guidelines for their use, sequential drug trials are necessary to identify the most useful drug and dose titration to find a safe and effective dose.

Adjuvants to Enhance Analgesia

Adjuvants to enhance analgesia have been previously discussed in this chapter. Acetaminophen, NSAIDs, hydroxyzine, and dextroamphetamine have been demonstrated to provide additive analgesia to patients chronically receiving opioids.

Adjuvant Analgesics for Neuropathic Pain

The common neuropathic pain syndromes in patients with cancer include injury to the peripheral nerves and the plexus by tumor invasion, chemotherapy, surgery, or viral agents. Cancer-related bone pain may be a neuropathic pain syndrome as well.³⁹ Depending on the intensity of pain, nonopioid and opioid analgesics are the first-line agents. However, neuropathic pain has a variable responsiveness to opioid drug regimens and may be less responsive than other types of pain.⁸⁹ Some of the commonly used adjuvant drugs for managing this population of patients are described in the following sections.

Antidepressants

The tricyclic antidepressants (TCA) have historically been one of the most useful classes of psychotropic drugs applied in pain

management.^{127,128} Their analgesic effects are mediated by the enhancement of serotonin activity. Data from controlled trials indicate that both the tertiary amine TCAs (amitriptyline, doxepin, imipramine, and clomipramine) and the secondary amine compounds (desipramine and nortriptyline) have analgesic effects. Another major class of antidepressants, the SSRIs, is increasingly used as adjunctive therapies, given their preferable side effect profile compared to TCAs. Paroxetine, for example, has been shown to have analgesic properties in patients with neuropathic pain.¹²⁸ Similarly, duloxetine, a balanced and potent dual reuptake inhibitor of serotonin and norepinephrine, has recently been demonstrated to be an active analgesic for the management of diabetic peripheral neuropathic pain.¹²⁹ It was also shown to be superior to placebo in treating painful chemotherapy-induced peripheral neuropathy, yielding improvements in pain, function, and quality of life at a dose of 60 mg daily.¹³⁰

These drugs have been reported to be effective in treating continuous dysesthesias as well as intermittent lancinating dysesthetic pain. The doses used for analgesia are far below those needed to produce an antidepressant effect, and the analgesic properties appear to be independent of the mood-altering effects. Patients should be started on low doses—for example, amitriptyline at 25 mg nightly—and the dose titrated up to achieve adequate analgesia in a 2- to 4-week trial. Blood levels should be measured to determine both patient compliance and drug absorption because of wide individual variation. Patients who are unable to tolerate amitriptyline or who are predisposed to experiencing its sedative, anticholinergic, or hypotensive effects should be considered for a trial with a secondary amine tricyclic antidepressant, an SSRI such as paroxetine, or duloxetine. In the management of cancer patients with pain, antidepressant drugs are the first-line therapeutic approach for neuropathic pain, and every attempt should be made to provide the patient with a several-week trial before discontinuing these drugs.

Anticonvulsants

The role of anticonvulsants in the management of patients with neuropathic pain is based, in part, on the fact that the mode of action is to stabilize membranes and alter sodium and calcium influx.¹³¹ Many patients with neuropathic pain complain of paroxysmal, brief, and lancinating pains. To date, clinical experience with the anticonvulsants has been positive. The drugs most commonly used include gabapentin, carbamazepine, and phenytoin and pregabalin. Survey studies have suggested the usefulness of valproic acid, clonazepam, lamotrigine, topiramate, and oxycarbazepine.¹³² A systematic review confirms these findings.^{133,134} Gabapentin is considered the first-line anticonvulsant to manage neuropathic pain, although some meta-analyses suggest that it is equivocal with the other anticonvulsants.¹³³ Controlled trials in patients with diabetic neuropathy, postherpetic neuralgia, and AIDS neuropathy demonstrate the effectiveness of this agent in reducing pain. Dosages range from 900 to 1,800 mg per day.¹³⁴ The major drug side effect is sedation. Patients should be started at 300 mg per day and rapidly titrated to 900 mg per day; some patients may need to start at even lower doses, such as 100 mg per day, to avoid sedation. Pain relief in up to 30% to 50% of patients has been suggested.

Clinical studies with carbamazepine demonstrate efficacy, but the usefulness of this drug in the cancer population is limited by its potential to produce bone marrow suppression, particularly leukopenia. The dosing guidelines used for the treatment of seizures are suggested in managing neuropathic pain. Each of the drugs should be initiated at low doses and gradually titrated upward. There is anecdotal experience to suggest that administering intravenous loading doses of phenytoin to patients in an acute crisis with severe lancinating pain may be of clinical value. Both valproate and clonazepam have been reported anecdotally to be useful

in managing neuropathic pain, but these are considered third-line agents in this patient population.¹³² Currently, there are no high-quality data relating the plasma level and pain relief for any of these drugs. In patients with persistent neuropathic cancer-related pain, pregabalin is another option; in a randomized controlled trial of patients with noncancer neuropathic pain, over half of the patients treated with pregabalin experienced a decrease in their mean pain intensity over 50%.¹³⁵ However, a recent systematic review highlights the absence of conclusive, high-quality data on the efficacy of pregabalin in treating neuropathic cancer pain.¹³⁶ Sequential trials of different agents are necessary to identify the most useful treatment for each patient.¹²⁷

Local Anesthetics

The use of both brief intravenous local anesthetic infusions (lidocaine) and maintenance oral anesthetic drugs has demonstrated some efficacy in the management of chronic neuropathic pain, particularly in those patients with both lancinating and continuous dysesthesias. Mexiletine is the oral local anesthetic for which there are pilot data to support analgesic efficacy.¹³⁷ The initial dosage of mexiletine is low, at 150 mg per day, with gradual upward dose titration. Electrocardiograms should be monitored at higher doses, and measurement of blood levels of mexiletine may be useful to prevent toxicity. Currently, there are no good data available to predict which patients might respond to the use of oral local or intravenous anesthetics. A recent Cochrane review suggests that lidocaine and oral analogs are safe and superior to placebo; these agents should be tested further in the population of patients with neuropathic cancer pain.¹³⁸

Epidural local anesthetics (bupivacaine, lidocaine) have been most widely used to manage neuropathic pain, either alone or in combination with an opioid. Alternatively, the use of brief intravenous infusions of lidocaine may be helpful in patients who have an opioid-refractory continuous dysesthesia that has not responded to an antidepressant or anticonvulsant.¹³⁹ These drugs clearly serve as a second-line approach, with individualized therapy the rule. An anesthesia pain specialist or palliative medicine specialist should be called to assist with these complex and potentially dangerous medications.

Cutaneous Local Anesthetics

The use of cutaneous anesthesia has been suggested to be most helpful in patients who have significant allodynia and marked hyperesthesia. The topical application of a local anesthetic, such as an eutectic mixture of local anesthetics, has been demonstrated to be efficacious in patients who undergo painful procedures, especially children.¹⁴⁰ The cream should be applied under an occlusive dressing to increase skin penetration and augment analgesic efficacy. The use of high-concentration lidocaine (5% and 10%) has also been reported to be effective in patients with significant allodynia associated with postherpetic neuralgia.¹⁴¹ Current indications for its use include peripheral nerve injury, peripheral neuropathy, ischemic pain, peripheral vascular disease, and unstable angina. Few cancer patients have been treated using this approach and, therefore, it is not possible to fully assess its role in cancer pain management.

Corticosteroids

A series of controlled and uncontrolled surveys have demonstrated that the use of chronic corticosteroid therapy to reduce pain in patients with breast and prostate cancer improves quality of life.^{142,143} In a controlled study of corticosteroid use in patients with far-advanced disease, transient improvement in appetite, analgesia, and mood were noted, but they were not sustained after the initial effect. The major pain-related indications for corticosteroid use

include refractory neuropathic pain, bone pain, pain associated with capsular expansion or duct obstruction, and headache due to increased intracranial pressure. In certain cancer pain syndromes, such as epidural cord compression, 85% of patients who received 96 mg of dexamethasone as part of their radiation therapy protocol reported significant pain relief associated with a marked reduction in analgesic requirements.¹⁴⁴ Similarly, in patients with tumor infiltration of the brachial and lumbosacral plexus, corticosteroids provided additive analgesic effects. The risk of adverse effects associated with corticosteroid therapy varies with the duration. Long-term use may be associated with GI toxicity and acute psychosis. A wide range of dosages has been suggested, including a dose of 30 mg per day in patients with prostate cancer, which was effective at providing improved quality of life and reduced pain. With epidural cord compression, initial doses of 96 mg of dexamethasone with maintenance doses of 96 mg, with subsequent tapering in 10 days, have been associated with effective analgesia.¹⁴⁴ However, more recent data suggest that lower doses are similarly efficacious, with reduced toxicity. Giving between 6 and 10 mg of dexamethasone intravenously or orally every 6 hours is reasonable and appears to be just as effective, with a lower rate of anxiety, restlessness, insomnia, hyperglycemia, and delirium.¹⁴⁵

Other Adjuvant Drugs

A wide variety of other drugs have been used to manage neuropathic pain, including benzodiazepines, neuroleptics, α_2 -adrenergic agonist drugs, NMDA antagonists, and peptides. Of the benzodiazepines, clonazepam is commonly used in patients with lancinating or paroxysmal pain. The use of these drugs must be balanced with their potential to cause somnolence and cognitive impairment. They serve as second- to third-line therapy in patients who have not responded to antidepressant or anticonvulsant drug therapy. Of the neuroleptics, pimozide has been reported to be analgesic in patients with trigeminal neuralgia.¹⁴⁶ Methotrimeprazine has been demonstrated to have analgesic properties comparable to those of morphine.¹⁴⁷ This drug has sedative, anxiolytic, and antiemetic properties and is commonly used in patients who have excessive opioid side effects. It provides analgesia by a nonopioid mechanism.

The coadministration of these drugs with opioids can often be effective in patients with neuropathic pain. Of the α_2 -adrenergic agonist drugs, clonidine has been demonstrated to be analgesic in controlled trials.¹⁴⁸ It can be administered by either the oral or transdermal route and has been reported to be specifically effective in patients with dysesthetic pain, who demonstrate sympathetic hyperactivity. After intrathecal administration, clonidine was reported to improve pain in patients with intolerable neuropathic pain. Dextromethorphan and ketamine are two commercially available NMDA antagonists. The mechanism of action relates to the fact that the NMDA receptor reduces the development of the wind-up phenomenon, which occurs as a result of changes in the response of central dorsal horn neurons with neuropathic pain. Ketamine has demonstrated analgesic effects in observational studies, but an adequately powered randomized trial failed to show that ketamine infusion led to improved analgesia beyond that offered by opioids plus nonopioid coanalgesics.¹⁴⁹⁻¹⁵³ Calcitonin has been reported to provide analgesia in patients with sympathetically maintained pain and in patients with acute phantom pain.¹⁵⁴ The mechanism underlying these analgesic effects is unknown, but it has suggested the empiric use of calcitonin in patients with refractory neuropathic pain.

Adjuvant Drugs for Bone Pain

Metastatic disease to bone is the most common cause of pain in patients with cancer. Analgesic drug therapy is commonly used to manage pain during the initial treatment with either chemotherapy

or radiation therapy. Numerous investigators have identified a management approach for bone pain, which includes the use of specific surgical palliative approaches, radiotherapeutic approaches, hormonal therapies, and bone resorption inhibitors. Patients with multifocal metastatic bone disease that is refractory to routine treatments may benefit from the use of a series of agents, including the bisphosphonate compounds, gallium nitrate, calcitonin, and radiopharmaceuticals. The newer models of metastatic bone pain as neuropathic pain imply that more traditional neuropathic pain drugs may have an important role in managing bone pain.³⁹ For example, in a murine bone pain model, opioids and tricyclic antidepressants demonstrated analgesic efficacy.¹⁵⁵ The selection of any one of these treatments to manage metastatic bone pain needs to be individualized.

Bisphosphonate drugs such as pamidronate, zoledronate, clodronate, and etidronate bind to bone hydroxyapatite, inhibiting osteoclast activity, and are highly effective in the management of bony metastatic disease and in multiple myeloma.¹⁵⁶⁻¹⁶⁰ The major indication for these drugs is to prevent skeletal morbidity, with data in breast cancer patients and patients with multiple myeloma showing efficacy in reducing fractures and bone pain. Pamidronate is usually administered as a brief infusion in a starting dose of 60 to 120 mg. Analgesia, if it occurs, usually appears within days but may accrue for many weeks with repeated infusions. In two studies, pamidronate at dosages of 30 to 60 mg every 2 weeks produced relief of pain in 30% to 60% of patients.^{157,160} The analgesic effect of bisphosphonates appears to be dose dependent. Current recommendations include a regimen of intravenous pamidronate, 60 mg every 2 weeks for at least two or three treatments. If no response is obtained, therapy can be discontinued. If the drug is effective, a biweekly regimen can be continued. Zoledronate is administered at 4 mg intravenously over 15 minutes every 3 to 4 weeks. A systematic review suggests that it may be the most effective bisphosphonate in prostate cancer.¹⁵⁶ Clodronate may be administered orally (1,600 mg per day) and has been demonstrated to be efficacious in patients with breast cancer and multiple myeloma.

Calcitonin has also been reported anecdotally to be useful in patients with malignant bone pain, but the appropriate dose and dosing frequency have not been well defined.¹⁶¹ Gallium nitrate has also been used with some efficacy in patients with metastatic bone pain, but due to limited experience, appropriate dosing guidelines have not been well defined, and nephrotoxicity has been reported.¹⁶²

A new class of bone-modifying agents targets the so-called RANK ligand, or receptor activator of nuclear factor kappa B. High-quality clinical trials data suggest that denosumab, a monoclonal antibody against this new target, provides further reductions in skeletal-related events in patients with metastatic breast and prostate cancers beyond that provided by zoledronic acid.^{163,164} Although there appeared to be less bone pain in breast cancer patients who received denosumab, research has focused on fracture rates; further research is needed to explore the impact of denosumab on pain itself, especially in light of its modest impact beyond traditional bisphosphonates and its significant cost.

Strontium-89 and samarium-153 are bone-seeking radiopharmaceuticals that have been recognized as useful in the treatment of bone pain secondary to metastatic disease.¹⁶⁵⁻¹⁶⁷ Their use is indicated in patients with refractory multifocal pain due to osteoblastic lesions who have a life expectancy of longer than 3 months, who have sufficient bone marrow reserve (i.e., a platelet count above 60,000 and a white blood cell count above 2,400), and for whom there is no further planned myelosuppressive chemotherapy. The onset of effect is slow and may require several weeks, with peak effects at 2 to 3 months. Bone marrow suppression is the major adverse effect, with irreversible thrombocytopenia. Both radiopharmaceuticals have similar analgesic efficacy and side effects. More recently, radium-223, a novel alpha-particle-emitting compound, was shown to have significant efficacy in metastatic castrate-resistant prostate cancer.¹⁶⁸ It improved survival by 3.6 months and did

so without significant myelosuppression or other adverse events. Early studies with this agent suggest a significant palliative effect on bone pain.¹⁶⁹ Patients with advanced prostate cancer and bone pain should be considered for treatment with this agent.

Adjuvants to Treat Side Effects

Nausea and vomiting, confusion, sedation, and constipation are common opioid-induced side effects. Side effects should be managed expectantly, rather than waiting until patients are experiencing negative consequences of analgesic therapy that aggravate the pain and suffering of cancer. The use of drugs to manage these effects has been discussed previously. The uses of caffeine, methylphenidate, and dextroamphetamine to reduce opioid-induced sedation have all been demonstrated in clinical trials. Haloperidol is the treatment of choice to manage hallucinations and agitated delirium in patients receiving opioid analgesics. The use of bowel regimens to manage depressed GI motility is critical. Because nearly all patients have some constipation when receiving opioids, a bowel regimen should be prescribed along with all opioid therapies, unless there is a serious contraindication.

PSYCHOLOGICAL APPROACHES

Psychological approaches should be an integral part of the care of the cancer patient with pain.¹⁷⁰ Studies strongly support an association between cancer pain and psychological distress, predominantly manifested as mood disturbance, anxiety, and depression.¹⁷¹ Pain catastrophizing (i.e., the tendency to ruminate about pain and negatively evaluate one's ability to deal with pain) leads to increased pain intensity, pain interference, and anxiety. Similarly, patients who lack confidence in their ability to control pain experience lower quality of life and higher psychological distress. Worse pain leads to decreased social interactions, reduced social functioning, and poor social networks. At the other end of the spectrum, increased self-efficacy and active coping manifested by the sense of ability to control or decrease pain is associated with improved pain control. Given these psychological factors, it follows that psychological approaches would be effective adjuvant interventions for cancer pain.

Established behavioral therapies for cancer pain fall into three categories: (1) comprehensive cognitive behavioral therapy (CBT); (2) hypnosis and imagery-based CBT; and (3) psychoeducational interventions.¹⁷² Comprehensive CBT comprises varied packages of adaptive strategies taught to a patient to maximize coping. There are several basic components, namely: (1) providing patients with a rationale that emphasizes pain as a complex experience influenced by thoughts, feelings, and behavior; (2) providing systematic training in one or more cognitive or behavioral strategies for controlling pain (e.g., progressive relaxation, imagery, goal setting, activity pacing) typically carried out over a series of sessions; and (3) emphasizing that the skills can only be mastered through home practice. In hypnosis-based CBT, a trained therapist helps the patient achieve a relaxed state and then actively provides specific hypnotic suggestions designed to enhance pain control and relaxation. In imagery-based CBT, also called *guided imagery*, the patient is taught how to intentionally focus his or her attention on specific mental images so as to divert attention from pain. Psychoeducational interventions combine patient education with behavioral techniques such as skills training, personal interaction with the learner, and repeat visits to reinforce key messages and skills. Biofeedback and caregiver-assisted approaches have been advocated and studied as well, but to date, most evaluations of these methods have been uncontrolled or preliminary.¹⁷⁰

Behavioral therapies have a defined role in the management of nonmalignant pain,¹⁷³ but their role in cancer pain is less clear. A systematic review of behavioral interventions for cancer pain that compared their relative efficacy was conducted in 2005.¹⁷⁰ Cognitive behavioral interventions were effective in the management

of cancer-related pain. Imagery and hypnosis-based interventions were most effective. Education-focused interventions with brief CBT were intermediate, with 56% of the studies positive. Comprehensive CBT interventions were least effective, with less than half of studies positive and no obvious relationships between components of the comprehensive CBT package, intensity of the intervention, and outcome. It appears that psychological approaches that incorporate therapeutic hypnosis and guided imagery have a role in the management of cancer-related pain, especially pain associated with acute situations such as a lumbar puncture or oral mucositis in the setting of bone marrow transplant. Psychoeducational interventions may have a role, especially nursing-based education programs with skills training for the patient and caregivers. Clearly, more studies are needed to better define when these approaches are indicated.

ANESTHETIC AND NEUROSURGICAL APPROACHES

Anesthetic and neurosurgical approaches are most effective at treating patients with well-defined localized pain. Tables 146.7 and 146.8 outline the indications for their use. Of cancer pain patients, 10% to 20% require these approaches, together with pharmacologic approaches, to obtain adequate analgesia.

Several factors are important in selecting the appropriate procedure for each patient. Diffuse pain problems are more common in cancer patients, whereas most neurosurgical and anesthetic procedures are useful for the management of well-defined and localized pain, thus the role of these approaches is limited at best. Further complicating their use is the small number of professionals who have expertise in these procedures. As patients become more cognizant of their disease and treatment options, they are often hesitant to undergo neurodestructive procedures. Patients may consider their pain to be an important marker for their disease and are frightened of the potential, although unlikely, complications of these procedures. As a result, these procedures are often performed late in the illness, and a full evaluation of their effectiveness and duration of action is limited by patients' overriding medical problems.

Local Anesthetics

Anecdotal reports and several controlled studies support the use of cutaneous, subcutaneous, intravenous, intrapleural, and epidural local anesthetics in the management of patients with somatic, visceral, and neuropathic pain.

Intravenous lidocaine can be considered as both a diagnostic and therapeutic approach in patients with neuropathic pain.¹⁷⁴ If such patients obtain an analgesic response, a trial of oral mexiletine or the use of continuous subcutaneous lidocaine should be considered to determine whether prolonged relief may be possible, as previously discussed. Case reports suggest that continuous subcutaneous infusions of lidocaine may have a role in improving neuropathic cancer pain, but a small, randomized study did not support these findings.¹⁷⁵

Intrapleural local anesthetics have been used for acute pain in the chest wall and have been adapted for the management of chronic cancer pain.¹⁷⁶ Anesthetic delivered via a subcutaneously tunneled intrapleural catheter offered long-term relief of right upper quadrant pain from hepatic metastases in a patient with significant pain from tumor infiltration of the liver. This novel method offers an alternative approach for patients with local or regional pain in the pleural and abdominal regions.

Epidural local anesthetics are used to manage localized pain syndromes, usually below the waist. Intermittent and continuous epidural infusions of local anesthetics have been used to manage the difficult chronic pain associated with metastatic disease below the waist, often involving the sacrum and lumbosacral plexus.¹⁷⁷

TABLE 146.7

Types of Anesthetic Procedures Commonly Used in Cancer Pain

Type of Procedure	Most Common Indications
Inhalation therapy with nitrous oxide Intravenous barbiturates (sodium pentobarbital) Local anesthetic by intravenous, subcutaneous, or transdermal application Trigger point injections	Breakthrough pain, incidental pain in patients with diffuse poorly controlled pain Diffuse body pain and suffering inadequately controlled by systemic opioids Neuropathic pain in any site with local application to the area of hyperesthesia or allodynia Focal muscle pain
Nerve Block Peripheral Epidural Intrathecal	Pain in discrete dermatomes in chest and abdomen or in distal extremities Unilateral lumbar or sacral pain; midline perineal pain; bilateral lumbosacral pain Midline perineal pain; bilateral lumbosacral pain
Autonomic Stellate ganglion Lumbar sympathetic vascular insufficiency of the lower extremity Celiac plexus Intermittent or continuous epidural infusion with local anesthetics Intermittent or continuous epidural or intrathecal with local opioid analgesics Intermittent or continuous intraventricular infusions with opioid analgesics Chemical hypophysectomy	Reflex sympathetic dystrophy Reflex sympathetic dystrophy of the lower extremities; lumbosacral plexopathy Mid-abdominal pain from tumor infiltration Unilateral and bilateral lumbosacral pain; midline perineal pain; neuropathic pain from the mid-thoracic region down Unilateral and bilateral pain below the mid-thoracic region; often combined with local anesthetics Head and neck pain and upper chest pain Diffuse bone pain

This method consists of infusing a local anesthetic via a subcutaneous infusion pump or reservoir to a catheter temporarily or permanently placed in the epidural space. If the amount and concentration of the anesthetic are varied, effective pain relief can be achieved without interrupting significant motor or autonomic function. The risk of infection is minimized because local anesthetics have antimicrobial effects. The use of continuous low-dose infusions of local anesthetics is associated with minimal systemic side effects. Further studies on the use of this technique in

comparison with standard therapies are needed to define its place in the management of the cancer patient. Its major advantages are that the resultant analgesia is not cross-tolerant with the analgesia produced by the opioid analgesics, and that temporary use of this technique allows for reducing the amount of systemic opiate drugs and, therefore, partially reversing tolerance. This has been a useful preliminary approach in patients for whom the use of spinal opiate analgesia is considered but who have developed tolerance from large doses of systemic opiates. This approach is also most useful

TABLE 146.8

Neuroablative and Neurostimulatory Procedures for Relief of Pain from Cancer

Site	Procedure	Indications
<i>Neuroablative Procedures</i>		
Nerve root	Rhizotomy	Useful in somatic and neuropathic pain from tumor infiltration of the cranial and, rarely, intercostal nerves
Spinal cord	Dorsal root entry zone lesion	Useful in unilateral neuropathic pain from brachial, intercostal, and lumbosacral plexopathy and postherpetic neuralgia
	Cordotomy	Useful in unilateral pain below the waist; often combined with local neurolytic blocks in perineal and bilateral lumbosacral plexopathy; may be performed bilaterally
	Myelotomy	Useful in midline pain below the waist but rarely used because it involves extensive surgery
Brain stem	Mesencephalic tractomy	Useful in pain in the nasopharynx and trigeminal region
Thalamus	Thalamotomy	Useful in unilateral neuropathic pain in the chest and lower extremity
Cortex	Cingulotomy	Useful through a stereotactic approach for diffuse pain
Pituitary	Transsphenoidal hypophysectomy	Useful in pain control of bone metastases in endocrine-dependent tumors, breast, and prostate
<i>Neurostimulatory Procedures</i>		
Peripheral nerve	Transcutaneous and percutaneous electrical nerve stimulation	Useful in reducing painful dysesthesias from tumor infiltration of nerve or trauma (e.g., neuroma)
Spinal cord	Dorsal column stimulation	Of limited use in neuropathic pain in the chest, midline, and lower extremities
Thalamus	Thalamic stimulation	Of rare use in neuropathic pain in the chest, midline, or lower extremity

in patients who experience an acute pain crisis, such as the patient with a pathologic hip fracture who is not a surgical candidate; this approach would allow the patient to move about in bed.

Peripheral Nerve Block

Peripheral nerve blocks are used both diagnostically to localize the nerve distribution and therapeutically to interrupt pain transmission within a determined nerve distribution. This technique is limited to areas of the body in which the interruption of both motor and sensory function will not interfere with the patient's functional status. It is most commonly used in patients who have pain in the head, chest, or abdomen.¹⁷⁸ This technique is also limited by the fact that each peripheral nerve subserves sensory function over many levels, and usually several nerves must be blocked to provide adequate analgesia. These techniques are most useful in patients with somatic pain; neuropathic pain is rarely controlled by peripheral nerve blocks alone. Examples of successful blocks include gasserian ganglion blocks for craniofacial pain, intercostal blocks for chest wall infiltration from a tumor, and paravertebral blocks for radicular pain. In patients with somatic pain who respond to a local anesthetic block, neurolytic blockade with either alcohol or phenol may provide more prolonged relief. A block produced by phenol tends to be less profound and of shorter duration than that produced by alcohol. Phenol has local anesthetic as well as neurolytic effects.

The most common peripheral neurolytic block is a paravertebral block for localized intercostal pain. Fluoroscopic, ultrasonic, or computed tomographic localization assists in more accurately interrupting the individual intercostal nerve.

Epidural and intrathecal neurolytic blocks have been used primarily to manage patients with far-advanced disease whose pain is either unilateral in the chest or abdomen or midline in the perineum. These approaches are less useful in managing upper and lower limb pain associated with brachial and lumbosacral plexopathy because of the high risk of motor weakness associated with effective neurolytic blockade by this route. Epidural phenol blocks are useful in the management of chest wall pain over several dermatomes. Such an approach obviates the need for multiple paravertebral injections. Phenol is injected in small increments (1 to 2 mL per segment) over 2 or 3 days by an epidural catheter, and preliminary data demonstrate 80% pain relief in patients with documented somatic pain. Epidural and intrathecal phenol blocks have been used to manage perineal pain, but no studies have delineated the superiority of one approach over the other. Case series reviews suggest that an average of 60% of patients experience good relief, 21% achieve fair relief, and 18% obtain poor relief.¹⁷⁷ The duration of pain relief is poorly documented; the overall estimate for relief of pain with both subarachnoid alcohol and phenol blocks suggests a mean duration of pain relief of between 2 weeks and 3 months.

The selection of patients for management with epidural or intrathecal neurolytic agents is based on the following criteria: exhaustion of appropriate antitumor approaches; clear clinical and radiologic definition of the pain; poor candidacy for percutaneous cordotomy; failure of nonopioid, opioid, and adjuvant analgesics to produce adequate analgesia without significant side effects; a favorable response to diagnostic or epidural or intrathecal blocks producing at least 75% pain relief; and an MRI of the spine or myelography done before the procedure that rules out tumor infiltration of the subarachnoid space. Complications are of two kinds. With an intrathecal injection, a self-limiting spinal headache may occur. Complications that result from the action of neurolytic substances on nerve fibers include motor paresis, loss of sphincter function, impairment of touch and proprioception, and troublesome dysesthesias. Injection in the thoracic region has a lower complication rate. If a patient already has both motor and autonomic dysfunction before the use of neurolytic blockade, these often remain the same or may worsen. Patients should be informed of the risk of these procedures, with particular attention

given to the fact that they may develop motor paresis and bladder dysfunction—specifically, incontinence—after the blockade.

Celiac Plexus Block

A sympathetic block is effective in conditions with vasomotor or visceromotor hyperactivity. This hyperactivity accompanies many of the cancer-related pain syndromes such as visceral pain or plexopathies. The most commonly used sympathetic block is that of the celiac ganglion for pain due to abdominal malignancy, including cancer of the pancreas, stomach, duodenum, liver, gallbladder, adrenal gland, and colon. Nociceptive fibers of the splanchnic, sympathetic, vagal, phrenic, and somatic nerves converge on the celiac ganglion, which is amenable to a regional block; this block successfully treats 70% to 85% of patients.¹⁷⁹

Standardized approaches for the use of this technique have been described using computed tomographic monitoring or fluoroscopic control. After placement of the needle, 25 mg of absolute alcohol mixed with local anesthetic and contrast is injected. The major side effect of the procedure is transient hypotension; patients must be well hydrated and monitored carefully during the procedure and for 4 to 6 hours afterward. Significant neurologic complications occur in less than 1% of patients if proper technique is used. Complications include paraparesis, postural hypotension, and urinary difficulties.

Although there has been debate about the usefulness of this procedure in patients with pancreatic cancer, it should be considered as one option, together with pharmacologic approaches, in managing these patients. A recent systematic review of five randomized trials of celiac plexus block for advanced pancreatic cancer demonstrated that overall the procedure led to less pain, opioid use, and constipation, albeit with small effect size of questionable clinical significance.¹⁸⁰ The use of a thoracic endoscopy to perform sympathetic blockade in patients with cancer may replace the standard celiac plexus approach.

Lumbar Sympathetic Block

A lumbar sympathetic block may provide significant relief of intractable urogenital pain or pain due to carcinomatous invasion of local nerves and the plexus in the perineum and lower extremity.¹⁸¹ This ganglion conveys visceral nociceptive afferents from the pelvic viscera. Pain caused by cancer of the sigmoid colon or rectum may be relieved by a bilateral lumbar sympathetic block if the disease is confined to those viscera. Similarly, pain caused by cancer of the seminal vesicles or prostate, and pain caused by uterine cancer confined to the body of the uterus, may be relieved by this block. In many instances, however, the block must be extended to the T12 ganglion. A lumbar sympathetic block alone is usually not useful in patients with lumbosacral plexopathy; therefore, the role of this procedure is limited to the management of pain at specific anatomic sites.

Stellate Ganglion Block

A stellate ganglion block may sometimes be useful for pain in the face, upper neck, ear, and hemicranium. However, the potential complications of the stellate ganglion block limit the use of neurolytic solution with this technique, because there is a high risk of spillage of the neurolytic material into the brachial plexus, with secondary nerve injury and focal pain.

NEUROPHARMACOLOGIC APPROACHES

Epidural and Interspinal Approach

Epidural and intraspinal analgesia, using opioids alone or in combination with (1) local anesthetics, (2) clonidine, (3) both local anesthetics and clonidine, or (4) experimental agents, is used to

manage chronic cancer pain in patients with a reasonable (1-year) expected survival.¹⁸² In all instances, patients should have a trial of an epidural or intraspinal drug combination before permanent implementation is considered. It is advised that patients have a continuous intrathecal trial lasting as long as possible before permanent implementation. A wide array of external and implantable catheters and pumps is available with specific indications and uses. Both computer-controlled battery-operated pumps and continuous fixed-infusion pumps are used. The cost of the pump, the patient's psychosocial status and social support systems, and the patient's ability to care for the pump and port are important considerations in the decision to use such devices. As discussed previously, a randomized clinical trial of intrathecal opioids compared to comprehensive medical management reported improved pain relief, less drug toxicity, and improved survival.¹¹⁵

NEUROABLATIVE AND NEUROSTIMULATORY PROCEDURES FOR THE RELIEF OF PAIN

Table 146.8 summarizes the commonly used neurosurgical approaches to cancer pain. A detailed review of these procedures is beyond the scope of this chapter. A review of the current literature suggests the limited use of most of these ablative and stimulatory procedures. The integration of these procedures is often dependent on the specific training of the consultant neurosurgeon, and medical oncologists need to work effectively in a team to decide the optimal use of these approaches.^{183,184}

TRIGGER POINT INJECTION AND ACUPUNCTURE

Patients with significant musculoskeletal pain often identify specific tender trigger point areas, and injection of these trigger points with either saline or local anesthetic is associated with significant pain relief. Effective relief of pain from trigger point injections is not by itself diagnostic of musculoskeletal pain, however, and an evaluation of the cause of the pain is still necessary to rule out other specific sources.

Acupuncture has been used to treat both acute and chronic pain. The selected acupuncture points are manually or electrically stimulated with a needle until the patient feels the sensation. A wide variety of acupuncture techniques are available, ranging from a traditional Chinese approach to a Western adaptation. Laser acupuncture with external laser probes has also been used. Randomized and systematic data are emerging in support of acupuncture to manage pain; however, a lack of detailed pain assessments with specific acupuncture techniques and lack of a critical review of the patient population make it difficult to interpret these observations.^{185,186} Based on its current empiric use, this approach is relatively safe, but its benefit in cancer patients with pain remains undefined.

PHYSIATRIC APPROACHES

Rehabilitation medicine plays an important role in the multidisciplinary approach to the patient with cancer pain.¹⁸⁷ Physiatrists are concerned with a patient's physical functioning and provide expertise in assessing how impairment in a patient's physical capacity affects his or her ability to function. A wide variety of interventions are available, including transcutaneous electrical nerve stimulation (TENS), diathermy (heating pads, ultrasound treatments, and hydrotherapy), and cryotherapy (ice and vapocoolants). Assistive devices and braces, as well as therapeutic exercise and massage, are important. Trigger point injections and acupuncture have also been used. These interventions are commonly used

in combination with other pain therapy approaches, particularly behavioral and pharmacologic approaches. Rehabilitation approaches are discussed throughout the text specific to the cancer patients' needs. A large body of data supports the use of rehabilitative interventions in acute and chronic nonmalignant pain, but similar studies have not addressed the rehabilitation needs of the cancer pain patient. Neurologic dysfunction is one of the common components in patients with cancer pain, and aggressive neurorehabilitation is necessary to promote ambulation in these patients and provide them with functional independence.

ALGORITHM FOR CANCER PAIN MANAGEMENT

An algorithm has been developed that integrates all of these management approaches for cancer pain. It attempts to integrate assessment techniques, drug therapy, behavioral approaches, and anesthetic and neurosurgical approaches and stresses continuity of care. Treatment begins with a diagnostic evaluation that addresses the medical, psychological, and social components of pain. A plan is developed to treat the cancer and pain. If the anticancer treatment is effective, pain relief usually occurs and the drugs used for analgesia can be discontinued without difficulty. Pain treatment begins with the use of analgesic drugs, starting with nonopioid drugs alone or in combination. If these drugs are successful, no further therapy is necessary. If severe, persistent pain does not respond to analgesic drugs, or if the side effects of the drugs are not tolerated, the physician should consider switching analgesics (e.g., from oral morphine to methadone), changing the route of administration (e.g., from oral to subcutaneous), or performing a cordotomy for localized pain. A trial of an adjuvant drug together with the opioid and nonopioid drug would also be appropriate. In patients with excessive sedation or confusion, the use of a neurostimulant or haloperidol provides adequate treatment of the side effects of the opioid drugs and maintains the patient's analgesia while markedly reducing concurrent side effects. Alternatively, epidural or intrathecal opioids may be considered if systemic analgesics produce excessive side effects such as confusion or sedation. If the pain is localized (e.g., intercostal pain from tumor infiltration of the chest wall), neurolytic blocks are indicated. If the pain is unilateral and below the waist, a cordotomy should be considered. For diffuse pain, nitrous oxide inhalation may be tried. Behavioral approaches, including guided imagery, should be integrated from the onset of treatment and used along with the medical and surgical approaches.

FUTURE DIRECTIONS

The study of pain in cancer patients offers a unique opportunity to use clinical observations to advance biologic knowledge. There is a critical need to expand both the research and educational efforts in cancer pain to improve the control of pain in these patients. Information on the basic mechanisms of pain modulation can be culled only from a careful study of these clinical pain problems. These studies can teach us the physiologic and psychological differences between acute and chronic pain problems, the importance of the evolution of psychological factors, the difference between pain and suffering, the clinical pharmacology of analgesic drugs, and the behavioral mechanisms humans use to suppress pain. The use of innovative approaches based on sound scientific principles and advances in research technology offers the opportunity to understand the complex phenomenon of pain. The development of animal models to test new therapies, the new insights learned from the molecular genetics of opioid receptors, and the increasing knowledge base of the molecular mechanisms of neuropathic pain, bone pain, and visceral pain offer the promise for translating these discoveries into the improved care of the patient with pain.

147 Nutritional Support

Laleh G. Melstrom, Vadim P. Koshenkov, and David A. August

BACKGROUND

Nutrition and diet play a major role in cancer. Dietary factors are a significant component of the identifiable attributable risks of cancer.¹⁻³ Cancer-related malnutrition and cancer cachexia are prominent elements that cause signs and symptoms of cancer and are major contributors to patient distress. Comparable historically to tuberculosis (*consumption*) or even AIDS, cancer is often thought of as a *wasting disease*. Furthermore, malnutrition and weight loss often contribute to the death of cancer patients.^{4,5} More recently, the role of overnutrition in cancer pathogenesis and prognosis has been identified.

Undernutrition is a hallmark of cancer. Approximately 40% of cancer patients present with weight loss, and cancer cachexia syndrome (CCS), with its profound implications for quality of life and survival, may develop in as many as 80% of patients with advanced malignancies.^{6,7} A loss of more than 10% of usual body weight at the time of diagnosis is prognostic for survival; a rate of weight loss of greater than 2.75% per month also confers a poor prognosis.^{7,8} Weight loss in cancer patients is associated with symptom distress (including fatigue, depression, and social withdrawal), poor quality of life, and increased surgical morbidity.⁹⁻¹⁶ In fact, many cancer patients may not be candidates for potentially curative life-prolonging treatment because of the risk of life-threatening complications that their malnutrition confers.

Overnutrition (body mass index greater than 30 kg/m²) is becoming a more frequently recognized problem in cancer patients, in part because of the obesity epidemic in the United States. Obesity is an attributable cause in more than 15% of cancer deaths in the United States, including cancers usually associated with wasting (such as liver cancer, pancreas cancer, gastric cancer, and esophageal cancer) and in *female cancers* such as uterine cancer, cervix cancer, and breast cancer.¹⁷ Hypothesized links between the pathophysiology of cancer mortality and obesity include: delayed detection on physical exam and screening studies; the difficulty of administering precise surgery, radiation therapy, and chemotherapy in obese patients resulting in decreased efficacy and increased side effects; the role of lipocytes in steroid and sex-hormone metabolism; the altered cytokine milieu in obese patient; and the proinflammatory/pro-oxidant effects of obesity.¹⁸

Despite our current understanding of the role of malnutrition in cancer pathogenesis, pathophysiology, and patient outcomes, the ability to avoid the consequences of under- and overnutrition in cancer patients remains a work in progress. The nutrition care of cancer patients should focus on the goals of recognizing the presence and/or risk of malnutrition; assessing nutritional needs and requirements; defining and implementing appropriate nutrition interventions while avoiding ineffective and potentially harmful therapies; maintaining function and quality of life; and improving the ability to administer effective anticancer treatments.

CAUSES OF MALNUTRITION IN CANCER PATIENTS

Metabolic, cytokine, and clinical factors contribute to the development of malnutrition in cancer patients (Table 147.1). The role of each of these factors varies from patient to patient. Anorexia is a prominent contributor to weight loss in many cancer patients. Although multiple factors contribute to cancer-associated anorexia, it primarily results from cytokine and metabolic derangements.^{19,20} Although many factors may diminish nutrient intake, the underlying problem is a metabolic milieu that prevents the effective utilization of nutrients. Supporting this contention are a number of observations: parenteral nutrition support may be used to overcome diminished nutrient intake or gut failure, but this only rarely reverses the weight loss and clinical stigmata of CCS; the clinical and metabolic features of simple starvation in humans differ markedly from those seen in cancer patients, suggesting decreased intake is not the underlying cause of cancer-associated weight loss; cancer weight loss may precede changes in appetite; and in some situations, the perceived anorexia is actually an adaptive decrease of food intake in response to weight loss.²¹⁻²³ Therefore, even with an effective treatment of other causes of weight loss in cancer patients, the metabolic and clinical consequences of cancer cachexia may not resolve.

Other factors that contribute to weight loss in cancer patients include symptom distress and psychosocial factors, alterations in taste (dysgeusia), gastrointestinal dysfunction, and side effects of cancer therapy. The symptom-related and psychological factors associated with cancer that may alter food intake include pain, nausea, vomiting, anxiety, depression, and social isolation. Dysgeusia may be a direct side effect of chemotherapy, radiation therapy, and surgery, but it may also be psychological in origin (including food aversions and anticipatory nausea and vomiting).^{24,25} Gastrointestinal dysfunction is common in cancer patients; it may relate to direct effects of tumor (i.e., obstruction, compression of hollow viscuses), or to side effects or complications of therapy. Cancer surgery is invariably accompanied by a temporary catabolic state and decreased nutrient intake, and this may be prolonged by the development of complications such as obstruction, infection, and fistula formation. These may cause symptom distress, including alterations in taste, early satiety, pain, cramps, vomiting, diarrhea, and constipation. Chemotherapy often induces transient nausea and vomiting or injury to gastrointestinal mucosa with resultant stomatitis, mucositis, diarrhea, and/or typhlitis, all of which may be exacerbated by neutropenia. Radiation therapy can cause acute gastrointestinal injury accompanied by many of the previously mentioned symptoms and also chronic radiation enteritis with malabsorption and stricture formation.

CANCER CACHEXIA SYNDROME

The word “cachexia” comes from the Greek words *kakos* (bad) and *hexis* (condition). It is not surprising that the development of CCS confers a worse prognosis. The clinical features of CCS include

TABLE 147.1

Causes of Weight Loss and Malnutrition in Cancer Patients

- A. Metabolic Factors
 - a. Cytokine-, peptide-, and hormone-induced metabolic changes
 - b. Cytokine-mediated anorexia
- B. Symptom Distress
 - a. Depression and other psychosocial factors
 - b. Pain, nausea, diarrhea, constipation, fatigue, and other symptoms
- C. Alterations in taste (dysgeusia), conditioned food aversion
- D. Gastrointestinal dysfunction
 - a. Obstruction, dysmotility, fistula, and malabsorption
- E. Side Effects of Cancer Therapies
 - a. Nausea, vomiting, diarrhea, fatigue, mucositis, enteritis, infection, etc.

weight loss, anorexia, fatigue, anemia, and hypoalbuminemia. Cancer cachexia can be present at any stage of disease, although it is more common with advanced malignancy. Weight loss is a central component of the undernutrition that occurs in cachectic patients. It varies between tumor types, and is most profound for tumors of the pancreas and the upper gastrointestinal tract.⁷

The etiology of CCS is multifactorial. Anorexia of malignancy is defined as a spontaneous decrease in food intake,²⁶ and is most often mediated by cytokines.²⁴ An abnormal metabolic rate; altered cellular metabolism of lipids, proteins, and carbohydrates; and a deranged cytokine milieu (Table 147.2) are the other causes of cancer cachexia. The interplay of these factors varies from patient to patient.

Energetics

Early studies that evaluated resting energy expenditure (REE) in cancer patients concluded that it is increased.^{27,28} However, these investigations did not account for fat-free mass (FFM) when calculating the REE. Weight-losing patients initially lose fat mass, and body composition should be accounted for when estimating REE.^{29,30} Even with these adjustments, inaccuracies still exist in the estimation of REE in cancer patients.^{31–33}

The type of malignancy and the host response have been hypothesized to result in the variability of the metabolic rate that has been observed in cancer patients.^{31,32,34–39} For example, although patients with hepatobiliary neoplasms are mostly hypometabolic, gastric and lung cancer patients are frequently hypermetabolic.^{40–42} Factors

TABLE 147.2

Cytokine Milieu and Effects in Cancer Cachexia

Cytokine	Effects
TNF- α	Lipolysis, muscle degradation, increased glucose turnover
Interferon- γ	Potentiates lipolysis, decreases protein synthesis
Interleukin-1 (IL-1)	Induces anorexia, early satiety, peripheral proteolysis, potentiates release of IL-6
IL-6	Severe wasting
Proteolysis-inducing factor	Skeletal muscle degradation
Lipid mobilizing factor	Lipolysis

such as increased acute phase reactants, prolonged duration of illness, and advanced cancer have been associated with an elevated REE, whereas the stage of the tumor has not.^{32,35–38} Additionally, because of anorexia and other factors, cancer patients may not adjust their food intake to compensate for the altered REE.²⁶ The hallmark of REE in cancer patients is its variability and unpredictability.

Intermediary Metabolism

Increased turnover (cycling) of proteins and lipids is a feature of CCS, leading to decreased skeletal muscle mass and depleted fat stores. Augmented proteolysis and attenuated peripheral protein synthesis cause severe muscle loss in weight-losing patients with advanced cancer, which can result in respiratory complications and death.^{43,44} Proteolysis-inducing factor (PIF) is a major mediator of protein catabolism in cancer patients; it activates nuclear factor kappa B (NF- κ B), which then turns on the ubiquitin-proteasome proteolytic pathway.²⁰ By mass, most of the weight loss in cancer cachexia occurs from the depletion of fat stores. The primary mechanism behind this is elevated fat cell lipolysis. Similar to PIF, lipid-mobilizing factor (LMF) is central to the process of adipocytic lipolysis via regulation of hormone-sensitive lipase (HSL).⁴⁵ Interestingly, both proteolysis and lipolysis are not suppressed with the administration of exogenous nitrogen⁴⁵ and glucose.⁴⁶ With respect to the metabolism of carbohydrates, multiple aberrations stem from the Warburg effect, an early 20th century observation that glycolysis is the main process for energy generation in cancer cells.⁴⁷ This energy-inefficient process leads to an increase in hepatic gluconeogenesis and can cause the normal tissues to be energy starved.

Cytokines and Hormones

In CCS, many of the processes that have just been described are driven by an altered cytokine milieu (see Table 147.2). Both tumor cell production and host responses contribute to the deranged cytokine milieu.⁴⁸

Although integral to local host defenses in the face of inflammation or infection, tumor necrosis factor- α (TNF- α) can have harmful systemic effects.⁴⁹ These include muscle breakdown mediated by the ubiquitin-proteasome pathway and nitric oxide synthase expression, fat depletion that occurs because of increased lipolysis through the activation of HSL and decreased lipogenesis, and anorexia that is induced when TNF is produced or administered in the brain.⁵⁰ Evidence for the role of TNF in cachexia comes from multiple animal models.^{51,52} Similar to TNF, interferon- γ (IFN- γ) is an important contributor to muscle wasting and fat burning through the activation of these same processes.⁵³ Antibodies to these two key cytokines have been developed with some success in suppressing the metabolic changes of CCS, but no single agent has been able to prevent most of its features.^{49,53}

Interleukin-1 (IL-1) and interleukin-6 (IL-6) are two proinflammatory cytokines that further contribute to CCS. IL-1 induces anorexia, increases peripheral breakdown of muscle, and promotes the release of IL-6.^{53,54} In turn, IL-6 has been demonstrated to elevate the rate of hepatic gluconeogenesis and peripheral proteolysis, and can result in more profound wasting than TNF.^{53,55} Despite the almost indistinguishable effects of TNF and IL-6, the latter (unlike TNF) is easily found in the serum of cancer patients with cachexia, and likely works through different mechanisms.⁵³

Besides cytokines, several hormones and tumor-derived proteins have been implicated in CCS. These include leptin, serotonin, PIF, and LMF. Proteolysis-inducing factor and LMF are predominantly produced by tumor cells, whereas leptin and serotonin are generated by host tissues. PIF contributes to peripheral muscle wasting and to decreased protein synthesis, whereas LMF is central to lipolysis. Interestingly, LMF is detectable in weight-losing cancer patients, but not weight-stable cancer patients.⁵⁰

The key function of leptin, an adipocyte-derived hormone, is to regulate body fat mass by reducing appetite and increasing REE.⁵⁶ It does so via hypothalamic neuropeptides.⁴⁸ When there is an increase in food intake, leptin levels are elevated. This leads to the suppression of appetite stimulants ghrelin and neuropeptide Y (NPY) and the stimulation of appetite suppressors corticotropin-releasing factor (CRF) and melanocortin. Persistently decreased levels of leptin have been identified in cachectic patients, indicating that tumors are capable of mimicking leptin and causing sustained anorexia and weight loss.^{48,55} Another hormone that has been found to contribute to the anorexia of cancer cachexia is serotonin.⁴⁸ Several mechanisms have been proposed for this, including the depression of appetite and the inhibition of ghrelin secretion.^{57,58}

The multiplicity of factors, both clinical and metabolic, that underlie CCS have, to date, frustrated most attempts to reverse its devastating clinical sequelae.

NUTRITION SCREENING AND ASSESSMENT

Nutrition screening to identify cancer patients at risk for malnutrition and a nutrition assessment to elucidate their nutrient requirements are the first step in the nutrition care of cancer patients.¹⁸ Objective parameters such as albumin, transferrin, and body weight changes are used in various formulae to predict preoperative risk in malnourished cancer patients (Table 147.3). The Prognostic Nutritional Index (PNI) has been validated prospectively and calculates the percentage risk of an operative complication in an individual. It can differentiate patients at low risk for nutrition-related complications (<10%) from those that are at high risk (>50%).⁵⁹ The Nutrition Risk Index (NRI) was utilized to stratify nutrition risk in the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group trial of perioperative parenteral nutrition and classifies individuals as either well nourished or malnourished.⁶⁰ The Hospital Prognostic Index (HPI) identifies high-risk patients and evaluates the efficacy of hospital therapy.⁶¹

As effective, and more generalizable and practical, are various questionnaire-based tools; they can effectively and reproducibly categorize nutrition risk in cancer patients. The most frequently utilized and validated tool is the Patient Generated Subjective Global Assessment (PG-SGA). Prognostic factors such as weight loss, performance status, and nutrition-related symptoms are assessed in the PG-SGA. The clinician combines physical examination findings (especially loss of subcutaneous fat and the presence of muscle

wasting, ankle and sacral edema, and ascites) with historical factors such as weight change, change in dietary intake, presence of gastrointestinal symptoms, functional capacity (performance status), and primary diagnosis to establish a global assessment of nutrition status (A: well nourished, B: moderately malnourished, C: severely malnourished). A numerical score can be added to the global rating creating the *scored PG-SGA*, which is the standard tool utilized by Oncology Dietetics Practice Group of the American Dietetics Association. The PG-SGA is practical, cost-effective, validated, and considered by some to be a *gold standard*.⁶²

PHARMACOTHERAPY OF CANCER-ASSOCIATED WEIGHT LOSS AND MALNUTRITION

Cancer cachexia and the associated weight loss cause symptom distress and impair quality of life in cancer patients. They are associated with fatigue, anorexia, early satiety, and social isolation, as well as other symptoms.^{63,64} Furthermore, cancer treatments are often accompanied by gastrointestinal symptom distress relating either to the underlying cancer or, more generically, to the hormonal and cytokine milieu that accompanies the CCS. Qualitative research suggests an important role for psychosocial interventions directed at both the patient and family members to address these symptoms.⁶⁵ Much of the focus, to date, however, has been on pharmacologic interventions.

Progestational agents have been the mainstay of the pharmacotherapy of cancer-associated anorexia and weight loss. Megestrol acetate and medroxyprogesterone acetate have been shown to improve appetite and to ameliorate weight loss in studies of patients with cancer and cachexia.^{66,67} Improved quality of life has been demonstrated in prospective studies in patients with cancer cachexia treated with megestrol acetate, with minimal side effects.^{68,69} Doses studied ranged from 160 to 1,280 mg per day, and maximal weight gain was generally seen within 8 weeks. The mechanism of action may, in part, be mediated via alterations in IL-6 levels.⁷⁰ One study suggests that combining megestrol acetate with a cocktail of anti-inflammatory and antioxidant nutrients may have an additional benefit.⁷¹ Dronabinol, a marijuana derivative, has been shown to improve appetite and cause weight gain in small studies. Combined therapy with megestrol acetate dronabinol is not superior to megestrol acetate as a single agent.⁷²

Anabolic steroids have no proven efficacy. In human trials, corticosteroids produce transient improvement in nutritional parameters and appetite, but continued use is associated with a negative nitrogen balance, net calcium loss, glucose intolerance, and immunosuppression.⁷³ Agents such as growth hormone, insulin-like growth factor I, insulin, ghrelin, and melatonin, although promising in rodent models, have not been shown to be helpful in humans in improving nutrition status or quality of life.⁷³⁻⁸⁰ Cyproheptadine, an antihistamine and serotonin antagonist, can reduce diarrhea and reverse weight loss in patients with carcinoid syndrome.

Cytokine-directed therapies offer the promise of potentially reversing the cascade of metabolic and hormonal events that result in cancer cachexia. Animal studies are promising. However, although some agents have demonstrated effects in humans, none have been demonstrated to be clinically effective.¹⁸ Thalidomide and pentoxifylline have been shown to inhibit TNF- α , but have not demonstrated clear efficacy in clinical trials.^{81,82}

Eicosapentanoic acid (EPA) and docosahexaenoic acid (DHA) are α -3 omega fatty acids found in high concentrations in fish oils that have anti-inflammatory properties.^{83,84} Unfortunately, they have not been shown to be effective in clinical trials in patients with cancer cachexia.^{84,85}

Medications to relieve cancer- or treatment-related symptoms that impair oral intake can be important adjuvants to reduce or even eliminate the need for nutrition support in many cancer

TABLE 147.3

Nutrition Screening Tools

- A. Prognostic Nutritional Index: % risk of perioperative complication = $158 - 16.6$ (albumin; grams per deciliter [g/dL]) - 0.78 (triceps skin fold thickness; mm) - 0.2 (serum transferrin; g/dL) - 5.8 (delayed type hypersensitivity reaction; mm)
- B. Nutritional Risk Index: $1.519 \times$ the serum albumin (grams per liter) + $0.417 \times$ (current weight/usual weight) $\times 100$
 - a. Patients are characterized as malnourished if they had a score of 100 or less on the Nutritional Risk Index
- C. Patient Generated Subjective Global Assessment (PG-SGA)
 - a. Patient History: weight change, change in dietary intake, gastrointestinal symptoms, change in functional capacity, diagnosis
 - b. Physical Exam: loss of subcutaneous fat, muscle wasting, ankle edema, sacral edema, ascites
 - c. The previous are combined to create a numerical score to categorize patients as mildly, moderately, or severely malnourished.

patients.⁸⁶ Nausea, vomiting, diarrhea, and constipation are common. They can lead to an aversion to eating, with resultant weight loss. When these symptoms are present, a formal evaluation to look for an underlying cause and intervention by a registered dietitian has been shown to be helpful.⁸⁷ General approaches include the use of antiemetics, promotility agents, antidiarrheals, fiber, laxatives, and (when pancreatic insufficiency is suspected) pancreatic enzyme replacement.^{88,89} Depression occurs in 25% to 45% of patients with cancer and can lead to a loss of appetite and weight loss.^{90,91} Antidepressant medications can help.⁹²⁻⁹³

NUTRITION SUPPORT OF CANCER PATIENTS

Because malnutrition is associated with a poor prognosis in cancer patients, it seems intuitive that nutrition support should improve cancer outcomes. Unfortunately, this notion is an oversimplification. The mere provision of nutrition support does not guarantee that the cancer patient will optimally utilize the nutrients to improve clinical outcomes. However, evidence does suggest that some form of nutrition support can be effective and can improve clinical outcomes in cancer patients who are currently undergoing anticancer treatment (surgery, chemotherapy, and/or radiation) AND who are moderately or severely malnourished OR who are anticipated to be unable to meet their nutrition needs orally for a period greater than 7 to 14 days in perioperative patients and greater than 14 days in nonsurgical patients.⁹⁴ Guidelines that specify the cancer patients who are likely to benefit from nutrition support (i.e., the provision of nutrients other than orally) have been published by major nutrition organizations.^{94,95} Evidence-based guidelines published by the American Society for Parenteral and Enteral Nutrition for nutrition support during anticancer treatment and in hematopoietic cell transplantation are summarized in Table 147.4.

The routine use of nutrition support in cancer patients is not indicated. More than 35 clinical trials, some of them prospective and randomized, including more than 5,500 patients, have been summarized.⁹⁶ In adequately nourished patients, nutrition support by the enteral or parenteral route does not improve outcomes in patients receiving chemotherapy or radiation therapy or who are undergoing cancer surgery, and in fact, nutrition support may actually harm these patients.⁹⁶ Nutrition support should be reserved for those patients who are actively receiving anticancer treatment and who are malnourished or who are at high risk of becoming acutely malnourished because of an anticipated inability to take in adequate oral nutrition for 7 to 14 days or longer.

Optimal Route of Administration of Nutrition Support

On the initial presentation, dietary counseling and oral supplementation is often the best approach to support the nutrition needs of cancer patients.⁹⁷⁻¹⁰⁰ However, this may not be feasible secondary to side effects of cancer therapy, generalized cancer cachexia, abnormal physiology secondary to the malignancy, or anatomic factors that preclude oral intake. When oral supplementation is not an option, enteral nutrition (EN) is preferred. The enteral route is more physiologic, has fewer associated complications (especially infection), has a decreased incidence of associated hyperglycemia, and is more cost effective than parenteral nutrition (PN).¹⁰¹⁻¹⁰³ EN can improve nitrogen balance and stimulate weight gain in cancer patients.¹⁰⁴ EN is generally contraindicated in patients with bowel obstruction, abdominal distention, ileus, severe diarrhea, gastrointestinal bleeding, and high output external fistulas.

If use of the gastrointestinal tract is not feasible, then PN should be used. PN can facilitate weight gain; however, this is primarily in the form of fat.¹⁰⁵ Historically, it was thought that the use of PN may mitigate morbidity and decrease mortality in the periop-

TABLE 147.4

Nutrition Support Guideline Recommendations During Adult Anticancer Treatment (A.S.P.E.N. Clinical Guidelines)⁹⁴

1. Nutrition Support Therapy During Anticancer Treatment

- Patients with cancer are nutritionally at risk and should undergo nutrition screening to identify those who require a formal nutrition assessment with development of a nutrition care plan.
- Nutrition support therapy should not be used routinely in patients undergoing major cancer operations.
- Perioperative nutrition support therapy may be beneficial in moderately or severely malnourished patients if administered for 7–14 days preoperatively, but the potential benefits of nutrition support must be weighed against the potential risks of the nutrition support therapy itself and of delaying the operation.
- Nutrition support therapy should not be used routinely as an adjunct to chemotherapy.
- Nutrition support therapy should not be used routinely in patients undergoing head and neck, abdominal, or pelvic irradiation.
- Nutrition support therapy is appropriate in patients receiving active anticancer treatment who are malnourished and who are anticipated to be unable to ingest and/or absorb adequate nutrients for a prolonged period of time (7–14 days).
- The palliative use of nutrition support therapy in terminally ill cancer patients is rarely indicated.
- Omega-3 fatty acid supplementation may help stabilize weight in cancer patients on oral diets experiencing progressive, unintentional weight loss.
- Patients should not use therapeutic diets to treat cancer.
- Immune-enhancing enteral formulas containing mixtures of arginine, nucleic acids, and essential fatty acids may be beneficial in malnourished patients undergoing major cancer operations.

2. Nutrition Support Therapy in Hematopoietic Cell Transplantation

- All patients undergoing hematopoietic cell transplantation with myeloablative conditioning regimens are at nutrition risk and should undergo nutrition screening to identify those who require formal nutrition assessment with development of a nutrition care plan.
- Nutrition support therapy is appropriate in patients undergoing hematopoietic cell transplantation who are malnourished and who are anticipated to be unable to ingest and/or absorb adequate nutrition.
- Enteral nutrition should be used in patients with a functioning gastrointestinal tract in whom oral intake is inadequate to meet nutrition requirements.
- Pharmacologic doses of parenteral glutamine may benefit patients undergoing hematopoietic cell transplantation.
- Patients should receive dietary counseling regarding foods that may pose infectious risks and that require safe food handling during the period of neutropenia.
- Nutrition support therapy is appropriate for patients undergoing hematopoietic cell transplantation who develop moderate to severe graft versus host disease accompanied by poor oral intake and/or significant malabsorption.

erative setting in gastrointestinal malignancy patients. However, many studies suggest that in adequately nourished patients, the perioperative use of PN in patients with gastrointestinal malignancies actually increases the incidence of infections and does not improve survival.⁹⁴ However, severely malnourished patients can

benefit because the use of PN in the perioperative setting in these patients can reduce the incidence of surgical complications and can improve survival in comparison to standard isotonic fluids.¹⁰⁶

Optimal Timing for Initiation of Nutrition Support

Once the ideal route of nutrition is established, the timing of initiation of nutrition support must be considered. Historically, enteral feeding was discouraged following abdominal surgical procedures; *bowel rest* was thought to promote anastomotic healing and prevent nausea and vomiting. More recently, it has been recognized that early oral and enteral feeding can promote healing and reduce length of stay.¹⁰⁷ Failure to consider nutrition and diet issues perioperatively can result in lost opportunities to maintain nutrition status and to avoid nutrition-related complications. In contrast, a delay in the initiation of PN may be appropriate, even in those patients in whom oral or enteral feeding is not possible. In a prospective, randomized trial, critically ill patients, including cancer patients, patients in whom EN was attempted early but in whom the initiation of PN was delayed for 7 days had a shorter length of intensive care unit (ICU) stay and also had reductions in the incidence of infectious complications, organ dysfunction, and hospital length of stay compared to patients in whom PN was initiated on day two.¹⁰⁸

Perioperative PN appears to be beneficial in moderately or severely malnourished patients if administered for 7 to 14 days prior to an operation.¹⁰⁶ In mildly or borderline malnourished patients, there is no demonstrable benefit to preoperative PN.

Prescribing Nutritional Support

Energy requirements are determined by a patient's age, gender, body composition, and energy expenditure. Multiple formulas

have been suggested to determine caloric requirement, but none has been demonstrated to be more reliable.¹⁸ Typically, non-physiologically stressed patients require approximately 1.0 g per kilogram of body weight per day of protein and 25 kcal per kilogram of body weight per day of nonprotein calories. Essential fatty acids (linoleic and linolenic acids are generally used in the United States) are provided, approximately 1 to 2.0 g per kilogram per day, to supplement calories and to prevent essential fatty acid deficiency. There are additional fluid, electrolyte, vitamin, and trace mineral requirements (Table 147.5). Enteral formulas come premixed and contain all of the required nutrients. PN is generally individually prescribed, and vitamins and trace elements must be added.

Enteral Nutrition

The selection of a formula for EN is based on an assessment of both nutrient and fluid requirements. The calorie concentration in balanced formulae can range from 1.0 to 2.0 kcal per milliliter. The nonprotein component is derived from carbohydrates and lipids. Those diets with more carbohydrates have a higher osmolarity than isocaloric diets containing lipids.

Access for EN can be via percutaneous gastrostomy, operative gastrostomy, feeding jejunostomy (placed endoscopically or operatively), or via a nasojejunal tube.¹⁰⁹ Feeding rates should start at 30 mL per hour and increase at set intervals (12 to 24 hours) to achieve an assessed caloric goal.

Hyperosmolar formulas are generally not administered to the jejunum directly. If patients develop symptoms of diarrhea (most frequent) or constipation, changes should be made to either the rate or formulation of the tube feedings; antimotility agents and/or fiber can often be added to feedings to treat these symptoms. Additionally, with diarrhea, it is reasonable to check a *Clostridium difficile* toxin prior to making other changes.

TABLE 147.5

Vitamin and Mineral Requirements¹³⁹

Vitamin and Mineral	Units	Recommended Dietary Allowance (RDA) for Daily Oral Intake	Daily Amount Provided (Recommended) by Standard Intravenous Preparations
Vitamin A (retinol)	IU	1,760 (females); 3,300 (males)	3,300
Vitamin D (ergocalciferol)	IU	200	200
Vitamin E (tocopherol)	mg TE	8–10	10
Vitamin K (phyloquinone)	μg	20–40	0
Vitamin C (ascorbic acid)	mg	60	100
Thiamine (vitamin B ₁)	mg	1.0–1.5	3.0
Riboflavin (vitamin B ₂)	mg	1.2–1.7	3.6
Niacin	mg	13–19	40
Pyridoxine (vitamin B ₆)	mg	2.0–2.2	4.0
Pantothenic acid	mg	4–7 (adults)	15
Folic acid	mg	0.4	0.4
Vitamin B ₁₂	mg	3.0	5
Biotin	μg	100–200	60
Zinc	mg	15	5
Copper	mg	2–3	1
Manganese	mg	2.5–5	0.5
Chromium	mg	0.05–0.2	0.1
Iron	mg	10 (males); 18 (females)	3

Regardless of the route of EN, all tubes need to be flushed at least daily with 20 to 25 mL of saline or water to ascertain tube patency. Tubes can also be dislodged, and patients should present urgently back to the clinician to reinsert a tube into an established track prior to scarring and closure.

Parenteral Nutrition

Central venous access is necessary to administer PN because of its hyperosmolarity. Commonly, PN is comprised of hypertonic glucose (25%), amino acids (4.25%), lipids, electrolytes, and essential vitamins, minerals, and trace elements. The caloric density of these formulae is usually 1 kcal per milliliter and, therefore, 2 to 2.5 L of volume a day provides 2,000 to 2,500 kcal and all essential nutrients. To prevent essential fatty acid deficiency, patients should receive at least 500 mL of a 20% fat emulsion containing both linoleic and linolenic fatty acids weekly.

Specialty Nutrition Formulas: Immune Enhancing and Formulas for Organ Failure

In order to address special needs based on physiologic deficiencies, there are multiple specialty nutrition formulas. There have been numerous studies evaluating the potential benefits of immune-enhancing formulas. These are enteral formulas that have been tested both in the perioperative and ICU setting and contain various combinations of arginine, glutamine, RNA, and/or omega-3 fatty acids. Although findings are variable, in general, these formulas result in fewer infectious complications and perhaps shorter lengths of stay in the postoperative setting.¹¹⁰⁻¹¹⁶

EFFECT OF NUTRITION SUPPORT ON TUMOR GROWTH

Historically, concern has been voiced concerning the potential for nutrition support to stimulate tumor growth and metastasis.¹¹⁷ In murine models, PN provided in excess of energy requirements can more than double tumor growth rate.¹¹⁸⁻¹²⁰ In humans, the provision of nutrition support may stimulate tumor cell proliferation and protein synthesis, but this finding is not consistent.¹²¹⁻¹²⁴ There are no clinical outcomes data that suggest a deleterious effect of nutrition support when used in malnourished patients on tumor growth and spread. These data emphasize the sensibility of using nutrition support in cancer patients when malnutrition or the risk of malnutrition is clearly demonstrated.^{96,117}

GLYCEMIC CONTROL IN PATIENTS WITH CANCER

Hyperglycemia is frequently observed in stressed, critically ill patients and in patients receiving nutrition support. Multiple factors

(many of which are present in cancer patients) contribute to this, including elevated levels of stress hormones, systemic activation by inflammatory cytokines that promote insulin resistance, and the administration of carbohydrate-rich nutrition support.¹²⁵ In seriously ill patients, including cancer patients, the occurrence of hyperglycemia is associated with increased morbidity and mortality.¹²⁶ Five major trials have investigated the role of tight glycemic control in critically ill patients receiving nutrition support.¹²⁶⁻¹³¹ They have been nicely summarized.^{131,132} Many of the patients in these trials were cancer patients. In these trials, intravenous insulin was used in the experimental groups to maintain blood sugars below approximately 100 mg per deciliter, and in the conventional treatment groups, the blood sugar target was higher (140 to 200 mg per deciliter). In general, mortality was increased in the tight glucose control groups. All of these trials observed a higher incidence of hypoglycemia in the stringent control groups than in the conventional therapy groups. It seems prudent in critically ill cancer patients receiving nutrition support to target a blood sugar in the 140 to 180 mg per deciliter range to attain at least some of the benefits of more stringent glucose control but without risking the possible increase in mortality that may result from overly tight control.^{133,134}

PALLIATIVE NUTRITION SUPPORT IN PATIENTS NOT RECEIVING ANTICANCER TREATMENT

The use of PN support in patients with advanced cancer and not actively receiving anticancer treatment remains controversial.⁹⁴ This is despite evidence that PN support in this setting is often futile and may be harmful. In a palliative setting, a patient's quality of life should be the primary factor addressed when considering the use of home PN.^{135,136}

In determining the utility of palliative home PN, important considerations include the patient's estimated survival, potential risks and benefits, and the patient's and family's wishes. The goals of nutrition support in this particular setting are to prolong life and to ameliorate nutrition-related symptoms that cause undue suffering.¹³⁷ A review of home PN in cancer patients who are terminally ill noted that the most frequent indications were obstruction, malabsorption, fistula, and radiation enteritis.¹³⁸ Overall, there is some suggestion of a survival benefit. The patients that are potential beneficiaries of home PN are those with a good performance status (Karnofsky score >50); those with inoperable bowel obstruction; those with minimal symptoms from a disease involving major organs such as brain, liver, and lungs; and those with indolent disease progression. Guidelines suggest PN support should only be offered if a patient is a candidate for active anticancer therapy and/or the patient is expected to have a survival greater than 40 to 60 days.¹¹⁰ Additionally, in the context of home PN, patients must have caretaker support nearly 24 hours per day. There are few patients that meet the previous criteria for home PN. Honest and compassionate discussions are necessary with these patients, their families, and their referring physicians in order to optimize decision making and the delivery of palliative care in this end-of-life setting.

148 Sexual Problems

Veronica Sanchez Varela, Eric S. Zhou, and Sharon L. Bober

INTRODUCTION

Rapid and recent advances in cancer care now mean that the majority of newly diagnosed cancer patients will “live beyond cancer.” This shift has resulted in a consistently increasing focus on maintaining and/or restoring quality of life for cancer survivors. Despite widespread acknowledgment that sexual function is often profoundly disrupted by cancer treatment, there is still a deafening silence when it comes to addressing this quality of life issue for a majority of cancer patients and survivors. Often, oncologists do not feel comfortable addressing sexual problems and instead focus on treatment outcomes related to survivorship rather than quality of life.¹ However, several studies have shown that patients, both male and female across diseases, are often disappointed by the lack of information, support, and practical strategies provided by their clinicians to help manage the sexual changes secondary to cancer and cancer treatments.²⁻⁴

Although there are real barriers to bringing frank conversation about sexuality into the routine clinical oncology encounter, we would like to begin this chapter by clarifying why it is important for clinicians to address this topic with patients and survivors. Sexuality and intimacy have been shown to help lessen emotional distress and improve psychosocial adjustment in the face of cancer.⁵ Acknowledging the importance of sexuality to patients’ quality of life, the World Health Organization has recently declared that maintaining sexual health indeed falls under the purview of physicians. For patients who endure so many losses as a result of cancer, including social, financial, physical, and emotional disruptions, the loss of sexual function adds a burden that is only magnified by the shame and embarrassment that this aspect of life is not only changed, but also feels unspeakable. Moreover, patients worry that their experience of “damage” cannot be undone and often wrongly assume that sexual dysfunction cannot be adequately addressed. Many of these assumptions are unwittingly reinforced by clinicians who, by not addressing the topic, mistakenly give patients the message that “nothing can be done”—an unfortunate occurrence because the majority of typical sexual problems facing cancer patients and cancer survivors can indeed be effectively treated.

Several studies have examined medical professionals’ barriers to communication about sexual health needs with their patients. It has recently been suggested that these barriers appear to fall into three categories: issues related to patient characteristics, provider characteristics, and systems issues.⁶ Patient characteristics refer to a range of assumptions about a patients’ sexuality based on age, gender, partner status, sexual orientation, prognosis, economic and social class, as well as religious, cultural, and ethnic backgrounds that may deter clinicians from asking about sexual health. For example, doctors may assume that an older person who is widowed or divorced is no longer sexually active or that if a patient is from another culture it would be inappropriate to ask about sexual concerns. Provider characteristics refer to the training, experience, knowledge, and attitudes of the provider that may either deter or facilitate conversations about sexuality after cancer.

Lack of experience and lack of knowledge have repeatedly been shown to explain why sexuality is not addressed^{7,8} with cancer patients and survivors. Finally, systems issues are often reported as major barriers to this topic. Oncologists will aver that there is no time to address sexuality when there is barely enough time to manage more pressing concerns.⁷ Oncologists are also concerned about the lack of available resources for patients if a patient were to endorse a problem.¹

The aim of this chapter is threefold: (1) to familiarize clinicians with the most common sexual problems for men and women that are related to specific cancers and their particular treatments; (2) to review intervention options for sexual problems including acknowledgment of current resources that are readily available to both clinicians and patients, and (3) to provide clear and straightforward language that clinicians can use to initiate a brief discussion about sexuality with their patients as well as to overview some brief and previously validated measures of sexual dysfunction that can be incorporated into standard practice in order to assess sexual dysfunction more systematically.

CANCER IN MEN

Prostate

The relative 5-year survival rate for those diagnosed with localized stage disease approaches 100%.⁹ The combination of the increase in diagnosed cases, increasing survival rates, and the decreasing age at diagnosis has made sexual dysfunction following prostate cancer treatments a progressively more pressing issue.^{10,11}

Surgery

One of the primary treatment options for men diagnosed with early stage disease is a prostatectomy, which can have a major impact on the sexual functioning of the patient.^{10,12} During surgery, the seminal vesicles are removed and the vas deferens is cut, which causes dry orgasms and urinary incontinence during orgasm. This is associated with poor satisfaction with orgasms, and the avoidance of sexual activities.¹³⁻¹⁷ In addition, the cavernous nerves may be affected during surgery, which can cause erectile dysfunction in up to 90% of men.¹⁸⁻²⁰ Therefore, nerve-sparing surgical approaches are preferred because they are proven to be effective in helping patients sustain erectile function postsurgery, especially if bilateral nerve-sparing surgery is feasible.^{19,21-25} Age, ethnicity, preoperative sexual and overall physical function, extent of neurovascular bundle preservation, and the surgeon’s level of experience are factors related to postsurgical sexual function.^{23,26-33} The recovery period for the nerves related to erectile function is approximately 18 to 24 months.²⁷ Additionally, the denervation caused by surgery may result in smooth muscle atrophy, erectile tissue apoptosis, and/or hypoxia-induced tissue damage, all of which can contribute to reduction in penile length and circumference.³⁴⁻³⁷

There are currently a variety of treatments for erectile dysfunction. With the advent of sildenafil, the first-line treatments for erectile dysfunction are oral medications because they are effective and noninvasive.³⁸ However, they may be ineffective in men who are older, and men who had low erectile functioning prior to surgery, as well as for men who have neurovascular bundle damage as a result of surgery.³⁹⁻⁴¹ Oral agents also may result in physical side effects (e.g., headache, muscle pain) and psychological side effects (e.g., concern about medication use).^{42,43} Because oral medications may not be effective for 18 to 24 months postsurgery, alternative treatment options can be considered and include intracavernous injection therapy, transurethral alprostadil, and vacuum erection devices. Intracavernous injection therapy is effective in the majority of patients,⁴⁴⁻⁴⁶ although its use can be anxiety provoking. Up to half of patients who are offered injection therapy either refuse or stop treatment within first 6 months.^{47,48} Transurethral alprostadil is also effective.⁴⁹ The use of vacuum erection devices can be beneficial for men who experience penile shortening,⁵⁰⁻⁵² although approximately 1 in 5 men discontinue use due to discomfort, difficulty with operating the device, penile bruising, and social inconvenience.⁵² Finally, the use of a penile prosthesis can be a helpful treatment for erectile dysfunction,⁵³⁻⁵⁶ although it is typically reserved for patients who fail other treatments given its invasive and irreversible nature.⁵⁷ Combination treatments (e.g., both phosphodiesterase type 5 inhibitor [PDE-5] and vacuum erection devices) may provide the most hope for the recovery of erectile function.^{58,59}

From a rehabilitation, rather than a treatment, perspective, oxygenation preserving strategies including the use of vacuum erection devices,^{50,51} daily low-dose PDE-5 inhibitor use,⁶⁰ intracavernous injection of vasoactive agents,⁶¹ and hyperbaric oxygen therapy⁶² can help to reduce tissue fibrosis.⁶³ This penile rehabilitation therapy can be helpful with the preservation of erectile tissue and is associated with improved erectile function.^{64,65} There is some debate regarding the efficacy of penile rehabilitation therapy,⁶⁶⁻⁶⁹ including questions regarding the use of on-demand, rather than daily, dosing of PDE-5 inhibitors,⁷⁰ dosing, and timing of rehabilitation therapy.^{71,72} Recent evidence suggests that there may be subsets of patients who would benefit from penile rehabilitation.^{73,74}

Radiation

External beam radiation and brachytherapy are also treatment options for men with early stage prostate cancer. Patients may believe that radiation therapy will have less of a negative impact on sexual function, and often times may choose radiation therapy over surgery as a way to preserve sexual health. However, radiation therapy, in all forms, is associated with sexual dysfunction, although radiation therapy patients experience different functional trajectories compared to prostatectomy patients.^{23,75} Radiation patients report their highest sexual functioning immediately posttreatment, and then proceed to decline subsequently, which is in direct contrast to surgery patients, where their sexual function tends to improve over time.⁷⁶⁻⁸⁰ Although there are better outcomes for younger men (≤ 60 years),⁸¹ up to a third of radiation therapy patients become impotent 3 years posttreatment.⁸² This progressive decline in sexual function is caused by fibrosis that continues to develop after radiation treatment is completed.⁷⁶ Although brachytherapy tends to be associated with a less severe side effect profile compared to external beam radiation, sexual function is still likely to be compromised as a result of treatment. Brachytherapy patients report changes to their overall sexual function,⁸³ reduced ejaculate volume, premature or diminished orgasms,⁸⁴ and declines in erectile function.⁸⁵ Risk factors for erectile dysfunction after brachytherapy include greater age, poorer pretreatment functioning, and prostate volume.⁸⁶

Treatment for erectile dysfunction in radiation therapy patients is similar to surgery patients, with first-line therapy being oral treatment.⁸⁷ However, the scar tissue that builds up over time on the

nerves may limit the effectiveness of oral medication, and patients who achieve potency after radiation therapy may experience a slow decline in function.^{88,89}

Hormone Therapy

In men diagnosed with late stage disease as well as high-risk disease, androgen deprivation therapy is the most common course of treatment. It is also associated with a range of side effects, including marked sexual dysfunction, such as decreased libido, elevated erectile dysfunction, and lower levels of sexual activity.⁹⁰⁻⁹⁴ Additionally, treatment-related side effects such as body feminization, hot flashes, fatigue, and decreased mood and self-esteem also greatly impact sexual health among men who choose hormone therapy.⁹⁵ Treatment for erectile dysfunction associated with hormone therapy is consistent with options used after surgery and radiation. However, the more difficult sexual dysfunction to treat is the low libido. Medical options, such as increasing testosterone levels, are counter to androgen-deprivation therapy. There has been recent research evaluating the role of estrogen in restoring libido among men undergoing hormone therapy.⁹⁶ Use of targeted cognitive-behavioral interventions designed to improve communication, reduce relationship distress, and improve coping skills and self-esteem have shown promise in terms of improving adjustment and reducing distress for men on androgen deprivation therapy.⁹⁷⁻¹⁰¹

Quality of Life Implications of Sexual Dysfunction

All active treatment options for prostate cancer are associated with compromised sexual functioning,¹⁰² which has been identified as the most common cause of disease-specific distress among survivors.^{11,102-105} Even if sexual function returns to baseline levels, prostate cancer survivors often continue to report sexual bother.¹⁰⁶ Men who struggle with sexual dysfunction are at risk for mood-related disturbances, which impacts their posttreatment adjustment and quality of life.^{107,108} Sexual dysfunction presents a multidimensional challenge that requires multidisciplinary support from physicians, nurses, physical therapists, and psychologists who work together in treating both the physical and psychological impact of treatment.¹⁰⁹⁻¹¹¹ In any intervention work, it is important to consider the relational context,¹¹²⁻¹¹⁴ although this is often overlooked.^{115,116}

Testicular

Testicular cancer is the most common cancer among men between the ages of 20 and 34 years.¹¹⁷ These statistics signal to the fact that these men are in their sexual prime and at a likely age to start a family, making the sexual and fertility aspects of testicular cancer treatment an important topic.¹¹⁸ Most commonly, these men report that treatment for their cancer impacts their orgasm intensity and frequency (20% to 38%), causes problems with ejaculation (6% to 51%), lowers libido (20% to 35%), and causes erectile dysfunction (17% to 40%).¹¹⁹⁻¹²² As a result, up to 43% of testicular cancer patients report decreased sexual activity, and approximately 1 in 5 are dissatisfied with their sexual experience following treatment.^{123,124} For these patients, their sexual function appears to reach a low point about 3 months posttreatment, and tends to recover over the course of 1 year,¹²⁵⁻¹²⁷ although there are survivors for whom treatment-related sexual side effects can last for up to 5 years.¹²⁸

The primary concern for many men with testicular cancer is fertility. Although there are variations, abnormal sperm concentrations can be seen in up to half of testicular cancer survivors.^{120,129} Testicular cancer survivors have various fertility options, including sperm cryopreservation and intracytoplasmic sperm injection.^{130,131} Patients benefit greatly from receiving information about reproductive options¹²⁰ as well as a discussion about broader sexual health issues (Table 148.1).¹³²

TABLE 148.1

Medications for Sexual Problems (Men)

Medication	Purpose	Notes	References
Oral PDE-5 inhibitor	Erectile dysfunction	First-line treatment. Ineffective in some men (older, lower function previously, treatment-related nerve damage), and immediately posttreatment. Both physical (e.g., headache, dizziness) and psychological (dependence) side effects can occur. Daily low-dose use may help repair damaged blood vessel endothelium and improve erectile function.	38, 40, 42, 43, 60
Intracavernosal injection therapy	Erectile dysfunction	Effective treatment. Patient adherence is a significant challenge. Patients benefit from effective training, and psychoeducation about proper use.	44, 47, 48
Estrogen therapy	Libido	Consideration of parenteral estrogen add back. Preliminary research. May be helpful in improving libido in androgen-deprived men.	96
Testosterone replacement therapy	Erectile dysfunction, libido, vitality	Effective in treating symptoms of hypogonadism. Lack of controlled studies to document its safety in prostate cancer survivors.	285–289

CANCERS THAT AFFECT MEN AND WOMEN

Bladder

The most common presentation of bladder cancer is in the form of transitional cell carcinoma, and although most cases tend to be superficial when first diagnosed, repeated treatments may be required to treat recurrences. Treatments for bladder cancer mainly include surgery, radiation therapy, immunotherapy, and chemotherapy, with surgery used in most of the cases. From a sexual health perspective, treatment of bladder cancer by radical cystectomy is the procedure that has received the most attention given its likely negative implications on sexual functioning.¹³³ The efficacy of laparoscopic surgery in terms of oncologic control has been recently studied,^{134–136} but it is not clear if it differentially impacts sexual functioning.¹³⁷

Male Sexual Function

A standard radical cystectomy for treating bladder cancer in men involves the removal of the bladder as well as the prostate, seminal vesicles, vasa deferentia, and the removal or damage of the neurovascular bundles, leaving the patient with the likely consequent loss of sexual function.¹³⁸ Alternatively, a nerve-sparing cystectomy is associated with a temporary decrease in function after surgery, commonly followed by a return to function.^{139–143} Unfortunately, oncologic failure rates for nerve-sparing cystectomies are higher.^{144–146} This has resulted in a debate regarding the minimization of cancer risk, while maximizing sexual function preservation.^{142,147–150} In addition, men report body image issues as a result of their need for urinary diversion following surgery,^{133,151} which is associated with sexual dissatisfaction.¹⁵²

For men who are treated with radical or nerve-sparing cystectomy, erectile dysfunction prevails at similar rates to those seen after prostatectomy or nerve-sparing prostatectomy, respectively, and its treatment follows the standard of care for erectile dysfunction in men treated with a prostatectomy. Early PDE-5 inhibitor intervention is associated with improved sexual function and satisfaction.¹⁵³ However, almost half of male bladder cancer patients do not seek treatment for their sexual dysfunction postsurgery.^{138,154}

Female Sexual Function

The standard radical cystectomy for bladder cancer in women involves the removal of the bladder, urethra, anterior vaginal wall, uterus, and ovaries and it is likely to result in sexual dysfunction,^{155–157} including weakened libido, dyspareunia, decreased lubrication, and diminished ability or inability to achieve orgasm.^{158,159} Consequently,

many women who undergo non-nerve-sparing cystectomies report discontinuing sexual intercourse following surgery.¹⁵⁷ The use of nerve-sparing surgical procedures has recently been evaluated in an attempt to reduce the impact of treatment on the significant sexual dysfunction caused by a radical cystectomy.¹⁵⁷ Women who undergo nerve-sparing surgery retain sexual function comparable to presurgical levels,^{141,157,160} as well as increased potential of fertility preservation.¹⁶¹ However, there has been limited exploration of the oncologic impact of nerve-sparing surgeries for these women.

Treatment for sexual dysfunction amongst female bladder cancer survivors is similar to recommendations for female survivors of breast, gynecologic, and colorectal cancers. For women who experience physical and/or psychological difficulties resulting from the extent of their cystectomy, vaginal reconstruction surgery may be a viable option.¹⁶²

Head and Neck

Head and neck cancers are considered to be among the most impactful with regard to the patient's posttreatment quality of life. Treatment for head and neck cancer can include surgery, radiation therapy, targeted therapy, and/or chemotherapy. Even when function-sparing approaches are utilized, treatment can still result in facial alterations, as well as changes to saliva quality and/or quantity, breathing, and speech,¹⁶³ which cannot be completely corrected with follow-up treatments.^{164,165} Head and neck cancer survivors report lowered self-esteem and body image as a result of these treatment-related side effects, which negatively impact their intimate relationships.^{166–168} These survivors report feeling less attractive, a reduced libido, and decreased overall satisfaction with their sexual relationships.^{169–173} In particular, females, and those who were diagnosed with more advanced stage disease, who underwent surgery, or whose treatment caused more extensive disfigurement are at elevated risk for sexual dysfunction.^{169,174,175}

The majority of these patients do not discuss implications of their disease and treatment on body image and sexual health with their medical providers.¹⁷² Sexual health rehabilitation is not well understood in this population.^{176,177} Open communication about possible sexual side effects of treatment between providers and patients is associated with improved psychosocial adjustment.^{175,178}

Blood, Bone Marrow, and Lymphatic System

Treatment of systemic disease often involves intense interventions with chemotherapy, whole-body irradiation, and/or bone marrow transplant and may cause side effects, including sexual

dysfunction. In particular, preparative regimes of high-dose chemotherapy and total body irradiation may result in ovarian failure and low-estrogen levels for women, and gonadal and cavernosal arterial insufficiency in men.¹⁷⁹ Sexual problems in bone-marrow transplant patients may still be present several years after the procedure and include difficulty obtaining an erection, ejaculation, and orgasm for men and concerns about body appearance, vaginal dryness, and painful intercourse and orgasm for women.¹⁸⁰ Moreover, a longitudinal study of sexual function in long-term survivors of hematopoietic cell transplantation documented that at 5 years after treatment, sexual dysfunction is a major problem for this population, with male survivors continuing to have lower sexual function and female survivors having lower scores for sexual activity and function compared to controls.¹⁸¹ Another important issue that often develops for females after transplant is genital graft-versus-host disease (GVHD). Female genital GVHD after transplant is a complication that tends to receive little attention despite the significant impact it has on the survivor's quality of life. Female tract GVHD may manifest in several forms, from irritation of the vagina or the vulva to ulceration and vaginal stenosis, and it has been found to be present in at least 25% of the transplant survivor population.^{182,183} Research studies suggest that an early detection of genital GVHD is highly treatable with steroids and vaginal dilators, and therefore, education on active self-surveillance should be given to patients in addition to a plan for regular gynecologic follow-up posttransplant.^{183,184}

Studies that investigate the effectiveness of interventions for sexual dysfunction in women after bone-marrow transplantation are scarce, but therapies including vaginal lubricants, dilators, and vibrators can be recommended to improve some of the sexual side effects of treatment. In men, there is evidence to support that a number of patients recover sexual function over time,¹⁸¹ and that testosterone cypionate and sildenafil have shown to improve erectile dysfunction in this population.¹⁷⁹ More importantly, many survivors and their partners may feel hesitant or even fearful to resume sexual activity after bone marrow transplantation given concerns about immunosuppression, such as coming in contact with germs. These concerns may prevail even after survivors have been cleared by their medical team to resume sexual activity. It is important, therefore, to anticipate and openly discuss these concerns with survivors and their partners while offering gentle guidance and reassurance about their eligibility to resume sexual activity.

Colorectal

Treatments for colorectal cancer mainly include surgery, radiation therapy, and chemotherapy, with surgery used in most of the cases.⁹ Colorectal cancer surgery often causes damage to the sympathetic and parasympathetic nerves and results in erectile and ejaculatory disorders in men and dyspareunia, decreased libido, and changes in the orgasm experience in women.¹⁸⁵ And although the impact of radiotherapy in colorectal cancer survivors has rarely been addressed, the available research suggests that radiation is associated with sexual dysfunction in both men and women.¹⁸⁶

Because most colorectal cancer patients are over 50 years of age and may presumably have a higher incidence of non-cancer-related sexual dysfunction, studies that use a longitudinal design to assess the prevalence of sexual dysfunction in these survivors are of particular interest. In a longitudinal study by Jayne et al.,¹⁸⁷ the authors compared treatment outcomes in patients who underwent a laparoscopic-assisted surgery versus open surgery for colorectal cancer, including quality of life and sexual functioning. The authors assessed functioning preoperatively and at 2 weeks and 3, 6, 18, and 36 months after surgery and found that although there was no change from baseline in sexual functioning or enjoyment for men and women in both arms, men tended to report more sexual problems from 3 months onward in the laparoscopic arm and from 6 months onward in the open surgery arm. The authors also found

that body image was worse than at baseline from 2 weeks onward for all patients. Therapies recommended for prostate cancer survivors, such as the use of sildenafil,¹⁸⁸ appear to be adequate for a number of male colorectal cancer survivors who suffer from erectile dysfunction following treatment. Likewise, therapies recommended for breast and gynecologic cancer survivors, such as the use of water-based lubricants, vaginal moisturizers, and vaginal dilators, can also be recommended for female colorectal cancer survivors who suffer from vaginal dryness and/or stenosis after radiation.¹⁸⁶ More specific to colorectal cancer survivors are the negative emotional reactions to the colostomy, such as poor body image and reduced self-esteem, which are commonly present and may negatively impact intimacy. But patients and their partners can and do learn how to manage the impact of an ostomy on sexuality, and there are resources available for this purpose. Patients with ostomies should receive information on deodorants to minimize odor, as well as on foods that are likely to cause stronger odors, gas, or diarrhea. Patients should also receive information on pouch covers, and suggestions such as changing positions to avoid pain during intercourse and emptying the stoma before sexual activity.¹⁸⁹ Additional information for patients and their partners can also be found through the United Ostomy Associations of America, Inc.

CANCER IN WOMEN

Breast

Difficulty with sexual function, loss of desire, changes in body image, and disruption of emotional relationships are primary sexual complications of breast cancer from diagnosis through all stages of treatment and into survivorship. Chemotherapy, radiation, surgery, and adjunctive hormonal therapy, whether delivered alone or in combination with each other, all have the potential to negatively impact sexual function. The survival rates of breast cancer for localized disease continue to improve and are now 95% or better.⁹ Not only will the majority of breast cancer survivors go on to become long-term cancer survivors, but studies have also shown that the majority of partnered women will remain sexually active either after diagnosis or at the end of treatment.^{190,191}

A number of factors have been identified regarding who is at risk for developing sexual problems after breast cancer. Women who have premorbid sexual dysfunction,¹⁹² negative self-concept,¹⁹³ depression, and relationship discord¹⁹⁴ are all more likely to struggle with sexual problems. In one recent prospective study assessing the impact of breast cancer on women's sexuality, a younger age was found to be the most salient predictor of lower sexual function in addition to a lack of partner status.¹⁹⁵ Unfortunately, there is a wide range of sexual problems that are related to breast cancer, and reports of sexual problems range from 30% to 100%.¹⁹⁶ More specifically, 23% to 64% of women report problems with desire, 20% to 48% report arousal or lubrication problems, 16% to 36% report problems with orgasm, and 35% to 38% report problems with pain or dyspareunia.¹⁹⁷⁻¹⁹⁹ Problems with body image are also quite common both during and after treatment, although there is some evidence that certain areas of distress such as feeling feminine or perceived attractiveness tend to improve over time.^{190,200,201}

Surgery

Conceptually, losing one or both breasts would seem to be one of most dramatic ways to damage a woman's core sense of femininity, body integrity, and attractiveness. Concern about body image in the face of breast surgery and potential breast changes and breast loss is prevalent with approximately 30% to 67% of women reporting concern with body image.^{194,202} Breast-conserving surgical procedures and reconstructive surgery have become a standard part of breast cancer care, and it is generally assumed that breast-conserving surgery (lumpectomy versus mastectomy) as well as

breast reconstruction is essential in helping women maintain a positive body image.²⁰³ Several studies have shown that women who undergo modified radical mastectomies have poorer body image than those who have had breast-conserving procedures. In Moyer's meta-analysis²⁰⁴ of 40 studies comparing quality of life differences between breast-conserving surgery and mastectomy between 1980 and 1995, it was shown that patients undergoing breast conservation had a better body image compared to mastectomy patients.

However, aside from body image and maintaining body integrity, breast surgery can still have a significantly negative impact on sexuality. In particular, women who undergo breast reconstruction are typically left with a complete lack of sensation, including nipple sensation. The nipple has been shown to be the most sensitive area of the breast and loss of nipple sensation is akin to losing a key erogenous zone for many women.²⁰⁵ Although their breast shape may be restored, the loss of feeling is not. In addition to the use of saline-filled or silicone gel-filled implants, women may also have tissue flap procedures where tissue from a woman's body may be harvested from her abdomen, back, thighs, or buttocks in order to reconstruct a breast. These surgeries, although more intensive than implant surgery, offer the advantage of reconstruction that often feels and looks more natural without the concern about implant rupture or the need to replace implants over time. However, flap procedures necessitate a second surgical site and additional scars. There is growing attention now being paid to the use of nipple-sparing mastectomy; however, although the nipple and areola may be left in place and breast tissue is removed, sensation is no longer intact.²⁰⁶

Chemotherapy

Disruption of sexual function after breast cancer seems to be significantly related to whether a woman undergoes chemotherapy as part of her treatment.^{190,194,196,197,200,207} Ganz¹⁹¹ looked at the impact of breast cancer treatment on sexual function and found that women who had either a lumpectomy or mastectomy followed by chemotherapy were more likely to report negative sexual outcomes than patients who had surgery alone. Schover²⁰⁷ has noted that younger women who undergo abrupt chemotherapy-related menopause are at the highest risk for sexual problems, and that the rates of sexual dysfunction in these women are clearly higher than would be expected in a healthy, community-based sample. In particular, the intensive estrogen deficiency that comes with chemotherapy-induced menopause often leads to severe vaginal dryness and vaginal atrophy, which makes penetration painful. Painful intercourse due to vaginal dryness is one of the most common sexual problems after breast cancer, and it is one of the primary factors also implicated in women's experience of decreased desire, another common and often vexing problem for breast cancer survivors.^{207,208} Testosterone deficiency related to premature ovarian failure has also been discussed as a factor related to a loss of desire after breast cancer, but research has not uniformly supported this hypothesis.^{209,210} Rather, a loss of desire appears to be multidimensional, with causes that span a bio-psycho-social continuum.

Hormonal Therapy

Endocrine therapy including selective estrogen receptor modifiers (SERM) and aromatase inhibitors (AI) now play an important role in breast cancer treatment for both premenopausal as well as postmenopausal women. Tamoxifen has been used as systemic adjuvant treatment for over 20 years and primary side effects are hot flashes, fatigue, and nausea. Regarding sexual function, tamoxifen use has been associated with vaginal dryness and low desire,²¹¹ although in the large-scale Breast Cancer Prevention Trial, there were no differences found in the frequency of sexual activity between those using tamoxifen versus placebo.²¹² Raloxifene, another SERM, does not appear to confer a significant difference from tamoxifen in patient-reported outcomes on physical health

and depression, but sexual function has been reported as being slightly better than in women taking tamoxifen.²¹⁵ More recently, sexual side effects of raloxifene treatment have been examined and no deleterious effects were found.²¹⁴ The third-generation AIs (anastrozole, letrozole, and exemestane) have become an integral component in the care of postmenopausal women with estrogen-receptor-positive breast cancer and are currently being evaluated for use in chemoprevention.²¹⁵ A significant and distressing exacerbation of postmenopausal gynecologic symptoms such as extreme vaginal dryness and dyspareunia has been reported in several studies investigating the quality of life of women taking AIs, including in the first and largest Arimidex and Tamoxifen Alone or in Combination (ATAC) trial with over 9,000 participants.²¹⁶ It has been noted that as use of AIs has become the gold standard of care for postmenopausal breast cancer survivors, it is imperative to explore comprehensive management of these gynecologic symptoms that impair sexual function.²¹⁷

Radiotherapy

Radiation therapy for breast cancer is generally localized to the breast. Radiation can result in skin fibrosis, additional loss of sensitivity in the skin, and fatigue, all which can contribute to low desire. However, there has hardly been any research conducted that specifically examines the effects of breast cancer-related radiotherapy on sexuality.

Intervention

Several approaches for addressing sexual problems after breast cancer have been identified. Most approaches focus on individually based information and education about the management of sexual side effects, such as vaginal dryness. The minority of interventions have been developed aimed at working with couples to establish new norms for intimacy after cancer. Ganz and colleagues²¹⁸ demonstrated that nurse-delivered individually based counseling was more successful in managing menopausal and sexual side effects from treatment over a 4-month period than usual care. Alternatively, it has been suggested that interventions need to actively involve women's partners in order to produce lasting benefits on sexual functioning.²¹⁹ It is our perspective that optimal intervention is essentially based on "two tracks" and addresses sexuality in both an individual and relational context.

Track 1: Focus on the Individual. It is imperative that women receive information and education about how to maintain and restore good sexual health in the context of maintaining good vaginal health as well as overall well-being after breast cancer. In anticipation of the common side effects of both chemotherapy-induced menopause as well as adjuvant hormonal therapies, we believe that all women should receive information as part of their overall treatment planning about (1) nonhormonal vaginal moisturizers, (2) water-based vaginal lubricants, (3) pelvic floor strengthening (Kegel) exercises, and (4) the value of maintaining blood flow to vaginal tissue to prevent vaginal atrophy. This kind of information is readily available to patients through a number of resources, including a free, recently updated booklet by the American Cancer Society called "Sexuality and Cancer: For the Woman Who Has Cancer and Her Partner." This booklet is free to patients and can be obtained in hard copy or online. In addition, the National Cancer Institute as well as the Lance Armstrong Foundation have information about sexuality on their Web sites.

Track 2: Focus on the Relational Context. For the majority of breast cancer patients who are in a partnered relationship, it may also be important to acknowledge that sexuality is experienced in a context. Often, patients do not realize that partners may benefit from looking at some of the same educational resources, and many popular books and Web sites about sexuality after breast cancer actually have sections that are specifically written for partners.

It can be a great relief to patients to get the message that not only are sexual problems common after breast cancer, but also that although the majority of partners want to be helpful when it comes to reconnecting sexually, they too may be unsure of how to proceed and may need guidance. For patients that are not currently in a relationship, sexuality is, in part, still a relational experience whether based on past relationships or in the context of hopes for future relationships. Patients who are not partnered are frequently unsure of how to proceed in terms of dating and lack of confidence in initiating new sexual relationships after their treatment. Often, these patients gain enormous benefit from being able to talk about these challenges and strategize about communication with a new potential partner.

Gynecologic Cancers

Treatments for gynecologic cancer often result in sexual dysfunction that may affect a substantial number of patients and can persist for many years after diagnosis. The effect of surgeries on the genitals can impact a patient's self-esteem and body image and can create significant physical barriers, such as pain, to satisfactory sexual experiences. In addition, women who receive radiation therapy are at risk for developing vaginal fibrosis and stenosis, and hormonal interventions are likely to result in an abrupt development of menopausal symptoms, all of which can considerably disrupt sexual functioning.²²⁰ For instance, Carmack et al.²²¹ found that sexual problems were quite prevalent in ovarian cancer patients, with 80% reporting problems with vaginal dryness, 75% reporting problems reaching orgasm, and 62% reporting pain or discomfort during penetration. Moreover, research has found that ovarian cancer survivors report significantly less sexual pleasure than disease-free controls.²²²

In a cross-sectional study of women diagnosed with early-stage cervical carcinoma, Bergmark et al.²²³ noted that long-term survivors reported sexual function changes that appear to persist over time, including decreased lubrication and genital swelling during arousal, reduced perceived elasticity during intercourse, and distress over these changes. Moreover, the authors²²³ found that the changes in sexual function reported by the survivors were associated with the effects of surgery, whether or not the treatment included radiotherapy. Later results obtained by Jensen et al.,²²⁴ who studied early-stage cervical cancer survivors longitudinally, suggest that although low sexual interest and vaginal dryness seem to persist for years after a radical hysterectomy, other changes such as distress by a reduced vaginal size and problems completing sexual intercourse after surgery are likely to resolve over time. In contrast, research also suggests that women treated with radiation for advanced, recurrent, or persistent cervical cancer report sexual problems including low sexual interest, lack of lubrication, dyspareunia, and inability to complete sexual intercourse throughout the first 2 years after treatment and with little improvement over time.²²⁵

Even though most women who are diagnosed with cervical cancer are younger, Bergmark et al.²²³ found that women of all ages included in their study are likely to consider sexuality an important aspect of their lives, and therefore, providers should feel particularly encouraged to discuss with their patients possible disease- and treatment-related sexual changes that may occur.

There is limited information of the sexual outcomes associated with vulvar cancer treatment. However, the available research suggests that vulvar cancer survivors experience significant sexual dysfunction.^{226,227}

Intervention

Research studies on interventions that may be used for women treated for gynecologic cancers and who experience subsequent sexual dysfunction are limited, and mostly focus on information giving and suggestions to manage specific symptoms.²²⁸ For instance, for women who experience vaginal dryness, silicone-based or

water-based lubricants may be recommended. The use of vaginal dilators a few times per week, and even in combination with Kegel exercises, help stretch the vaginal tissue after radiation. As a general recommendation, vaginal dilation should start as soon as the woman is comfortable, but usually within 4 weeks after completion of radiotherapy.²²⁸ Of note, research has suggested that psychoeducational interventions that combine information with motivational and behavioral skills are more effective than information alone in improving adherence to the use of vaginal dilators in younger women treated for gynecologic cancer.²²⁹ Moreover, psychoeducation may be particularly useful at decreasing some of the distress associated with sexual changes following gynecologic cancer treatment.²³⁰ For women who experience vaginismus after radiation therapy, a combined approach of pharmacotherapy and sex therapy should be recommended.²²⁸ In addition, information should be given to patients on techniques to restore the blood flow to the clitoris and the vagina.²³¹ It is important to also consider that sexuality is more than the ability to complete sexual intercourse. For survivors who feel unable to have intercourse, either due to physical or psychological factors, counseling may facilitate the exploration and broadening of sexual and intimate interactions that feel comfortable to the survivors and their partners.

BRCA Mutation Carriers

Related to the sexual problems that both breast and gynecologic cancer patients face, women with a *BRCA1* or *BRCA2* mutation represent a vulnerable population that has received very little attention regarding sexual dysfunction. The hereditary cancer genes, *BRCA1* and *BRCA2*, confer a remarkably high lifetime risk of both breast (55% to 85%) and/or ovarian cancer (15% to 44%).²³² A prophylactic bilateral mastectomy (PBM) has been shown to reduce the risk of breast cancer in mutation carriers by over 90%,²³³ and a prophylactic bilateral salpingo-oophorectomy (BSO) significantly reduces both ovarian cancer risk over 80% and the risk of breast cancer by at least 50%.²³⁴ Although BSO and PBM are the most effective options to reduce cancer risk in *BRCA* carriers, their impact on sexual functioning should not be underestimated. It is recommended that female *BRCA1* carriers have their ovaries and fallopian tubes removed prophylactically by age 35 to 40 years, whereas *BRCA2* carriers may be able to defer this surgery until their mid 40s because the average time for developing ovarian cancer in *BRCA2* carriers is somewhat later. However, for both groups, recommendations for BSO is long before the average age of natural menopause, meaning that these women will face an abrupt, surgically induced onset of menopause with all of the related sexual side effects such as vaginal dryness and irritation, pain with penetration, decreased arousal, and loss of desire. Like breast cancer patients who undergo breast surgery, mutation carriers who opt for PBM will face similar issues regarding surgical scars, loss of sensation, and changes in perceived self-image secondary to potentially significant body changes. However, unlike other cancer patients, often, *BRCA* carriers identify their genetic mutation in a context in which they themselves do not have cancer, and may have to wrestle with the decisions about surveillance versus risk-reducing surgery with moderate to little support and a paucity of adequate counseling and guidance, including regarding management of sexual side effects of surgery.²³⁵

Regarding intervention, *BRCA* carriers should receive the same information and education regarding the management of premature menopause as is given to other cancer patients, including recommendations for managing vaginal dryness using vaginal moisturizers and water-based lubricants. In contrast to women who have already had breast cancer, it has been shown that short-term hormone replacement therapy does not appear to negate the risk-reduction benefit gained by prophylactic surgery,²³⁶ thus making systemic hormone replacement as well as localized vaginal estrogen both reasonable options to be explored (Table 148.2).

TABLE 148.2

Medications For Sexual Problems (Women)

Medication	Purpose	Notes	References
Nonestrogenic vaginal moisturizer	Vaginal atrophy	Can decrease symptoms of vaginal dryness and dyspareunia. For some women, vaginal moisturizer use alone is insufficient because its impact on vaginal tissue health is limited.	228, 290, 291
Local estrogen replacement (intravaginal)	Vaginal atrophy/ urogenital atrophy	Estrogen replacement is contraindicated for some female cancer survivors. Use of local estrogen replacement therapy may be contraindicated for patients receiving aromatase inhibitors because of increased systemic estradiol levels. Various systems of delivery; use of creams can be messy.	292–294
Intravaginal DHEA	Vaginal atrophy, arousal, orgasm	DHEA is an androgen, but the specific mechanism of action on its role in sexual function has not been clarified. Only intravaginal, and not oral, DHEA has been shown to improve sexual function.	196, 295–297
Ospemifene (Selective estrogen receptor modulator)	Vaginal atrophy/ dyspareunia	FDA approved. Acts as an estrogen agonist in the endometrium. Preliminary research findings. No safety data for cancer patients.	298–300
Testosterone replacement therapy	Libido	Can be effective in improving libido, although many other bio–psycho–social factors contribute to libido that are not addressed by this therapy (e.g., relationship function, physical health comorbidities).	210, 301

DHEA, dehydroepiandrosterone; FDA, U.S. Food and Drug Administration.

CANCER IN CHILDREN AND YOUNG ADULTS

Cancer during childhood and adolescence can have a tremendous impact on the patient's psychosexual development.²³⁷ Treatment puts these young patients at risk for significant sexual dysfunction and infertility,^{238–242} as well as impairing their normal social development, which can result in increased isolation, more limited sexual behavior (e.g., less frequent masturbation, communication with friends about sex), longer delays before dating, and decreased interest in and satisfaction with sex.^{243–246} In light of these potential challenges in their psychosexual maturation, about one-third of survivors report at least one distressing long-term sexual problem, with females more likely to report sexual dysfunction.²⁴⁷ Problems with sexual function are associated with poorer psychological and quality of life.^{247,248}

Adolescent and young adult cancer survivors do not receive adequate age-appropriate information and counseling regarding issues related to their sexual development.^{246,249–251} Limited intervention research has demonstrated that a psychosocial intervention can help to improve sexual knowledge and body image and can decrease anxiety related to sexual issues.²⁵² Furthermore, survivors report limited (and, often, inaccurate) knowledge about fertility issues following treatment,^{253,254} which is concerning because the majority of patients who are childless at diagnosis report a desire for future offspring.²⁵⁵ For both genders, there are medical options for fertility preservation that should be discussed with the patient as soon as is feasible.²⁵⁶

RELEVANT SOCIOCULTURAL CONSIDERATIONS

It is now well documented that specific racial and ethnic groups in the United States have a higher risk for developing certain cancer diagnoses that directly affect sexual organs. For instance, African American men have a higher risk of developing prostate cancer compared to Caucasians,²⁵⁷ and Latinas have twice the risk

of developing cervical cancer compared to non-Hispanic Caucasians.²⁵⁸ But beyond gaining knowledge on the cancer facts and figures for different racial and ethnic groups, becoming aware of the impact that culture has on the development of sexual beliefs, attitudes, and practices may be one of the best tools for providers when understanding and helping cancer patients of diverse backgrounds who are coping with sexual dysfunction.

Guidelines for what constitute normative sexual behaviors and gender-specific role prescriptions are greatly influenced by consensus within particular communities,²⁵⁹ and it has been found that certain prescribed gender roles can intensify sexual problems.²⁶⁰ The following are some of the differences that have been observed in sexual attitudes and quality of life in cancer patients and survivors of diverse ethnicities and their implications for medical practice.

Special Considerations for Male Patients

Recent findings on issues related to sexual functioning for African American prostate cancer patients report results that are worth noting. Although having erectile dysfunction is likely to lead to psychological consequences for men across races and cultures, it has been found that African American men are significantly more likely than Caucasian men to consider sexual side effects when choosing treatment for prostate cancer.²⁶¹ In the same study by Jenkins et al.,²⁶¹ African American men were more likely than their Caucasian counterparts to indicate that an erection is an essential element to sex and to seek help for sexual problems. According to Johnson et al.,²⁶² African American men, in spite of showing better recovery of sexual function at 12 and 60 months after diagnosis and treatment with prostatectomy, were more likely than non-Hispanic Caucasians to report that sexual function continued to be a moderate to big problem. Knowledge of these reported differences, and specific factors such as the fact that African American prostate cancer patients seem likely to have positive attitudes about seeking treatment for an erectile problem, may assist providers in framing a culturally sensitive discussion with prostate cancer patients of African American origin with regard to their options for treatment and management of sexual side effects.

Special Considerations for Female Patients

A few studies document special considerations for minority, female cancer patients, and survivors with regard to their sexual functioning. For African American breast cancer survivors, particular concerns about body image are reported, such as keloid formation and total body hair loss,²⁶⁵ and body image concerns in general appear to be greater for African American than for Caucasian women.²⁶⁴ Although findings suggest that African American breast cancer survivors view their sex lives as less disrupted by cancer compared to their Caucasian counterparts,²⁶⁵ feeling sexually attractive has been found to be predictive of subsequent psychological well-being for this population.²⁶⁶ Similar to breast cancer survivors of other ethnicities, African American breast cancer survivors report a need to receive more information from their health-care providers regarding sexual dysfunction as a possible side effect of treatment.²⁶³ However, research suggests that African American women may prefer to address their sexual health concerns in a one-to-one context rather than in group settings.^{263,266} Moreover, a randomized trial of peer counseling in African American breast cancer survivors documented that brief psychoeducational interventions can be effective at addressing informational needs on sexual health for this population.²⁶⁷

For Latino, Asian, and Native American women, the literature on sexual outcomes in cancer treatment and appropriate interventions for treatment-related sexual dysfunction continues to be limited. However, Asian and Latina cervical cancer survivors have reported great concern with the effects of treatment on their appearance, with Latinas expressing more negative feelings about the impact of treatment on their bodies and their relationships compared to Asian, African American, and Caucasian survivors.²⁶⁸ Moreover, cultural factors such as the language barrier for Latinas,²⁶⁸ and the perception of sex as taboo for women from many Asian societies²⁶⁹ ought to be considered as prevalent impediments in accessing services and to address treatment-related sexual dysfunction. In spite of these challenges, however, the available research findings suggest that psychoeducational interventions may be appropriate for Latinas,²⁷⁰ and factual information on sexuality after cancer, preferably delivered by nurses or doctors, is often sufficient and acceptable to Asian and African American women cancer survivors as a way to address their concerns.^{263,271}

DISRUPTION OF INTIMACY AND RELATIONAL CONSIDERATIONS

In addition to the myriad of physiologic changes that can disrupt sexual function after cancer diagnosis, it is important to acknowledge the significant interpersonal shifts that may take place and subsequently affect sexuality. For instance, women's perceptions of their partner's reactions to their appearance after cancer consistently predict their own acceptance of their self-image and of their sense of femininity.²⁷² Moreover, women often do not feel comfortable voicing this aspect of their cancer experience with their partners out of a fear of rejection, and partners are afraid to broach the subject out of fear of causing distress.²⁷³ Similarly, male patients tend to avoid conversations with their wives about their sexual challenges that result from cancer treatment²⁷⁴ and speculate how their wives feel about their sexual functioning.²⁷⁵

This interpersonal silence can quickly become the *elephant in the room* and, over time, disruptions in intimate functioning can become more difficult to address, with either one or both partners misperceiving each other's feelings and intentions. Consistent with this understanding, levels of relationship distress and emotional well-being have been found to be more related to variables such as arousal, orgasm, and sexual satisfaction than hormonal levels in women.²⁷⁶ From a provider perspective, what seems most relevant is that providers are particularly well-positioned to assist

couples in communicating more openly about their fears and to answer questions regarding sexual dysfunction, by providing them with available resources on social support and information on cancer treatments that affect sexuality.²⁷⁷ Research shows that psychoeducational group interventions targeting communication training and sex therapy show promise in improving women breast cancer survivors' relationships and sexual functioning even without including a partner in the intervention.²⁷⁸ Moreover, Manne and Badr²⁷⁹ have proposed an integrative theoretical framework for understanding and addressing the challenges that couples face during and after cancer. By focusing on relationship processes that contribute to intimacy, this framework can help providers facilitate a discussion of the illness as something that happens to the relationship, rather than to individual partners.

Communication about Sexual Problems

Although the optimal time to initiate discussion about sexual concerns may vary, it is essential that clinicians prepare patients for potential changes that may be encountered and to let them know that they welcome discussions about sexual health concerns. This allows patients to prepare for managing side effects and potentially may help patients make better informed decisions about treatment options. It is our belief that clinicians should learn to address this topic as though they would any other topic. Along with setting expectations, practical information should be provided, and this information can be offered at multiple time points across the continuum of cancer care.

Asking about Sexual Problems

One straightforward model that has been proposed is the BETTER Model,²⁸⁰ which stands for: (1) **B**ring up the topic; (2) **E**xplain that you are concerned with quality of life, including sexual health; (3) **T**ell patients that you will help find appropriate resources as needed; (4) **T**iming needs to be taken into consideration, including letting patients know that they can ask for information at any time point; (5) **E**ducate patients about expected sexual side effects; and (6) **R**ecord your assessment in the patient's medical record. Specific language that clinicians can use to "bring up the topic" includes phrases such as: "How has your treatment affected your sexual health?" or "Tell me how your sexual function has been since you started treatment." Although clinicians often worry that patients will be offended or embarrassed if asked about sexual health, multiple studies clearly indicate that patients want to talk about this topic with their doctors and that they desire more information about possible sexual side effects of treatment. Furthermore, patients will rarely initiate conversation on this topic for fear of embarrassing their doctor and also out of concern that their symptoms are not treatable. For a majority of patients, it is invaluable to receive a brief, yet clear message that serves to normalize their symptoms and reassure them that they are not alone and that resources are available.

Use of Validated Assessment Tools

The overwhelming majority of cancer patients do not receive any kind of standardized screening for sexual dysfunction. One method of gaining information and assessing how patients are doing relative to others is to use a brief screening inventory in one's oncology practice. Recently, Jeffery and colleagues²⁸¹ published a large-scale review article of sexual function measures to be used with cancer patients. The large majority of published articles relevant to measurements were focused on prostate cancer (76%), followed by breast (9%) and then gynecologic cancer (7%). Upon review, the authors identified three measures that, after undergoing extensive psychometric testing including trial administration in a clinical oncology setting, were deemed psychometrically valid for broad use. These measures are the University of California, Los Angeles Prostate Cancer Index/Expanded

Prostate Cancer Index Composite (UCLA PCI/EPIC),²⁸² the International Index of Erectile Function (IIEF),²⁸³ and the Female Sexual Function Index (FSFI).²⁸⁴ The 20-item UCLA PCI is a measure of quality of life after prostate cancer and the IIEF is a measure specifically of sexual function after prostate cancer. Both are available at no cost, and the IIEF is self-administered in 5 to 10 minutes and may be easiest to use in a clinic setting. The 19-item FSFI is a general measure of sexual functioning for women, and it was the only measure for women that met the authors' criteria for being a "standard-setting" instrument. The FSFI is also readily available free of charge and takes less than 15 minutes to complete. This measure has been used with a broad range of female cancer patients, including breast, gynecologic, urologic, and rectal cancers.

Intervention

For the majority of cancer patients, a moderate amount of information and education, such as getting information about personal lubricants and vaginal moisturizers, is often adequate to address their needs. For others, more intensive consultation and/or referral may be necessary. For example, oncology practices often have educational *tip sheets* about managing fatigue, diet, and emotional changes that

offer some basic information and usually give additional resource information; it is reasonable to add sexual health to such a roster.

For some patients, it may be valuable and/or necessary to make a referral for more intensive therapy. Additional intervention may include counseling with a licensed therapist who specializes in sex therapy and/or couples counseling. Other relevant referrals may be for urology, gynecology, endocrinology, psychiatry, and physical therapy, including pelvic physical therapy in particular. Collaborative relationships should be developed across disciplines and within the community so that when a problem is identified, established resources are available. Often, it can be useful within an oncology practice to identify one clinician—either a physician, nurse, social worker or psychologist—who can serve as the primary resource person for sexual health issues and who can be responsible for updating available resources and maintaining relevant contacts with community referral sources. It is important to note that several professional organizations, such as the American Psychosocial Oncology Society (APOS, www.apos-society.org), the Society for Sex Therapy and Research (SSTAR, www.sstarnet.org), and the American Association of Sexual Educators, Counselors and Therapists (AASECT, www.aasect.org), all have directories and resources for locating professionals who specialize in working with sexual dysfunction.

INTRODUCTION

Coping, distress, and support are crucial psychological issues that every cancer patient faces with his or her health-care team. The diagnosis of cancer is a life-altering experience for anyone. The nature of the patient's response to it will affect mood, adherence to treatment, and the quality of his or her social support. Effective coping with the disease involves dealing with its direct and indirect effects, ranging from managing the details of medical appointments to handling existential dread. Facing the illness and its consequences requires acknowledging and managing strong but inevitable emotions that can interfere with medical care,¹ family and vocational engagement, sleep, diet, and exercise.²

A wide range and prevalence of psychiatric and psychological problems affect patients and families before, during, and after cancer care and treatment. Recent studies in adults treated in outpatient cancer clinics demonstrate a 40% to 50% clinically relevant level of distress.^{3,4} Some have even called for screening for distress to be the *sixth vital sign*, especially in certain patient groups, such as those with head and neck and neurologic cancers.⁵

In addition, there are also physical symptoms of the cancer and its treatments that overlap with the somatic symptoms that are included in many psychiatric conditions. For example, it is often very difficult for even skilled clinicians to determine the extent to which fatigue, decreased appetite, or sleep problems are related to depression or anxiety versus certain types of cancer and targeted therapies and their side effects. It is thus easy to misattribute the symptoms of a mood disorder to the cancer itself and fail to notice important opportunities for treatment. Despite the complexity involved in coping with serious medical and psychiatric problems, there are some guiding principles for understanding patient dynamics and potential psychological issues.

COMMON PSYCHIATRIC CONDITIONS

Although there are many psychiatric conditions that occur in patients with cancer, the more commonly diagnosed are depression, anxiety (panic, post-traumatic stress disorder [PTSD], phobias), adjustment disorders, and delirium.

Although many would like to maintain a positive view of the diagnosis and treatment for cancer, it still is for many a trauma analogous to experiencing an assault, accident, or natural disaster. Patients can often remember the date and time they received their cancer diagnosis. They can remember exactly where it was discussed, who said it, the specific words that were used, and how they felt. These are life-altering, life-changing moments that are, psychologically, often transformative. In the initial stages of diagnosis and early treatment, the use of the term *acute stress disorder* (ASD) or *post-traumatic stress disorder* (PTSD) may best encapsulate the psychological problems that occur. In one study of breast cancer patients after treatment, 5% to 10% met diagnostic criteria for PTSD,⁶ and there was little change in their status over the ensuing year.⁷ Often, patients experience disbelief, inability to sleep, fears, and intrusive thinking. Lives

and schedules change from the mundane routine of going to work or school, to being in a whirlwind of doctors' appointments, receiving news and data in technical language, making appointments for surgery, blood draws, chemotherapy, and radiotherapy.

As patients move through the various stages of cancer care, so too does the trauma response—from acute stress to a more chronic PTSD.^{8–10} The adjustment to the trauma can also become chronic. Even the cessation of acute treatment can be fraught with anxiety about recurrence. At the same time, many patients and their families also experience what has been called post-traumatic growth, an altered perspective on what matters in life that comes from facing and dealing with major life stressors.¹¹ This ability to come to terms with trauma and enhancing domains that include relating to others, appreciation of life, and spiritual change occurs in a substantial proportion of cancer patients^{12,13} and, in some cases, predicts better long-term adjustment.¹⁴

Often, patients have mixed states or combinations of symptoms, such as depression and anxiety. Furthermore, there are symptoms that often are not diagnosed but are quite difficult for patients to manage, such as difficulties with falling asleep and staying asleep and problems adhering to complex and lengthy medication regimens. This is especially difficult when patients have cognitive changes related to the underlying cancer (as in brain tumors) or to the chemotherapeutic agents (cisplatin, steroids). Some of these regimens alter the efficiency with which the brain processes information storage and retrieval.¹⁵

SCREENING FOR PSYCHOLOGICAL PROBLEMS

As part of good, routine clinical care, it is important to obtain a working diagnosis and treatment plan for each patient regarding psychiatric problems. There are numerous screening tools that are available for clinical as well as research purposes.^{16–18} A regular, ongoing evaluation of emotional distress affects management and treatment of psychiatric issues and contributes to better patient outcome, satisfaction, doctor–patient communication, and improved overall oncologic care.¹⁹ Approximately one-third of patients in outpatient oncology clinics experience significant levels of distress, with greater degrees of distress in patients who have tumors with poorer prognosis and outcomes.²⁰ This means that any screening tool must include a routine, systematized method for busy clinicians to review the measures and provide clinical assessment, treatment, and referral as appropriate. The patient data should be included in the medical record and should provide sufficient diagnostic information to guide mental health care. The diagnostic criteria in the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM-5) provide the essential definitions of specific mental disorders utilized in practice.²¹

In 1997, the National Comprehensive Cancer Network published the Distress Management Guidelines as a tool for oncology clinicians to develop a differential diagnosis of distress, including common psychiatric disorders and psychosocial and spiritual problems. The panel addressed the issue of the difficulty of psychiatric

symptoms that overlap with underlying oncologic disease and treatments and noted that using the term *distress* was a good starting point for clinicians, patients, and families to talk about problems. Using an algorithmic approach, clinicians are guided by the presenting symptoms, possible interventions, evaluation, and treatment options. As a self-report method of measuring and screening for distress, patients are asked to mark their level of distress on a visual analog tool, called the distress thermometer. Along with the distress thermometer is a problem list the patient uses to indicate possible causes of distress such as practical, emotional, family, spiritual, or physical. Using a cutoff of 4 or 5 out of a possible score of 10 provides an indication of distress and has been validated against other screening tools for psychological distress.⁴ Psychosocial screening provides an opportunity to determine baseline distress and then prospectively evaluate response to psychosocial treatments.²²

COPING

Cancer patients and their families are confronted with new situations arising from the illness itself or from the demands of the treatment (Table 149.1). Moos and Schaeffer²³ summarize these challenges as the need to preserve a reasonable emotional balance, maintain a sense of competence and mastery, sustain relationships with family and friends, and prepare for an uncertain future. Cancer patients benefit from help in improving their coping skills or in learning new and more adaptive ones. Previous coping strategies may no longer be appropriate to the new situation. Social support directed at the expression of emotion helps cancer patients to maintain realistic optimism and mitigate distress.²⁴⁻²⁸ The adaptive tasks that are necessary in order to adjust to the illness involve several different kinds of coping skills: the evaluation of novel information, decision making, learning to express emotions, mobilizing social support, and increasing role flexibility. Adaptive coping has been divided into three types: information focused, emotion focused, and problem focused.^{29,30} Problem-focused coping skills are important to help the cancer patient live with the illness and manage its treatment. However, emotional adjustment to the illness is also essential. Some studies have shown that avoidant strategies may be less adaptive in the long run than task-oriented and approach strategies,³¹ although in the context of medical illness, coping is situation specific.^{30,32,35} A broad coping-skills repertoire, consisting of both problem- and emotion-focused strategies, increases the probability of matching the response to the particular demands of a given stressful medical situation (Table 149.2).

TREATMENT INTERVENTIONS

Psychosocial

The appropriate treatment for psychological symptoms associated with cancer can be determined by clarifying the nature of emotional distress (anxiety, depression, psychosis), the use of pharmacotherapy to relieve acute and chronic symptoms, and the selection of appropriate psychosocial interventions for treating problems related to anxiety, depression, existential concerns, somatic symptoms, and social or communication problems.³²⁻³⁴

TABLE 149.1

Principles of Adaptive Coping with Cancer

Stressors are best handled by:

- Facing rather than fleeing
- Altering perception
- Coping actively
- Expressing emotion
- Social support

TABLE 149.2

Stage-Specific Coping Challenges and Medical Responses

Stage of Cancer	Coping Challenge	Physician Response
Initial diagnosis	Existential anxiety	Rapid and clear evaluation
Acute treatment	Helplessness	Invite participation in treatment decisions
	Fatigue/disruption of social roles	Invite involvement of family/friends
End of acute treatment	Increased sense of vulnerability/anxiety about relapse and long-term treatment effects	Treatment summary and long-term follow-up plan
	Medical isolation	Survivorship program
Relapse	Anxiety about disease progression/treatment effects	Clear communication
	Truncated future	Compassion
	Loss of social contacts	Commitment to providing care Reordering priorities Group and other support

The efficacy of psychosocial treatments for depression and anxiety in medically ill patients, particularly brief psychodynamic, educational, supportive, and interpersonal therapies, hypnosis, and behavioral and cognitive-behavioral methods, has been supported by numerous outcome studies.³⁵⁻³⁹

Psychoeducational Interventions

Principles of Psychoeducational Intervention

Medical knowledge enhances the sense of control and mastery a person has over his or her disease, and educational interventions generally yield positive outcomes. Interventions for medical patients are usually more effective when they provide patients with cues for using the knowledge related to their disease and daily management²⁹ or with some emotion-focused components, which helps them to adjust and live through the different phases of the illness. Anticipatory guidance is an important component of these interventions, helping patients to prepare to respond to future as well as current disease-related problems. The evaluation of outcomes of psychoeducational interventions indicates consistent if modest improvement.^{38,40-46}

Coping Skills Training

Education-based group interventions that provide informational support can facilitate the initial adjustment of early stage breast cancer patients by improving self-esteem, body image, and perceived control and by reducing uncertainty about the illness.^{47,48} Women who lack personal resources and support benefit the most. Many of these approaches have demonstrated benefit in controlled trials. One cognitive-behavioral stress management group program proposed a multimodal type of intervention combining 20 therapy hours of relaxation training, coping skills training, cognitive restructuring, assertiveness and anger management training, and social support for women with breast cancer. Patients improved in self-reports of benefits from cancer, but no improvement on the distress measures was found.⁴⁹ In this study, the greatest changes in positive benefits were reported by women who were low in optimism. An eight-session educational intervention, providing

training in stress management, problem solving, goal setting, and assertiveness, produced improvements in general quality of life, as well as specific competence in managing emotional, financial, and legal problems.⁵⁰ A five-session family intervention for women with recurrent breast cancer, designed to improve communication, enhance information seeking, improve coping, and manage symptoms, did not affect overall quality of life but did reduce negative appraisal of the cancer and reduced hopelessness.⁵¹ A multidimensional cancer rehabilitation program produced improvements in physical functioning and reductions in distress.⁵² A more existentially oriented approach emphasized finding ways to develop a sense of meaning and has been shown to enhance self-efficacy, optimism, and self-esteem among breast and colorectal cancer patients.⁵³ It is quite clear that facing the existential threat posed by cancer in a supportive way improves coping and reduces distress rather than demoralizing cancer patients.^{54,55-56}

Mindfulness Training

Mindfulness-based stress reduction is an adaptation of Zen Buddhist meditation techniques taught in weekly courses. The focus is on enhancing the ability to live in the moment and to tolerate stresses as real but transient phenomena, while more comfortably relating to one's body, and often employing gentle yoga exercises as well.⁵⁷ Such techniques have been used to good effect with cancer patients. A meta-analysis of 10 studies documented a significant (moderate effect size; $d = 0.48$) overall improvement in quality of life and possible benefit for various aspects of physical health.⁵⁸ A 7-week group training for patients with a variety of cancers resulted in significantly reduced distress.⁵⁹ Other studies have shown that a combination of such techniques with more traditional group therapy produced reductions in intrusive thinking and other post-traumatic stress symptoms⁶⁰ as well as reduced depression and fear of recurrence and produced higher energy levels⁶¹ among women with breast cancer. A recent study of mindfulness for primary breast cancer patients demonstrated greater reductions in stress symptoms than in an intervention involving emotional expression or a control group, and that both treatment conditions resulted in normalization of diurnal cortisol levels.⁶² Similar mindfulness interventions have also been shown to result in lower mean cortisol, reduced Th1 (proinflammatory) cytokines, and lower systolic blood pressure,⁶² as well as improved natural killer cell cytotoxicity.⁶³

Electronic Technology-Based Interventions

Technology-assisted interventions have proven highly effective. A peer-modeling videotape shown to patients shortly after diagnosis produced increases in vitality and post-traumatic growth and decreases in depression and intrusive thoughts.⁶⁴ A combined home visiting and telephone intervention resulted in reduced pain.⁶⁵ Computer-based patient support tools provided information, decision support, and interaction with other patients and produced not only increments in knowledge, but also better patient-doctor interactions and enhanced social support.⁶⁶ Support groups have been adapted to the Internet with remarkably good effect. Online-mediated social support for cancer-related fatigue have proven very beneficial as well.⁶⁷ Real-time leader-conducted groups for breast cancer patients have produced significant reductions in depression and pain.⁶⁸

Excellent Internet resources for information about various types of cancer and their treatments, as well as supportive services, are now available. These include the National Cancer Institute's Web site, its database of cancer treatments, and its associated phone information line. Web sites with authoritative information about supportive care services include those sponsored by the American Cancer Society. The Wellness Community Web site is maintained by the Cancer Support Community, a collaboration of the Wellness Community and Gilda's Clubs, which maintain a network of facilities that provide free community supportive services, including classes and support groups. Another excellent example is the Breast Cancer Connections Web site.

Cognitive-Behavioral Therapy

The cognitive-behavioral approach⁶⁹ is built on the assumption that previous social learning, developmental history, and significant experiences lead people to form a unique set of meanings and assumptions, or cognitive schemas, about themselves, the world, and their future. These schemas are then used to organize perception and to govern and evaluate behavior.⁷⁰ When specific schemas are activated, they directly influence the content of a person's perceptions, interpretations, associations, and memories from a given time. Cognitive-behavioral therapy (CBT) was developed as a short-term (12 to 20 sessions) intervention for depression, targeting patients' thoughts and their relation to behavior and their affect. CBT for cancer patients generally features a multicomponent intervention integrating coping skills training, stress management, and an intervention designed to enhance cognitive and behavioral processes that will be useful in adjusting to illness.³⁶ The CBT therapist seeks to identify maladaptive cognitions, turn them into testable hypotheses, and submit them to empirical investigation, so the patient can then reject, modify, or retain these thoughts based on the evidence. Alternatively, more adaptive cognitions and behaviors are similarly examined and tested. In the early sessions, the goal of CBT is to establish a therapeutic relationship, identify primary problems, produce symptom relief, and educate the patient about the process of psychotherapy, CBT, and the role of thoughts, images, and beliefs on emotions and behavior. Together, the therapist and patient decide on the treatment goal, a plan for subsequent therapy sessions, and homework assignments intended to augment the therapy and direct structured practice. The initial homework might require the patient to identify and record maladaptive cognitions (e.g., automatic thoughts). As therapy progresses, verbal techniques are employed to trigger automatic thoughts and associated assumptions and reveal core beliefs or schemas. In an environment of collaborative empiricism, the patient learns to identify, logically and empirically evaluate, and justify the usefulness of systematic biases, cognitive distortions and dysfunctional assumptions, and thoughts, images, and beliefs that underlie emotional distress. The therapist helps the patient challenge cognitive distortions such as overgeneralization, catastrophizing, "should" statements, magnification, minimization, dichotomous thinking, and the fallacies of control, worry, fairness, and attachment. Cognitive restructuring techniques and guided discovery help the patient choose more adaptive cognitions and behaviors. Cognitive techniques used in CBT include thought stopping, self-instruction, distraction, direct disputation, labeling distortions, and development of replacement imagery. Behavioral techniques such as activity scheduling, relaxation training, social skills training, mastery and pleasure ratings, assertiveness training, bibliotherapy, homework, behavioral rehearsal, and in vivo exposure are also employed.

The efficacy of CBT as a treatment for depression is well established.⁷¹ A review of empirically supported treatments for psychosomatic disorders determined that CBT is efficacious for chronic pain management and some cancers.³⁶

Group Psychotherapy

Group intervention in a variety of forms has become an increasingly popular, effective, and efficient means of providing psychosocial support for cancer patients.^{72,73} Groups of different types may encompass theoretical approaches that include the psychodynamic, existential, educational, and cognitive-behavioral, among others.⁷² Although some cancer patients are disinclined to join a support group, most are initially reluctant to undertake other aspects of cancer treatment as well. Factors associated with reluctance include less favorable views of such groups, feeling less control over their cancer, using less active coping styles, and having less distress.^{74,75} Although men may initially be more reluctant than women to openly discuss emotional problems relating to cancer, cognitive aspects of coping can be a good starting point, and men with prostate cancer report information sharing with other patients as a helpful aspect of group experience. Although reactions to catastrophic illness may differ for individuals with preexisting psychopathology,

most cancer patients share with their emotionally healthy counterparts the need for support in dealing with diagnosis and treatment, changes wrought by disease, social isolation, and existential issues.

Common elements of group psychotherapeutic intervention include the following:⁷³

1. *Social support.* Psychotherapy, especially in groups, can provide a new social network with the common bond of facing similar problems. At a time when the illness makes a person feel removed from the flow of life and when many others withdraw out of awkwardness or fear, group psychotherapeutic support provides a new and important social connection. Indeed, the very thing that damages other social relationships is the ticket of admission to such groups, providing a surprising intensity of caring among members from the very beginning. Furthermore, members find that the process of giving help to others enhances their own sense of mastery of the role of *patient* and increases their self-esteem, imbuing the experience of illness with a new meaning.
2. *Emotional expression.* The expression of emotion is important in reducing social isolation and improving coping. Yet patients often believe that they are controlling the psychological and even physical impact of the disease by suppressing their emotional reaction to it. This attitude is often reinforced by friends and family who are made anxious by a display of appropriate fear or sadness in the patient, and by medical professionals as well, who perceive a patient's sadness as an indication of nihilism about treatment or loss of hope. Persistent negative affect, as is seen in depression, often elicits anger in those involved with the patient, because the patient seems unwilling rather than unable to modulate his or her feelings. However, normal anxiety and sadness related to having cancer is phasic and is better managed through expression and discussion. Indeed, there is evidence that emotional expression actually facilitates the resolution of long-term negative emotion.^{25,54} Encouragement of emotional expression can enhance intimacy in families, providing opportunities for direct expression of affection and concern. The use of the psychotherapeutic setting to deal with painful affect also provides an organizing context for handling its intrusion. When unbidden thoughts involving fears of dying and death intrude, they can be better managed by patients who know that there is a time and a place during which such feelings will be expressed, acknowledged, and dealt with. Furthermore, disease-related dysphoria is more intense when amplified by isolation, leaving the patient to feel that he or she is deservedly alone with the sense of anxiety, loss, and fear that he or she experiences. Being in a group where many others express similar distress normalizes their reactions, making them feel less alien and overwhelming.
3. *Detoxifying dying.* Processing existential concerns by facing rather than avoiding issues such as dying and death, which could be considered likely to exacerbate depression, actually helps to reduce it. This approach encourages patients to face what they most fear and find some aspect of it they can do something about (e.g., control the process of dying when death is unavoidable). This helps patients to feel more active and less helpless, even in the face of dying. Others have combined principles of cognitive therapy with a focus on existential concerns,⁷³ finding it an effective approach to reduce symptoms of distress. Death anxiety, in particular, is intensified by isolation, in part because patients often conceptualize death in terms of separation from loved ones. This can be powerfully addressed by psychotherapeutic techniques that directly confront such concerns in a supportive social setting. Yalom⁷⁶ has described the ultimate existential concerns as death, freedom, isolation, and meaninglessness. Rather than avoiding painful or anxiety-provoking topics in attempts to "stay positive," this form of group therapy addresses these concerns head-on with the intent of helping group members make better use of the time they have left. The goal is to help those facing the threat of death to see it from a new point of view. Facing even life-threatening issues can directly help patients shift from emotion-focused to problem-focused coping.^{29,30,77}
4. *Reorganizing life priorities and living in the present.* The acceptance of the possibility of illness shortening life carries with it an opportunity for reevaluating life's priorities. Facing the threat of death in a way that facilitates a sense of active coping can aid in making the most of what remains in life.⁷⁸ This can help patients take control of those aspects of their lives they can influence, while grieving and relinquishing those they cannot. Progress in life goal reappraisal, reorganization of priorities, and perception of benefits may also mediate improvement in symptoms and enhance quality of life.⁷⁹
5. *Enhancing family support.* Psychotherapeutic interventions can also be quite helpful in improving communication, identifying needs, increasing role flexibility, and adjusting to new medical social, vocational, and financial realities.⁸⁰ The group format is especially helpful for such a task, in that problems expressing needs and wishes can be examined among group members as a model for clarifying communication in the family.
6. *Improving communication with physicians.* Support groups can be quite useful in facilitating better communication with physicians and other health-care professionals.^{81,82} Groups provide mutual encouragement to get questions answered, to participate actively in treatment decisions, and to consider alternatives carefully.
7. *Symptom control.* Many group and individual psychotherapy programs teach specific coping skills designed to help patients reduce cancer-related symptoms such as anxiety, anticipatory nausea and vomiting, and pain. Techniques used include specific self-regulation skills such as self-hypnosis, meditation, biofeedback, and progressive muscle relaxation. Hypnosis is widely used for pain and anxiety control in cancer to attenuate the experience of pain and suffering and to allow painful emotional material to be examined.⁸³ Group sessions that involve instruction in self-hypnosis provide an effective means of reducing pain and anxiety and consolidate the major themes of discussion in the group.^{84,85} Hypnosis is an altered state of consciousness, composed of heightened absorption in focal attention, dissociation of peripheral awareness, and enhanced responsiveness to social cues.⁸¹ It has a long tradition of effectiveness in controlling somatic symptoms such as pain and anxiety. Patients with the requisite hypnotic capacity can be taught to utilize self-hypnosis to reduce or eliminate pain and the tension that accompanies it. Hypnotic techniques have been shown to effectively reduce cancer pain^{81,84,85} and to facilitate medical procedures.⁸⁶ Hypnotic intervention actually alters perceptual processing in the brain, with reduced response to painful stimuli as measured by event-related potentials⁸⁷ and positron-emission tomography.⁸⁸

OUTCOME

Clinical trials have demonstrated the benefit of group therapy for breast cancer patients,^{76,89-91} with notable reductions in pain^{84,85} and emotional distress.^{54,92} A systematic review of the literature that included two meta-analyses and nine well-designed randomized controlled trials indicated that psychoeducational interventions not only enhance patient knowledge about their cancer and its treatments, but also reduce depression, anxiety, nausea, and pain.³⁸ A Cochrane database review concluded that group psychotherapy for cancer patients significantly reduces depression, even in the setting of advanced disease.⁹³

IMPLICATIONS FOR CANCER PROGRESSION AND MORTALITY

There are literature that raises the possibility that psychotherapeutic intervention may affect survival time as well as quality of life.⁹⁴⁻⁹⁸ Eight of 15 published randomized trials demonstrate such an effect.⁹⁹ Spiegel et al.⁹⁴ initially reported that a year (minimum) of supportive-expressive group psychotherapy resulted in a significant 18-month increase in survival time in metastatic breast cancer patients. A 6-week cognitive behavioral group intervention composed of education, stress management, coping skills training, and psychological support for malignant melanoma patients found significantly lower death rates at 10-year follow-ups in the treatment group.¹⁰⁰ A study of individual psychotherapeutic support offered at the bedside early in the course of disease to a group of gastrointestinal cancer inpatients also had favorable results on survival,⁹⁷ which has been confirmed at 10-year follow-ups.⁹⁷ A randomized replication trial of supportive-expressive group psychotherapy among 125 women with metastatic breast cancer found positive effects on mood,⁵⁴ but no overall survival advantage,¹⁰¹ although there was a significant interaction with tumor type, such that women with estrogen receptor-negative tumors who had been randomized to the group condition lived significantly longer than estrogen receptor-negative controls. An educational group intervention among 227 women with primary breast cancer demonstrated that those who were randomized to receive group support had significantly lower rates of relapse and mortality at 11-year follow-ups.¹⁰² A randomized trial of a palliative care intervention involving an average of four visits that focused on choices about resuscitation preference, pain control, and quality of life among 151 patients with non-small-cell lung cancer demonstrated a significant reduction of depression and pain, and also a significant 2.7-month improvement in survival time (median survival, 11.85 versus 8.9 months; $p = 0.02$).¹⁰³

However, seven other trials found no effect of psychosocial intervention on survival time.^{55,90,104-108} One large multicenter trial that utilized supportive-expressive group psychotherapy with metastatic breast cancer patients showed reduced distress and pain but no survival advantage.¹⁰⁴ However, the treatment arm in this study was more depressed than the controls at the beginning of the study, which indicated a risk for shorter survival prior to intervention.¹⁰⁹ In another three of these trials, psychotherapy produced no psychological benefit^{90,106,107}; therefore, a survival improvement would be unlikely. Taken together, these studies suggest that psychosocial effects on survival time are most pronounced when medical treatments have become less effective.⁹¹ No study has found that psychotherapy, even involving direct confrontation with dying and death, shortens survival. The potential benefit of psychotherapeutic support on cancer progression remains an open research question, but receives further support from evidence that being married is associated with a 12% to 33% improvement in overall survival.¹¹⁰ This study involved analysis of Surveillance, Epidemiology, and End Results (SEER) data in the United States from 2004 to 2008 involving 734,889 cancer patients with lung, colorectal, breast, pancreatic, prostate, liver/intrahepatic bile duct, non-Hodgkin lymphoma, head/neck, ovarian, or esophageal cancer. Being married was associated with better outcome with each of these cancer types, independent of demographics, stage, and treatment. Thus, social support would seem to have a tangible effect on disease progression and survival time.

PSYCHOTROPIC MEDICATION

Antidepressants

It is becoming increasingly clear that, as is the case with major depression in general, depression that arises in the context of cancer is responsive to antidepressant treatment.¹¹¹ Using various measures

of depression and outcome, studies indicate that paroxetine,¹¹¹ mianserin,¹¹² fluoxetine,¹¹³ amitriptyline,¹¹¹ and desipramine¹¹⁴ are useful in treating depression in patients with cancer (Table 149.3). Antidepressants decrease depressive symptoms, improve functional capacity, reduce cachexia, ameliorate some menopausal symptoms, and reduce pain.¹¹⁵

Fisch et al.¹¹⁶ found that treatment with fluoxetine significantly improved depressive symptoms and some measures of quality of life when compared to placebo in cancer patients with a variety of tumors with an expected survival of 3 to 24 months. Importantly, these patients were recruited based on reporting that they were bothered by a depressed mood at a severity of "somewhat" or greater and not by meeting criteria for full major depression. Another large trial compared paroxetine to placebo in cancer patients with fatigue and found that the antidepressant significantly lowered depressive (but not fatigue) symptom scores.¹¹⁷

In double-blind trials, fluoxetine, paroxetine, and venlafaxine have been shown to reduce hot flashes,¹¹⁸ and mirtazapine and the anticonvulsant gabapentin have been reported to decrease pruritus in cancer patients.¹¹⁹ Venlafaxine, bupropion, and the tricyclic antidepressants have been shown to relieve neuropathic pain, which frequently accompanies cancer and its treatment.¹²⁰ Trazodone, a tetracyclic antidepressant, which in low doses (50 to 150 mg) is often used as a sedative hypnotic that does not produce dependency, has also been used to treat a variety of adjustment disorders among breast cancer patients.¹²¹

Cancer patients treated with cytokines such as interferon- α often become significantly depressed, with a substantial increase in suicidal ideation and acts.¹²² Pretreatment of such patients with selective serotonin reuptake inhibitors (SSRI) actually reduces the risk of developing depression.¹²³ There are increasing data that suggest that depression-specific symptoms may disproportionately contribute to the relationship between depression and morbidity or mortality in the context of medical illness.^{109,124,125}

These findings may also provide an explanation for the oft-repeated observation that agents with catecholaminergic activity are generally more effective than SSRIs in the treatment of neurovegetative and somatic symptoms, such as pain and fatigue, even when these symptoms occur outside the context of a diagnosable mood disorder.¹¹⁷ Combination treatment may also be especially helpful in more severe depressions.¹²⁶ Evidence that proinflammatory cytokines contribute to the development of depression, even in medically healthy individuals,⁹⁹ may explain the utility of combined serotonin-norepinephrine or dopamine treatment, such as adding desipramine or bupropion with an SSRI or using a serotonin-norepinephrine reuptake inhibitor, such as venlafaxine or duloxetine. These approaches may be more effective than selective serotonergic agents alone in the treatment of major depression, especially when comorbid pain is present. Stimulants such as amphetamine, methylphenidate, and modafinil can also be used effectively either alone or in combination with antidepressants, especially to provide more rapid onset. They rarely trigger anorexia in this population,¹²⁷ and they are also agents of choice for cancer patients with short expected survival periods.

Tamoxifen and Selective Serotonin Reuptake Inhibitors

Tamoxifen continues to be used as an important selective estrogen receptor modulator (SERM) to reduce the risk of recurrence in estrogen receptor-positive postmenopausal breast cancer patients. In order to be clinically active, tamoxifen is converted to 4-hydroxy-tamoxifen (endoxifen) and other active metabolites by cytochrome P450 (CYP) enzymes. Over 80 different major alleles of CYP2D6 genes have been identified, many of which confer decreased or absent CYP2D6 activity, and patients can be divided into poor, intermediate, extensive, and ultrarapid metabolizers based on their genotype.¹²⁸

TABLE 149.3

Antidepressants: Selective Serotonin Reuptake Inhibitors and Newer Antidepressants

Generic	Brand Names	Starting Dose	Maximal Suggested Dose (24 h)	Sedating	Forms Available	Comments
Bupropion	Wellbutrin, Zyban	75 mg	300 mg	✓	SR (twice per day); XL	Use <150 mg per dose except XL; fewer sexual side effects; risk of seizures; also for smoking cessation
Citalopram	Celexa	10 mg	40 mg	SolTabs		
Duloxetine	Cymbalta	20 mg	60 mg	✓		Also for neuropathic pain; taper slowly
Escitalopram	Lexapro	5 mg	20 mg			Isomer of citalopram
Fluoxetine	Prozac, Sarafem	5 mg	60 mg			Moderate benefit for hot flashes, premenstrual syndrome
Mirtazapine	Remeron	15 mg	45 mg	✓✓	SolTabs	Very sedating; stimulates appetite
Paroxetine	Paxil	5 mg	40 mg	✓		Also for hot flashes; slow taper
Sertraline	Zoloft	25 mg	200 mg			
Trazodone	Desyrel	50 mg	300 mg	✓		Primarily for insomnia
Venlafaxine	Effexor	25–37.5 mg	375 mg		XR	Also for hot flashes and neuropathic pain; slow taper

SR, sustained release; XL, extended release; XR, sustained release.

Breast cancer patients treated with tamoxifen who were homozygous for a poor metabolizer genotype had significantly lower serum concentrations of endoxifen than those with an active genotype.¹²⁹ In a review of retrospective studies evaluating the effect of *CYP2D6* genotype on breast cancer outcomes, Goetz et al.¹³⁰ found that patients with estrogen receptor–positive breast cancer, homozygous for the poor metabolizer genotype and treated with tamoxifen monotherapy, were more likely to experience a recurrence of breast cancer than those patients who carried the allele coding for active enzyme. Stearns et al.,¹³¹ in a prospective clinical trial, evaluated the effects of the coadministration of tamoxifen and paroxetine, a selective serotonin reuptake inhibitor, at the time, commonly used to treat depression and hot flashes. The authors found that the use of paroxetine, which inhibits *CYP2D6*, decreased the plasma concentration of endoxifen, suggesting that the *CYP2D6* genotype and drug interactions should be considered in patients treated with tamoxifen.

More recently, Kelly et al.,¹³² in a population-based cohort study, studied postmenopausal women aged 66 years or older living in Ontario who had been treated between 1993 and 2005 with tamoxifen for breast cancer and overlapping treatment with a single SSRI, finding that, after adjustment for age, duration of tamoxifen treatment, and other potential confounders, absolute increases of 25%, 50%, and 75% in the proportion of time on tamoxifen with overlapping use of paroxetine were significantly associated with 24%, 54%, and 91% increases in the risk of death from breast cancer, respectively. The authors concluded that paroxetine use during tamoxifen treatment is associated with an increased risk of death from breast cancer, supporting the hypothesis that “paroxetine can reduce or abolish the benefit of tamoxifen in women with breast cancer.”

In addition to paroxetine, sertraline and venlafaxine have also been noted to reduce the metabolism of tamoxifen.¹²⁹ Lash et al.¹³³ found no reduction of tamoxifen effectiveness among patients using citalopram. With the accumulation of studies, Desmarais et al.,¹³⁴ in an important review, provide recommendations that clinicians who are treating patients with breast cancer should carefully evaluate the best and safest options for treatment of depression, reviewing pharmacologic profiles, while being very mindful of the risks of untreated depression. In an interesting study regarding the prevention of depression in patients receiving treatment for head and neck

cancer, Lydiatt et al.¹³⁵ studied the prophylactic use of escitalopram oxalate to determine if the incidence of depression could be reduced in patients receiving primary therapy for head and neck cancer. Results in the nondepressed group showed that prophylactic escitalopram reduced the risk of developing depression by more than 50%. Quality of life was also improved for 3 consecutive months in the nondepressed group after the cessation of escitalopram.

Antianxiety Agents

It is becoming increasingly clear that the antidepressants, as discussed previously, have antianxiety properties as well and can be utilized effectively for the frequent problem of mixed anxiety and depression. Benzodiazepines can provide immediate short-term relief of anxiety symptoms, but generally are not a good strategy for long-term treatment, in part because of the problem of habituation and a tendency to produce dependence. Withdrawal from high doses can be a serious medical problem. Although many of the newer benzodiazepines such as lorazepam are relatively short acting, the problem of symptom recurrence may be addressed in the future with longer acting formulations.¹³⁶ In addition, many of the antianxiety agents are used for insomnia with good effect and, after, are used in the short term for symptom management (Tables 149.4 and 149.5).

Antipsychotics

Neuroleptics are rarely used among cancer patients, but they can be highly effective at managing symptoms of delirium, which can occur during worsening of medical status, with metabolic disequilibrium associated with cachexia, mood disorders, and psychosis associated with steroid treatment and as a preterminal event (Table 149.6). Disorientation to time, place, and person coupled with agitation can be misunderstood as a sign of poor pain management, but increases in opiates and other analgesics, which can be very useful when pain is the problem, may contribute to further delirium. Initially small but increasing doses of antipsychotics such as haloperidol either orally or intravenously can be very helpful in controlling delirium and agitation.¹³⁷

TABLE 149.4

Antidepressants: Tricyclics

Generic	Brand Name	Starting Dose	Maximal Suggested Dose (24 h)	Comments
Amitriptyline	Elavil	10 mg	300 mg	25–50 mg for pain
Desipramine	Norpramin	10 mg	300 mg	
Doxepin	Sinequan	10 mg	150 mg	Very antihistaminic; sedating; also for itching
Imipramine	Tofranil	10 mg	300 mg	
Nortriptyline	Pamelor	10 mg	150 mg	25 mg for pain

Adapted from Holland JC, Greenberg DB, Hughes MK, et al., eds. *Quick Reference for Oncology Clinicians: The Psychiatric and Psychological Dimensions of Cancer Symptom Management*. Charlottesville, VA, US; International Psycho-Oncology Society(IPOS) Press; 2006, with permission.

TABLE 149.5

Hypnotics

Generic	Brand Name	Starting Dose	Maximal Suggested Dose (24 h)	Half-Life Short/Med	Comments
Eszopiclone	Lunesta	1 mg	3 mg	Half-life short	For sleep
Oxazepam	Serax	10 mg	30 mg	Half-life short	For sleep, also for alcohol withdrawal
Temazepam	Restoril	7.5 mg	30 mg	Med	For insomnia
Triazolam	Halcion	0.125 mg	0.5 mg	Half-life short	For insomnia
Zaleplon	Sonata	5 mg	20 mg	Half-life short	For sleep
Zolpidem	Ambien	2.5 mg	10 mg	Half-life short	For sleep, technically nonbenzodiazapine but shares properties (dependence, withdrawal)

Adapted from Holland JC, Greenberg DB, Hughes MK, et al., eds. *Quick Reference for Oncology Clinicians: The Psychiatric and Psychological Dimensions of Cancer Symptom Management*. Charlottesville, VA, US; International Psycho-Oncology Society(IPOS) Press; 2006, with permission.

TABLE 149.6

Antipsychotic Medications: Major Tranquilizers

Generic	Brand Name	Starting Dose	Maximal Dose	Forms Available	Administration Routes	Comments
Chlorpromazine	Thorazine	10 mg	200 mg			Parenteral; postural hypotension; sedation; hiccups
Haloperidol	Haldol	0.25 mg	30 mg	IV, PO	IV, PO	Antiemetic; risk of extrapyramidal side effects; parenteral
Olanzapine	Zyprexa (Zydis)	2.5 mg	20 mg	Wafer, PO		Wafer form (Zydis); weight gain; antiemetic sedation; long-term risk of diabetes; can cause restlessness
Perphenazine	Trilafon	2 mg	32 mg			
Quetiapine	Seroquel	25 mg	500 mg		PO	Antihistamine associated somnolence; 5-hour half-life
Risperidone	Risperdal	0.25 mg	8 mg			Postural hypotension; smaller risk of Parkinson's than typical agents

IV, intravenous; PO, by mouth.

150 Communicating News to the Cancer Patient

Eric J. Cassell

INTRODUCTION

Helene Fink was a 56-year-old woman with stage IV breast cancer. Toward the end of the course of the disease, her bone marrow was filled with tumor cells, with all the usual hematologic sequelae. Her pain was well-controlled and she continued an active life in seeming disregard of her disease. Her oncologist was concerned that Mrs. Fink did not appreciate the gravity of her situation, so she explained to the patient in detail what was happening and how serious it was. The patient stopped her activities and became bedridden. The oncologist explained to me at length that she believed in telling patients the truth and that truth-telling was essential for the patient's well-being, especially in the contemporary scene. She also called the patient's husband to explain the importance of telling the truth. It took considerable effort to get the patient back to her previous level of activity, which continued until shortly before her death 3 months later.

This scenario is quite common. Apparently, the physician's goal in such settings is to make sure the patient knows the truth. The emphasis is on telling the truth. All clinical actions, all actions meant to have an impact on the patient—in oncology, as elsewhere—should have a goal. For example, diagnostic actions have a goal-specific therapy; chemotherapy, radiation, or other modalities have a goal, usually curative, palliative, or local control of disease. The goal of cancer treatment, in general, has long been to improve survival. Recently, this has been modified by the addition of the goal to treat without decreasing quality of life. A general statement of these goals is that they are meant to help the patient.

Patient communication—talking with patients—is a clinical action. Therefore, talking with patients should also have a goal: As with the other clinical acts, it should help the patient be better. In the case of Helene Fink, the communication of her oncologist had a negative impact. Truth-telling is not a primary goal; telling the truth is a moral imperative. With rare exceptions, it is obvious that you should tell the truth. Put another way, your communication with the patient should be truthful, but that should be only one of several functions that that communication serves.

PREVENTING ILLNESS

The goal of increasing length of survival in the treatment of cancer has achieved considerable prominence over the past several decades. Although this is understandable, people do not get up in the morning just to survive; when they do—like soldiers in battle—survival is in the service of living a life. People get up in the morning to live their lives, to work, to play, to take care of their families, to become famous, or to achieve their goals in life, just like you and your family. Perhaps you believe your patients cannot do that because they are too sick. It is true that many patients with advanced disease are sick. By *sick*, the author means requiring care in bed, or, if out of bed, requiring regular skilled care. Most people (including doctors) think patients are sick because of the symptoms or because of their advanced disease. Symptoms are often very unpleasant, but the medical community has become

very good at symptom relief; still, the patients are sick. Ask them, and they will tell you (whatever their other symptoms may be) that they are “weak,” that they have “no energy,” or that they have “run out of gas.” They have all the characteristics of the sick: They are disconnected from their world, they have the feeling that they have no control over their lives, they have lost the normal feeling of indestructibility, their cognitive function is not what it was, they are filled with uncertainties, and they do not really understand (as hard as they try) what is happening to them. These features and others characterize the phenomenon called *the state of illness*.

The state of illness is usually brought on by the symptoms and presence of serious disease, but the state of illness is an independent phenomenon. It is not a necessary accompaniment of serious disease. Many clinicians have known patients with serious disease who are not as sick as described here. This was true of Mrs. Fink before the conversation about her bone marrow. They have also known others who were similarly sick, but in whom the disease and symptoms were not serious. The state of illness is an independent phenomenon. It is a state of being. The *Oxford English Dictionary* definition of a *state* is, “A combination of circumstances or attributes belonging for the time being to a person . . . a particular manner of existing as defined by the presence of certain circumstances or attributes; a condition.” (For example, the state of love, the state of grief, or a state of helplessness.) States of being are not psychological or physical alone. States of being are physical, psychological, social, and personal. States of being are pervasive, with effects ranging from the molecular to the social. The state of illness can be worsened independently of the disease, and it can be improved independently of the disease. A state of illness is aggravated by pain and other symptoms, but particularly by inadequately controlled pain. The state is also activated or worsened by uncertainty and fear (the two are often related), and it is made worse by actions that remove independence or increase dependence on the staff. (Like the ubiquitous intravenous bag and pole.) Patients can leave the state of illness even though the disease is not better. An important therapeutic goal is ending a state of illness. The primary modalities for the relief of the state of illness are symptom relief and talking with the patient—communication.

COMMUNICATION

The spoken language is the most important tool in medicine; almost nothing happens in its absence. Physicians commonly train themselves to meet very high standards of expertise, but this everyday tool gets about as much respect and training in its use as paperwork.^{1,2} Yet the most common complaint that patients have now and have had for decades past is that doctors do not talk to them. It has been repeatedly shown that patients who understand what is happening to them and why, are more cooperative and compliant with physician's suggested regimens. The implication is that what you say to patients really matters. Every word matters. Sometimes physicians say, “I can't watch every word,” but that would be like a surgeon saying, “I can't watch my scalpel every moment.” Physicians are all so accustomed to talking and using words in their

everyday life that they forget the impact of words on the listener. And they forget that doctor–patient communication is not ordinary conversation. The spoken language acts on the person, and what acts on the person acts on every part of the person. In talking with patients, physicians themselves are the primary therapeutic agent. The vehicle through which virtually everything that physicians do to and with patients is the relationship between the patient and the physician. That relationship is best that is built on trust, and trust is best engendered by the truth. That is not the end of the story; it is the beginning.

Talking to patients necessarily transmits information, and in communication, it is the information that counts; therefore, physicians should be aware that they are involved in information control. There are specific tasks that should be accomplished by information flowing to patients. First, it should reduce uncertainty. Second, it should improve the patient's ability to act. Finally, it should improve the relationship between the physician and patient. It follows that information that you provide to patients should meet certain tests. Does it reduce the patient's uncertainty now or in the future? Does it improve the patient's ability to act? Does it improve your relationship with the patient (now or in the future)? If information wisely used can do those things, then information poorly used can create uncertainty, paralyze action, and destroy the relationship. Going back to the example of the patient Helene Fink, explaining to her the entire nature of her disease had all those negative effects, *even though it was true*.

Here follows a small tangent about death and the issue of denial. Most patients receiving treatment for cancer are aware of the possibility of dying. It has been on their minds since their diagnosis, but not always within awareness. They are often afraid of the subject, or of talking about it; like many people (maybe even you), patients are afraid of dying. It is usually not dying (ceasing to be) that they are afraid of; instead, the author believes it is separation from others. One way in which worries about death are handled is denial. Is denial in and of itself a bad thing? This author personally does not believe that it is, especially as the opposite face of denial may be panic. The important question is whether the denial is getting in the way of anything else important; for example, treatment or family relationships. Further, the author thinks you should be very cautious if you decide to break through denial. For this reason, the author usually does not tell people things, but rather answers their questions. When they do not ask the questions, the author can usually stimulate the question wanting to be answered. Telling Helene Fink the truth scared her and got her angry at her physician.

In giving information to a patient, a statement is only complete when it includes (1) what it is (the facts), (2) what it means, and (3) what is to be done about it. Here is an example:

What it is: “Your platelet count is lower today, which is why you are not getting your chemotherapy.”

This is what it means: “The platelet count drops because of the action of the chemotherapy on your body. Today's platelet count is the expected reaction to the drugs and will cause you no harm. There is nothing unusual about it. It will not reduce the effect of your treatment if you do not get chemotherapy today.”

This is what we are going to do about it: “There is no need to do anything about your platelet count. Because the platelet count is one way we decide how much medicine you should get, we will be testing it regularly. It usually comes back to a point where you can get your chemotherapy in about a week.”

Patients frequently ask questions about what something is—for example, a pain, a new symptom, something on their skin, or a swelling somewhere. Physicians commonly give an “it is a this or that” answer. For example, “Oh that is a bruise,” or “The swelling is some edema in your foot.” The same rule applies as previously, the answer should not be it is a this or a that, but this is what it is,

this is what it means, and this is what is going to be done about it. “The black and blue mark is just a bruise. Because your platelet count is low from the chemotherapy you are going to bruise more easily than you used to. When your platelet count is normal again after the chemotherapy, that will stop happening. We don't have to do anything because it doesn't require any treatment.”

EXPLANATIONS

Explanations should be brief, clear, unambiguous, and jargon free. The test of the adequacy is not what you say, but what the patient understands. The best way to find that out is to ask the patient to repeat what you just said. Remember, the explanation is focused on the patient's need for information. And the enemy of clarity is ambiguity.

Here is an example from an actual interaction (with a physician who prided himself on his communication skills). “It looks as though we'll probably get out of the woods. Most of the bad stuff seems pretty well gone and I doubt if we'll have trouble again if things hold the way they are.”

Think what these phrases really mean:

- “. . . probably get out of the woods.” Will we or won't we?
- “. . . most of the bad stuff . . .” Is it gone or is it not? And what about the rest?
- “. . . I doubt if we'll . . .” Do you believe it or not?

This is the way physicians commonly talk to patients. This is supposedly done this way because physicians do not want to commit themselves. If challenged, physicians may say, “I'm not God. I don't know what is going to happen.” Or, “I don't have a crystal ball.” Patients know both statements are true. But such statements are beside the point. The physician may not have a crystal ball, but he or she knows better than the patient what can happen and what will probably happen. It has been shown repeatedly that people do not understand clearly what percentages mean such as, “You have a 30% chance of recurrence.” Cognitive psychologists have demonstrated that people understand information better if it has been translated into natural frequencies. (You have a 3 in 10 chance of recurrence, or there is a 7 in 10 chance that you will not have a recurrence.) It is not necessary to pretend or lie. Here is a possible way to say the same thing that does not suggest omniscience, but that, at the same time, is reassuring. “These tests show regression of your cancer. You are getting a very good response to treatment and I believe you're going to do well.” You can stop there; there is no reason to express doubt. If you believe you are not being truthful because you have not shared the whole truth, ask whether the patient has any questions. If there are questions, answer them honestly but briefly and wait for more questions. Do not answer a question that has not been asked. If the patient wonders whether things could turn bad again, here is a possible response. “You and I both know that I can't promise that this good response will keep up, but I expect it to. And even though that may leave you with some doubt or maybe you find it worrisome, don't make bad news out of good news. This is good news. We're doing well. Let's keep it up.”

UNCOMFORTABLE QUESTIONS

If the patient asks a question that you do not want to answer, you can buy some time to find out what the patient is really asking by, “What do you mean by that?” Or, “I'm not sure I understand what you're asking me, say it again in a different way.” If it is a direct difficult question that does not mince words, then answer it in the same manner in clear, unambiguous, spare, jargon-free, truthful language. Say no more than you must say to answer the question, and then wait for the next question. The same rules apply here as outlined previously: Say what it is, say what it means, and say what

you are going to do about it. Do not leave the patient hanging in the air with statements like, “Let’s wait a month and see how things stand.” Be more specific. “In a month, we will repeat your CT scan. I expect that it will still show a good response. If you’ve had some growth of your tumor, we will decide what that means and then, if necessary, modify your treatment.” You will notice that the author has repeatedly used the words “we,” “we’ll,” “we’re,” and “let’s” (as in, “let us”). In each instance, you are telling the patient that you and the patient are a team, that the patient is not alone, and that you are right there with him or her.

Earlier, the author said that he did not believe that fear of death is a fear of ceasing to exist, but a fear of separation from others. He does not know if that is a correct interpretation, but he does know that patients greatly fear being abandoned by or distanced from their doctors. It does not take many words to express your continued connection to the patient, no matter what happens.

INFORMATION

Information can be conveyed in different quantities ranging from terse to fulsome. It has degrees of detail, complexity, or sophistication and should be tailored to the patient’s ability to understand. It has timing. There is a big difference between conveying information to a patient in a recovery room or to someone who has come to the office specifically to discuss a diagnosis or treatment. It has timing. Choose your place and choose your time. If the patient wants information before you are ready, tell him or her that you are going to discuss this in detail at such and such a time and ask if that will be all right. If the patient insists on talking at that moment, then be brief and again refer to future discussion. Information has relevance; stay on the subject. And, finally, information has truth content.

Information is flowing all the time from multiple sources. Information comes to the patient from the environment. For example, a patient in a radiation suite in most hospitals is getting a lot more information than you may wish from simply looking around the waiting area. He or she gets information from knowledge stored in memory. Needs, wishes, desires, fears, or fantasies are another source of information. Other people may also provide information, such as family, friends, nurses, attendants, technicians, and other doctors. Everybody! And everybody is talking all the time. Patients get information from their bodies as they interpret the feelings they have as well as what they see. Remember, you are only one source of information among many. Information is flowing all the time. Even no information is information.

The Internet represents a special problem. It seems that everyone goes to the Internet to find out about their disease, treatment, doctors, and the institutions in which they get care. Whatever the question, the Internet overflows with information. As of the time of this writing, if you enter “ingrown toenail” into Google, more than 440,000 sites become accessible. If you search Google about cancer of the breast, more than 59 million sites become accessible. Diverse sources of information inevitably bring conflict, and disagreement between sources of information produces uncertainty. The more pressing the need to act, the less tolerable is uncertainty.

Increased uncertainty often makes patients more fearful. Their fear increases the difficulty they experience when decisions have to be made, which also increases fearfulness. Uncertainty and fear reinforce the state of illness. One solution to the problem of uncertainty is increased trust in doctors. That is one of the reasons why patients put so much faith in their doctors’ words and actions. This may make it uncomfortable for physicians who know that they are far from invulnerable, but it is much easier for patients. Also, it is one of the reasons that it is so important to maintain strong doctor-patient relationships. Too many times, doctors react to the amount

of trust that patients lay on them by insisting that the patient make his or her own decision (see later discussion). This makes it more difficult for the patients in situations wherein they need support and in whom they should invest their trust. “Thank you—together we’ll do the best we can,” is much better than, “You know that I’m not infallible and that I can’t make your decisions for you.”

MEANING

The topic of meaning, in general, is complicated, but some things about it are straightforward. Physicians do not act directly because of events, objects, or relations; they act because of the meaning of these things. Information does its work because it acts on meaning. Meaning has two characteristics that are important to this discussion. The first is significance. For example, “Dark clouds signify rain” or “Postmenopausal bleeding means I have cancer.” Meaning also conveys importance. For example, “Rain will ruin the picnic” or “I could die from that kind of cancer.” Importance is another way of saying value. And values, although they may be shared, are always personal; importance is always importance to someone. These two characteristics of meaning are present whenever you are talking and whenever the patient is listening. That is why it is so important to find out what significance the patient is giving to your explanation and what its importance is to the patient.

Another characteristic of meaning is that it can be changed. Sometimes, when you can do nothing else for a patient, you can change the meaning that the patient has assigned to objects, relations, events, or the words that you have used. For example, when someone presented in 1950 with what we now identify as stage I Hodgkin’s lymphoma, after the diagnosis he or she was met with lies and pessimism. Now, the same patient is met with smiles and optimism. But for the individual patient, on first being diagnosed, death is still possible because you do not know for sure what the outcome will be. Why the smiles? For this patient, on first diagnosis, only the meaning of the disease has changed, but that is enough to change the physician’s attitude and hearten both patient and family. To change the significance of the events, you must change the patient’s meaning—the patient’s objective knowledge of the world. To change the importance of events, you must address their impact on the patient—how they will affect the patient in the present and in the future.

Meaning is also used here in the sense of purpose. This was popularized by Viktor Frankl³ in his book, *Man’s Search for Meaning*. Here, patients may search for the meaning of the fact of their cancer, or use the disease as a spur to find a new meaning in their life. This not the sense in which the author has been using the word. Meaning is important to physicians because words do not simply have a denotation, a dictionary meaning, or a personal or connotative meaning, but because every meaning has cognitive, emotional, physical, and spiritual dimensions. Words act on the body to the molecular level. As a simple example, if somebody tells you something with a meaning that induces fear in you, the fear may be felt like a gripping in the chest and may be accompanied by all the physiologic manifestations of fear.⁴ The words do not cause the fear; rather, the fear is part of the meaning of the words. In the same way, the physiologic events are not caused by fear; they are a part of fear itself.

CAFETERIA EXPLANATIONS

It cannot be said too strongly: Give up, get past, eschew, and forget about cafeteria information and decision making. Simply laying out the information and asking the patient to make the decisions is not fair to the patient and it takes away from you one of your important therapeutic options: control of the information. Cafeteria decisions abandon the patient when he or she needs you most. You

can honor the patient's autonomy and honor the realistic need for clinicians to maintain the control of the case by helping patients make decisions that you believe are in their best interests because they know those interests. Ask yourself how well you would be able to make a decision if you were frightened, uncertain, and fundamentally ignorant about the issues involved in the decision. If just knowing the medical facts was enough to make decisions,

doctors, when they are patients, would be the best decision makers of all. Doctors know that that is not true. Sick people need help expressing their best interests.

Communication, as with all other therapeutic agents, should be goal directed. The goal is to help the patient be better, whatever the outcome. The spoken language is a powerful tool toward that end and worth learning how to use effectively.

151 Specialized Care of the Terminally Ill

Robert S. Krouse and F. Amos Bailey

INTRODUCTION

The evolution of cancer care has led to survival advantages for many cancer patients. Some cancers, such as breast and colorectal, may be considered a chronic disease in many settings. Nonetheless, clinicians must be prepared for the specialized care for cancer survivors and those living with progressive cancer whose suffering is unique, complex, and multifaceted as described by Eric Cassel in his essay "The Nature of Suffering".¹ Now, recognition of the needs of patients has propelled the development of programs to provide concomitant palliative and supportive care with cancer treatment to help address the myriad concerns for both patients and their family and caregivers.

INTERDISCIPLINARY CARE FOR PATIENTS WITH ADVANCED CANCER

Specialized care for terminally ill cancer patients requires appropriate interdisciplinary care. Members of the interdisciplinary team (IDT) will include physician providers representing medical, surgical, and radiation oncology. Importantly, palliative medicine specialists, who work in tandem with nursing, social work, pastoral care, and other providers, can develop and lead integrated holistic care plans that reflect the goals of care and the values of patients.

Palliation is increasingly becoming recognized as an important component of care of the cancer patient for specialties treating cancer patients with advanced disease. In the terminally ill patient, chemotherapy, surgery, and radiation therapy may have the potential to provide palliation of symptoms and improve health-related quality of life (HRQOL) and extend survival. Decisions related to disease-modifying treatments must take into account the patient's functional status, often as expressed by performance status, and the goals of care. The intent of treatments must be clear, because patients and families will often have unrealistic goals based on the potential outcomes for treatments offered.^{2,3}

Clearly, all providers caring for patients with advanced cancer should work closely together to ensure that the patient and family are able to maximally benefit from our interventions while minimizing iatrogenic harm. Importantly, as death becomes more imminent, patients and families often benefit from the IDT support during this stressful time.

EARLY PALLIATIVE CARE

Recent studies of concomitant palliative care with standard oncologic care have demonstrated that patients with concomitant treatment had improved HRQOL, a reduction in symptom burden, and the potential to reduce use of aggressive treatment at end of life,⁴ while having an improvement in survival.⁵ Therefore, ideally, patients who present with advanced stage cancers and those experiencing progressive disease despite treatment will have access

to concomitant palliative care early in their treatment course. This can allow for better support as described previously, but can make the transition from a focus on disease-modifying treatment to more symptom-focused care less jarring. This also recognizes that the complex issues of suffering with its physical as well as psychosocial and spiritual dimensions are most often present from the time of diagnosis and may vary in intensity and distress throughout the course of disease. Certainly, patients, families, as well as providers experience increased intensity of suffering near the end of life and practical expertise in the care of the dying is recognized as one of several important themes of care in order to achieve a "Good Death".⁶ To do this, the team must engage in new types of conversations with patients and their families and among themselves and broaden their assessments to be able to ensure physical comfort, address psychological needs, and identify goals of care and social and spiritual sources of distress.

COMMUNICATION

Communication skills are key for all providers to have successful interactions with patients and families. Communication skills can be learned and honed. Patient and family perceptions of quality and satisfaction with medical care are closely linked to the ability to effectively communicate the clinical situations, treatment options, and empathic support for all involved. There are a number of communication skill training programs, and all providers should work to continuously improve communication skills and consider specific training. When providers can communicate their clinical situation effectively with patients and families, they are better equipped to make decisions that focus on achievable goals of care in the terminally ill cancer patient.

SPECIFIC PROBLEMS IN THE SETTING OF ADVANCED CANCER

There are many specific issues that require attention in the terminally ill beyond pain and psychological distress. When patients present with these issues, the evaluation of the extent of disease, overall performance status, and treatment options may take some time to ascertain.

Aggressive palliative treatment of symptoms should be undertaken. At this point, discussions with the patient, their family or caregivers, and the medical team should then review the patient's goals of care and align them with available treatment options. Some patients may opt for a more palliative focused approach, whereas others may choose, if potentially feasible, operative or interventional approaches. Patients must be supported in that interventions are not always successful to relieve symptoms, and the problem may recur. It may be difficult to weigh the risk and benefits of interventions. Involvement of the IDT is important because the patient will need support in the provision of complex medical information in such a way as to be able to make an informed decision.

Regardless of the outcome of any intervention, the patient is likely to have a limited survival such that ongoing palliative/hospice support in the hospital or after discharge is needed.

DYSPNEA

Dyspnea, the uncomfortable sensation or awareness of breathing or needing to breathe (i.e., shortness of breath), is a commonly encountered symptom in cancer patients, which results from multiple disease processes and can lead to limited function and poor HRQOL. The prevalence of dyspnea among cancer patients has been reported to be between 21% to 90%, depending on the type and stage of cancer.⁷

The pathophysiology of dyspnea is multifactorial and incompletely understood.⁸ Researchers believe the cerebral cortex integrates this sensory input with other cognitive and emotional factors as well as motor information from the respiratory center.⁹

The *gold standard* for the diagnosis of dyspnea is the self-report of the patient. There are no other reliable, objective measures of dyspnea. Respiratory rate, oxygen saturation, and arterial blood gas determinations do not necessarily correlate with, or measure dyspnea. Hypoxemic patients may not be dyspneic, and those with dyspnea are often not hypoxic or remain dyspneic when hypoxemia is resolved. The severity scales developed for pain (numerical, visual analog scale) have been reliably used to assess dyspnea.¹⁰

The goal of the symptomatic management of dyspnea is to relieve the patient's sense of breathlessness. Specific therapy to manage underlying causes (e.g., bronchodilators, stent placement to relieve focal obstruction), is appropriate in selected patients. To manage the experience of shortness of breath, both pharmacologic and non-pharmacologic interventions have been shown to be effective.

Oxygen supplementation has a perceived benefit by patients who are dyspneic that far exceeds the number who have hypoxemia.¹¹ There is likely a placebo effect of oxygen, partially based on the medical symbolism inherent in its administration. It is recommended to use the least confining oxygen supplement possible for the comfort of the patient and the ability to communicate with the family. In the imminently dying, if the patient is comfortable with nasal prong oxygen, fans, and opioids, it is not necessary to monitor the oxygen saturation or escalate oxygen therapy for relatively asymptomatic hypoxia. It has also been observed that similar relief is experienced from cool air blowing on the face, such as from a breeze or a fan.

Opioids are the most effective medication for the symptomatic control of dyspnea.^{12,13} In opioid-naïve individuals, small amounts of morphine can relieve dyspnea.¹⁴ For those on baseline opioids, start by increasing the opioid dose by 25%.¹³ Patients frequently report anxiety concurrent with dyspnea, and these symptoms can reinforce each other. Dyspnea frequently leads to anxiety, and anxiety can also exacerbate dyspnea. Opioids alone may break the cycle by relieving dyspnea, but they do not have a direct anxiolytic effect. Anxiolytics (e.g., benzodiazepines) are frequently prescribed for anxiety related to dyspnea. However, when tested, the evidence for their effectiveness is not persuasive.¹⁵ Therefore, benzodiazepines should not be used alone as first-line therapy for dyspnea.

MALIGNANT BOWEL OBSTRUCTION

Malignant bowel obstruction (MBO) is defined as: (1) clinical evidence of a bowel obstruction via history, physical exam, or radiographic examination, (2) bowel obstruction beyond the ligation of Treitz, (3) intra-abdominal primary cancer with incurable disease, or (4) non-intra-abdominal primary cancer with clear intraperitoneal disease.¹⁶ It occurs most frequently with ovarian and colorectal cancers, but occurs with other abdominal and, occasionally, with nonabdominal malignancies. MBO may be related to tumor, its treatment (e.g., radiation enteritis), or benign etiologies

(e.g., adhesions, internal hernia). The goals of treatment include relieving nausea and vomiting, allowing oral intake, alleviating pain, and permitting the patient to return to their chosen care setting.

When patients are admitted to the hospital, conservative measures (e.g., nasogastric tube, decompression, intravenous hydration, nothing by mouth [NPO]) is typically initiated. Palliative pharmacologic therapies have the goals of reducing intestinal inflammation and edema and/or controlling pain, nausea, vomiting, and dehydration. Pharmacologic options include: (1) anti-secretory agents (e.g., somatostatin analog, steroids, scopolamine); (2) pain medications (e.g., morphine, fentanyl, hydromorphone, methadone); and (3) antiemetic therapy (e.g., haloperidol, prochlorperazine). Opioids act both directly to relieve pain related to intestinal obstruction, as well as to reduce painful bowel contractions against the obstruction. Antiemetics can be given through a variety of nonoral routes to control vomiting,¹⁷ although complete relief of emesis is achieved in a minority of patients through antiemetics alone. Hormonal manipulation of gut activity has substantially added to the armamentarium of MBO management. Octreotide, a synthetic analog of the gut hormone somatostatin, dramatically decreases gastrointestinal (GI) secretions and reduces bowel motility, often markedly reducing or resolving MBO symptoms.¹⁸ Duration of treatment may be short lived (median: 9.4 to 17.5 days),¹⁸ although symptoms are frequently relieved for the life of the patients. Anticholinergic medications, such as scopolamine, can decrease peristalsis and secretions and can lead to improved control of vomiting and intestinal colic for malignant GI obstruction. Although direct comparisons of these agents have not yielded clear recommendations,^{19,20} a combination of these medications may offer synergistic benefits. Finally, corticosteroids are commonly used as adjunctive agents or alone in MBO management, with the goals of decreasing tumor-associated bowel edema and of providing antiemetic benefits. Although a meta-analysis has suggested no statistical benefit of corticosteroid use, a subset of patients may benefit from them, and medication-related morbidity is low,²¹ particularly in patients in the terminal stages of their disease. If surgery is being considered, it has been shown that somatostatin or its analogs are likely not a risk to an operation. Steroids may carry operative risks and should be initiated with caution.

Persistent obstructions in the face of palliative treatments or evidence of complete obstructions are indications that a surgical procedure should be considered unless actively dying. Many patients are deemed inoperable (6.2% to 50%).²² This may be due to poor operative risk or contraindications to surgery. Poor operative risk must be assessed based on comorbidities (e.g., cardiac and pulmonary function), the amount and location of metastatic disease (e.g., overwhelming metastasis to the liver causing malfunction), and current functional status (e.g., Karnofsky score: <50%). Potential contraindications for surgery in patients with incurable cancer and MBO include ascites (greater than 3 L) and, in particular, ascites that rapidly recur after drainage, carcinomatosis, multiple obstructions, or a palpable intra-abdominal mass.^{17,23}

The optimal procedure is that which is the quickest, safest, and most efficacious in alleviating the obstruction. Although bowel resection may lead to the best outcome,^{24,25} a bypass may be a safer option, and the placement of a gastrostomy tube for intermittent venting might be optimal in some settings. In addition, an intestinal stoma may be necessary after resection or to adequately bypass the blockage. Cytoreductive procedures (e.g., resection of an intraperitoneal tumor) frequently carry a high morbidity and usually are only considered with very low-grade tumors, such as pseudomyxoma peritonei.

Although it is recognized that improvement in HRQOL after surgery is variable (42% to 85%),^{22,26} there is no consistent parameter used to determine this clinical outcome; operations may offer an advantage of an increased survival. Surgical risks must be carefully considered prior to an operation, because morbidity (42%)²⁷ and mortality (5% to 32%)^{22,25,27} are common, and the reobstruction rate is high (10% to 50%).²²

Endoscopic procedures are suitable for patients who are poor operative candidates or who decline an open operative intervention. The major approaches include stenting and percutaneous endoscopic gastrostomy (PEG) tube placement. Stenting may include procedures to initially canalize the lumen (e.g., laser or balloon dilatation). PEG tubes are generally well-tolerated *venting* procedures that can alleviate symptoms of intractable vomiting and nausea for upper GI obstructions.²⁸ A study from M.D. Anderson Cancer Center found that percutaneous gastrostomy tubes were utilized for palliation in 23% of small bowel obstructions in patients with advanced malignancy.²⁹ Complications related to PEGs are rare, even when puncturing other organs.²⁸ The presence of significant ascites is a relative contraindication. In combination with other medical techniques, both open and percutaneous gastrostomy offers the possibility of intermittent oral intake. Endoluminal wall stents have a high success rate for relief of symptoms (64% to 100%) in complete and incomplete colorectal obstructions,³⁰ and in over 70% of upper intestinal malignant obstructions including gastric outlet, duodenal, and jejunal obstructions.³¹ Although risks include perforation (0% to 15%), stent migration (0% to 40%), or reocclusion (0% to 33%), stents can frequently lead to adequate palliation for long periods of time.³⁰ Stent occlusion by tumor in-growth is usually amenable to another endoscopic intervention.

MALIGNANT BILIARY OBSTRUCTION

Malignant biliary obstruction is an obstruction of the biliary tract due to cancer. Malignancies associated with MBO are pancreatic cancer, cholangiocarcinoma (most commonly ampullary cancer, followed more uncommonly by lymphoma, duodenal cancer, and metastatic disease). Hyperbilirubinemia may become symptomatic, leading to pruritus, bleeding diathesis, and liver failure. Patients need prompt relief of the biliary obstruction before embarking on any other palliative treatments. Two major treatment approaches are currently available: (1) surgical bypass and (2) stent management (via gastroenterology or interventional radiology).

There are multiple studies comparing methods, especially stenting versus surgery.³² Endoscopic stenting has been shown to have similar success rates as surgery. Although most patients receive stents, recurrence rates are higher and subsequent hospitalizations may be lower for patients who have surgical bypass.³² Metal stents have improved patency compared to plastic stents with lower recurrent obstruction rates, although this may require a second procedure if not placed initially. One approach is to perform endoscopic stent placement in patients considered to have short life spans with a limited potential for recurrent obstruction and to perform surgical bypass for patients with less aggressive tumors, longer expected life expectancy, or limited access to endoscopic expertise for treatment of recurrent obstruction.

If the bile duct is entered via an endoscopic retrograde cholangiopancreatography (ERCP) but a stent could not be placed, it may necessitate a relatively urgent surgical procedure due to the potential cholangitis risk. If urgent surgery is not realistic due to patient comorbidities, overall status, or operating room availability, a transhepatic drain placed by an interventional radiologist is indicated. If a laparoscopic exploration is first undertaken for a potentially resectable mass and metastatic disease is noted, it is reasonable to abort the procedure with the hope that a less morbid endoscopic stenting can be accomplished. Also, if endoscopic stenting fails or is unavailable, an open or laparoscopic bypass is warranted. If, at open exploration, the patient is found to be unresectable, it is reasonable to proceed with a surgical bypass.

There are multiple options to surgically bypass the biliary system (e.g., cholecystojejunostomy, choledochojejunostomy, choledochoduodenostomy). The overall morbidity of surgical bypass is almost 20%, and the recurrence rate is 0% to 15%.³² It has been shown that choledochoduodenostomy has the fewest

complications at only 3%.³³ Of course, the ability to mobilize the duodenum may not be possible in all patients. A laparoscopic biliary bypass might be performed in expert hands.³⁴

GASTRIC OUTLET OBSTRUCTION

Gastric outlet obstructions typically occur in the setting of gastric, peri-pancreatic, and duodenal tumors. Procedures are considered in the setting of persistent nausea, vomiting, eructation, and early satiety. They also may be considered when there is evidence of duodenal compression on radiographic or endoscopic evaluations.

Although few centers have the technical expertise, endoscopic stents for gastric outlet obstruction may be quite successful (approximately 90%) with rare complications.^{35,36} In addition, if the stent fails due to tumor in-growth or migration (around 10%), another stent can often be placed.^{35,36}

Another endoscopic option is percutaneous gastrostomy, with some centers reporting use in almost a quarter of their patients with gastric outlet obstruction and advanced malignancy.²⁶ Unfortunately, this will not allow the patient to eat, and should only be considered in patients for whom a stent fails or is unavailable and who would not tolerate a surgical procedure.

If endoscopic stenting fails for the gastric outlet blockage or is unavailable, an open or laparoscopic bypass is warranted. There are several technical variations of a surgical bypass procedure (gastrojejunostomy), but the results are similar. This can be achieved safely via open or laparoscopic techniques. For an unresectable gastric cancer, the laparoscopic technique has been shown to have less suppression of immune function, less pain, shorter hospital stays, lower postoperative morbidity, and earlier recovery of bowel movements than an open procedure.³⁷ Additionally, there might be slightly better emptying if this is done to the posterior wall of the stomach. A distal gastric tumor may also be resected with a palliative intent.

It has been shown that symptomatic patients (e.g., vomiting prior to operation) typically have a poor outcome (approximately 90% did not have relief of symptoms) to gastric bypass. In comparison, if patients were not symptomatic but had evidence of impending obstruction, only about 40% had a poor outcome.³³ One consideration as to the reason for this is that symptomatic patients are potentially sicker with a greater tumor burden.

Antrectomy along with gastrojejunostomy in the setting of unresectable pancreatic cancer has been shown to have excellent results until death in one small series.³⁸ There is limited evidence in the literature to support this procedure in the setting of gastric outlet obstruction, and a simpler bypass may be more reasonable.

Finally, in the setting where a surgical biliary bypass is planned, there is some controversy as to whether a preemptive gastric bypass (gastrojejunostomy) in the asymptomatic patient is warranted. Because a late gastric obstruction occurs from 9% to 23%,³⁹⁻⁴¹ a duodenal bypass should be considered at the time of biliary bypass, especially if the patient is of good performance status with limited disease (no or minimal metastasis).

MALIGNANT ASCITES

Ascites in the terminally ill cancer patient may be due to overwhelming liver metastasis, cirrhotic liver disease, or carcinomatosis. It can be a difficult problem to manage, and treatment may be determined by the extent of the ascites, the condition of patient, or etiology. If ascites are minimal, no therapy is indicated. Larger volumes of ascites can lead to discomfort, fullness, or respiratory problems. Diuretics along with paracentesis is typically the primary treatment option. Typically, spironolactone is used in combination with furosemide. Alternative options should be considered if diuretics no longer are of benefit or if percutaneous aspirations become painful and frequent. Chemotherapy has been shown to

be efficacious in certain settings.^{42,43} Intraperitoneal verapamil may enhance chemotherapy response.⁴⁴ Intercavitary chemotherapy may also have efficacy, especially in the setting of ovarian cancers. Multiple agents have been used, and ascites can be controlled in 33% to 85% of patients.⁴⁵ Targeted agents, such as catumaxomab⁴⁶ and aflibercept^{47,48} may also play a role in treating malignant ascites.

There are multiple more invasive treatments for malignant ascites. If the patient has very advanced disease, simpler approaches should be initiated. If the patient has a longer life span, more invasive techniques may be considered. Probably the simplest intervention is the insertion of permanent intraperitoneal drainage catheters. This will allow for the serial drainage of fluid by the patient or their caretaker. Catheters can be placed surgically or by the interventional radiology team via computed tomography⁴⁹ or ultrasound guidance.⁵⁰ Multiple types of catheters have been used, including a pigtail catheter, peritoneal dialysis catheters (e.g., a Tenckhoff catheter), pleural cavity catheters (e.g., a PleurX catheter), fenestrated port-a-catheters, and even a Foley catheter.⁵¹⁻⁵⁵ The patient and/or caregiver can be trained to drain excess peritoneal fluid when the patient is symptomatic. The success rates for permanent intraperitoneal catheters functioning until death is quite high (90%).^{50,51} There is low procedural morbidity. The major complications are obstruction and infection and are around 17%,^{50,51} although catheter sepsis has been reported to be 35%.⁵⁶ To avoid infection, there must be meticulous insertion technique, close patient follow-up, and liberal use of antibiotics. In fact, many catheter-related infections can be treated with antibiotics.^{50,57} Sometimes the catheters may need to be removed due to infection, occlusion, or leakage around the catheter. Leakage has been reported to be alleviated by continuous drainage⁵¹ or a suture around the drain.⁵⁶

Another option for malignant ascites is a peritoneovenous shunt. The two most common are the LeVeen and the Denver shunt. Ascitic fluid travels from the peritoneal cavity into the venous circulation due to higher peritoneal pressures. Complications include sepsis, disseminated intravascular coagulation (DIC), heart failure, and pulmonary embolism leading to a rapid death. Although the incidence of major complications may be less common than previously reported for peritoneovenous shunts, the overall complication rate can be quite high (14% to 51%).⁵⁸⁻⁶¹ DIC is the major complication that most frequently will lead to a patient's death. It has been reported to occur from 5% to 10% in these procedures. Congestive heart failure is another major complication. The more common complication is shunt occlusion. The advantage of the Denver shunt over the LeVeen shunt is that the Denver shunt has a pump to help the shunt remain patent (26% Denver versus 50% LeVeen shunt occlusion rates).⁶⁰ Denver shunts have been shown to have a quite high function rate until death (96%).⁵⁹ The risk of infection is variable (0% to 18%),⁵⁹ and this may lead to shunt removal if not relieved with antibiotics. Importantly, relief of symptoms can be as high as 87.5%.⁵⁹ Therefore, a peritoneovenous shunt may be an excellent option in properly selected patients.

Hyperthermic intraperitoneal chemotherapy (HIPEC), without cytoreduction, is an accepted approach for the palliation of malignant ascites with good early data. In addition, this procedure can be performed laparoscopically in an attempt to minimize complications.⁶² A much more invasive surgical technique includes a major debulking of carcinomatosis followed by intraperitoneal hyperthermic chemotherapy. This procedure is only available at specialized institutions, but will likely be infrequently performed for palliation in the future based on the results emerging from HIPEC without cytoreduction and laparoscopic HIPEC.⁶³ In the carcinomatosis patient, cytoreduction and intraperitoneal chemotherapy can have dramatic effects on ascites. In one report, 79% of patients did not have recurrence for the remainder of their life (median survival: 7.6 months).⁶⁴ Surprisingly, their group has also shown that this procedure can lead to an acceptable HRQOL and return-of-function status for many patients.⁶⁵ Palliative treatment of malignant ascites with cytoreduction and HIPEC may be of historical interest only because the contribution from cytoreduction

may be minimal based on reports of laparoscopic HIPEC. Laparoscopic HIPEC without cytoreduction is a less technically demanding procedure with a shorter length of stay and a decreased risk of surgical complications. A recent systematic review of 76 patients undergoing palliative laparoscopic HIPEC reported that the procedure was considered successful in 72 patients (95%), defined as a complete regression of ascites with no deaths and a morbidity rate of 12%.⁶⁰ Laparoscopic HIPEC appears to be safe and highly effective for the treatment of malignant ascites. The morbidity, although low, suggests that this procedure is best utilized in settings of ascites refractory to less aggressive treatments.^{45,66} The improvement in ascites and the lack of a need for catheters or follow-up procedures is encouraging, but it should be noted that none of the studies of palliative laparoscopic HIPEC have included symptom assessment or HRQOL outcomes measures. HIPEC has also been shown to be accomplished via ultrasound guidance, further making this technique possible for patients with advanced disease.⁶⁷

WOUNDS

There are multiple different kinds of wounds related to advanced cancer. These are often directly related to tumors, but may be due to treatments such as surgical procedures (e.g., lymph node dissections, tumor resections) or radiation therapy (e.g., nonhealing ulcers). Primary cancers that frequently lead to wound problems include breast cancer, skin cancers, soft tissue sarcomas, or soft tissue manifestations of other cancers (e.g., lung cancer). Special consideration must be taken related to the primary tumor type, and interdisciplinary decision making is imperative. Finally, due to debilitation, patients may have pressure sores, which complicate their overall course and lead to suffering. In the debilitated patient, pressure sores are more likely to occur. The prevention of pressure sores, as well as other wounds, is of primary importance.

Many wounds, especially related to radiation injury or in the severely malnourished, may not heal. Therefore, this should not be a goal of treatment, but focus should be on control of pain, odor, and mess. Wound care is of primary importance. This may include local debridement as indicated to keep the wound as clean as possible. Although surgical options for wounds are limited, operative intervention has been reported in 38% and primarily involves incision and drainage or debridement.⁶⁸ Only a minority of patients are able to undergo wide excision and closure of tumors causing wound problems.

One example of a chronic wound problem is chest wall complications of breast tumors. IDT care is imperative to recommend optimal therapy. Even in the terminally ill, chemotherapy, especially if the patient is chemo naïve, may have a role. Radiation therapy is unlikely to have a great effect with a very large tumor. Surgical resection, or *toilet* mastectomy, may be utilized in the setting of a fungating incurable breast cancer to remove the tumor with the intent of wound control. It is always important to know the previous treatments to better understand possible success. This will also help to identify the optimal reconstruction alternatives as well as the extent of resection that is possible. The surgical literature is not very helpful in directing the extent of resection, and this must be based on surgeon judgment. Reconstruction options include primary closure, skin grafts, and an omental flap with skin graft, musculocutaneous flaps, or free flaps. The major surgical complications that must be considered include infection, open wounds, and flap loss. The extent of procedure must be considered along with the patient's overall medical status and likely survival. The recurrence rates in this setting may be high. In one small series, it was noted to be 73%,⁶⁹ and 20% to 52% in some of the larger series.⁷⁰⁻⁷³ The majority of these recurrences were quite small, however, and could be locally excised or observed in patients who already had other major metastatic disease. Local wound morbidity is variable, and most are quite minor, such as local skin necrosis in a skin graft, which will not have

great impact on the patient's life. Importantly, if there is major local wound morbidity, this could have a profound effect on the patient for the remainder of his or her life.

Related to amputation, there are multiple small reports that do indicate good to excellent palliation.⁷⁴ Complications may be over 50%, including flap necrosis, infection, and death. Complication rates will depend on the extent of amputation. In addition to amputation, limb perfusion most commonly utilizing melphalan with or without tumor necrosis factor alpha (TNF- α) has been advocated in some centers for melanoma or sarcoma recurrences. Complete response rates are 45% to 72%, usually greater if TNF- α was used.⁷⁵ Importantly, it has been shown that HRQOL can be excellent, with reasonable long-term function.⁷⁵

Additional morbid options are possible based on the site of the tumor and medical status of the patient. These may include amputations, limb perfusions, and major head and neck resections. Although these options may seem quite radical in the setting of palliation, they may be reasonable solutions based on symptoms and if the patient can withstand a large procedure. There have been many reports concerning local wound care for tumor-related wounds.

Finally, local wound care for tumor-related wounds is extremely important, and has been shown to have great impact on HRQOL. For example, controlling odor and seepage has been shown to lead to less isolation, greater comfort, and increased psychosocial well-being.⁷⁶ This straightforward approach to some wounds will lead to the best outcomes for many patients facing the end of life.

BLEEDING

Tumor-related bleeding is a difficult problem for terminally ill cancer patients. Bleeding may be related to superficial tumors such as recurrent breast, head and neck, or sarcomas. Symptoms related to deeper tumors include hemoptysis (e.g., primary or metastatic lung tumors), hematemesis (e.g., gastric cancer), melena or hematochezia (e.g., colorectal tumors), vaginal bleeding (e.g., cervical or endometrial carcinomas) or hematuria (e.g., renal or bladder tumors). In addition, patients may have a coagulopathy related to illness or treatments. Surgical intervention for GI bleeding is infrequently required. If surgery is indicated, the optimal surgical option will depend mainly on the location and reason for bleeding, along with the least morbid and most efficacious procedure possible. Nonsurgical options include radiation therapy, arterial embolization, and endoscopic procedures. For bronchial bleeding, bronchoscopic techniques may be warranted.

The IDT should be involved if possible to discuss the best therapeutic algorithm. Surgical options may be quite simple (e.g., local excision) or quite complex (e.g., gastrectomy).

One example where the IDT involvement may be helpful is with rectal tumor bleeding. Surgical options are typically complex with high morbidity. In addition, intestinal stomas would likely be needed. Local excision may be considered, although this procedure may be technically difficult or not possible in this setting. Therefore, patients would likely be better served with nonsurgical attempts to stop bleeding, which can be highly efficacious (e.g., radiation therapy, interventional radiology embolization). Again, the success of alternative approaches will be based on the availability and expertise at each institution.

Finally, it is a well-known strategy in hospice care for a patient with a known massive bleeding risk but no optimal or indicated intervention for the patient and family to be prepared for this outcome with dark sheets and sedation. Dark sheets are recommended so that blood will be less visible and disturbing for the patient and family. Medication for sedation should be immediately available and provided in adequate doses if exsanguination is a potential complication of the cancer to mitigate distress for the patient at that time. If sedation should be required for longer period (i.e., hours to short days), palliative sedation is often appropriate and emergent consultation with palliative medicine would be appropriate.

IMPENDING DEATH

Patients in the last days or hours of life often have unrelieved physical suffering, as well as significant emotional, spiritual, and social distress. Recognizing that a person is entering the imminently dying or terminal phase of their illness is critical to appropriate care planning, with a shift to comfort care. Defining when this phase begins is not always straightforward. Patients at the end of life are frequently not recognized as dying. As a result, suffering may not be properly appreciated or managed, and the patient's overall condition may even be exacerbated by the continuation of standard medical treatments. Palliative medicine providers in the hospital are an important resource to provide for care of the imminently dying by employing the best practices of end-of-life care from the home hospice setting, which are not routinely available in in-patient settings. The involvement of a palliative IDT will benefit not only patients and their family, but also their oncology team, because providing care to actively dying patients presents unique challenges that often require special expertise. Patients in their final days require careful symptom management, and families need support and coaching as death approaches.

Preparing the Family for the Dying Process

Patients and families are usually unaware of the changes that typically occur during the last hours of life and the actual moment of death. Health-care professionals should explain the expected changes in cognition and physical function before they occur in order to alleviate distress and to prevent panic. This is particularly useful for families planning a home death, or for those closely involved in institutional care. Frequent points for education to families/friends that are sitting in vigil with a patient may include:

- The interpretation of purposeless bodily movements or grimaces as expressions of physical discomfort or emotional distress.
- The *death rattle*—a loud wet rattling respiration due to small amounts of secretions in the back of the throat—may be interpreted as dyspnea or choking by family members.
- Encouragement of those present to speak to, touch, and comfort their loved one. Although it is not possible to know the patient's experience, it is often observed that a familiar voice, touch, and music may have a calming presence for some patients.

Among the issues that are important to resolve, if not previously discussed, are preferences for location of care and for limits on invasive or aggressive resuscitative therapies that often are ineffective in a patient with end-stage disease. Communication between caregivers and patients/families is particularly important for seriously ill hospitalized patients in whom there is a considerable mismatch between what patients prefer and what treatments they actually receive.^{77,78} Finally, clinicians should review and discontinue orders that may no longer be necessary, including nonessential medications, scheduled laboratory tests, radiographic studies, and telemetry or other monitoring.

Nonessential drugs (i.e., those that are no longer consistent with the overall care plan) should be discontinued if possible.⁷⁹⁻⁸¹ These may include antihypertensives, lipid-lowering medications, calcium and iron supplements, vitamins, diabetic medications, and prophylaxis for thrombus with injections of heparin compounds. The continuation of medications for angina or heart failure should be guided by a clinical assessment of need; poor control of these conditions may adversely impact HRQOL during the final weeks, although this is unlikely in the final days.

The management of patients with diabetes at the end of life must be tailored to the individual patient's needs and the severity of the illness. In general, the risks and consequences of hypoglycemia are greater than those of hyperglycemia in patients at the end of life; looser control of blood sugars is appropriate. If at all

possible, sliding scale insulin, which requires painful finger sticks to assess blood sugars, should be avoided.

Anticonvulsants are generally maintained; however, the need for the initial prescription should be scrutinized; ongoing treatment may not be needed if the anticonvulsant was started for neuropathic pain or seizure prophylaxis. If the patient has a documented seizure disorder, it is imperative that an alternative route of administering such as intravenously (IV) or subcutaneously (SQ) for lorazepam and levetiracetam or diazepam per rectum be instituted if and when the oral route is lost to prevent the recurrence of seizures.

Most medications can be stopped abruptly; however, certain medications should be gradually stopped (tapered) to prevent complications. As a general rule, this includes cardiovascular medications and those affecting the central nervous system (e.g., beta-blockers, clonidine, antidepressants, benzodiazepines).

It is recommended that a comfort care order set or guide be used to formulate care plans to ensure that there are environmental

orders for the comfort and support of both the patient and the family; nonpharmacological interventions such as fans; eye, mouth, and skin care; as well as orders for comfort medications such as an opioid, antipsychotic, anxiolytic in usually lower but frequent doses. The care order should also take into account that the oral and intravenous routes may not be practical during the dying process. In almost all cases, symptoms can be managed with sublingual, subcutaneous, or per rectal routes. As required drugs for common symptoms (including pain, dyspnea, nausea, delirium, anxiety, and noisy respiratory secretions) should be prescribed according to an agreed upon protocol. This ensures that needed medications are available for comfort care at any time, without the delay in obtaining an order.

Providing care to actively dying patients presents unique challenges for the clinician. Patients in their final days require careful symptom management, and families need support and coaching as death approaches.

152 Rehabilitation of the Cancer Patient

Michael D. Stubblefield

INTRODUCTION

Physical medicine and rehabilitation, also known as rehabilitation medicine or physiatry, is the medical specialty concerned with restoring and/or maintaining the highest possible level of function, independence, and quality of life. This relatively new specialty has evolved into a number of subspecialties to meet the needs of patients from all age groups whose primary medical issues may be cardiac, pulmonary, amputation, spinal cord injury, traumatic brain injury, sports injury, or pain to name a few. Cancer rehabilitation is a rapidly emerging subspecialty of rehabilitation medicine whose primary focus is the evaluation and management of neuromuscular, musculoskeletal, pain, and functional disorders that result from cancer and/or its treatments, including surgery, chemotherapy, and radiation. This chapter will discuss the principles of a safe and effective evaluation and rehabilitation of many of the common disorders encountered by cancer patients throughout the cancer continuum. The full scope of a cancer survivor's rehabilitation needs is vast and cannot be adequately addressed in one chapter due to space limitations. A comprehensive reference on the topic of cancer rehabilitation is available.¹

The American Cancer Society estimates that in 2013 there were 13.7 million cancer survivors, 1.7 million new cancer patients, and 580,000 cancer deaths in the United States (Fig. 152.1).² The number of cancer survivors is expected to grow to 18.1 million by the year 2020.³ The rapidly growing number of cancer survivors is more than 50 times the relatively stable estimate of 273,000 US spinal cord injury survivors in 2013.⁴ Despite this marked disparity in numbers, there are more than 20 fellowship programs to train spinal cord injury physicians but only 2 to train cancer rehabilitation physicians.⁵ This translates into scores of well-trained spinal cord injury physicians but only a handful of cancer rehabilitation physicians to take care of the millions of patients who need their services. More should be done to increase the ranks of well-trained cancer rehabilitation physicians.

COMPLICATIONS OF CANCER AND ITS TREATMENT

The complications of cancer and its treatment represent a broad and diverse group of disorders that are covered in detail throughout this textbook. In the context of cancer rehabilitation, several specific disorders are of interest because they can heavily impact the safety and effectiveness of rehabilitative efforts. It is imperative for the clinician to fully understand that there are no absolutes in oncology and that every decision made with or on behalf of a patient has an implicit cost-benefit analysis underlying it. This is as true for the physical or occupational therapist deciding if it is safe to ambulate a patient as it is for the neurosurgeon deciding whether to attempt resection of metastatic disease compressing the spinal cord. Poor outcomes are common in cancer and can happen at any time, often unexpectedly and occasionally dramatically. The challenge for the rehabilitation specialist is to maximize

function and quality of life while minimizing, to the best of their ability and knowledge, any potential adverse outcomes.

Direct Effects of Cancer

The direct effects of cancer are often obvious, with the clinical impact on function being dependent largely on the location and extent of disease. Examples are a large lung mass compromising pulmonary function and, subsequently, endurance and stamina, or an epidural metastasis to the spine compressing the spinal cord causing weakness and pain. A working understanding of several of the direct complications of cancer including its effects on the central and peripheral nervous system and on bony integrity, are of great importance in cancer rehabilitation and will be discussed in detail in subsequent sections.

Paraneoplastic Effects

Paraneoplastic syndromes (PNS) are rare disorders (<1% of cancer patients) that cause tissue or organ damage via remote effects of a primary or metastatic cancer.⁶ Most PNS occur because the tumor secretes a substance that mimics normal hormones or that interferes with circulating proteins. Systemic paraneoplastic disorders include cancer cachexia, hypercalcemia, Cushing syndrome, and Trousseau syndrome.⁷⁻¹⁰ A number of PNS affect the central nervous system (CNS) (limbic encephalitis, encephalomyelitis, cerebellar degeneration, opsoclonus-myoclonus, optic neuropathy/retinopathy, brain stem encephalitis, stiff person syndrome, motor neuron disease, necrotizing myopathy) and peripheral nervous system (sensory neuronopathy, acute sensorimotor neuropathy, chronic sensorimotor neuropathy, neuromyotonia, chronic gastrointestinal pseudo-obstruction/autonomic neuropathy, Lambert-Eaton myasthenic syndrome, myasthenia gravis, inflammatory myopathy) with potentially devastating impacts on function and quality of life.¹¹ These disorders, although relatively rare, represent a significant therapeutic challenge to the rehabilitation specialist.

Chemotherapy

Chemotherapy is a cornerstone of cancer treatment for many malignancies and may be given either with intent to cure or to prolong life. The myriad complications of the ever growing number of agents are discussed at length in other chapters. The impact of these complications on function and quality of life depends on the specific derangement or complications induced by the agent. Anemia, neutropenia, thrombocytopenia, myopathy, cardiomyopathy, neuropathy, contracture, fatigue, thromboembolism, nausea, and edema are just a few of the common disorders resulting from chemotherapy that can have a major impact on rehabilitation efforts. Several of these complications and their specific implications for rehabilitation will be discussed in subsequent sections.

Figure 152.1 Pie chart illustrating the number of cancer survivors (13,800,000), new cancer cases (1,700,000), and cancer deaths (580,000) in 2013. (From Cancer Facts & Figures 2013. American Cancer Society Web site. <http://www.cancer.org/research/cancerfactsfigures/cancerfactsfigures/cancer-facts-figures-2013>.)

Radiotherapy

Approximately 50% of cancer patients will be treated with radiation therapy at some point during the course of their disease, and radiation may play a critical role in as many as 25% of cancer cures.¹² Despite the important beneficial effects of radiation in cancer care, its adverse effects on normal tissue are a major source of disability for both patients with active cancer and cancer survivors.¹³ Evaluations and treatment of the long-term complications of radiation are extremely important components of the clinical activities of the cancer rehabilitation specialist and will be discussed in detail in the following paragraphs.

Surgery

Postsurgical impairments depend not only on the anatomic site and extent of the procedure, but also on any medical comorbidity the patient has. Surgical complications are common in the cancer setting and impact heavily on overall outcome as well as rehabilitation needs. Rehabilitation is often instrumental in returning function and quality of life to patients following surgery. Efforts may be directed at the restoration of functional disorders ranging from diminished stamina following prolonged bed rest to restoration of a limb following hemipelvectomy. The postsurgical rehabilitation needs of any given patient are unique.

Thromboembolism

There is considerable and high quality data available on the prevention and treatment of thromboembolism, including comprehensive guidelines specific to the cancer and rehabilitation settings.^{14,15} There is comparatively little data concerning the safe and effective rehabilitation of patients with thromboembolism. The dogma from the not too distant past was to immobilize patients with deep vein thrombosis (DVT) and range of motion (ROM) exercises for anywhere from 2 to 10 days presumably to allow the clot to mature by the formation of fibrin cross-links and to thereby decrease the risk of dislodging the clot to form a pulmonary embolism (PE).¹⁶ This commonly followed, long-held, and nonevidence-based recommendation was ultimately supported by a limited study suggesting that immobilization of the affected limb

for at least 48 to 72 hours while the patient is anticoagulated was justified and prudent to prevent PE.¹⁷ Partsch¹⁶ describes a survey of 31 international experts who gave the recommendation to immobilize patients for 4 to 5 days prior to intensifying physical activity. The development of low-molecular-weight heparin (LMWH) prompted a reevaluation of the bed rest recommendation as patients with acute DVT treated with LMWH injections at home did at least as well in terms of recurrent thromboembolism and bleeding as did patients treated in the hospital with unfractionated heparin delivered intravenously.^{18,19} Although not directly applicable to patients in either the inpatient or outpatient rehabilitation setting, the realization that no increase in morbidity or mortality was seen in patients with acute DVT treated with LMWH injections served as justification for liberalization of the bed rest recommendation that had inhibited rehabilitation efforts, particularly on inpatient rehabilitation units.

Although the question of when a patient with lower extremity DVT can begin to ambulate has not been answered with the same evidence-based rigor as other questions concerning thromboembolism, there is a growing body of clinical trials on the topic that support the safety and potential benefits of early mobilization.^{16,20-25} Several reviews and one meta-analysis are also available and support the safety and benefits of early mobilization following both DVT and PE while dispelling the recommendation for bed rest as part of the early management of thromboembolism.^{16,26-31}

Upper extremity DVT (UEDVT) represents about 10% of DVTs and can be idiopathic but is more often associated with central venous catheter use, pacemakers, or cancer.³² The relative incidence of UEDVT may be rising due to increased use of central venous catheters and is associated with PE in up to one-third of patients. Other conditions associated with UEDVT include post-thrombotic syndrome, superior vena cava syndrome, septic thrombophlebitis, thoracic duct obstruction, and brachial plexopathy.³³ Despite the high incidence of conversion of UEDVT to PE, no studies are available to address the multitude of questions concerning the rehabilitation of patients with UEDVT. This lack of data concerns such basic issues as the safe timing and type of exercise that can be safely done following the diagnosis of UEDVT as well as if and when decongestive therapy (massage, wrapping, pumps) for upper extremity swelling disorders such as lymphedema can be performed. Lack of even basic data on these matters represents a major shortcoming in our overall knowledge on the topic of cancer rehabilitation and challenges our ability to guide risk-benefit analyses for patients with UEDVT who will likely benefit from physical therapy (PT), occupational therapy (OT), or decongestive therapy.

Although not strictly evidence based due to major shortcomings in the literature concerning the rehabilitation of patients with thromboembolism, the guidance developed by the author and used at the Memorial Sloan-Kettering Cancer Center (MSKCC) is presented in Table 152.1. It is critical to remember that each patient and situation is unique and that these recommendations are only starting points that should not supersede clinical judgment and assessment of the risks and benefits to the patient of engaging in a given activity.

Other Medical Disorders

The evidence base for the safe and effective rehabilitation of patients with a variety of general medical disorders is also limited. Despite this limitation, guidance with widespread clinical use has evolved on such issues as thrombocytopenia, anemia, neutropenia, cardiac dysfunction, pulmonary dysfunction, and electrolyte abnormalities. In general, these recommendations applied to rehabilitation are based on indirect evidence from the medical literature. Exercise precautions for cancer patients with a variety of disorders are presented in Table 152.2. Again, the potential risks and benefits of pursuing any course of therapy must be carefully weighed.

TABLE 152.1

Guidelines for Physical, Occupational, and Lymphedema Therapy in Patients with Venous Thromboembolism

- Lower Extremities
 1. For patients with acute lower extremity deep vein thrombosis (DVT), with or without pulmonary embolism (PE), and no inferior vena cava (IVC) filter, therapy (including physical, occupational, and lymphedema with bandaging and manual lymphatic drainage [MLD]) can be initiated once they are therapeutic on an anticoagulant. Resistive exercises should generally be deferred for 48–72 hours. Definition of therapeutic anticoagulation by modality:
 - Low–molecular-weight heparin (LMWH) preparations are preferred because they are therapeutic immediately following the first injection. Monitoring is not required. Common preparations include: enoxaparin (Lovenox), dalteparin (Fragmin), and tinzaparin (Innohep).
 - Unfractionated heparin may take 1–2 days to become therapeutic but patients are more prone to bleeding complications than with LMWH. The adjusted partial thromboplastin time (APTT) should be monitored and therapy can begin when it is between 50 and 70.
 - Warfarin (Coumadin) may take several days to become therapeutic. The International Normalized Ratio (INR) should be monitored and therapy can begin when it is between 2 and 3.
 2. For patients with acute lower extremity DVT (with or without PE) and an IVC filter, therapy can be initiated immediately regardless of their anticoagulation status.
 3. For patients with acute lower extremity DVT who cannot be anticoagulated and an IVC filter cannot be placed, therapy can be started immediately but should be functional in nature (ambulation, balance, ADL training) and avoid resistive and repetitive exercises. Such patients are at very high risk for PE and death. Therapists are advised to discuss therapy interventions with the patient’s primary or rehabilitation medicine physician so that the relative risks and benefits of therapy can be better delineated.

- Upper Extremities
 1. Upper extremity DVT carries the same risk for PE and death as lower extremity DVT. IVC filters are not protective. For patients with acute upper extremity DVT with or without PE, therapy (including physical, occupational, and lymphedema with bandaging and MLD) can be initiated once they are therapeutic on an anticoagulant. Resistive exercises should generally be deferred for 48–72 hours. (See anticoagulation guidelines previously.)
 2. For patients with acute upper extremity DVT who cannot be anticoagulated therapy should be functional in nature (ambulation, balance, ADL training) and should avoid resistive and repetitive exercises. Such patients are at very high risk for PE and death. Therapists are advised to discuss therapy interventions with the patient’s primary or rehabilitation medicine physician so that the relative risks and benefits of therapy can be better delineated.

TABLE 152.2

Exercise Precautions for Cancer Patients

Medical Problem	Laboratory Values	Recommendations
<i>Thrombocytopenia</i> Normal values: platelets 150,000–450,000/m ³	30,000–50,000/m ³ 20,000–30,000/m ³ <20,000/m ³	ROM, aerobic activity, light weights (1–2 lb; no heavy resistance or isokinetic exercise); ambulation Self-care, gentle passive/active ROM, aerobic activity, ambulation Ambulation and self-care with assistance as needed for safety; minimal/cautious activity; essential ADLs only
<i>Anemia</i> Normal values: hematocrit 37%–47%; hemoglobin 12–16 g/dL	Hematocrit <25%, hemoglobin <8 g/dL Hematocrit 25%–35%; hemoglobin 8–10 g/dL Hematocrit >35%; hemoglobin >10 g/dL	ROM exercise, isometrics; avoid aerobic or progressive programs Light aerobics, light weights (1–2 lb) Activity as tolerated
<i>Neutropenia</i> Normal values: ANC >1.500/mm ³	ANC 500–1,000/mm ³ ANC <500/mm ³	Infection risk moderate; consider increased hygiene procedures and limited contact with other patients, particularly if further nadir anticipated Infection risk high; strict hygiene and limit contact with other persons
<i>Pulmonary Dysfunction</i> Pulmonary function tests, chest radiograph	Maintain pulse oximetry >90% 50%–75% of predicted FEV ₁ or diffusion capacity 75%+ of predicted FEV ₁ or diffusion capacity Large plural effusions or pericardial effusions or multiple metastases to lungs	Titrate O ₂ supplementation Light aerobic exercise Most programs fine ROM; few submaximal isometrics; consult cardiologist and oncologist
<i>Cardiac Dysfunction</i> Ejection fraction, electrocardiogram	Recent PVCs; fast atrial arrhythmia; ventricular arrhythmia; ischemic pattern	No aerobics; consult cardiologist
<i>Electrolyte Abnormalities</i> Na K ⁺	Below 130 Below 3.0 or above 6.0 requires treatment	No exercise No exercise

ADLs, activities of daily living; ANC, absolute neutrophil count; FEV₁, forced expiratory volume in 1 second; PVCs, premature ventricular contractions.

NEUROMUSCULAR COMPLICATIONS OF CANCER AND CANCER TREATMENT

The treatment of neuromuscular complications of cancer is a major component of the services offered by both the rehabilitation medicine physician and the physical and occupational therapists. Such disorders include those of the brain, spinal cord, nerve roots, plexus, peripheral nerve, and muscle.³⁴

Brain Dysfunction

The brain, along with the myriad cognitive and physical functions that it serves, is often compromised in the cancer setting. Such dysfunction can result from direct effects of the tumor, radiation, radiation necrosis, paraneoplastic effects, or other medical disorders.

Brain tumors vary widely in aggressiveness and prognosis. Even a benign or relatively low-grade lesion may have severe functional consequences depending on its location. It is unclear to what extent tumor type or location impacts rehabilitation prognosis; however, some studies suggest a tendency for better gains in meningioma patients and in those with left hemispheric lesions.^{35,36}

The most common neurologic deficits in brain tumor patients undergoing acute rehabilitation include impaired cognition (80%), weakness (78%), and visual-perceptual impairment (53%) with most patients having multiple impairments.³⁷ Although overall prognosis may be a factor, most rehabilitation disposition decisions are guided by the patient's neurologic status, clinical course, and activity tolerance. A patient whose neurologic status is actively worsening will likely not benefit from intensive rehabilitation.

Specific rehabilitation interventions depend on the combination of deficits and are generally similar to measures used for patients with other etiologies of brain disorders, such as traumatic brain injury or stroke. Rehabilitation efforts are directed toward such goals as the improvement of bed mobility, transfers, self-care, ambulation, and if necessary, wheelchair training. Strategies are employed to promote functional cognition, clear communication, bowel and bladder continence, safe swallowing, adequate nutritional intake, optimal sensory input (including vision and hearing), and restorative sleep. Attention must be paid to the prevention of complications of impaired mobility such as skin breakdown or DVT. Similarly, complications related to the primary tumor and other comorbidities such as pain, neurologic decline, seizure, and depression should be evaluated and treated. The hemiplegic patient will generally benefit from gait training with an assistive device and a brace such as an ankle-foot orthosis (AFO) when appropriate. Proper arm positioning, with support of the shoulder to prevent pain in a flaccid or spastic limb, should be used. A variety of adaptive equipment are available for individuals who must perform tasks one handed, such as reachers, sock donners, and elastic shoelaces.

Cognitive strategies often rely on compensations such as keeping a regular routine and maintaining a journal or *memory notebook*. The patient's insight into cognitive deficits may be impaired, and education regarding these deficits can allow the patient to more effectively compensate and allow family, friends, and caregivers to have appropriate expectations. In some cases, especially those in which cognitive status is anticipated to remain fairly stable, in which functional expectations are high, or where conflict or confusion exists about the patient's abilities, neuropsychological testing helps to more fully define the extent of cognitive deficits and also to elucidate cognitive strengths. For example, determining whether an individual learns best with auditory, written, or nonverbal presentations can facilitate the most efficient compensation for cognitive deficits. Pharmacologic and nonpharmacologic therapies to address pain, spasticity, mood, bowel/bladder, and sleep/wake issues are often indicated.

Functional recovery is similar in patients with brain tumors as compared with acute stroke.³⁸ Better functional improvement is a significant predictor of longer survival in patients with brain

metastases and glioblastoma multiforme (GBM). The literature suggests that the length of stay for inpatient rehabilitation for brain tumor patients is generally shorter than patients with other brain disorders such as traumatic brain injury and stroke.^{35,36} This may relate to better initial functional status; other possible contributing factors include fewer behavioral sequelae, better social supports, and expedited discharge planning due to prognostic factors.³⁹ In one study, although functional status improved during rehabilitation, quality-of-life scores did not improve until the discharge home. The functional independence measure (FIM) and the disability rating scale are more sensitive than the Karnofsky performance status scale in detecting changes in functional status.⁴⁰

Spinal Cord Dysfunction

Symptomatic spinal cord injury (SCI) due to spinal metastasis occurs in up to 5% of all cancer patients.⁴¹ Patients with cancer can develop SCI as a direct result of their cancer, its treatment (e.g., radiation), and other preexisting or acquired conditions. SCI in the cancer setting can present a significant decision-making and management challenge.⁴² This challenge is compounded as cancer-related SCI most often occurs as a late complication when poor overall prognosis and declining medical status can significantly and adversely impact rehabilitation interventions and functional prognosis.

Life expectancy following spinal surgery varies with cancer type. One study demonstrated a median survival of 7.7 months for all cancer types combined, with colon cancer patients surviving only 3.3 months and lung cancer patients only 3.6 months. Sarcoma, prostate, renal cell, and breast carcinoma did better, with median survival ranging from 7.8 to 15.4 months.⁴³ A retrospective evaluation of patients with neoplastic SCI admitted for inpatient rehabilitation demonstrated a combined median overall survival time of only 4.1 months from the date of rehabilitation admission to death. Patients with gastrointestinal cancer had an even poorer prognosis with a median survival of only 0.6 months.⁴⁴ The phase of cancer treatment can have a profound impact on survival and prognosis for functional recovery. A patient with metastatic prostate or breast cancer, for instance, whose initial presentation is with SCI and has not received systemic therapy, can be expected to have a much better prognosis for survival and functional restoration than a patient who has undergone and failed multiple treatment options.

SCI in the cancer setting can result directly from the cancer (epidural, leptomeningeal, or intramedullary tumor; Fig. 152.2), indirectly from the cancer (paraneoplastic phenomenon), or from treatment of the cancer (radiation, chemotherapy, surgery). Other causes of SCI in the cancer setting may include infection (meningitis, epidural abscess, discitis/osteomyelitis), vascular disorders (hemorrhage, infarct), degenerative disorders (cervical spinal stenosis), and even metabolic disorders (osteoporotic compression fractures).

The vertebral body is the most common site of metastasis within the spine, largely reflecting its volume relative to other spinal structures. Metastatic tumors of the spine are more common than primary spine tumors. Cancers that commonly metastasize to the spine are those of the breast, lungs, prostate, and kidneys.⁴⁵ Epidural tumors are the most common cause of SCI in cancer and can arise from the vertebra, enter the spinal canal through the neural foramen or be deposited hematogenously in the epidural space. Leptomeningeal metastases occur in 3% to 8% of all cancer patients and can be associated with significant neurologic dysfunction. The most common tumors that metastasize to the leptomeninges include leukemia, lymphoma, melanoma, and breast and lung cancers.⁴⁶ Intramedullary tumors are the rarest of the tumors that affect the CNS but can produce profound neurologic deficits that vary depending on the location and pathology of the tumor.

SCI from epidural-based tumors generally affects all spinal tracts either completely or to varying degrees. Asymmetric compression does occur and can have unpredictable patterns in early

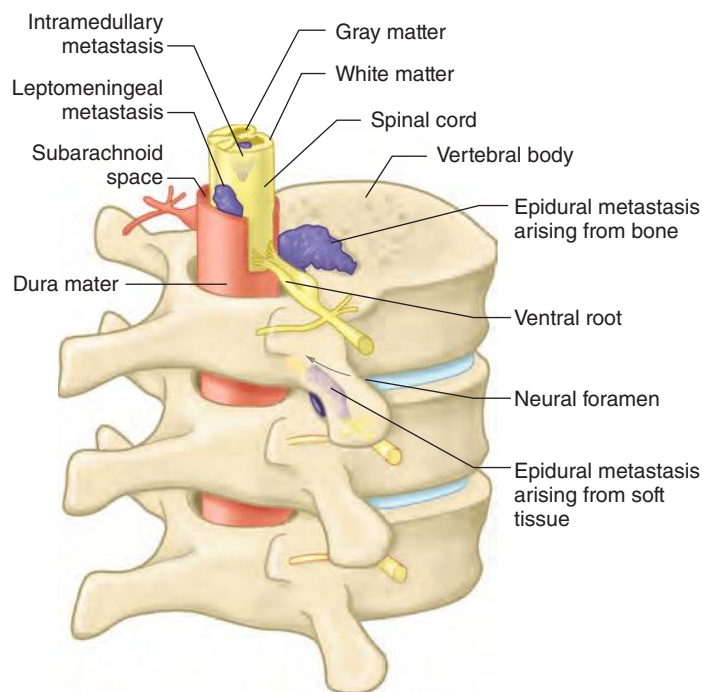

Figure 152.2 The spinal cord and nerve roots can be affected by metastatic or primary tumors arising from epidural, intramedullary, or leptomeningeal spaces.

compression but generally progresses to affect all components of the spinal cord. Clinically, such patients present with weakness, bowel and bladder dysfunction, and multimodal sensory loss including light touch, pain, vibration, and proprioception. Pain, if present, is usually local.

The level of injury significantly affects the potential for functional recovery. It should be noted that the degree of functional recovery anticipated in a patient with a nonmalignant cause of SCI (such as trauma from a motor vehicle accident) is generally greater than that anticipated in malignant SCI. This is because patients with cancer tend to develop SCI later in their disease and usually progress in their cancer and other medical comorbidities.

The care of patients with acute SCI includes the maintenance of ventilation in those with high levels of injury. It also includes the treatment of pain, autonomic dysregulation, and bowel and bladder dysfunction. Patients are at risk of developing DVT, PE, pulmonary and urinary tract infections, fecal impaction, decubiti, immobilization hypocalcemia, spasticity, contractures, and osteoporosis. A comprehensive treatment plan includes DVT and PE prophylaxis, spirometry, and chest physiotherapy; the initiation of intermittent urinary catheterization every 4 to 6 hours when urine volumes are less than 2,000 mL per day; the initiation of a bowel program; turning every 2 hours; and use of high-airflow mattresses, use of heel protectors, and daily PT and ROM.^{15,47}

The use of LMWH is currently recommended for DVT and PE prophylaxis during the acute management phase of SCI.¹⁵ The independent use of low-dose unfractionated heparin, elastic compression stockings, and intermittent pneumatic compression devices is not recommended. When used alone, they appear to be relatively ineffective. It is recommended that LMWH be continued or converted to full-dose oral anticoagulation for a minimum of 3 months or at least until completion of the rehabilitation phase.⁴⁸

Patients with injuries above the T6 level are at risk of developing autonomic dysreflexia, which is defined as an increase in blood pressure of greater than 20 mm Hg above baseline. It results from stimulation of the splanchnic division of the sympathetic nervous system by a noxious stimulus below the level of the lesion and causes the sympathetic responses of vasoconstriction and hypertension. Autonomic dysreflexia constitutes a medical emergency and must be evaluated and treated immediately.

The patient's ability to participate in rehabilitation therapies while undergoing further treatments must be considered when an acute or subacute inpatient rehabilitation program is sought. Rehabilitation programs for those with SCI due to spinal tumors have been shown to improve mobility and self-care.⁴⁹ Research indicates that clinical and functional status is a valuable prognostic factor for survival of those with SCI due to metastatic tumor disease.⁵⁰ The rehabilitation program should be started as early as possible and should be of short duration.⁴⁴ Thus, the selection of patients who have the potential to improve function may improve survivability as well as quality of life and ability to perform activities of daily living (ADL) and mobility.

Peripheral Nervous System Dysfunction

Radiculopathy can result from a variety of disorders that affect one or more nerve roots and is a very common cause of pain and disability in the cancer setting. Radiculopathy can occur from compressive or less common noncompressive etiologies. Although the incidence of radiculopathy in cancer patients and survivors is unknown, it is likely that most nerve root pathology results from the same degenerative disorders, largely spondyloarthropathies, that affect the general population with a prevalence of 3% to 5%.⁵¹ One large study on the epidemiology of cervical radiculopathy in a population of patients in Rochester, Minnesota placed the average annual age-adjusted incidence at 83.2 per 100,000.⁵² Degenerative causes of radiculopathy can be discogenic (e.g., herniated nucleus pulposus), from hypertrophy of ligaments and other soft tissues (e.g., ligamentum flavum), or from excess bone formation (e.g., osteoarthritis). The narrowing of the spinal canal or neural foramen with subsequent compression of neural and vascular structures resulting from one or more degenerative processes is called spinal stenosis. Lumbar spinal stenosis is estimated to affect 1 in 1,000 persons older than 65 years of age.⁵³

Compressive radiculopathy resulting directly from cancer most commonly results from an epidural tumor that can arise from the vertebral body, paravertebral structures, or the epidural space itself.⁵⁴ Intramedullary tumors, including leptomeningeal and intramedullary disease, can also cause compressive radiculopathy. Of these, compression by leptomeningeal disease is far more common affecting 5% to 8% of patients with cancer.⁵⁴

Noncompressive causes of radiculopathy include radiation, chemotherapy, and paraneoplastic syndromes as well as disorders such as acute idiopathic demyelinating polyradiculoneuropathy (AIDP), a subtype of Guillain-Barré syndrome (GBS), chronic idiopathic demyelinating polyradiculoneuropathy (CIDP), amyloidosis, sarcoidosis, diabetes mellitus, and rheumatologic disorders (Fig. 152.3).¹ *Herpes zoster* is also a common cause of radiculopathy in the cancer setting causing a dermatomal vesicular rash known as shingles.⁵⁵ *Herpes zoster* causing dermatomal pain without a rash is termed zoster sine herpette.⁵⁶ An eruption of *Herpes zoster* is related to immunosuppression from cancer, steroids, and chemotherapy with 1% to 2% of cancer patients having at least one infection during the course of their disease.⁵⁷ Polyradiculopathy from radiation may mimic a leptomeningeal tumor because the cauda equina may demonstrate enhancement on magnetic resonance imaging (MRI; see Fig. 152.3).⁵⁸ Although relatively uncommon, radiculopathy from radiation has been reported as sequelae of testicular cancer, vertebral metastases, and lymphoma.⁵⁹⁻⁶⁴ In the author's clinical experience, radiation-induced radiculopathy is most commonly seen in Hodgkin lymphoma (HL) survivors who have received mantle field (MF) or periaortic radiation and head and neck cancer patients often in conjunction with plexopathy. Additionally, in rare instances, radiculoplexopathy can result from single fraction (2,400 cGy) radiation. Neurotoxic chemotherapy can also adversely affect the nerve root as part of a more generalized neuropathy. Patients with preexisting radiculopathy from a degenerative or other cause

may be particularly predisposed to the adverse effects of neurotoxic chemotherapy.^{65,66} Subacute motor neuronopathy is a paraneoplastic disorder described in patients with HL, non-Hodgkin lymphoma, and thymoma as a subacute lower motor neuron syndrome that primarily involves the lower extremities without pain, significant sensory loss, or upper motor neuron findings. Secondary thinning of the ventral nerve roots and widespread patch segmental demyelination of spinal nerve roots and the brachial and lumbosacral plexus can be seen histologically in addition to patchy degeneration and loss of anterior horn cells and occasional inflammatory infiltrates.⁶⁷ Non-cancer-related causes of noncompressive radiculopathy including diabetes, rheumatologic disorders, and idiopathic radiculoneuropathies such as GBS and CIDP not uncommon in the general population should be included in the differential diagnosis when evaluating cancer patients and survivors with signs and symptoms suggestive of radiculopathy.

Plexopathy affects as many as 1% of cancer patients.⁶⁸ The cervical, brachial, or lumbosacral plexus can be involved and the etiology can be neoplastic or radiation induced as well as idiopathic (idiopathic brachial neuritis, CIDP, GBS), diabetic (diabetic radiculoplexus neuropathy), or traumatic (surgery). Malignancy most commonly affects the brachial plexus followed by the lumbosacral plexus and, least commonly, the cervical plexus.⁶⁹ Benign tumors of the plexus are usually reported to be more common than malignant ones.⁷⁰⁻⁷² Radiation plexopathy is a common component of the radiation fibrosis syndrome (RFS) that is characterized by

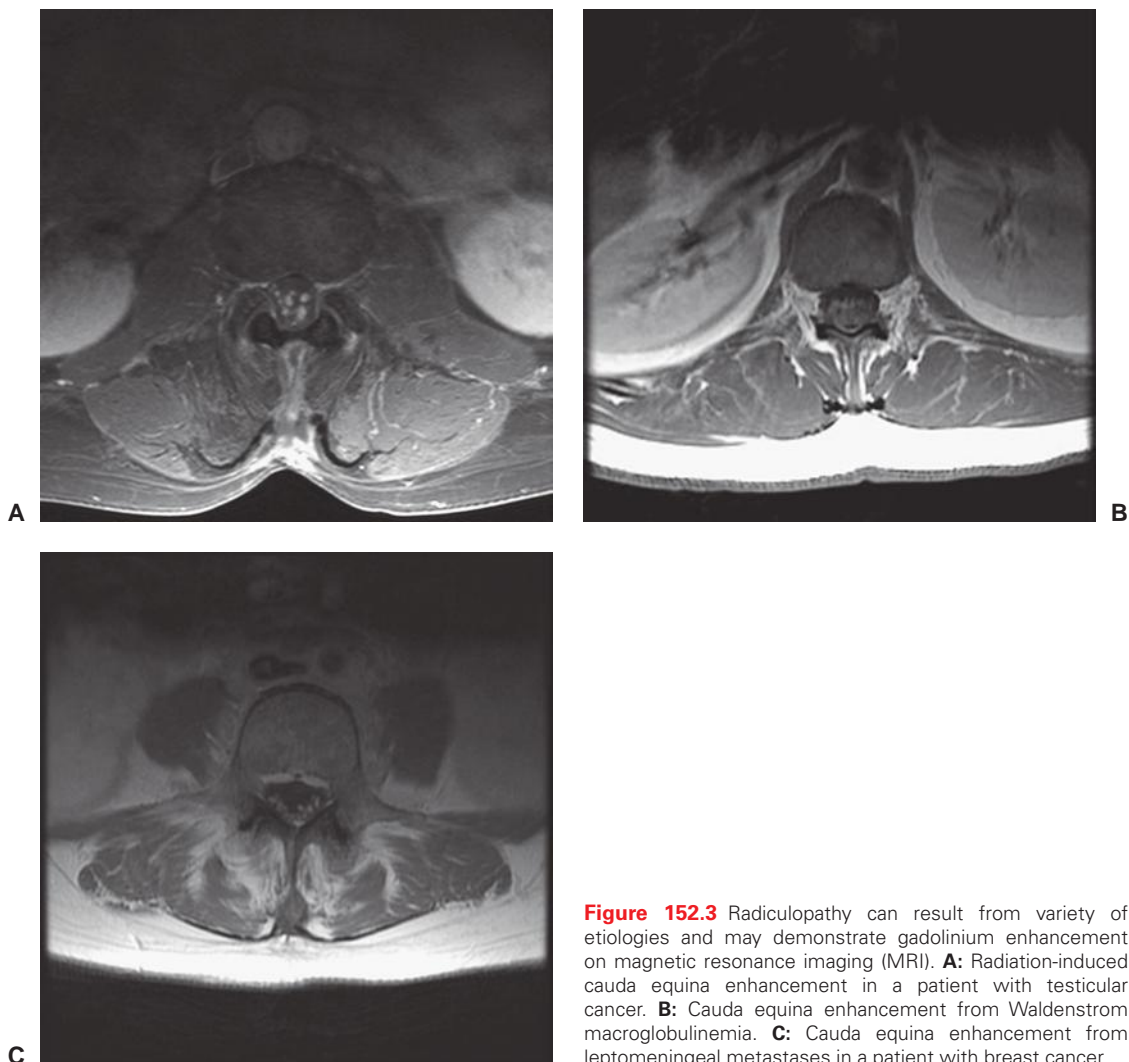

Figure 152.3 Radiculopathy can result from variety of etiologies and may demonstrate gadolinium enhancement on magnetic resonance imaging (MRI). **A:** Radiation-induced cauda equina enhancement in a patient with testicular cancer. **B:** Cauda equina enhancement from Waldenström macroglobulinemia. **C:** Cauda equina enhancement from leptomeningeal metastases in a patient with breast cancer.

insidious fibrosis with axonal demyelination and, ultimately, axonal loss. Radiation plexopathy is commonly seen with radiculopathy. Radiation to the plexus can rarely cause a mild reversible syndrome but is more commonly a delayed and progressive one.⁷³ The risk of brachial plexopathy in the adjuvant breast cancer setting is <1% when the dose per fraction is 2 Gy and the total dose is 50 Gy or the dose per fraction is 2.2 Gy to 2.5 Gy and the total dose is 34 Gy to 40 Gy. However, if the dose per fraction is 2.2 Gy to 4.58 Gy and the total dose is 43.5 Gy to 60 Gy, the brachial plexopathy risk increases to 1.7% to 73%.⁷⁴ Delayed radiation-induced brachial plexopathy usually occurs after a latent interval that can vary from a few months to several years with a peak onset of neurologic symptoms occurring between 2 and 4 years after radiation.⁷⁵ The upper plexus is commonly affected preferentially in HL survivors treated with MF radiation and head and neck cancer patients possibly due to the longer course of the upper trunk and lateral cord of the brachial plexus through the neck as well as the pyramidal shape of the thorax providing less protective tissue. Additionally, the upper plexus may represent the most caudal extent of radiation delivered for some head and neck cancer patients.

Differentiating radiation induced from malignant plexopathy is a diagnostic challenge and both etiologies may be present together. Imaging with gadolinium-enhanced MRI is the diagnostic test of choice when excluding a tumor of the brachial plexus.⁷⁶ Positron-emission tomography/computed tomography (PET-CT) has a role to play in selected cases. Malignant etiologies of plexopathy are generally more painful than radiation-induced plexopathy, although either can manifest severe pain.⁷⁷ Myokymia on needle electromyography is suggestive of a radiation-induced etiology but does not exclude a malignant component.⁷⁸

Idiopathic brachial neuritis (IBN), also known as neuralgic amyotrophy, Parsonage-Turner syndrome, and other synonyms, have an incidence of approximately 2 to 3 per 100,000 person-years.⁷⁹ The disorder can be idiopathic or hereditary. The idiopathic form is often precipitated by antecedent events such as infection, immunization, strenuous exercise, surgery, and a variety of other causes.⁷⁹ Clinically, IBN is classically characterized by severe and acute burning pain in the shoulder and arm that may last for several days or weeks and is followed by muscle weakness, atrophy, and sensory loss. IBN may go unrecognized in cancer patients if only the obvious cancer and treatment-related causes of brachial plexopathy are considered. Similarly, diabetic radiculoplexus neuropathies can affect the cervical, thoracic, and lumbosacral nerve roots as well as the brachial and lumbosacral plexus. Perhaps the best known of these disorders is diabetic lumbosacral radiculoplexus neuropathy (DLRPN), also known as diabetic amyotrophy among other synonyms. DLRPN usually presents clinically with unilateral acute to subacute and severe lower extremity pain in the thigh or leg that may spread to the entire extremity.⁸⁰ Like IBN, DLRPN may go unrecognized in the cancer setting if only neoplastic or treatment-related etiologies are considered and can occur even with relatively low blood glucose levels as might be seen with steroid-induced hyperglycemia.

Neuropathy is any condition arising from the damage and dysfunction of the peripheral nerves including the motor, sensory, and autonomic nerves that connect the CNS (brain and spinal cord) to the rest of the body.⁸¹ The peripheral nerve includes the nerve root and plexus as well as the peripheral nerve proper. Peripheral neuropathy is common in the cancer setting as a result of neurotoxic chemotherapy or radiation as well as from direct and paraneoplastic effects of cancer. Neuropathy is also very common in the general population with diverse etiologies that can affect cancer patients even if unrelated to malignancy or its treatment. Such etiologies include toxic or metabolic derangements (diabetes mellitus, vitamin B-12 deficiency, alcoholism), inherited disorders (Charcot-Marie-Tooth), paraprotein disorders (monoclonal gammopathy of unknown significance [MGUS]), critical illness neuropathy, and idiopathic disorders such as CIDP or GBS just to name a few.⁸² The clinical manifestations of neuropathy may

include any combination of weakness, sensory deficits, pain, and autonomic dysfunction with resultant gait and other functional deficits. Often, multiple peripheral nervous system disorders such as radiculopathy and neuropathy coexist, compounding the clinical features of each disorder. It is important to remember that, as described previously, any preexisting pathology at any part of the neuron (nerve root, plexus, or peripheral nerve), even if asymptomatic, may predispose the patient to the development of weakness, paresthesias, pain, and other signs and symptoms commonly described as *neuropathy* when challenged with a neurotoxic chemotherapy or another insult to the peripheral nervous system. This phenomenon is termed *neuronal predisposition*.^{65,66}

Peripheral neuropathy is one of the most common chronic complications of cancer and its treatment. It may be caused by a variety of chemotherapeutic agents including the taxanes (paclitaxel, docetaxel), the vinca alkaloids (vincristine, vinorelbine, vinblastine), the platinum analogs (cisplatin, carboplatin, oxaliplatin), bortezomib, thalidomide, and others.^{65,83-85} The clinical, pathophysiologic, and electrodiagnostic features of the various neurotoxic chemotherapeutics vary significantly. The taxanes and vinca alkaloids are tubulin inhibitors and cause a predominately length-dependent motor and sensory axonal polyneuropathy in a distal symmetric distribution.⁸³ Clinically, this causes paresthesias, pain, sensory ataxia, and potentially, weakness during and immediately following treatment that usually improves when the treatment is stopped. The platinum analogs, however, damage the cell body of the sensory nerves in the dorsal root ganglion, and at higher doses can damage the anterior horn cell within the spinal cord. It is the accumulation of the platinum analogs within the neuron cell body with subsequent DNA damage and altered cellular activities that underlie the toxicity.⁸⁶ The clinical manifestations include severe sensory deficits including sensory ataxia and pain usually without significant weakness. Because the platinum analogs accumulate in the cell body, the deficits can progress for months following treatment, a phenomenon known as *coasting*. Electrophysiologically, neuropathy due to platinum analogs, may demonstrate a widespread decrease in sensory nerve action potential (SNAP) amplitudes *without* a proximal to distal gradient. In such cases of non-length-dependent neuropathy, it is possible to see an electrophysiologic pattern wherein the SNAP amplitudes in the upper extremities (shorter nerves) are lower than those in the lower extremity nerves (longer nerves).⁸⁷ This pattern is useful not only in differentiating non-length-dependent from length-dependent neuropathies associated with tubulin inhibitors, but also from other causes of peripheral nervous system dysfunction likely to be encountered in the oncology setting including radiculopathy, chronic idiopathic demyelinating polyradiculopathy, and diabetic neuropathy.

The need for an evaluation of neuropathy is largely dependent on the context in which a patient develops neuropathic signs and symptoms. If a patient develops the expected signs and symptoms from chemotherapy or other treatment that is expected to produce those symptoms, then no further investigation is generally indicated. It is when a patient develops signs and/or symptoms that exceed what is generally anticipated, or at a time when they would not have been expected to have complications of treatment that a work-up is indicated. For instance, a patient with metastatic prostate cancer who develops lower extremity pain and weakness on hormonal therapy needs an evaluation as opposed to one who develops the same symptoms on paclitaxel. In the former case, it is prudent to consider a very broad differential diagnosis and eliminate possibilities systematically and logically because many of the causes of such symptoms are curable or highly treatable. Oncologic causes such as epidural spinal cord compression, leptomeningeal metastases, intramedullary metastases, and paraneoplastic disorders should be considered along with degenerative causes of lower extremity pain and weakness such as spinal stenosis, disk herniation, facet arthropathy, and compression fracture. Similarly, idiopathic and acquired causes of neuropathy should be considered

including disorders such as diabetic amyotrophy, vitamin B-12 deficiency, Lyme disease, alcoholism, paraprotein neuropathies (MGUS), and CIDP. As with the nerve root and plexus, radiation can cause damage to any peripheral nerve in the radiation field. Such damage is usually obvious when it affects one or more named nerves in an extremity but may be less obvious when it affects nerves on the trunk such as the dorsal scapular nerve to the rhomboid muscles or the supraspinatus nerve to the supra and infraspinatus muscles. These nerves are commonly affected by MF radiation and radiation for head and neck cancer. Radiculopathy mimicking peripheral neuropathy is an extremely common cause of lower extremity symptoms in cancer patients due to their often advanced age and predisposition to spinal degenerative disease. Acquired neuropathy, including MGUS and CIDP, are also relatively common and should be considered in the evaluation of patients with idiopathic neuropathies.^{82,85}

A prospective neuropathy assessment algorithm intended to be used before and during the administration of neurotoxic chemotherapy in breast cancer patients is presented in Figure 152.4.⁶⁶ Although intended for breast cancer patients, this algorithm, including the evaluation and assessment outlined, is widely applicable.

Myopathy

Myopathy in the cancer setting can occur as a result of a variety of processes including direct invasion by a primary or metastatic tumor, paraneoplastic disorders, inflammatory disorders (polymyositis, dermatomyositis, inclusion body myositis), infiltrative disorders (amyloid), toxins, or more commonly as a result of corticosteroid use or critical illness. Radiation can cause a focal nemaline rod myopathy.⁸⁹ Skeletal muscle metastases are relatively rare but can occur from a variety of tumor types including lung, breast, melanoma, thyroid, and liver.⁹⁰ Paraneoplastic necrotizing myopathy characterized by rapidly progressive proximal muscle weakness that occurs over months can be seen in association with breast, small cell lung, gastrointestinal, genitourinary, bladder, ovarian, and prostate carcinomas as well as melanoma, multiple myeloma, and head and neck cancer.⁹¹ Each of the inflammatory myopathies has a distinct clinical phenotype and unique myopathologic features.⁹² Amyloid myopathy is rare but can be seen as a complication of multiple myeloma or primary amyloidosis.^{93,94} Vincristine, alcohol, and a variety of other agents can cause a toxic myopathy.⁹⁵

By far, the most common therapy-induced myopathy is steroid myopathy from glucocorticoid use. Steroid-induced myopathy is

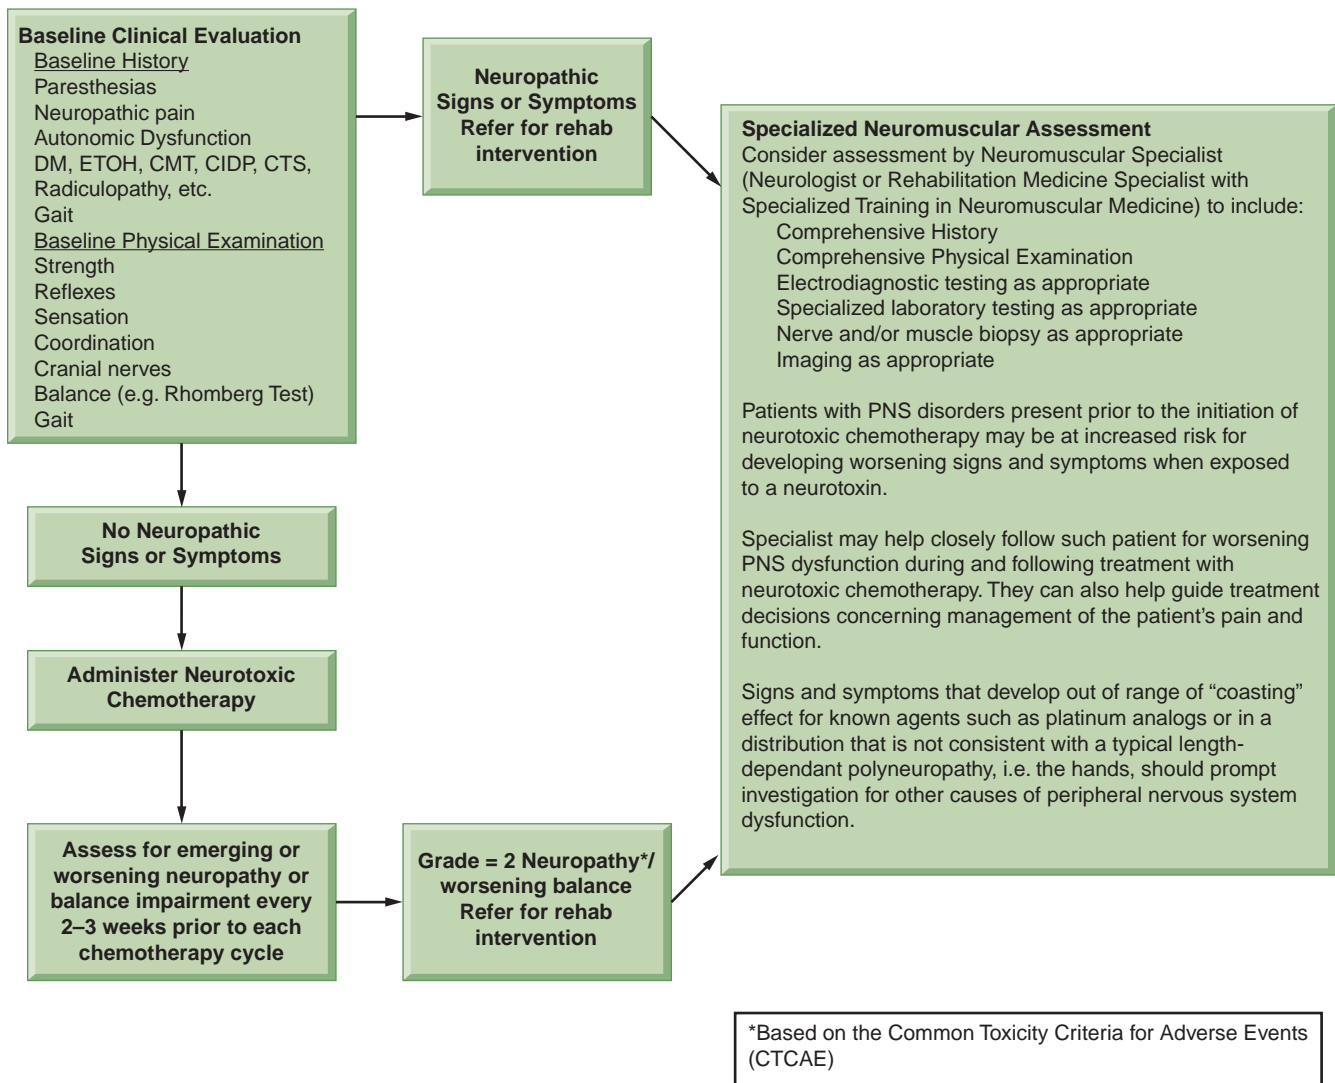

Figure 152.4 A neuropathy assessment algorithm intended to be used before and during the administration of neurotoxic chemotherapy in patients with breast cancer. This algorithm is likely useful for other cancer types as well. DM, diabetes mellitus; ETOH, alcohol abuse; CMT, Charcot-Marie-Tooth disease; CTS, carpal tunnel syndrome. (Adapted Stubblefield MD, McNeely ML, Alfano CM, Mayer DK. A prospective surveillance model for physical rehabilitation of women with breast cancer: chemotherapy-induced peripheral neuropathy. *Cancer* 2012;118:2250–2260.

characterized by fast-twitch or type II muscle fiber atrophy with decreased fiber cross-sectional areas and reduced myofibrillar protein content.⁹⁶ Steroid use is associated with a variety of adverse side effects that are related to the total and daily dose, duration of therapy, and poorly understood patient susceptibility factors.⁹⁷ In one small prospective study, glucocorticoid use was found to contribute to proximal muscle weakness in 9 out of 15 (60%) patients and was severe enough to interfere with ADLs in 6 out of 15 (40%) treated patients.⁹⁸ The development of steroid myopathy was rapid, occurring within 15 days in 8 out of 9 patients who developed weakness. Of 16 patients, 10 (63%) also demonstrated a significant decline in respiratory function. Steroid myopathy is painless and usually demonstrates proximal weakness most evident on physical examination to affect the shoulder and hip girdle muscles with relative preservation of distal muscle strength. This pattern of weakness helps differentiate steroid myopathy from most types of neuropathy, which cause distal relative to proximal weakness. In addition, sensation and reflexes should be preserved in steroid myopathy but which is abnormal in neuropathy. Although most cases of steroid myopathy are mild to moderate, at its extreme measure, it can cause complete tetraplegia and respirator dependence. Most patients with steroid myopathy recover, some completely; however, the course of resolution can be on the order of months to years.

Critical illness myopathy is not unique to the cancer setting, but due to the nature of cancer, is commonly seen. Critical illness myopathy is often associated with critical illness polyneuropathy. Often, the first sign of these disorders is difficulty in weaning a patient from a ventilator that is not explained by pulmonary, cardiovascular, or another disorder.⁹⁹ The clinical features and time course for resolution of critical illness myopathy are similar to those of steroid myopathy.

Evaluation of Neuromuscular Disorders

The key components of neuromuscular evaluation are history and physical examination. The etiology of most disorders can be elucidated with accuracy and specificity by a skilled clinician in the majority of instances, even in the cancer setting. Additional evaluations with imaging and electrodiagnostic and laboratory testing is indicated when competing diagnoses are being considered and require exclusion. Imaging is extremely useful to exclude a tumor as a source of nerve compression, particularly of the spinal cord and nerve root. Although a variety of tests have utility in select situations, magnetic resonance imaging (MRI) is usually the modality of choice for imaging the central and peripheral nervous systems.^{100,101} Intravenous gadolinium is useful in the identification of peripheral nerve and plexus tumors, leptomeningeal disease, and intramedullary spinal cord tumors as well as to differentiate scar from tumor, exclude infection, and identify radiation changes.^{46,102} Nerve roots may enhance with gadolinium in AIDP and CIDP as well as radiation-induced radiculopathy (see Fig. 152.3).^{59-64,82} Electrodiagnostic testing is often extremely useful in clarifying the etiology of symptoms (radiculopathy versus plexopathy versus neuropathy versus myopathy), clarifying the type of neuropathy (i.e., axonal versus demyelinating, polyneuropathy versus mononeuropathy multiple versus mononeuropathy), localizing a lesion (i.e. femoral mononeuropathy at the inguinal ligament versus intrapelvic). Electrodiagnostic testing can also assist in chemotherapeutic or radiotherapeutic decision making, predict neurologic prognosis, and exclude disorders in the differential diagnosis. Specialized expertise is useful in the electrophysiologic assessment of cancer patients.⁸¹ Laboratory testing is often indicated in the evaluation of peripheral nervous system dysfunction, particularly neuropathy. Such tests may include complete blood count, erythrocyte sedimentation rate or C-reactive protein, vitamin B-12, folate (methylmalonic acid with or without homocysteine for low

normal vitamin B-12 levels), a comprehensive metabolic panel (fasting blood glucose, renal and liver function), thyroid function tests, serum protein immunofixation electrophoresis, glucose tolerance test if indicated to evaluate for impaired glucose tolerance, and urine protein electrophoresis with immunofixation.¹⁰³ Specialized laboratory investigations may also be indicated depending on other clinical features exhibited or expressed by the patient. Evaluations may include but are not limited to those for connective tissue diseases with vasculitis (antinuclear antigen profile, rheumatoid factor, anti-Ro/SSA, anti-La/SSB, antineutrophil cytoplasmic antigen antibody, cryoglobulins), infections (hepatitis B and C, HIV, cytomegalovirus), sarcoidosis (serum angiotensin converting enzyme), dysimmune disorders (antiganglioside antibody profile [GM1, GDLa, GDlb, GD3, GQ1b GT1b, antimyelin-associated glycoprotein]), and a paraneoplastic panel (anti-Hu, anti-CV2).¹⁰⁵

Treatment of Neuromuscular Disorders

The treatment of peripheral nervous system disorders can be highly specific (e.g., injection of a median mononeuropathy at the wrist) or extremely general (e.g., prescription of opioids for pain). The most common impairments experienced by patients with peripheral nervous system dysfunction include pain and weakness with subsequent disorders of mobility and ADLs. Skin breakdown, secondary musculoskeletal derangements (i.e., Charcot joint, rotator cuff tendonitis/adhesive capsulitis), contracture, osteoporosis, and other conditions can also result. Dysfunction of the peripheral components of the autonomic nervous system can cause orthostatic hypotension, gastroparesis, constipation, urinary retention, erectile difficulties, and a variety of other autonomic derangements.

Specific treatments depend largely on accuracy of diagnosis of the underlying disorder. For instance, severe and disabling hand pain may be from a CNS cause (thalamic or funicular pain), radiculopathy, plexopathy, a polyneuropathy, or a mononeuropathy such as the median mononeuropathy responsible for carpal tunnel syndrome. In addition to neuromuscular causes of pain, a variety of musculoskeletal disorders such as osteoarthritis and tenosynovitis, as well as infections and neoplasms, should be considered in the differential diagnosis because they can coexist with or mimic neuromuscular dysfunction.

A primary responsibility of the cancer rehabilitation physician is to be a diagnostician. An accurate diagnosis of pain and functional disorders is often instrumental in guiding oncologic colleagues on such matters as whether to continue neurotoxic chemotherapy or if a lesion requires chemotherapy. For instance, the treatment of hand pain that is due to carpal tunnel syndrome is very different from the treatment offered for a metastasis to the brachial plexus. A guide to the expected physical examination findings (pain/sensory abnormalities, weakness pattern, reflex abnormalities) anticipated from the various common central and peripheral nervous system abnormalities are listed in Table 152.3. A full accounting of the specific treatments for each of these disorders is beyond the scope of this chapter due to space limitations.

A comprehensive discussion on the management of neuropathic pain is discussed elsewhere in this textbook. Again, the first step in the effective treatment of neuropathic pain is its identification. Treatments may include behavior modification, PT and/or OT, modalities such as transcutaneous electric nerve stimulation (TENS) or ultrasound, splints and braces, injections, and other procedures and medications. Weakness and difficulties with ADLs can often be improved with PT and/or OT. Bracing may be required to compensate for weakness such as foot dorsiflexors where an AFO is often indicated. Discussions on nonpharmacologic pain management and orthotic use are presented in the following section.

TABLE 152.3

Physical Examination Findings in Painful Neurologic Disorders

Location	Pain/Sensory Abnormalities	Weakness Distribution	Reflex Abnormality
<i>Brain</i>			
Thalamus	Contralateral to lesion, varies from discrete (i.e., arm only) to entire side of body	None (unless other structures involved)	None (unless other structures involved)
<i>Spinal Cord</i>			
Ascending spinothalamic tracts	Contralateral if small lesion or bilateral if larger lesion, varies from discrete (i.e., arm only) to entire side of body	None (unless other structures involved)	None (unless other structures involved)
<i>Root</i>			
C-5	Posterior–lateral shoulder, lateral arm, lateral forearm	Rotator cuff, shoulder abduction > elbow flexion	Biceps tendon > brachioradialis tendon
C-6	Posterior–lateral shoulder, lateral arm, lateral forearm, thumb, index finger	Rotator cuff, shoulder abduction < elbow flexion, forearm pronation, wrist extension	Biceps tendon < brachioradialis tendon, pronator teres tendon
C-7	Posterior arm, posterior forearm, index/middle fingers	Elbow extension, wrist extension, finger extension	Triceps tendon
C-8	Posterior–medial arm, posterior–medial forearm, little/ring fingers	Long finger extensors, long finger flexors > hand intrinsics	Finger flexors
T-1	Anterior–medial arm, anterior–medial forearm (little/ring fingers generally spared)	Long finger extensors, long finger flexors < hand intrinsics	Finger flexors
T-2 to T-12	Corresponding thoracic dermatome (i.e., T4 nipples, T10 navel)	Corresponding thoracic myotome (rarely clinically evident)	None
L-1	Upper low back, lateral hip, groin	None	None
L-2	Upper/middle low back, lateral hip, groin, high anterior and medial thigh	Hip flexion > knee extension	Patellar tendon
L-3	Middle low back, lateral hip, middle anterior and medial thigh	Hip flexion < knee extension, hip adduction	Patellar tendon
L-4	Middle/low back, lateral hip, lateral thigh, knee, medial leg	Knee extension > ankle dorsiflexion	Patellar tendon
L-5	Low back, buttock, lateral hip, posterior/lateral thigh, lateral leg, dorsal foot, big toe	Hip abduction, knee flexion, ankle and toe dorsiflexion, foot inversion and eversion	Medial hamstring tendon
S-1	Low back, buttock, lateral hip, posterior thigh, posterior leg, lateral and plantar foot	Hip extension, knee flexion, plantar flexion, toe flexion	Achilles tendon, lateral hamstring tendon
S-2 to S-5	Posterior leg (S2), saddle anesthesia	None	None
Cauda equina syndrome	Varies, all lumbar roots possible, saddle anesthesia common	Varies, all lumbar roots possible	Varies, all lumbar roots possible
Conus medullaris	Varies, all lumbar roots possible, loss of bladder function common	Varies, all lumbar roots possible	Varies, all lumbar roots possible
<i>Plexus</i>			
Cervical	Anterior neck, ear lateral occiput, upper chest, and upper back	None	None
Upper trunk brachial	Shoulder, lateral arm, lateral forearm, lateral hand	Rotator cuff, shoulder abduction, elbow flexion, radial wrist extension (rhomboid and serratus anterior spared)	Biceps tendon, brachioradialis tendon
Middle trunk brachial	Posterior arm and hand	Elbow extension (partial), wrist extension, finger extension (brachioradialis spared)	Triceps tendon

(continued)

TABLE 152.3

Physical Examination Findings in Painful Neurologic Disorders (continued)

Location	Pain/Sensory Abnormalities	Weakness Distribution	Reflex Abnormality
Posterior cord brachial	Posterior arm and hand	Shoulder abduction (past first 30 degrees), elbow extension, wrist extension, finger extension	Triceps tendon
Lower trunk brachial	Medial arm, medial forearm, little/ring fingers	Long finger extensors, long finger flexors, hand intrinsics	Finger flexors
Lumbar	Anterior thigh	Hip flexors, knee extensors, leg adductors	Patellar tendon
Lumbosacral trunk	Buttock, lateral leg, dorsum of foot	Hip extensors (variable), knee flexors (variable), dorsiflexion, ankle inversion, ankle inversion, toe flexion	Medial hamstring tendon
Sacral	Buttock, lateral hip, posterior thigh, posterior leg, lateral and plantar foot	Anal sphincter (variable), hip extensors, knee flexors, plantar flexors	Achilles tendon
<i>Nerve</i>			
Occipital	Posterior head	None	None
Trigeminal	Face	Masticatory muscles (rarely clinically evident)	None
Intercostobrachial	Axilla, medial arm	None	None
Axillary	Lateral arm	Shoulder abduction, external rotation	None
Musculocutaneous	Lateral forearm	Elbow flexion, supination	Biceps tendon
Radial	Distal posterior arm, posterior forearm, posterior-lateral hand	Elbow extension (spared if lesion below spiral groove), wrist extension, finger extension, supination	Triceps tendon (if above spiral groove), none (if below spiral groove)
Ulnar	Anterior-medial hand, posterior-medial hand	Finger flexion (4th-5th digits), finger abduction (spares thumb abduction)	Finger flexors
Median	Anterior-lateral hand	Forearm pronation, wrist flexion, finger flexion (2nd-3rd digits), thumb abduction (spares finger abduction)	None
Lateral femoral cutaneous	Anterior-lateral thigh (spares medial thigh)	None	None
Femoral	Anterior-medial thigh (spares lateral thigh), medial leg, medial foot	Hip flexion (if intrapelvic lesion, spared if at inguinal ligament), knee extension	Patellar tendon
Sciatic	Posterior buttock, posterior thigh, posterior-lateral leg, plantar foot	Hip extension < knee flexion, dorsiflexion, plantar flexion, foot eversion and inversion, toe flexion	Achilles tendon, hamstring tendons
Peroneal	Anterior-lateral leg, dorsum of foot	Dorsiflexion, foot eversion	None
Tibial	Plantar foot	Plantar flexion, foot inversion	None
Polyneuropathy	Generally distal symmetric in a "stocking and glove" distribution	Generally in distal muscle groups	Varies, generally distal tendon reflexes
Mononeuropathy multiplex	Varies by nerves affected	Varies by nerves affected	Varies by nerves affected
Small fiber neuropathy	Generally distal symmetric in a "stocking and glove" distribution (affects pain/pinprick and temperature sensation but spares light touch, vibration and proprioception)	None	None

MUSCULOSKELETAL COMPLICATIONS OF CANCER AND CANCER TREATMENT

Musculoskeletal disorders represent a diverse group that includes derangement of muscle, ligament, tendon, joint, cartilage, bone, and associated tissues. Included are arthritis, tendonitis, tenosynovitis, bursitis, myofascial pain, and countless other disorders. The pain associated with musculoskeletal disorders is somatic from activation of nociceptors in affected structures as opposed to neuropathic. There may be considerable overlap as when neuromuscular disorders (e.g., C-5 radiculopathy) play a causal role in the development of musculoskeletal disorders (e.g., rotator cuff tendonitis).¹⁰⁴ As with neuromuscular disorders, musculoskeletal disorders are extremely common in the general population as well as in the cancer setting. The accurate assessment of musculoskeletal disorders, including the differentiation of benign from malignant etiologies of pain, is an important component of the cancer rehabilitation physician's duties. It is often the case that benign musculoskeletal disorders cause as much morbidity as malignant ones. The successful identification and treatment of these disorders can help improve the function and quality of life of cancer patients and survivors. A full accounting of the assessment and treatment of the countless musculoskeletal disorders is not possible due to space limitations.

Bony Metastases

Bone metastases are a common complication of cancer, occurring in 69% of patients with advanced breast cancer.¹⁰⁵ The primary risk of bony metastases is fracture with subsequent pain and disability. A long-bone fracture poses perhaps the greatest risk to the patient because it may prevent their ability to ambulate and perform ADLs. Preventing fractures before they occur is instrumental to maintaining function and quality of life in cancer patients. Improvements in oncologic treatments, such as hormonal and biologic therapies, have changed the time course to fix many bony metastases because patients with certain malignancies may go for months or even years with widely metastatic disease and no bony pain. When they do ultimately progress, the treatment of symptomatic bony metastases is radiation and/or surgery depending on where the lesion is located.

The concept of prophylactically fixing impending fractures was first presented by Griessman in 1947.¹⁰⁶ Although unproven, the potential benefits include a technically easier operation, decreased operating time and blood loss, fewer complications, reduced pain, and convenience. Several strategies have been developed to predict the risk of sustaining a pathologic fracture. These predictive models are only useful in the long bones.¹⁰⁷ Mirels proposed a scoring system to quantify the risk of sustaining a pathologic fracture through a metastatic lesion in a long bone based on the site (upper limb, lower limb, peritrochanter), pain (mild, moderate, functional), lesion type (blastic, mixed, lytic), and size relative to the diameter of affected bone ($<1/3$, $1/3$ to $2/3$, $>2/3$).¹⁰⁸ Each of these four variables was given a score of 1, 2, or 3 according to the degree of risk. It was determined that lesions with a cumulative score of 7 or lower could be safely irradiated without risk of fracture, but lesions with a score of 8 or higher required prophylactic internal fixation prior to irradiation. A more recent study comparing various methods found only axial cortical involvement of more than 30 mm and circumferential cortical involvement as predictive of fracture; the former measure has the advantage of being accessible via plain x-ray.¹⁰⁹ In practice, the actual lesion size may be difficult to delineate because of an infiltrative, permeating pattern and surrounding osteopenia. Factors such as histology (with highly vascular or lytic lesions perhaps at highest risk) and location (importance to weight bearing) are also considerations.¹¹⁰ Perhaps the best practical determinant of fracture risk is the degree of pain experienced by the patient both spontaneously and with evocative

maneuvers such as the FABER (Flexion Abduction External Rotation) test for intrinsic pathology of the hip joint. Patients with symptomatic lesions without systemic or radiotherapeutic treatment options are likely to progress and should generally have long-bone lesions corrected surgically.

Spine stability in the oncology setting is handled very differently from the traumatic setting. The Spine Oncology Study Group (SOSG) defines spinal instability as the "loss of spinal integrity as a result of a neoplastic process that is associated with movement related pain, symptomatic or progressive deformity, and/or neural compromise under physiologic loads."¹¹¹ The assessment of spinal instability is determined based on clinical and radiographic criteria. SOGS has developed an 18-point Spinal Instability Neoplastic Score (SINS) to aid clinicians in the diagnosis of neoplastic spinal instability. This grading scheme includes elements from six parameters: location, pain, alignment, osteolysis, vertebral body collapse, and posterior element involvement. Lesions with a low SINS (0 to 6) are considered stable and do not require surgery. Lesions with a high SINS (13 to 18) are considered unstable and likely need surgery. Lesions with an intermediate SINS require a further assessment. In an analysis, the SINS demonstrated excellent inter- and intraobserver reliability for detecting clinically relevant spinal stability.¹¹²

Bilsky has developed a conceptual framework to guide therapeutic decision making with respect to surgical, radiotherapeutic, and chemotherapeutic options for spine tumors.^{113,114} This tool for an individual patient assessment is known as the NOMS criteria and is based on an evaluation of the neurologic (N), oncologic (O), mechanical instability (M), and systemic disease (S) status of the patient. In this model, mechanical instability is defined simply as movement-related pain referable to a focus of the tumor. Instability pain is distinguished from biologic or tumor-related pain in that it does not respond to steroids. A tumor involving the atlantoaxial complex (C1–2) usually presents with rotational pain. Such patients are considered unstable if they have a fracture subluxation greater than 5 mm or angulation greater than 11 degrees with a greater than 3.5-mm subluxation. Patients meeting these radiographic criteria are generally offered surgery at presentation, whereas those with less than a 5-mm subluxation can be irradiated in a hard collar (usually a Miami J design because it comes in a variety of sizes, is more adjustable, and is more comfortable than other designs) and weaned 6 weeks following the completion of radiation. Bracing is rarely used to treat instability of the subaxial cervical, thoracic, and lumbar spine for instability because surgery is the treatment of choice in those instances. In cases where surgery is indicated but is unable to be performed because of other clinical contraindications or patient refusal, a thoracolumbar corset can provide limited support and pain relief. Used in combination with gait aids, such as a walker, the thoracolumbar corset minimizes torque across the spine. Bed rest should be avoided because additional functional loss will occur, and thromboembolic disease may complicate the course.

RADIATION FIBROSIS SYNDROME

Radiation therapy uses high-energy radiation to kill rapidly proliferating tumor cells. The less mitotically active normal body cells are relatively spared. The acute effect of radiation on tissues is mediated through the induction of apoptosis or mitotic cell death from free radical-induced DNA damage. Radiation fibrosis (RF) is the insidious pathologic tissue sclerosis that occurs in response to radiation treatment.¹⁵ The mechanism underlying RF is complex and involves interactions between multiple cell types that is dependent on the organ system involved.¹¹⁵ RF is associated with increased collagen synthesis, altered remodeling, and sequential activation of key fibrinogenic growth factors and cytokines such as transforming growth factor beta 1 (TGF β 1) and connective tissue growth factor (CTGF).¹¹⁵ Important to the process of RF is the

activation of fibroblasts by fibrogenic cytokines. Once activated, myofibroblasts may not require continued paracrine stimulation by fibrogenic cytokines. Autocrine stimulation may perpetuate fibrogenesis without continued inflammation or other external stimuli.¹¹⁵ This may explain the immortalization of the process of RF in cancer survivors wherein the progressive decline of organ function due to RF can continue, albeit at differing rates, indefinitely.

RF can damage any tissue type including skin, muscle, ligament, tendon, nerve, viscera, and even bone.¹¹⁶ The effects of radiation can be acutely experienced during or immediately following treatment. Radiation effects can also be early delayed (up to 3 months) or late delayed (more than 3 months) following the completion of treatment.¹¹⁷ Fatigue is generally an acute or early-delayed complication of radiation therapy. RF is generally a late complication, and may manifest years after treatment, progress rapidly or insidiously, and is not generally reversible.¹¹⁸

The term *radiation fibrosis syndrome* (RFS) describes the clinical manifestations that result from the progressive fibrotic sclerosis that follows radiation treatment.¹³ RFS occurs locally at the treated site, but may also cause distant effects when a neural, vascular, lymphatic, or other structure passing through a radiation field is damaged.¹¹⁹ The radiation field can be sharply localized or extensive.¹²⁰ The mantle radiation field used to treat supradiaphragmatic HL, for instance, involves all lymph nodes in the neck, chest, and axilla. The inverted-Y radiation field involves the periaortic and ilioinguinal lymph nodes. The combination of mantle and inverted-Y radiation is known as total nodal irradiation (Fig. 152.5). Such broad radiation fields can result in widespread neuromuscular sequelae including myelopathy, radiculopathy, plexopathy, neuropathy, and myopathy, either individually or in combination. This syndrome is termed *myelo-radiculo-plexo-neuro-myopathy*.¹³ Other well-known late effects of radiation for HL include secondary malignancies, cardiovascular disease, pulmonary disease, thyroid dysfunction, infertility, fatigue, and psychosocial issues.¹²¹

Radiation damage to the CNS is also classified temporally as acute, early delayed, and late delayed. Acute encephalopathy

occurs days to weeks after the initiation of treatment, and early-delayed encephalopathy at 1 to 6 months likely represents transient demyelination. Clinical manifestations include irritability, loss of appetite, exacerbation of tumor-like symptoms, Lhermitte's sign, and in children, somnolence syndrome.^{117,118} Late-delayed encephalopathy, caused by irreversible white matter necrosis, may rarely occur. Early-delayed encephalopathy usually responds well to corticosteroids, but late-delayed encephalopathies respond less consistently. Memory loss or cognitive dysfunction may result from brain atrophy after whole-brain irradiation. Other side effects of cranial irradiation include fatigue, loss of taste, decreased salivation, impaired gag reflex, and decreased hearing.¹²²

Radiation-induced myelopathy can manifest as a transient syndrome that usually occurs within 4 to 6 months of treatment. Delayed radiation myelopathy usually occurs 1 to 2 years after radiation, but may occur as soon as 3 months or more than 10 years later. It usually presents with lower extremity sensory symptoms (numbness, paresthesias, or dysesthesias), followed by weakness and loss of bowel and bladder dysfunction. It may progress over weeks to months in a stepwise fashion leading to paraplegia or quadriplegia in at least 50% of patients. Patients may rarely show spontaneous recovery but most continue to progress. Pain is not generally a prominent feature of radiation myelopathy.⁷³

RF can damage any peripheral nervous system structure.¹²³ Such injury can cause focal paraspinal muscle spasms, distant muscle spasms, referred pain, local pain, and weakness.¹⁰⁴ The upper brachial plexus may be more prone to damage than other plexus structures, arguably because of its superior location within the pyramid shaped chest where it is less protected by overlying tissue.⁶⁸ Muscle cramps commonly occur as a result of radiation damage and are thought to arise from spontaneous discharges at any level of the motor nerve with resultant volleys of neural activity being sent to and across the neuromuscular junction thereby involuntarily activating the muscle.¹²⁴ Myokymic discharges are common (but not pathognomonic) in radiation damage to the peripheral nervous system and are responsible for some of the

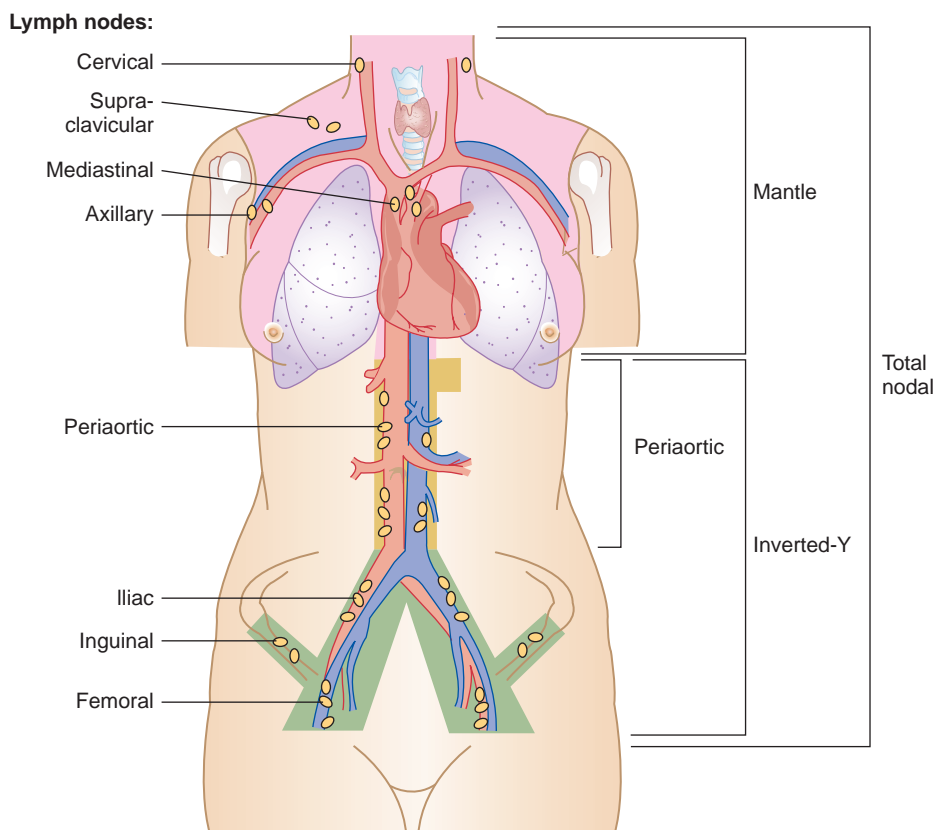

Figure 152.5 Radiation fields historically used in the treatment of Hodgkin lymphoma include the mantle, periaortic, and inverted-Y among others. When all nodes are radiated, this is known as total nodal irradiation. The late-term morbidity experienced by Hodgkin lymphoma survivors often depends on the extent of their radiation treatment. Contemporary treatment of Hodgkin lymphoma primarily involves chemotherapy and, when necessary, more targeted involved site radiation therapy, which generally uses smaller doses and affects less normal tissue.

muscle spasms seen in the RFS. Myokymia is seen clinically as vermiculations (wormlike movements under the skin) and have a characteristic sound and appearance on needle electromyography. Myokymia is thought to result from ephaptic cross-talk between motor nerves that have been focally demyelinated.¹²⁵ Progressive fibrosis in muscle fibers within the radiation field can cause a focal myopathy that is associated with nemaline rods.⁸⁹ Myopathic muscles are weak relative to normal muscle and prone to spasm and pain.

Although RFS can potentially result from treatment with radiation for any cancer type, it is commonly encountered in head and neck cancer and HL patients and survivors.

Radiation Fibrosis Syndrome in Hodgkin Lymphoma

No group of cancer survivors better typifies the potential for long-term radiation complications than those treated for HL.^{13,126} The high doses of radiation historically used in this group of patients are responsible for a variety of complications that can affect any organ system. The complications likely to be encountered in these patients depends largely on the radiation port used (MF, inverted-Y, total nodal), and thus the structures involved by radiation (see Fig. 152.5). Contemporary treatment regimens for HL have evolved considerably in recent years and now utilize chemotherapy as the primary modality and involved site radiation therapy (ISRT) if needed. Late radiation sequelae are less likely with ISRT because the amount of tissue treated and total doses used are generally smaller.

Although the majority of neuromusculoskeletal complications result from late effects of radiation, other morbidities such as cardiotoxicity may result from anthracycline exposure or a combination of radiation and anthracycline exposure.¹²⁶ The list of morbid non-neuromusculoskeletal conditions ascribed to HL is long and includes, but is not limited to, arterial disease (coronary artery disease, myocardial infarction, valvular heart disease, congestive heart failure, pericardial disease, electrical conduction abnormalities, carotid artery disease, peripheral arterial disease), lung disease (pulmonary fibrosis, pulmonary hypertension, chest wall restriction), autonomic dysfunction (carotid baroreceptor failure, orthostasis, gastric dysmotility, impotence), endocrine dysfunction (hypothyroidism, infertility), as well as a variety of gastrointestinal, genitourinary, and sexual disorders.^{121,126} Second primary malignancy followed by cardiovascular disease are the first and second leading causes of mortality for HL survivors, respectively.¹²⁶ The clinician who evaluates and treats HL survivors should be acutely aware of the vast potential for individual variation in the presenting symptoms and disorders in this complex group of patients.

Subacute myelopathy is estimated to occur in as many as 15% of patients treated with MF irradiation for HL¹²²; plegia rarely results. Brisk reflexes may be seen in the lower extremities accompanied by depressed or absent reflexes in the upper extremities in patients treated with MF radiation. This pattern is likely due to the combination of central and peripheral nervous system dysfunction in HL survivors treated with MF radiation. Detrusor-sphincter dysynergia, bowel dysfunction, spasticity, weakness, sensory abnormalities, ataxia, movement disorders, and abnormal gait have all been seen in the author's clinical practice as likely myelopathic manifestations of distant radiation. Subacute myelopathy is likely a contributing factor to the fatigue seen in many HL survivors. Myelopathy in HL rarely occurs in isolation and is usually part of a myelo-radiculoplexoneuro-myopathy. An MRI of the spinal cord rarely demonstrates parenchymal abnormalities, although degenerative changes are often seen in the elderly.

Radiculopathy in HL survivors is often part of a myelo-radiculoplexoneuro-myopathy but it is more commonly seen without clinically overt myelopathy. Neuronal predisposition from preexisting or emergent degenerative spine disease is likely

an extremely important etiologic factor in the development of radiculopathy. Radiculopathy can be seen in isolation, particularly when degenerative spinal disease at the affected level is present, but is more commonly part of a radiculo-plexopathy or a radiculo-plexo-neuro-myopathy. Patients treated with MF irradiation generally develop radiculopathy in the upper (C5, C6) roots but may have more widespread or patchy involvement. Patients treated with periaortic or inverted-Y radiation may develop radiculopathy at any lumbosacral root, but the L5 or S1 levels are most frequently involved, likely due to their coexistence with degenerative changes such as disk herniations and central or neuroforaminal spinal stenosis. A diffuse polyradiculopathy is commonly seen. Radiation-induced cauda equina syndrome should be suspected when no degenerative or other compressive etiologies are present on MRI to explain the nerve root dysfunction documented clinically and/or on electrophysiologic testing.

The electrophysiologic pattern of radiculopathy resulting from radiation is similar if not identical to radiculopathy seen from other causes. If the entire cauda equina is involved, the findings are more widespread and involve the distribution of multiple nerve roots. Myokymia may or may not be present and its absence does not exclude radiation as an etiologic contributor.¹²⁵ An electrophysiologic assessment of radiculopathy in HL survivors treated with radiation may be complicated due to the coexistence of plexopathy, neuropathy, and/or myopathy.

Plexopathy can affect both the brachial and lumbosacral plexus in HL survivors depending on the extent of radiation they received (e.g., MF, inverted-Y, total nodal). Brachial plexopathy is rarely seen without a component of radiculopathy, neuropathy of the nerves within the radiation field, and localized myopathy. Plexopathy, however, can be a prominent feature of radiation in HL survivors. Plexopathy seems less common in the author's clinical experience than radiculopathy. One possible reason for this observation is that the plexus is not directly affected by degenerative changes. Plexopathy from MF irradiation generally affects the upper brachial plexus (upper trunk and/or lateral cord) more severely than the rest of the plexus, but a pan-plexopathy can be seen. The pyramidal shape of the thorax provides less protection from radiation and the longer anatomic course of the upper plexus relative to other plexus structures may arguably explain this phenomenon.¹²⁷ Lumbosacral plexopathy from periaortic and inverted-Y radiation may be seen, usually in combination with the polyradiculopathy of the cauda equina syndrome. As with radiculopathy, the electrophysiologic assessment of plexopathy in HL survivors is usually complicated by the presence of other neuromuscular disorders.

Neuropathy associated with MF radiation affects only proximal nerves confined within the field. A polyneuropathy from prior treatment with neurotoxic chemotherapy or other causes, such as diabetes, may be present and may predispose the patient to the peripheral nervous system dysfunction caused by radiation. Radiation-induced mononeuropathy from MF radiation affects nerves arising directly from the brachial plexus. Nerves originating from the proximal and superior plexus are most commonly involved clinically and include the dorsal scapular nerve to the rhomboids and the suprascapular nerve to the supraspinatus and infraspinatus. Other commonly affected nerves include the long thoracic nerve to the serratus anterior, the intercostal nerves, and the phrenic nerve. Nerves originating from the lumbosacral plexus, including the femoral nerve and lateral femoral cutaneous nerve, can be affected from inverted-Y and total nodal radiation. Again, the electrophysiologic assessment of proximal mononeuropathies in HL survivors is usually complicated by the presence of a coexistent pathology such as radiculopathy, plexopathy, and focal myopathy.

Focal myopathy is a common neuromuscular complication of radiation in HL survivors. Given enough time, it likely develops to at least some degree in most if not all patients and is likely the major cause of neck extensor weakness in this population. The myopathy is characterized by nemaline rods and is sharply localized

Figure 152.6 A 50-year-old Hodgkin lymphoma survivor treated in 1982 with staging laparotomy, splenectomy, and radiation including Mantle (4,020 cGy), Waldeyer's ring (3,990 cGy), para-aortic/splenic pedicle (3,570 cGy), and right preauricular (800 cGy) as well as nitrogen mustard, vincristine, procarbazine, and prednisone. Although he is without evident disease, he suffers from a host of late effects of treatment including myelo-radiculoplexo-neuro-myopathy with subsequent severe upper and lower extremity weakness and gait disturbance requiring ankle-foot orthoses and a gait aid for ambulation. He has neck extension weakness. Note the marked atrophy of the cervicothoracic musculature including the cervical and thoracic paraspinal muscles, the rhomboids, and supraspinatus, and infraspinatus. The scapulae are protracted. His pectoral muscles are relatively spared due to shielding designed to protect the lungs.

to muscle fibers within the radiation field such as the cervical and thoracic paraspinal, rhomboid, supraspinatus, and infraspinatus muscles.⁸⁹

One of the most clinically obvious, ubiquitous, and disabling disorders afflicting HL survivors is cervicothoracic atrophy and neck extensor weakness (Fig. 152.6). At its worst, this usually painful condition can result in an inability to maintain the head in a normal upright posture long enough to participate meaningfully in ADLs or even complete neck drop. Atrophy of the cervicothoracic musculature is essentially universal in HL survivors treated with MF radiation. The underlying pathophysiology is likely various components of the myelo-radiculoplexo-neuro-myopathy (described previously) with myopathy being the major contributor. Needle electromyography (EMG) of the cervical paraspinal muscles in HL survivors treated with MF radiation generally shows mixed neuropathic and myopathic motor units.

Although there is no way to reverse the fibrosis and resultant cervical and thoracic atrophy that results from MF radiation, the function and quality of life of these patients can be meaningfully improved with PT to improve core as well as neck strength, posture, body mechanics, and endurance. Myofascial techniques are employed to release the anterior pectoral girdle. Proprioception of the neck and shoulders are often severely impaired. Lymphedema is almost universally present in the neck, thorax, and extremities and should be treated to improve proprioception and facilitate myofascial release. Emphasis on a lifelong home exercise program is of paramount importance if a durable benefit is to be achieved. In cases where neck weakness and pain impair ADLs despite adequate PT, the use of a cervical collar to assist elevation of the chin is recommended. The Headmaster Cervical Collar, manufactured by Symmetric Designs in Salt Spring Island, British Columbia, is smaller, lighter, and more comfortable than other collars

(Fig. 152.7). Some patients (i.e., those with anterior chest wall abnormalities) may prefer other designs, such as a soft cervical collar, and their preferences should be accommodated whenever possible. The cervical collar is not intended to be used at all times but as an energy conservation device. Patients who experience pain due to cervicothoracic muscle overload and/or fatigue as the day progresses are encouraged to use a collar whenever possible. Such activities include housework, meals, time spent in front of the computer, watching television, or reading. Use of the collar during such activities may rest the neck muscles so the patient can tolerate and enjoy activities that occur later in the day without wearing the collar. For instance, using the collar during work might make it possible to comfortably attend and enjoy dinner with family or friends after work without the aid of the collar.

Shoulder pain and dysfunction in HL survivors is usually causally related to their radiation treatment. Although the shoulder joint is largely outside of the direct effects of the radiation field, the nerves and muscles that actuate the shoulder are not. Directly radiated structures include the cervical nerve roots, brachial plexus, rotator cuff muscles, and nerves such as the suprascapular nerve that innervate the rotator cuff. Any damage to the C5 or C6 cervical nerve roots or upper brachial plexus can denervate and weaken the rotator cuff muscles and refer neuropathic pain to the lateral shoulder and arm. If rotator cuff weakness results in anterior translation of the humerus within the glenohumeral joint, then impingement of the rotator cuff tendons may develop and cause a secondary rotator cuff tendonitis and, potentially, a tertiary adhesive capsulitis due to the local inflammation within the shoulder capsule.^{104,128}

Imaging of the rotator cuff is only necessary if the clinical assessment, including physical examination, is not consistent with what is expected. For instance, an MRI is indicated if a palpable

Figure 152.7 The Headmaster Cervical Collar (Symmetric Designs Ltd., Salt Spring Island, British Columbia, Canada) is a simple and comfortable way to support the head in patients with weakened cervical paraspinal muscles from radiation and other cancer-associated causes. It is being modeled by a Hodgkin lymphoma survivor with severe cervicothoracic atrophy and neck extensor weakness.

mass is present or if the pain elicited is atypical (e.g., sharply localized to the spine of the scapula suggesting malignancy or fracture). Imaging is also useful if a patient has not responded to initial treatment measures and surgical intervention is contemplated. As a general rule, shoulder surgery should be avoided in RFS patients because it is unlikely to impact the progressive neuromuscular disorders that precipitated the shoulder dysfunction and will continue to drive the shoulder pathology. Conservative measures are the mainstay of treatment for shoulder pathology in HL survivors. PT is the primary modality and is the only treatment to confer a durable benefit. Therapy should address, among other disorders, rotator cuff weakness and tightness of the pectoral girdle with the goal of restoring the normal anatomic alignment of the shoulder at the glenohumeral joint and, thus, the rotator cuff tendons within the coracoacromial arch. Anti-inflammatory medications and/or nerve stabilizing agents are often indicated. Subacromial injection, although not curative, may facilitate PT efforts and comfort.

HEAD AND NECK CANCER

Treatment and disease-related neuromuscular and musculoskeletal complications are common in head and neck cancer survivors. Common complications requiring rehabilitation include

shoulder dysfunction, trismus, radiation-induced cervical dystonia, lymphedema, a variety of nerve injuries, and speech and swallowing dysfunction.

Shoulder pain is one of the most common sequelae of head and neck cancer treatments, being present in as many as 70% of patients following nonselective neck lymph node dissection.¹²⁹ Radical neck dissection (RND) involves the removal of all the ipsilateral cervical lymph node groups (from levels I to V) as well as the spinal accessory nerve (SAN), the internal jugular vein, and the sternocleidomastoid muscle (SCM).¹³⁰ Modified radical neck dissection (MRND) involves the excision of all lymph nodes routinely removed by RND but with preservation of one or more of the nonlymphatic structures (e.g., the SAN, internal jugular vein, or the SCM).¹³⁰ In selective lymph node dissection (SND), nonlymphatic structures are spared, whereas the excision of lymph node groups is based on the pattern of metastases.¹³⁰ In addition to pain, neck dissection can cause reduced ROM in the neck and shoulder, loss of sensation, and loss of neck and shoulder function.¹³¹

The role of exercise for the treatment of shoulder dysfunction in patients treated for head and neck cancer has been subject to investigation with several randomized prospective trials.¹³²⁻¹³⁴ A Cochrane review of these trials concluded that progressive resistance training is more effective than standard PT treatment for shoulder dysfunction in patients treated for head and neck cancer in terms of improving pain, disability, and shoulder joint ROM.¹³⁵ Quality of life, however, was not improved. Although statistically significant, the relative benefits were small compared to traditional PT.

In addition to PT, medications including nonsteroidal anti-inflammatory drugs (NSAIDs), nerve stabilizers, and in some cases, opioids have a role in the treatment of chronic shoulder pain associated with neck dissection in head and neck cancer survivors. Subacromial corticosteroid injections can be useful for severe exacerbations of pain or to facilitate therapy but only offer temporary relief.

The prevalence of trismus in treated head and neck cancer patients ranges from 5% to 38%.¹³⁶ Impairment in mouth opening may have an adverse effect on quality of life by compromising functions such as chewing, swallowing, respiratory function, oral hygiene and health, the ability to survey for recurrence, and intimacy. Normal mouth opening for an adult ranges from 23 to 71 mm as measured between the incisors.¹³⁷ The wide variation in reported incidence reflects the lack of uniform criteria for the definition of trismus.¹³⁸ Trismus in the head and neck cancer setting can result from tumor invasion into critical structures of mastication including the masseter and pterygoid muscles and/or their neural innervation, the temporal mandibular joint (TMJ), and/or other supportive tissues.¹³⁹ Surgery and radiation therapy are well-known causes of trismus. Radiation can result in trismus in up to 45% of patients who received curative doses.¹⁴⁰ Trismus evolves most rapidly 1 to 9 months after the completion of radiation therapy.¹⁴¹ The mandibular opening worsens as the dose of radiation delivered to the pterygoid muscles increases, and the probability of developing trismus is reported to increase 24% for every 10 Gy of additional radiation delivered.^{142,143} Noncancer- and cancer treatment-related causes of trismus are also common in the cancer setting and include infection, trauma, and osteoradionecrosis of the jaw.¹⁴⁴

Multiple modalities have been used in the treatment of trismus. PT is the mainstay of trismus treatment and is often used alone or in combination with other modalities. Despite widespread and accepted use, the use of PT to treat trismus in the head and neck cancer population has not demonstrated the ability to improve trismus.¹⁴⁵⁻¹⁴⁷ A more recent prospective randomized trial, however, did demonstrate the benefit of exercise in slowing the progression of trismus and improving swallowing function in nasopharyngeal carcinoma patients treated with radiation.¹⁴⁸ Hyperbaric oxygen and pentoxifylline have shown modest efficacy.^{149,150} Forced mouth opening under general anesthesia can

improve trismus, but the effect is often short lived and potentially complicated by alveolus fracture and rupture of adjacent soft tissues. Surgical coronoidectomy has demonstrated significant efficacy in a noncontrolled study of head and neck cancer patients who had failed PT but is not in widespread clinical use.¹⁵¹ Botulinum toxin injection has been reported to have potential benefit in treating selected complications of the RFS including trismus.¹⁵² A study of the efficacy of botulinum toxin injection into the masseters of head and neck cancer patients with radiation-induced pain and trismus did not demonstrate significant improvement of trismus, but did demonstrate significantly reduced local pain.¹⁵³

A variety of jaw opening devices are available to treat trismus (Fig. 152.8).¹⁵⁴ Devices commonly used in clinical practice include stacked tongue depressors, corkscrew devices, the TheraBite (TB) Jaw Motion Rehabilitation System, and the Dynasplint Trismus System (DTS). The TB demonstrated efficacy in a small trial (seven patients) when used within 6 weeks of surgery for oropharyngeal carcinoma.¹⁵⁵ A larger trial demonstrated that TB increased mouth opening an average of 5.4 mm, but the odds of increasing mouth opening 5 mm or more was reduced as the time from oncologic treatment to the start of exercise lengthened.¹⁵⁶ TB combined with unassisted exercise also demonstrated efficacy in patients who had undergone radiation therapy within the preceding 5 years (most within the preceding year) when compared with unassisted exercise and mechanically assisted mandibular mobilization using stacked tongue depressors combined with unassisted exercise.¹⁴⁷

The fabrication and/or use of dynamic jaw opening devices to treat both benign and oncologic causes of trismus have been detailed in reports as early as 1968.¹⁵⁷⁻¹⁶² The DTS is a commercially available dynamic jaw opening device that operates on the

principle of low-torque, prolonged duration stretches. It has demonstrated efficacy in achieving improved jaw opening in a retrospective evaluation of 48 patients with trismus from four cohort groups including radiation therapy for head and neck cancer, dental treatment, oral surgery, and stroke.¹⁶³ Although the 20 patients in the head and neck cancer cohort improved their maximal interincisal distance by a mean of 13.6 mm, little demographic and oncologic information was given save that they all received radiation therapy. A retrospective cohort study demonstrated the efficacy of the DTS as part of a multimodal treatment strategy with improvement in the maximal interincisal distance from 16 mm to 27 mm ($p < 0.001$).¹⁶⁴

In clinical practice, the devices of choice are the TB and DTS. Stacked tongue depressors and corkscrew devices are relatively ineffective. The TB may be effective early in the course of trismus development, is inexpensive, is easy and intuitive to use, and is readily available. The device is inserted in the mouth and activated to near tolerance by squeezing leveraged handles for seven repetitions of 7 seconds. This is usually repeated seven times per day. Though often effective at improving mouth opening, this regimen may cause rebound spasm of the masseter and pterygoid muscles. If the patient has had trismus for more than 3 months, the DTS may be a better option because it works on the principle of low-torque, prolonged stretches, which have been demonstrated to be more effective at improving ROM in an experimental model involving contracted rat knees than high-torque, short duration stretching.¹⁶⁵ A custom bite plate is fabricated for the device and its use is progressed until the patient is able to tolerate the device for 30 minutes three times per day. PT is usually used in collaboration with a jaw stretching device to ensure its proper use, to provide and teach muscle massage techniques, and to address other neuromuscular

Figure 152.8 Jaw stretching devices use to treat trismus include (A) stacked tongue depressors, (B) corkscrew devices, (C) the TheraBite Jaw Motion Rehabilitation System (TB), and (D) the Dynasplint Trismus System (DTS). (From Stubblefield MD, O'Dell MW. *Cancer Rehabilitation Principles and Practice*. New York: Demos Medical Publishers; 2009, with permission.)

and musculoskeletal issues such as neck pain, stiffness, or weakness that often accompany trismus. Pain medications may be necessary to diminish the pain and spasm of mastication muscles. Generally, nerve stabilizing agents such as pregabalin, gabapentin, or duloxetine are used initially. Botulinum toxin injections will not improve oral opening in isolation, but may decrease the dynamic muscle spasm that contributes to trismus and makes other therapeutic interventions, including PT and jaw opening devices, more effective.

Radiation-induced cervical dystonia can result not only from the treatment of head and neck cancers, but from the treatment of any tumor treated with radiation that involves the occiput, cervical spine, or upper thoracic spine including metastatic disease from any cancer type, sarcomas, lymphomas such as HL, or thyroid cancer.¹⁶⁶ Idiopathic cervical dystonia is broadly defined as a movement disorder characterized by involuntary contractions of the head and shoulders that may be twisted into abnormal positions including torticollis, laterocollis, retrocollis, and anterocollis.¹⁶⁷ In radiation-induced cervical dystonia, RF likely contributes to ectopic activity in the distribution of the cervical plexus, the spinal accessory nerve, and the cervical nerve roots. This ectopic activity may be asymmetric or contribute to pain, soreness, tightness, or aberrant positioning of the head and neck characteristic of cervical dystonia. More often, symptoms are at least partially bilateral. As RF progresses, posturing of the head and neck becomes less pronounced and fixed contractures can develop. Most patients complain of neck tightness, which progresses slowly and insidiously and is almost always accompanied by varying degrees of pain. Inability to position the head due to progressive fibrosis can affect swallowing, phonation, and ADLs such as driving and work-related tasks important to one's quality of life.

The natural history of radiation-induced cervical dystonia is usually one of progression. Aggressive PT with an emphasis on a lifelong home exercise program designed to maintain head and neck ROM is critical. It is usually easier to prevent a contracture than to treat one. Medications may be useful in treating the symptoms of radiation-induced cervical dystonia but are not a substitute for ROM exercises. Medications of potential benefit include muscle relaxants such as baclofen, nerve stabilizers such as pregabalin, and analgesics.

Botulinum toxin injections can be effective at treating the pain and spasms associated with radiation-induced cervical dystonia. Botulinum toxin injections will not directly treat fixed contracture, but may facilitate the progression of ROM through PT and a home exercise program. Techniques used in the treatment of radiation-induced cervical dystonia are very similar to those used for idiopathic cervical dystonia. A clinical evaluation with particular emphasis on the patient's anatomy, which may have been compromised by neck dissection, and the patient's historical account of symptoms, as well as physical examination are instrumental in choosing targets and dosing for botulinum toxin injection therapy. The dosages and technique are often modified on subsequent visits to maximize efficacy. Potential complications of botulinum toxin injection include bleeding and infection, especially if injections are near recent or active injection sites, spinal stabilization hardware, or tumor. Neck drop can occur when injecting weak or liminal cervical paraspinal muscles or the trapezius. Precipitation or worsening of dysphagia is particularly problematic because patients with RFS that involves the neck often have preexisting deficits. Overtreatment with botulinum toxin can potentially result in aspiration or the need for a feeding tube.

LYMPHEDEMA

Lymphedema is the abnormal accumulation of protein-rich lymphatic fluid in an extremity, face, neck, trunk, or genitalia. Primary lymphedema is due to aplastic or hypoplastic development of the lymphatics, whereas secondary lymphedema is usually the result of infection, tumor, or lymphatic injury. Risk factors for

lymphedema include the extent of surgery (e.g., axillary lymph node dissection, the number of lymph nodes dissected, mastectomy) and being overweight or obese.¹⁶⁸ Radiation therapy involving the lymph nodes is also a well-known factor in the development of lymphedema.¹⁶⁹ In addition to breast cancer, lymphedema can result from any type of cancer in which the lymph nodes are involved directly or by treatments such as radiation or surgery. Pelvic, colorectal, and head and neck cancers are commonly associated with lymphedema. If untreated, the accumulation of protein-rich lymphatic fluid can result in fibrotic deposition with progressive sclerosis further worsening the lymphedema and ultimately resulting in elephantiasis.¹⁷⁰ Lymphedema is not usually a painful condition but can cause the sensation of extremity heaviness or constriction. Increased weight, traction, and altered biomechanics can contribute to secondary neuromuscular and musculoskeletal pain disorders in patients with lymphedema.¹⁰⁴

The reported incidence of lymphedema in breast cancer varies depending on the diagnostic criteria used and the means of assessment. For instance, a recent systematic review and meta-analysis of unilateral arm lymphedema in breast cancer survivors measured an incidence of 16.6% for all of the 72 studies that met their inclusion criteria, 21.4% for the 30 included prospective cohort studies, and 28.2% for the 9 studies that used more than one diagnostic method to measure lymphedema.¹⁶⁸ The authors also found that lymphedema was approximately four times higher (19.9%) in women who had axillary lymph node dissection than those who underwent sentinel node biopsy (5.6%).

Swelling can occur immediately following surgery and resolve spontaneously without necessarily heralding the onset of lymphedema. Axillary web syndrome is characterized by palpable cords in the breast, underarm, medial arm, antecubital fossa, forearm, and/or abdomen that develop following axillary lymph node dissection (38% to 72%) or sentinel lymph node biopsy (20%). Fortunately, the disorder, which is often associated with pain and shoulder ROM limitations, is usually self-limited. New onset lymphedema that develops after the acute treatment phase of the primary disease should prompt an evaluation for recurrence. Imaging is the modality of choice to exclude a recurrence. An MRI with gadolinium is usually sufficient, but a PET-CT scan may be necessary in borderline cases. A duplex Doppler ultrasound is often indicated to exclude deep venous thrombosis.¹⁷⁰ CT scans of the chest, abdomen, and pelvis commonly used by the primary oncologist as screening for visceral recurrences will likely miss an axillary or brachial plexus recurrence.

Peripheral edema from fluid overload, heart failure, pulmonary hypertension, hypoalbuminemia, and other causes are common in the cancer setting and require differentiation from lymphedema. This differentiation is made on clinical grounds by a history, physical examination, and laboratory evaluation when necessary. Typically, lower extremity lymphedema will involve the dorsal foot and spare the metatarsal-phalangeal joints and will not have peripheral vascular disease stigmata, vascular distention, or ulceration. Studies such as lymphoscintigraphy, which evaluates lymphatic transport and abnormalities, can clarify the etiology of venous edema from mixed or lymphatic edema. Lymphoscintigraphy is rarely done because it is very dependent on the skill of the examiner and carries considerable morbidity without providing significant information over a comprehensive clinical evaluation. Impedance plethysmography is a noninvasive technique that uses small changes in electrical resistance to evaluate and follow lymphedema.¹⁷¹

Improved cancer treatment approaches diminish but do not prevent the development of lymphedema.^{172,173} Lymphedema is not curable and must be managed as a chronic condition. At-risk patients should be educated about lymphedema and its complications, especially cellulitis. Risk-reduction strategies include skin care and protection and avoiding venipuncture, blood pressure measurements, or constricting clothing to the affected region. The current research regarding airline travel in at-risk individuals is limited and controversial. One study concluded that domestic

air travel (less than 4.5 hours) is low risk and that compression devices may actually contribute to increased swelling.¹⁷⁴

A variety of therapies have been trialed for the management of lymphedema including complex physical therapy (CPT), low-level laser therapy (LLLTL), pharmacotherapy, and surgery.¹⁷⁵ CPT (also known as complex decongestive therapy, complex decongestive therapy, or comprehensive decongestive therapy) is by far the most commonly used modality and consists of manual lymphatic drainage (MLD), exercise, nonelastic wrapping, application of compression garments, and skin care. The application of low stretch bandaging followed by compression stockings was found to be superior to compression stockings alone in a randomized, controlled, parallel-group trial for patients with both upper and lower limb lymphedema.¹⁷⁶ LLLTL was found to reduce the volume of the affected arm, extracellular fluid, and tissue hardness in approximately 33% of postmastectomy patients in one study and to reduce limb volume and increase shoulder mobility and hand grip strength in approximately 93% of postmastectomy lymphedema patients in a more recent study.^{177,178} Diuretics may have a role in treating lymphedema of mixed origin (e.g., cardiogenic plus lymphedema) but are not recommended for long-term use because, although they may reduce the intravascular fluid volume, they cannot effectively remove the elevated interstitial protein that characterizes lymphedema resulting in an osmotic gradient that facilitates rapid fluid reaccumulation. The benzopyrones (e.g., Coumarin (5,6-benzo-[a]-pyrone, or 1,2-benzopyrone) have had controversial findings and are not currently approved by the U.S. Food and Drug Administration.¹⁷⁹ Flavonoids have been reported to reduce stage 2 and 3 lymphedema; however, trials have been limited and they are not widely used in clinical practice.¹⁸⁰ Antibiotics, including second-generation cephalosporins and penicillins, are commonly used to treat cellulitis associated with lymphedema. Patients who have had multiple cellulitic infections may need to receive prophylactic antibiotics. A variety of surgical options exist for the management of lymphedema. These techniques can be categorized as physiologic (flap interposition, lymph node transplantation, lymphatic bypass, lymphaticovenous bypass) or reductive (direct excision, liposuction).¹⁸¹ In general, the data supporting these various options are limited and suffer from short follow-up intervals.¹⁷⁵ External pneumatic compression pumping alone or in combination with CPT is controversial.¹⁷²

The question of whether patients with lymphedema could exercise or lift weights was controversial until recently. Considerable high-quality data are now available to affirm that resistance exercise including weight lifting does not increase the risk of or exacerbate symptoms of lymphedema.¹⁸²⁻¹⁸⁴ In contradiction to the long-held dogma that weight lifting is not safe for patients with lymphedema, those in the weight lifting group of the Schmitz study demonstrated a decreased incidence of exacerbations of lymphedema as well as reduced symptoms and increased strength.¹⁸⁴ A later randomized prospective trial by Schmitz et al. demonstrated not only that women at risk for breast cancer–related lymphedema who lifted weights did not see an increased incidence of lymphedema, but also that the women in the highest risk group actually saw a decreased risk of lymphedema compared with the control group.¹⁸⁵ Comprehensive treatment of lymphedema should address weight control because of the association between increased body mass and lymphedema.^{172,182,183} Although the women in the majority of the trials evaluating the effects of resistive exercises wore compression garments, it is not clear that they are necessary for safe exercise.¹⁸⁶

REHABILITATION INTERVENTIONS

Therapeutic Exercise

The benefits of exercise in cancer patients during and after treatment, as well as for cancer survivors, are perhaps the best studied topic in cancer rehabilitation. Several systematic reviews and

meta-analyses have exhaustively evaluated the available evidence concerning the role of exercise in cancer.¹⁸⁷⁻¹⁹¹ Physical activity has been shown to have positive effects on physiology, body composition, physical functions, psychological outcomes, and quality of life after treatment for breast cancer.¹⁹⁰ When other cancer types are included, physical activity is also associated with reduced body mass index and body weight, increased peak oxygen consumption, peak power output, as well as improved quality of life.¹⁹⁰ Exercise also has a modest positive effect on depressive symptoms in cancer survivors.¹⁸⁹ The American College of Sports Medicine has issued guidelines on the safety and efficacy of exercise during and after cancer treatments and concluded that exercise results in improvements in physical functioning, quality of life, and cancer-related fatigue for several cancer groups.¹⁹²

Among the multiple rationales of exercise in the cancer setting are avoiding effects of deconditioning, which include muscle weakness and atrophy, loss of cardiopulmonary fitness, and improving efficiency of energy metabolism at a cellular level. Improved immune effects have also been reported with exercise in cancer survivors, including increases in natural killer cell cytolytic activity, monocyte function, proportion of circulating granulocytes, and decreases in the duration of neutropenia.¹⁹³ Appropriate precautions should be incorporated into the exercise program (see Tables 152.1 and 152.2). A physician recommendation to exercise improves compliance.¹⁹⁴ The program should incorporate interventions for strength, endurance, and flexibility, and should be individualized. When possible, the form of exercise should be one that is enjoyable and sustainable.

Another strong justification for exercise in cancer patients is weight reduction. Body mass index is directly proportional to tumor recurrence rates and all-cause mortality.¹⁹⁵ Obesity is also a risk factor for lymphedema.¹⁹⁶ Weight control and weight reduction require a limitation of caloric intake, but patients in the active treatment phase may have side effects that interfere with adequate nutrition, and in this setting, promoting increased caloric intake may be an integral part of management. The use of anabolic steroids has been described to augment weight gain and the building of muscle mass but is rarely used in clinical practice.⁷ Hydration must be adequate to prevent orthostatic hypotension.

An appropriate exercise program should be discussed with all cancer patients, with the exception of those with cachexia. Cachexia is defined as more than a 25% loss of lean bone mass or a body mass index 10% or less below normal range. Most cachectic patients are not consuming adequate amounts of protein or calories to meet basal needs and rehabilitation efforts should focus on maintaining basic functional skills and quality-of-life priorities. Any activity program that is attempted should be individualized, taking into account the patient's comfort and the incorporation of rest periods.

It is estimated that 50% to 90% of patients experience fatigue at some point during the continuum of the cancer experience.¹⁹⁷ Although much of the initial fatigue and the extremely pervasive nature of this disorder is likely due to primary treatment with chemotherapy and radiation, the disorder can persist for months or even years after treatment. The pathogenesis of cancer-related fatigue (CRF) is not well understood. A variety of pathogenic mechanisms are likely to contribute including tumor-related effects, effects of cancer treatment on the central or peripheral nervous system, muscle energy metabolism, comorbid medical conditions (anemia), hypothyroidism, cytokines, sleep disturbances (circadian rhythms), mediators of inflammation and stress, immune activation, hormonal changes related to effects on the hypothalamic pituitary axis, premature menopause in women, androgen deprivation in men, psychological factors (anxiety, depression), or other unknown factors.^{197,198} A Cochrane review concluded that aerobic exercise is beneficial for individuals with CRF during and after cancer therapy, specifically for those with breast and prostate cancer, but not for those with hematologic malignancies.¹⁹⁸ Another Cochrane review noted preliminary evidence for the use of psychostimulants to treat CRF but acknowledged that the number of trials was small

(5) and more data are needed before definitive recommendations concerning their usage and safety could be made.¹⁹⁹

Therapeutic Modalities

Physical modalities are nonpharmacologic agents used to produce a therapeutic effect in tissues.²⁰⁰ They include heat, cold, and electrotherapy. They are frequently used to reduce pain, facilitate stretch, aid in wound care, and introduce medications such as corticosteroids.

Heat includes superficial and deep-heating modalities. Superficial heat is applied to the surface of the skin to achieve the maximum tissue temperatures in skin and subcutaneous fat. Heat should not be applied to an area of acute trauma and inflammation and in patients with bleeding diatheses, edema, peripheral vascular disease, large scars, impaired sensation, or cognitive or communication deficits that impair their ability to report pain. Superficial heat is applied using heating pads, moist compresses, hydrocollator packs, paraffin baths, and whirlpool baths. Deep heat is directed to heat muscle, tendons, ligaments, or bone. It is most commonly applied using ultrasound waves. Deep heat modalities are generally avoided to an area where active regional malignancy exists for fear of causing tumor growth.^{201–203} This recommendation, however, is based on *in vitro* studies of tumor growth in mice subjected to ultrasound at intensities 10 times higher than are possible by standard machines.²⁰⁴ There is contradictory evidence that ultrasound at various intensities can actually have an antitumor effect.²⁰² It is unclear if this phenomenon represents a real clinical concern and if it can be extrapolated to other heating modalities such as laser or moist heat. Because of the reported risk of increasing tumor growth with such modalities, they are generally avoided, particularly in primary tumors subject to potentially curative treatment, unless the potential benefit is substantial and outweighs the unknown risks. In patients with metastatic disease, and in areas well away from a primary tumor, the risks of contributing significantly to tumor growth or spread, if any, are likely minimal.

Medication such as 1% lidocaine or corticosteroids can be applied using ultrasound. This technique is known as *phonophoresis*, which is often used to treat tendonitis, bursitis, scar tissue, neuromas, and adhesions that may be complications associated with cancer or its treatment.²⁰⁵

Cold modalities, also known as *cryotherapy*, are often used to treat acute pain and inflammation associated with musculoskeletal disorders, as well as myofascial pain, spasticity, and emergent care of minor burns. Cryotherapy is the treatment of choice for acute trauma and inflammation. It can also be used in patients with bleeding diathesis and large scars. Cryotherapy should not be used in cold-intolerant patients or those with cryoglobulins, cold hypersensitivity, and Raynaud's disease.

TENS is the most common form of electroanalgesia and enjoys widespread use, although its effectiveness in both acute and chronic pain conditions remains controversial in both benign and malignant conditions.^{206–208} It has been used to help reduce neuropathic and nociceptive pain conditions, depending on the type of TENS unit and parameters chosen. It is applied by placing one to four electrode pads surrounding the area of pain. A small stimulating unit is connected and specific frequency, pulse width, and amplitude settings are selected based on the type of pain and the patient's response. The analgesic effect of TENS may be the result of a combination of mechanisms, including acting as a counter-irritant in the CNS to inhibit activity of dorsal horn nociceptive neurons, activating the production of endogenous opioids, and possibly activating other neurotransmitter systems, including the serotonergic and substance P systems. As with deep heating modalities such as ultrasound, it is recommended that TENS should not be delivered over or near a malignancy unless it is being used in patients with terminal cancer. As with ultrasound, however, there is little evidence to support this recommendation.

Orthotics and Prosthetics

Patients with weakness or impaired balance often need equipment such as assistive devices for ambulation, bath equipment such as a tub bench and raised toilet seat, and other equipment for self-care such as reachers. A wheeled walker usually suffices for individuals with balance impairment or with mild weakness and allows for a quicker cadence than a standard walker, which must be manually lifted between steps. However, a standard walker is needed when more severe weakness is present or when protected weight bearing is needed.

Foot drop (weakness of dorsiflexion) is often seen in the cancer setting as a result of a brain, spinal cord, cauda equina, L-5 root, lumbosacral trunk, sciatic nerve, or most commonly, peroneal nerve injury. Patients with foot drop will often benefit from an AFO, which helps to restore a more normal gait pattern by allowing the foot to clear the ground without hiking the hip. A number of AFO designs exist. If the patient has some residual dorsiflexor strength, a relatively normal-shaped limb, and normal skin integrity, a prefabricated posterior leaf-spring orthosis may be adequate. For most patients, a custom-molded AFO or posterior leaf-spring orthosis is the brace of choice because of its better fit and more durable design. For patients with weakness of plantar flexion as well as dorsiflexion, a higher medial-lateral trim line will increase medial-lateral stability and help prevent ankle sprain. This modified AFO design may compromise the optimal gait, however, because it is generally too stiff to allow for passive dorsiflexion in the terminal stance phase of the gait cycle. This can be overcome by using a hinged AFO design with free dorsiflexion or a dorsiflexion stop at 15 degrees and a plantar flexion stop at neutral. This will provide excellent medial-lateral stability without significantly affecting terminal stance. For patients with severe spasticity or pain on ankle motion, a solid AFO is indicated. For most patients, a plastic orthotic is preferred because it is relatively aesthetic, lightweight, and can be used with different pairs of shoes. In instances in which lower extremity pain, fluctuating edema, skin fragility, deformity, or other circumstances prohibit the use of a plastic molded AFO, a double-metal upright AFO may be an option. There are a variety of other orthotics available to optimize deficits arising from other peripheral nervous system dysfunction. Knee-immobilizers, for instance, are often useful to control knee flexion in patients with femoral neuropathy or lumbar plexopathy.⁶³

NONPHARMACOLOGIC PAIN MANAGEMENT

Rehabilitation medicine typically emphasizes nonpharmacologic interventions in addition to medications to address pain associated with musculoskeletal and neuromuscular syndromes. The primary goal of this approach is to limit the impact of pain on function and to minimize disability. The emphasis of nonpharmacologic pain management may be of particular benefit in elderly patients who may not tolerate medications well. Historically, direct tumor spread is thought to account for most cancer pain.²⁰⁹ As treatments for cancer have improved and an emphasis has been placed on cancer survivorship, more pain disorders encountered in the cancer setting are related to causes other than the direct effects of a tumor. These disorders include treatment effects and degenerative diseases of various types.

The appropriate treatment depends on the nature and type of pain. The identification and treatment of depression, anxiety, fatigue, quality of sleep, and mood can have a marked impact on pain and should be considered as part of multimodal treatment where appropriate in all patients.^{210,211} Psychological strategies such as guided imagery, hypnotherapy, biofeedback, and deep breathing can be effective.²¹² Pain may respond to PT to improve muscle strength and condition as well as to improve joint ROM. Physical modalities including heat, cold, and electrotherapy may be of benefit where appropriate.²⁰⁰ Aerobic exercise has been shown to improve

mental outlook and may result in an improved ability to cope with pain in a variety of clinical settings including cancer.²¹³ Pain of muscle or bone etiology is usually worse on weight bearing or other mechanical stress and improves with rest. Splinting or assistive devices may help achieve protected weight bearing. Neuropathic pain may benefit from desensitization measures such as vibration or tapping. Topical agents such as anesthetic (lidocaine) patches or chili pepper extract-based ointments (capsaicin) can be tried (the latter should not be applied to the face). A local injection of anesthetic into trigger or tender points can be effective at relieving pain in

select patients, although there is no clear evidence to support either the benefit or ineffectiveness of such procedures.²¹⁴ Similarly, the injection of corticosteroids or viscosupplements into arthritic or inflamed joints may help decrease pain and improve function.²¹⁵ Complimentary therapies such as acupuncture, mind–body techniques, and massage therapy may help with a variety of cancer- and cancer treatment–related symptoms including pain.^{216,217} In severe cases, neurosurgical procedures, such as intrathecal pumps, dorsal column stimulation, and neuroablative procedures (neurectomy, rhizotomy, cordotomy) can be considered.

Section 2 Complementary, Alternative, and Integrative Therapies

153 Complementary, Alternative, and Integrative Therapies in Cancer Care

Catherine E. Ulbricht

BACKGROUND

Definitions

In the United States, complementary and alternative medicine (CAM) is defined by the National Center for Complementary and Alternative Medicine (NCCAM) as a group of diverse medical and health-care systems, practices, and products that are not normally considered to be conventional medicine.¹ Other terms used to refer to CAM include folkloric, holistic, irregular, nonconventional, non-Western, traditional, unconventional, unorthodox, and unproven medicines. NCCAM classifies CAM therapies into five categories or domains: alternative medical systems, mind-body interventions, biologically based therapies, manipulative and body-based methods, and energy therapies (Table 153.1).¹⁻³

Recently, the term *integrative medicine* has come into common use. The Consortium of Academic Health Centers for Integrative Medicine has defined this term as the practice of medicine that reaffirms the importance of the relationship between practitioner and patient, that focuses on the whole person, is informed by evidence, and makes use of all appropriate therapeutic approaches, providers, and disciplines to achieve optimal health and healing.

Prevalence

In the United States, an estimated 44% of the population used at least one CAM therapy in 1997.^{2,4-6} According to the 2007 National Health Interview Survey (NHIS), the prevalence of CAM use in the United States was approximately 38% for adults and 12% for children.⁷

Surveys published since 1999 suggest that between 25% and 83% of US adult cancer patients have used CAM therapies at some point after diagnosis, with variations in utilization rates depending on geographic area and type of cancer.⁸⁻²⁵ Earlier studies generally report lower overall prevalence of CAM use (9% to 54%), possibly due to increasing rates of use or broadening of the definition of CAM.^{26,27} Initial studies of CAM prevalence during the 1970s and 1980s focused on the toxicity of the anticancer therapy lometrexate. The reported prevalence of CAM was 9% to 16%,²⁷ but surveys within the past decade estimated the prevalence of use in pediatric oncology to be 31% to 87%; moreover, in many cases, the treating physician was unaware that their patients were using CAM.²⁸⁻³¹ Use of CAM is also prevalent among cancer patients outside the United States in all regions of the world, with significantly varying use among different regions.^{26,32,33}

In the West, CAM use appears to be more common among those with higher education levels and higher incomes. CAM use is also higher among young females who have had surgery, used chemotherapy, or had a history of CAM use before diagnosis.^{19,32,34,35}

ESTABLISHING AN INTEGRATIVE ONCOLOGY APPROACH WITH PATIENTS

Integrative Oncology Model

An integrative approach to cancer should be comprehensive, personalized, evidence-based, and safe. The conventional model of cancer treatment involves three different disciplines (surgery, radiation, chemotherapy), and integrative oncology aims to expand the interdisciplinary approach to include therapies such as acupuncture, yoga, meditation, diet, exercise, and other modalities. This is in response to the concept of treating the whole patient in all domains. Engel's biopsychosocial model of health care, first published in *Science* more than 30 years ago, describes one conceptual model of these domains of patient care and its importance in the treatment of all patients.³⁶ The Integrative Medicine Program at M. D. Anderson Cancer Center provides one example of how this framework may assist in creating comprehensive integrative care plans (Fig. 153.1). Without a comprehensive assessment and appropriate attention given to their needs, patients may perceive gaps in their care. Although symptoms such as severe pain or nausea are typically thought of as purely physical symptoms, if symptoms remain severe and chronic, they will often impact the psychosocial dimensions of health as patients may become more irritable, socially inactive, and fatigued due to insomnia. With comprehensive care plans, patients will have cancer treatments that address all of their needs in a more seamless manner. These plans will also have the greatest potential for improving the overall health and well-being of cancer patients. These basic comprehensive evaluations are aggregates of many different components; by addressing issues of nutrition, physical activity, symptom control, and other factors, these plans will help improve the performance of cancer patients throughout the continuum of care.

Physical Well-Being

Growing evidence supports the important role of physical activity and nutrition in the health of cancer patients, and these factors

TABLE 153.1

National Institutes of Health: National Center for Complementary and Alternative Medicine Categories	
Whole medical systems	Traditional Chinese medicine, Ayurvedic medicine
Biologically based therapies	Herbs, supplements, special diets
Mind–body therapies	Meditation, prayer, yoga
Body manipulation	Chiropractic, massage
Energy therapies	Qi gong, Reiki, magnetic

have been correlated with improved clinical outcomes. Moreover, several phytochemicals demonstrate pharmacologic effects on molecular targets in known cancer signaling pathways.³⁷ The Women’s Intervention Study reported that a 24% reduction in fat intake resulted in lower cancer recurrence rates.³⁸ Participants were randomized to increase fruit and vegetable intake and reduce dietary fat, but a significant reduction in breast cancer events was not found; however, when secondary analyses were performed, including physical activity, an increased survival of approximately 50% was found among women who were physically active and maintained a diet high in fruits and vegetables.^{39,40} Similar associations are beginning to be reported in colon cancer patients.^{39–42} The American Institute for Cancer Research (AICR) and the World Cancer Research Fund (WCRF) have created a combined report for guidelines regarding nutrition and physical activity to prevent cancer; the American Cancer Society (ACS) has also published guidelines for those with cancer.^{43–48} Additionally, a recent study examining obesity during neoadjuvant chemotherapy for breast cancer patients found obesity was correlated with decreased survival,⁴⁹ and a different study found that obesity predicts a second primary tumor on the contralateral breast.⁵⁰ Patients need to be encouraged to follow the ACS guidelines and the AICR/WCRF guidelines for cancer prevention and encouraged to adopt healthful behaviors in regard to physical activity and diet.

Psychosocial Well-Being: The Mind–Body Connection

The mind–body connection is an important aspect of integrative oncology, as emphasized in the recent Institute of Medicine (IOM) report “Cancer Care for the Whole Patient.”⁵¹ This comprehensive report states that “cancer care today often provides state-of-the-science biomedical treatment, but fails to address the psychological and social (psychosocial) problems associated with the illness. These problems—including . . . anxiety, depression or other emotional problems . . .—cause additional suffering, weakened adherence to prescribed treatments, and threaten patients’ return to health.” Extensive research has documented that mind–body interventions appear to address many of the issues mentioned in the IOM report.

The belief that what we think and feel can influence our health and healing dates back thousands of years.⁵² The importance of the role of the mind, emotions, and behaviors in health and well-being has been a part of medical traditions of the world, such as Chinese, Tibetan, and Ayurvedic medicine. Many patients with cancer turn to CAM therapies as a way to reduce stress; substantial evidence now shows the negative health consequences of sustained stress on health and well-being. The profound psychological and behavioral effects of stress may include post-traumatic stress disorder, increased health-impairing behaviors (e.g., poor diet, lack of exercise, substance abuse), poor sleep, and decreased quality of life.^{53–57} Research has shown that stress can also decrease compliance with regular health screening.^{58,59}

Many stress-induced physiologic changes can have direct effects on health, including persistent increases in sympathetic nervous system activity and the hypothalamic–pituitary axis that can cause increased blood pressure, heart rate, catecholamine secretion, and platelet aggregation.^{60–65} Furthermore, research has associated stress with increased latent viral reactivation, upper respiratory tract infections, and wound-healing time.^{66–70} Stress also deregulates a variety of immune indices, as shown in both healthy subjects and cancer patients.⁷¹ Such stress-induced physiologic changes can affect cancer progression, treatment, recovery, recurrence, and survival.^{72,73} Spiegel et al.⁷⁰ first published on the possible impact of a psychosocial intervention on breast cancer survival,

Integrative Oncology Clinical Model

Figure 153.1 Guiding model for integrative medicine at M. D. Anderson Cancer Center.

but subsequent studies have not consistently reproduced these results.^{74,75,77} However, recent research has demonstrated a survival advantage among breast cancer patients who received psychological intervention with more than 10 years of follow-up⁷⁸ as well as improved mood and quality of life during and after radiotherapy.⁷⁹ These studies underscore the importance of psychosocial intervention in cancer treatment.

Patient–Clinician Communication Regarding Complementary and Alternative Medicine

Research indicates that neither adult nor pediatric patients receive sufficient information or discuss CAM therapies with physicians, pharmacists, nurses, or CAM practitioners.^{21,28} Most patients do not bring up the topic of CAM because no one asks; thus, patients may believe it is unimportant to disclose. It is estimated that 38% to 60% of patients with cancer are taking complementary medicines without informing their health-care team.^{8,80} This lack of discussion is of grave concern because biologically based therapies (such as herbs) may interact with cancer treatments. Patients are commonly unaware of the differences between U.S. Food and Drug Administration (FDA)–approved medications (which require evidence of efficacy, safety, and quality control in manufacturing) and supplements, which are governed not by the FDA but by the Dietary Supplement Health and Education Act (DSHEA) of 1994. Supplements under this legislation are exempt from the same scrutiny the FDA imposes on medications; furthermore, these supplements are not intended to treat, prevent, or cure diseases. The common belief by patients that *natural* means safe needs to be addressed with education as some herbs and supplements have been associated with multiple drug interactions⁸¹ as well as increased cancer risk and organ toxicity. These specific concerns are addressed later in this chapter.

Existing research suggests that the majority of cancer patients desire communication with their doctors about CAM,⁸² and there is general agreement within the oncology community that in order to provide optimal patient care, oncologists must not only be aware of CAM use, but also be willing and able to discuss all therapeutic approaches with their patients.^{83,84} It is the health-care professional's responsibility to ask patients about their use of complementary medicines,⁸⁵ and the discussion should ideally take place before the patient starts using a complementary treatment—whether it is a nutritional supplement, mind–body therapy, or other CAM approach.

A number of strategies can be used to increase the chance of a worthwhile dialogue.⁸⁶ One approach is to include the topic of CAM as part of a new patient assessment. For example, when asking about medications, physicians should inquire about everything the patient ingests—including over-the-counter products, vitamins, minerals, herbs, and even the patient's diet. Physicians may consider having the patient bring in the actual bottles of herbs and supplements for evaluation. When asking about a patient's past medical history, physicians may ask other health-care professionals to determine if the patient has visited with naturopathic or chiropractic practitioners. If the issue of CAM arises, clinicians need to develop an empathic communication strategy that addresses the patient's needs while maintaining an understanding of the current state of the science. In other words, this strategy needs to be balanced between clinical objectivity and bonding with the patient so that it can benefit both the patient and the health-care provider. These patients need reliable information on CAM from evidence-based resources such as Natural Standard Research Collaboration (www.naturalstandard.com), as well as adequate time to discuss this information with their oncologists.

Safety Concerns

Many CAM therapies can potentially cause adverse outcomes, and are thus a major concern among health-care professionals.^{87–90} Nonbiologically based CAM therapies, such as massage or

acupuncture, often have minimal risks when performed by trained health professionals. In contrast, herbs and supplements should be considered more similar to prescription medications in that they have the potential to have powerful effects on the natural biologic processes of the body. This is especially true when natural plants are processed into concentrated formulations. The pathways by which CAM therapies may lead to negative clinical outcomes include metabolic interactions, treatment interactions, direct organ toxicity, direct biologic effects on the cancer, and unregulated low quality manufacturing of biologically based CAM. Some of these topics are briefly reviewed here.

Metabolic Interactions

Many botanical agents are pharmacologically active, raising concerns about pharmacodynamic effects that can lead to changes with conventional therapy, such as cytotoxic agents.⁸⁷ Published data are available regarding potential interactions between specific herbs or vitamins and prescription drugs.^{87,88,91–97} Overall, there is substantial clinical evidence of herb–drug interactions in general.⁸¹ Therefore, negative interactions should be considered prior to integrating herbs, vitamins, or nutritional supplements during chemotherapy.

Common chemotherapy agents metabolized through the cytochrome P-450 system and the specific isoenzymes responsible for their metabolism are a starting point to consider possible interactions. St. John's wort (*Hypericum perforatum*) is of particular concern, with multiple well-documented drug interactions. This herb appears to inhibit the hepatic enzyme cytochrome P-450 3A4 acutely, then induce it with repeated administration. A study of individuals given irinotecan (CPT11) reports a greater than 50% reduction in serum levels of the active metabolite SN38 after concomitant administration of St. John's wort.⁹⁸ Imatinib levels appear to be altered by similar mechanisms.⁹⁹ St. John's wort and similar herb–chemotherapy combinations should be used with extreme caution because of the potential for alterations in drug metabolism.

The common practice by patients of combining compounds, in which there is a lack of data regarding the pharmacodynamics and pharmacokinetics, creates a dangerous situation that may lead to inadvertent detrimental impact on clinical outcomes. This possible negative impact must be evaluated and discussed with patients whenever considering the use of untested natural products with other therapies.

Treatment Interactions

Antioxidant Interference with Chemotherapy or Radiation.

Because oxidative damage to cells may increase the risk of cancer, the use of antioxidant herbs and vitamins has been proposed for cancer treatment or prevention. Examples include vitamins A, C, and E, as well as lycopene, green tea, soy, grape seed extract, melatonin, and selenium. Concern has been raised that antioxidants may interfere with radiation therapy or some chemotherapy agents (e.g., alkylating agents, anthracyclines, or platinum), which themselves can depend on oxidative damage to tumor cells for their cytotoxic effects. Studies of the effects of antioxidants on cancer therapies have yielded mixed results, with some reporting antagonistic effects, others noting synergism (i.e., benefits), and most suggesting no significant interaction.^{89,90,100,101} A large randomized trial of head and neck cancer patients evaluated the use of beta-carotene and vitamin E for the reduction of radiation side effects.¹⁰² Results found a reduction in side effects, but also found decreased survival among patients taking beta-carotene and vitamin E. Additionally, the use of these antioxidants seemed to correlate to an increase in second primary cancer.¹⁰³ Whether antioxidants are beneficial or harmful is a critical question without a clear scientific answer at this time; rather, it remains an area of continuing study and controversy.^{104,105}

TABLE 153.2

Herbs and Supplements with Potential Hepatotoxic Effects

Ackee (*Blighia sapida*), *Alkanna* spp., American (false) pennyroyal (*Hedeoma pulegioides*), antineoplastons, bee pollen, birch oil (*Betula lenta*), blessed thistle (*Cnicus benedictus*),^a Boldo (*Peumus boldus*), borage (*Borago officinalis*), bush tea (*Crotalaria* spp.),^b butterbur (*Petasites hybridus*), chaparral (*Larrea tridentata*), coltsfoot (*Tussilago farfara*), comfrey (*Symphytum* spp.), creatine, dehydroepiandrosterone (DHEA), echinacea (*Echinacea purpurea*), *Echium* spp.,^b germander (*Teucrium* spp.), greater celandine (*Chelidonium majus*), groundsel (*Senecio* spp.),^b heliotrope (*Heliotropium* spp.), horse chestnut (*Aesculus hippocastanum*), jequirity (*Abrus precatorius*), Jin-Bu-Huan (*Lycopodium serratum*), kava (*Piper methysticum*), lesser celandine (*Ranunculus ficaria*), lobelia (*Lobelia inflata*), L-tetrahydrocannabinol (THP), mistletoe (*Viscum album*), niacin (vitamin B₃), niacinamide, nux vomica (*Strychnos nux-vomica*), Paraguay tea/yerba mate (*Ilex paraguariensis*),^b periwinkle (*Catharanthus roseus*), plantain (*Plantago* spp.),^a pride of Madeira (*Echium fastuosum*),^b polysaccharide K (PSK) (*Trametes versicolor*, formerly *Coriolus versicolor*), ragwort (*Senecio* spp.),^b rooibos (*Aspalathus linearis*), rosy periwinkle (*Catharanthus roseus*), rue (*Ruta graveolens*), saffras (*Sassafras albidum*), skullcap (*Scutellaria* spp.), sorrel (*Rumex acetosa*), tea (*Camellia sinensis*), turmeric (*Curcuma longa*), tu-san-chi (*Gynura segetum*),^b uva ursi (*Arctostaphylos uva-ursi*), valerian (*Valeriana officinalis*), white chameleon (*Atractylis gummifera*), white oak (*Quercus alba*), yerba mate (*Ilex paraguariensis*)^b

^a Contains tannins and may be hepatotoxic in large quantities.

^b Contains pyrrolizidine alkaloids.

Direct Organ Toxicity

Hepatotoxicity and Nephrotoxicity. The long-term use of concentrated natural products is an increasing concern. A recent report evaluating the risk for end-stage renal disease in Taiwan found that chronic use of traditional Chinese medicine herbs carried an increased risk of kidney failure.¹⁰⁶ Multiple herbs and supplements may cause hepatotoxicity or transaminitis based on human research or known hepatotoxic constituents and should be used cautiously in combination with other hepatotoxic agents (Table 153.2).

Hematologic Toxicity

Many herbs and supplements carry an increased risk of bleeding. Multiple case studies have reported clinically significant bleeding with the use of *Ginkgo biloba* (either alone or with aspirin or warfarin), and isolated case reports of bleeding with the use of saw palmetto (*Serenoa repens*), fish oil, and garlic (*Allium sativum*).⁸¹ The suspected mechanism for increased bleeding is interference with platelet function. Because herbal supplementation is common among cancer patients, surgical staff should screen patients presurgically for use of herbal and other dietary supplements. These agents should be discontinued before surgical procedures, and should be used cautiously with other agents that increase the risk of bleeding. Clinicians should also be cautious about taking natural products concurrently with warfarin, which is known to be sensitive to vitamin K intake and possible drug interactions. Numerous other herbs and vitamins may increase bleeding risk based on known constituents, preclinical data, or traditional use (Table 153.3).

Direct Biologic Effects on Cancer

A common concern is the potential for herbs and supplements to have procancerous effects. One clear example comes from Sidney Farber from Harvard University and the discovery of antifolate agents such as methotrexate, which came from the observation that folic acid supplementation actually promoted disease progression.¹⁰⁷ Until appropriate clinical trials have been completed on herbs and supplements for individual types of cancer, the resulting impact—whether beneficial, harmful, or neither—will remain unknown, and thus, caution will always be considered a prudent approach.

Phytoestrogens. Phytoestrogens are plant-based compounds structurally similar to estradiol and capable of binding to estrogen receptors as agonists or antagonists. Multiple popular herbs contain phytoestrogens, such as black cohosh (*Cimicifuga racemosa*), red clover (*Trifolium pratense*), and soy (*Glycine max*) (Table 153.4).

Although some epidemiologic evidence has found reduced breast cancer risk associated with the consumption of phytoestrogens,^{108,109} effects of these agents in hormone-sensitive cancers remain unclear, and use in patients with estrogen receptor–positive breast cancer is controversial (see the Soy section, which follows, for further discussion).

STANDARDIZATION AND QUALITY

The preparation of herbs and supplements can vary from manufacturer to manufacturer and from batch to batch within one manufacturer. Because the active components of a product are often not clear, standardization may not be possible, and the clinical effects of different brands may not be comparable. There may also be harmful contaminants in products not manufactured under good manufacturing practice (GMP). One example includes PC-SPES, an herbal formula for the treatment of prostate cancer. This product was taken off the market in 2002 by the FDA because different lots were found to contain warfarin, indomethacin, and estrogen diethylstilbestrol.¹¹⁰

SPECIFIC COMPLEMENTARY AND ALTERNATIVE MEDICINE THERAPIES

Many cancer therapies used are the same as those used in the general population for common noncancer indications such as St. John's wort (*Hypericum perforatum*) for depression, kava (*Piper methysticum*) for anxiety, *Echinacea purpurea* for common cold symptoms, or yoga, massage, and tai chi for overall well-being. This chapter lists some of the more common therapies about which oncologists might be questioned by their patients; this only represents a small sample of therapies. Several resources are available that can provide a summary of the available evidence regarding CAM therapies.

Biologically Based Therapies Used for Cancer Treatment and Secondary Prevention

Beta-Carotene

Two large randomized trials have been completed for the prevention of lung cancer: the Alpha-Tocopherol and Beta-Carotene Cancer Prevention Trial (ATBC) and the Beta-Carotene and Retinol Efficacy Trial (CARET).¹¹¹ Neither trial showed any efficacy of beta-carotene to prevent lung cancer among patients at elevated

TABLE 153.4

Herbs and Supplements Containing Potential Phytoestrogens or Phytoprogestins

Herbs Containing Potential Phytoestrogens (constituents reported to act as estrogen receptor agonists and/or to exhibit estrogenic properties in basic science studies, animal research, or human trials)

Aconite (*Aconitum* spp.), agrimony (*Agrimonia* spp.), alfalfa (*Medicago sativa*), alizarin (1,2-dihydroxyanthraquinone), allspice (*Pimenta dioica*), alpha-linolenic acid, amaranth (*Amaranth* spp.), anise (*Pimpinella anisum*), apple cider vinegar, arabinogalactan, arginine (L-arginine), arnica (*Arnica* spp.), ashwagandha (*Withania somnifera*), astragalus (*Astragalus* spp.), avocado (*Persea americana*), bay leaf (*Laurus nobilis*), bee pollen, belladonna (*Atropa belladonna*), beta-sitosterol, betel nut (*Areca catechu*), betony (*Stachys* spp.), bilberry (*Vaccinium* spp.), black cohosh (*Cimicifuga racemosa*),^c black currant (*Ribes nigrum*), black haw (*Viburnum prunifolium*), black hellebore (*Veratrum nigrum*), black horehound (*Ballota nigra*), black seed (*Nigella sativa*), bladderwrack (*Fucus vesiculosus*), blessed thistle (*Cnicus benedictus*), bloodroot (*Sanguinaria canadensis*), blue cohosh (*Caulophyllum thalictroides*), blue flag (*Iris versicolor*), boldo (*Peumus boldus*), boneset (*Eupatorium* spp.), borage (*Borago officinalis*), boron, boswellia (*Boswellia* spp.), bromelain, bugleweed (*Lycopus* spp.), bupleurum (*Bupleurum* spp.), burdock (*Arctium lappa*), butterbur (*Petasites* spp.), calabar bean (*Physostigma venenosum*), calendula (*Calendula* spp.), camphor, Canada balsam (*Abies balsamea*), cannabis (*Cannabis indica*), carrot (*Daucus carota*), cat's claw (*Uncaria tomentosa*), chamomile (*Matricaria recutita*), chasteberry (*Vitex agnus-castus*), cherry (*Prunus* spp.), chia (*Salvia hispanica*), chicory (*Cichorium intybus*), cinnamon (*Cinnamomum* spp.), cleavers (*Galium aparine*), comfrey (*Symphytum* spp.), cordyceps (*Cordyceps* spp.), cornflower (*Centaurea cyanus*), daisy (*Bellis perennis*), damiana (*Turnera diffusa*), dandelion (*Taraxacum officinale*), danshen (*Salvia miltiorrhiza*), deer velvet, devil's claw (*Harpagophytum procumbens*), dill (*Anethum graveolens*), dogwood (*Cornus* spp.), dong quai (*Angelica sinensis*), echinacea (*Echinacea* spp.), Essiac, eucalyptus (*Eucalyptus* spp.), evening primrose oil (*Oenothera biennis*), false pennyroyal (*Hedeoma* spp.), fennel (*Foeniculum vulgare*), fenugreek (*Trigonella foenum-graecum*), feverfew (*Tanacetum parthenium*), flax (*Linum usitatissimum*), fo-ti (*Polygonum multiflorum*), gamma-linolenic acid, gamma-oryzanol, garcinia (*Garcinia* spp.), garlic (*Allium sativum*), ginger (*Zingiber officinale*), ginkgo (*Ginkgo biloba*), ginseng (*Panax* spp.), goji (*Lycium barbarum*), goldenseal (*Hydrastis canadensis*), gotu kola (*Centella asiatica*), ground ivy (*Glechoma hederacea*), guggul (*Commiphora wightii*), hawthorn (*Crataegus* spp.), hop (*Humulus lupulus*),^a horny goat weed (*Epimedium* spp.), horse chestnut (*Aesculus hippocastanum*), horsetail (*Equisetum* spp.), hyssop (*Hyssopus* spp.), ignatia (*Strychnos ignatia*), jointed flatsedge (*Cyperus articulatus*), kava (*Piper methysticum*), kelp (Laminariales), kudzu (*Pueraria lobata*),^b lady's mantle (*Alchemilla* spp.), lady's slipper (*Cypripedium* spp.), lavender (*Lavandula spica*), lemongrass (*Cymbopogon* spp.), licorice (liquorice) (*Glycyrrhiza glabra*),^a lotus (*Nelumbo nucifera*), lovage (*Levisticum officinale*), maca (*Lepidium meyenii*), meadowsweet (*Spiraea/Filipendula ulmaria*), melatonin (N-acetyl-5-methoxytryptamine), milk thistle (*Silybum marianum*), mistletoe (*Viscum album*), mugwort (*Artemisia vulgaris*), muira puama (*Ptychopetalum olacoides*), mullein (*Verbascum thapsus*), neem (*Azadirachta indica*), niacin, noni (*Morinda citrifolia*), nux vomica (*Strychnos nux-vomica*), oleanander (*Nerium oleander*), Thevetia peruviana, oregano (*Origanum vulgare*), ovaraden, passion flower (*Passiflora incarnata*), peony (*Paeonia* spp.), peppermint (*Mentha x piperita*), pleurisy (*Asclepias tuberosa*), pokeweed (*Phytolacca americana*), pomegranate (*Punica granatum*),^a Pycnogenol, pygeum (*Pygeum* spp.), quassia (*Quassia* spp.), quercetin, raspberry (*Rubus idaeus*), red clover (*Trifolium pratense*),^b rehmannia (*Rehmannia* spp.), resveratrol, rhodiola (*Rhodiola* spp.), rhubarb (*Rheum officinale*), rose hip (*Rosa* spp.), rosemary (*Rosmarinus officinalis*), safflower (*Carthamus tinctorius*), sage (*Salvia officinalis*), sarsaparilla (*Smilax regelii*), saw palmetto (*Serenoa repens*), schisandra (*Schisandra chinensis*), Scotch broom (*Cytisus scoparius*, syn. *Sarothamnus scoparius*), sea buckthorn (*Hippophae* spp.), seaweed, shepherd's purse (*Capsella bursa-pastoris*), Siberian ginseng (*Eleutherococcus senticosus*, formerly *Acanthopanax senticosus*), sitosterol, skullcap (*Scutellaria* spp.), slippery elm (*Ulmus rubra*), soy (*Glycine max*),^b St. John's wort (*Hypericum perforatum*), star anise (*Illicium verum*), stinging nettle (*Urtica dioica*), sweet almond (*Prunus amygdalus dulcis*), sweet marjoram (*Origanum majorana*), sweet woodruff (*Galium odoratum*), tansy (*Tanacetum vulgare*), tea (*Camellia sinensis*), thyme (*Thymus vulgaris*), tribulus (*Tribulus* spp.), turmeric (*Curcuma longa*), verbena (*Verbena* spp.), white horehound (*Marrubium vulgare*), wild ginger (*Asarum* spp.), yucca (*Yucca* spp.).

Herbs and Supplements Containing Potential Phytoprogestins (constituents reported to exhibit progestin-like activity in basic science and/or animal studies).

Bloodroot (*Sanguinaria canadensis*), chasteberry (*Vitex agnus-castus*), damiana (*Turnera diffusa*), ephedra/ma huang (*Ephedra sinica*), oregano (*Origanum vulgare*), PC-SPES, saw palmetto (*Serenoa repens*), wild yam (*Dioscorea villosa*), yohimbe (*Pausinystalia yohimbe*, formerly *Corynanthe yohimbe*), yucca (*Yucca* spp.).

^a Estriol, estrone, estradiol, or estrogen constituents.

risk, primarily smokers or those with secondhand smoke exposure. Additionally, the ATBC study found a trend toward increased risk for lung cancer. Both trials found a higher mortality rate among those randomized to beta-carotene supplementation. A meta-analysis of nine randomized clinical trials of beta-carotene supplement also indicated an increase in stomach cancer with daily supplementation of 20 mg or higher.¹¹² Supplementation with beta-carotene is generally discouraged as a result of these studies.

Coenzyme Q10 (Ubiquinol/Ubiquinone)

Clinical Studies. Coenzyme Q10 (CoQ10) has been studied for the prevention of anthracycline cardiotoxicity based on purported antioxidant effects, but without conclusive results. Cortes et al.¹¹³

observed 10 patients who received adriamycin and received CoQ10 at a dose of 50 mg per day. A decreased incidence of cardiac dysfunction was reported. In another study, 20 children with acute lymphoblastic leukemia (ALL) or non-Hodgkin's lymphoma (NHL) who were treated with anthracyclines were randomized to CoQ10 therapy.¹¹⁴ There was decreased fractional shortening in both the CoQ10 treated and untreated groups, but no comparison was made between these two groups. The small sample size and poor study design limit the ability to draw firm conclusions.

Safety. High doses (greater than 300 mg per day) for long periods may elevate liver enzymes (aspartate aminotransferase and lactate dehydrogenase).¹¹⁵ Concern also exists when CoQ10 is used with antihyperglycemic,^{116,117} psychiatric and cardiovascular

agents, and warfarin or anticoagulants,^{118,119} based on conflicting evidence and secondary sources.^{120–122}

Polysaccharide K

Clinical Studies. An uncontrolled trial of polysaccharide K (PSK; *Trametes versicolor*, formerly *Coriolus versicolor*) reported improved survival in cancer patients compared with historical controls.¹²³ PSK has been reported to improve survival in colorectal,¹²⁴ gastric,^{125,126} breast,^{127–130} esophageal,^{131–133} lung,^{134–136} hepatocellular,¹³⁷ nasopharyngeal carcinoma,^{123,138} and in acute leukemia.^{139,140} However, other studies have reported no survival benefit with PSK as an adjuvant therapy.^{123,130,139,140} Preoperative carcinoembryonic antigen (CEA), Purified Protein Derivative (skin test agent; tuberculosis) (PPD), human leukocyte antigen A2 (HLA-A2), and human leukocyte antigen B40 (HLA-B40) have been reported to be associated with response to PSK therapy.^{127,141–148}

Safety. PSK generally seems to have a low incidence of mild and tolerable side effects.^{124,129} Cases of liver impairment and toxicity have been noted with PSK use, and gastrointestinal upset, darkening of the fingernails, leucopenia, thrombocytopenia, and coughing have been reported with extended use of PSK.^{138,149–151} Theoretically, concomitant use of PSK with anticoagulants or antiplatelets could increase the risk of bleeding, although clinical evidence of this interaction is lacking.

Essiac Herbal Combination Tea

Clinical Studies. The original proprietary formula of Essiac contained burdock root (*Arctium lappa*), sheep sorrel (*Rumex acetosella*), slippery elm inner bark (*Ulmus fulva*), and Turkish rhubarb (*Rheum palmatum*). There is a lack of reliable research available on Essiac. Mouse studies at Memorial Sloan-Kettering Cancer Center in the 1970s were not formally published, and 86 human case reports collected retrospectively in 1988 by the Canadian Department of National Health and Welfare yielded unclear results.¹⁵²

Safety. Concern has been raised about Essiac herbal tonic's potential to stimulate the growth of human breast cancer cells through estrogen receptor–mediated as well as estrogen receptor–independent mechanisms of action. A 2004 systematic review did not identify any published clinical trials to evaluate this herbal complex in patients with cancer.¹⁵² Despite this lack of evidence, Essiac and Essiac-like products (which may contain additional herbs) remain popular among cancer patients. Rhubarb and sheep sorrel contain oxalic acid, which is known to cause hepatic and renal damage in high doses.

Ginger

Clinical Studies. Although some evidence supports the use of ginger (*Zingiber officinale*) for nausea or emesis during pregnancy,^{153–162} ginger's effects on other types of nausea or emesis, such as chemotherapy-induced postoperative nausea or motion sickness, remain undetermined.^{163–169} Several randomized trials that utilized different doses of ginger along with standard antiemetics have found mixed results,^{166,169,170} although overall, the studies suggest that ginger is more effective than placebo.¹⁷¹ Thus, more studies are needed to further examine ginger therapy for chemotherapy-induced nausea and vomiting.

Safety. The most frequent side effects associated with ginger use are gastrointestinal upset, heartburn, gas, and bloating. Estrogen receptor–positive patients should be cautious because ginger may also exert high estrogenic potency, based on *in vitro* evidence.¹⁷² Ginger may inhibit platelet aggregation or decrease platelet thromboxane production, thus theoretically increasing bleeding risk. When ginger was used in patients who were taking nifedipine, antiplatelet aggregation was increased, which suggests a synergistic effect on the inhibition of platelet aggregation.¹⁷³

Ginseng

Clinical Studies. Ginseng (*Panax ginseng*, *Panax quinquefolius*) is a common ingredient in traditional Chinese medicine herbal formulas, but few clinical trials have evaluated the use of ginseng alone as an anticancer agent. A clinical trial evaluating American ginseng to treat cancer-related fatigue found nonsignificant trends toward benefit in higher doses compared to placebo.^{173,174} Similarly, an improvement in quality of life was found in another smaller randomized clinical trial utilizing sun ginseng.¹⁷⁵ A small study utilizing an American ginseng extract found a decreased length of respiratory symptoms.¹⁷⁶ Further clinical trials are needed to determine if ginseng will be beneficial for cancer patients without interfering with cancer treatments.

Safety. The most frequent side effects associated with ginseng include headache, insomnia, and gastrointestinal toxicities.¹⁷⁷ Concern exists when used in combination with diabetes medications (due to possible hypoglycemic properties), anticoagulants (due to increased risk of bleeding), monoamine oxidase inhibitors, and stimulants. Caution should be used when ginseng is taken with medications that are metabolized by cytochrome P-450 2D6.

Green Tea

Clinical Studies. Several large case-control and cohort studies have mainly focused on the prevention of gastrointestinal and breast cancers with green tea (*Camellia sinensis*). Results are variable, with some suggesting chronic tea consumption may decrease cancer risk and others reporting no benefits.^{178–187} Overall, the epidemiologic evidence suggests that green tea consumption may protect against cancer; however, these studies have been mostly observational, and other lifestyle choices of tea drinkers may confound these results. A few studies of green tea have shown some clinical benefits. A decreased occurrence of prostate cancer was reported among healthy men treated with green tea extract (GTE) versus placebo in a recent randomized, placebo-controlled study in 60 volunteers with high-grade prostate intraepithelial neoplasia.¹⁹⁰ The study reported a reduction in tumor development (9 of 30 versus 1 of 30) after 1 year of therapy compared to placebo. GTE has also been evaluated to treat premalignant oral lesions. Patients were randomized to three doses of GTE or placebo for 12 weeks. The two higher dose levels were associated with a higher response rate.¹⁷⁸ In a breast cancer study, green tea ingestion was associated with improved prognosis in stage I and II cancers, but no effect was seen on grade III cancers.¹⁸³ Additional human research is needed before a recommendation can be made for or against the use of green tea in cancer prevention or treatment.

Safety. Studies of the specific side effects of green tea are limited. However, green tea, a source of caffeine, is known to act as a central nervous system (CNS) stimulant and diuretic; it may also increase the production of stomach acid, worsen ulcer symptoms, increase heart rate, and raise blood pressure. One cup of green tea contains approximately 30 to 50 mg of caffeine, and excessive tea consumption may lead to adverse effects or toxicity. Green tea supplement capsules usually contain less caffeine (approximately 5 mg of caffeine per 500 mg extract).

Lycopene

Lycopene is a carotenoid present in human serum, the liver, adrenal glands, lungs, prostate, colon, and skin at higher levels than other carotenoids. Most dietary lycopene is derived from tomatoes and tomato-based products. Lycopene is also present in many other fruits and plant products, including apricots, pink grapefruit, guava, rose hip, palm oil, and watermelon. Antioxidant and antiproliferative properties have been reported in preclinical research, and there are more than 75 case-control or cohort studies

of the association between increased tomato/tomato-based product intake or serum lycopene levels with cancer risk. Approximately two-thirds of these studies suggest benefits in the range of 40% risk reduction, although fewer than half of the studies are statistically significant, and numerous studies provide negative results.¹⁹¹ A study that evaluated the association between intake of lycopene and specific tomato products and prostate cancer risk among 29,361 men during an average of 4.2 years of follow-up reported that lycopene intake was associated with a reduction of prostate cancer risk among men with a family history of prostate cancer, but not in the male population overall.¹⁹²

Maitake

Clinical Studies. In a small 2002 case series, therapy with Maitake (*Grifola frondosa*) powder and a proprietary Maitake extract (MD fraction) was associated with tumor regression in greater than 50% of patients with stages II to IV breast, lung, and liver cancer, whereas no improvements were observed in leukemia, gastric cancer, or brain tumors.¹⁹³ This series had limited information, particularly regarding patient baseline characteristics. A recent report from Memorial Sloan-Kettering Cancer Center found that Maitake mushrooms had a mixed response on a profile of immune cells; thus, the belief that these mushrooms are purely immunostimulatory is likely incorrect.¹⁹⁴

Safety. Although Maitake has not been well studied, a long history of dietary use suggests that it is safe in low doses. Possible adverse effects of concentrated extracts, based on animal research, include hypoglycemia and hypotension. It is not clear if this agent interacts with chemotherapy regimens.

Milk Thistle

Clinical Studies. One randomized clinical trial in children with acute lymphoblastic leukemia found a lower incidence of liver toxicity among children randomized to milk thistle (*Silybum marianum*) therapy.¹⁹⁵ Several other trials have evaluated milk thistle, but in combination with several other herbs or supplements; therefore, further study using milk thistle alone is needed before it can be recommended as an anticancer treatment.

Safety. Milk thistle has been investigated for anticancer effects in preclinical and clinical trials; the pharmacokinetics and its mechanisms, effectiveness, and adverse effects reported to date have been reviewed.¹⁹⁶ In clinical trials and traditional use, oral milk thistle has generally been reported as well tolerated in recommended doses for up to 6 years of use. Several studies report mild gastrointestinal symptoms, including nausea, heartburn, diarrhea, epigastric pain, abdominal discomfort, dyspepsia, flatulence, and loss of appetite. Urticaria, eczema, and headache have also been reported. Hypersensitivity and anaphylactic reactions have been associated with milk thistle ingestion in case reports. Because many patients in available clinical trials have liver conditions, it is unclear whether adverse effects are caused by milk thistle or by the underlying liver condition; the rates of adverse effects are often similar to placebo. Data from *in vivo* and *in vitro* studies suggest the inhibition of cytochrome p-450 (CPY450) 3A4 and 2C9 to varying levels.

Mistletoe

Clinical Studies. Multiple case series, retrospective analyses, and prospective trials of mistletoe (*Viscum album*, Iscador) extracts in humans have been published; these studies were largely conducted in Europe and have examined patients with breast, lung, cervical, colorectal, gastric, ovarian, and pancreatic cancers, as well as renal cell carcinoma and glioma. A 1994 systematic review included 11 controlled clinical trials, not all randomized, and

concluded that overall methodologic quality of studies was poor and results were indeterminate.¹⁹⁷ Subsequent publications have not provided definitive evidence of efficacy but have suggested survival advantages in patients with colorectal, gastric, or breast cancers.^{198–200} Negative results have been reported in patients with melanoma.²⁰¹ According to a 2006 reanalysis of previously published nonrandomized studies on mistletoe therapy, breast cancer patients showed increased survival; however, this required a further evaluation in a well-designed randomized controlled trial.²⁰² In another randomized trial of mistletoe, researchers evaluated the potential side effects from chemotherapy among breast cancer patients and concluded that patients randomized to mistletoe reported fewer side effects. No long-term evaluation was performed to explore the impact on efficacy of treatment.²⁰³

Safety. Mistletoe is contraindicated in patients with protein hypersensitivity or chronic progressive infections (e.g., tuberculosis). The most common reactions are erythema and hyperemia.¹⁹⁷ Other possible side effects include anorexia, general malaise, depressive moods, fever, local skin inflammation or pain at injection site, mydriasis and miosis/myalgia, and elevated liver enzymes.

Omega-3 Fatty Acids

Clinical Studies. Several population (epidemiologic) studies report that dietary omega-3 fatty acids (alpha-linolenic acid) or fish oil may reduce the risk of developing breast, colon, or prostate cancer.^{204–210} There is evidence from epidemiologic studies and randomized controlled trials that an intake of recommended amounts of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) in the form of dietary fish or fish oil supplements lowers triglycerides and reduces the risk of death from cardiovascular disease. Two randomized controlled trials report no significant benefits of supplementation with omega-3 fatty acids or fish oil in cancer patients with cachexia.^{211,212} Questions have been raised, however, about the proportion of DHA to EPA used in these trials. An ongoing National Cancer Institute (NCI)-sponsored clinical trial is examining the effects of fish oil alone or in combination with vitamin D₃ in cancer prevention.

Safety. The FDA classifies intake of up to 3 g per day of omega-3 fatty acids from fish as “generally recognized as safe.” Caution may be warranted in diabetic patients (due to potential hyperglycemic effects), patients at risk of bleeding, or those with low blood pressure or high low-density lipoprotein (LDL) cholesterol levels.²¹³ DHA may have greater effects than EPA.

An increased risk of bleeding is one of the primary concerns with fish oil supplementation.²¹³ Diets containing salmon oil, mackerel, or cod liver oil have been reported to prolong bleeding times significantly in healthy volunteers. However, in other studies of omega-3 fatty acid supplementation, no adverse effects on bleeding time have been observed. Increased bleeding time is suggested to result from either less thromboxane or higher prostacyclin levels. It is unclear if omega-3 fatty acids affect coagulation. Anecdotal evidence suggests that fish oil may increase the international normalized ratio (INR), a measure of bleeding time. However, clinical evidence suggests that fish oil does not affect coagulation, even when taken with anticoagulant therapy. Nevertheless, caution is warranted when omega-3 fatty acids (from plants or fish) are taken with anticoagulant agents. Some species of fish carry a higher risk of environmental contaminants, such as with methylmercury or other heavy metals.

Reishi

Clinical Studies. Treatment with reishi (*Ganoderma lucidum*) mushroom extract (GanoPoly) for 12 weeks resulted in a significant increase in plasma levels of interleukin 2 (IL-2), interleukin 6 (IL-6), and interferon gamma (IFN- γ), decreased IL-1 and tumor

necrosis factor alpha (TNF- α) levels, and increased natural killer (NK) cells in advanced-stage cancer patients.^{214,215} Well-designed, long-term studies are needed to confirm these results and to examine potential side effects.

Safety. Caution is recommended when reishi is used in patients with bleeding disorders/coagulopathies or in those taking anticoagulants, as reishi mushroom may alter platelet aggregation and prolong bleeding time.²¹⁶ Caution is also advised in patients with low blood pressure, diabetes, or in those taking antidiabetic agents or antihypertensives.

Resveratrol

Clinical Studies. Resveratrol is a naturally occurring hydroxystilbene identified in more than 70 plant species, including nuts, grapes, pine trees, and certain vines, as well as in red wine. Although there are several observational studies that correlate the consumption of wine with a decrease in cancer or cardiovascular disease risk,^{217,218} high-quality human trials supporting the efficacy of resveratrol for any indication are currently lacking in the available literature. Ongoing research is examining resveratrol and a possible role in increasing longevity and how it interacts with sirtuins.

Safety. Laboratory study suggests that resveratrol has antiaggregating and antithrombin activity, and may have additive effects when taken with other agents with the same actions²¹⁹; thus, use of resveratrol with antiplatelets could cause increased risk of bleeding, although clinical reports of drug interactions are lacking. Resveratrol apparently has the potential to act as an estrogen agonist or antagonist, depending on such factors as cell type and estrogen receptor isoform (ER- α or ER- β).^{220–222} Resveratrol has also been shown to inhibit vitamin D₃ receptor expression through estrogenic regulation.²²³ Clinical evidence of estrogen interactions is lacking. Some *in vitro* and *in vivo* studies suggest that resveratrol might interfere with paclitaxel.²²⁴ Resveratrol inhibited all of the cytochrome P-450 (CYP) tested (1A1, 1A2, 1B1, 2A6, 2B6, 2E1, 3A4, 4A), except for 2E1.²²⁵

Selenium

Clinical Studies. Initial evidence has suggested that selenium supplementation reduces the risk of developing prostate cancer in men with normal baseline prostate-specific antigen (PSA) levels and low selenium blood levels. This is the subject of large, well-designed studies, including the Nutritional Prevention of Cancer (NPC) trial and the Selenium and Vitamin E Cancer Prevention Trial (SELECT),^{226–240} as well as prior population and case-control studies.^{241,242}

The NPC trial with 1,312 Americans reported that 200 mg of daily selenium reduces the overall incidence of prostate cancer, although these protective effects only occurred in men with baseline PSA levels less than or equal to 4 ng per milliliter and those with low baseline blood selenium levels (less than 123.2 ng per milliliter).^{229–231,243} The NPC trial was primarily designed to measure the development of nonmelanoma skin cancers and not other types of cancers; therefore, these prostate cancer results cannot be considered definitive.

SELECT was started in 2001 with 32,400 men with serum PSA levels less than or equal to 4 ng per milliliter. The study was ended early due to an interim analysis that determined that the study could not meet its expected end point of a 25% reduction in prostate cancer. Subset analyses indicated selenium supplementation was associated with increased development of diabetes mellitus.

Safety. The level of selenium exposure that will cause chronic toxicity is not clear. Selenium toxicity may cause gastrointestinal symptoms (nausea, vomiting, abdominal pain, diarrhea, garlic-like

breath odor, and metallic taste), neuromuscular–psychiatric disturbances (weakness/fatigue, lightheadedness, irritability, hyperreflexia, muscle tenderness, tremor, and peripheral neuropathy), dermatologic changes (skin rash/dermatitis/flushing, fingernail loss/thickening/blotching/streaking/paronychia, and hair changes/loss), liver dysfunction, kidney dysfunction, thrombocytopenia (low blood platelets), immune alterations (NK cell impairment), thyroid dysfunction (decreased T₃), reduced sperm motility, or growth retardation.

Soy

Clinical Studies. Preliminary research using soy (*Glycine max*) to control hot flashes in women with breast cancer suggests that it is possibly safe,²⁴⁴ although the pending results of ongoing research in this area may provide more definitive safety data. Recent studies have indicated that moderate dietary soy intake (observed in most traditional Asian diets—no more than three servings daily) shows no risk and may have possible benefits to breast cancer patients, even among women with estrogen-positive breast cancers.^{245,246} However, because higher doses of soy may have estrogenic effects, which clearly increase the risk for progression of estrogen receptor–positive breast cancer, it is prudent for breast cancer survivors to avoid the high doses of soy and soy isoflavones that are provided by more concentrated sources (such as soy powders and isoflavone supplements).⁴³ Preliminary clinical evidence suggests that the short-term use of soy isoflavones does not elicit endometrial hypertrophy.

Safety. Soy is “generally regarded as safe” according to the FDA, and has long been a staple of Asian diets. Current epidemiologic and laboratory evidence suggests there are unlikely to be harmful effects when soy is provided in the diet consistent with amounts in a typical Asian diet.²⁴⁵

Turmeric

Clinical Studies. A phase 1 trial found limited toxicity with doses of turmeric (*Curcuma longa*, curcumin) as high as 8 g daily. A phase 2 clinical trial in pancreatic cancer found a limited response rate with 3 of 25 patients with either stable disease or a reduction in tumor size.²⁴⁷ Multiple clinical trials are ongoing to evaluate the use of turmeric and associated compounds for the treatment of cancer.

Safety. The most common side effect with turmeric reported in humans is gastrointestinal upset, including epigastric burning, dyspepsia, nausea, and diarrhea.^{247,248} High doses of turmeric are thought to be safe based on toxicology studies.²⁴⁷ The turmeric constituent curcumin has been reported to induce liver function test abnormalities in rats, and may be mildly hepatotoxic in high doses.²⁴⁸ Caution is warranted when using turmeric with hepatotoxic agents. Increased bleeding risk is a concern with high doses of curcumin.²⁴⁸ There is evidence that turmeric may interfere with cytochrome P-450 (CYP450) enzymes, which are responsible for breaking down various agents in the liver.²⁵⁰

Vitamin A

Vitamin A is comprised of retinol and its carotenoid precursors. All-*trans* retinoic acid, a retinol analog, is well established as a differentiation agent in patients with acute promyelocytic leukemia.²⁵¹ However, there is little evidence to support the use of nonprescription vitamin A supplements for cancer treatment or prevention. Trials have yielded variable results, suggesting no reduction in prostate cancer risk and possible increased risk of lung cancer in high-risk patients.²⁵² Due to the possibility of hypervitaminosis A with supplementation of this fat-soluble vitamin, chronic intake of large doses is discouraged.

Vitamin C

Limited clinical research has been conducted on vitamin C (ascorbic acid) for cancer prevention. In the 1980s, there was initial excitement over epidemiologic evidence correlating high dietary vitamin C intake with reduced rates of cancer, although use of vitamin C in observed populations may have correlated with other healthy lifestyle choices (e.g., diet, exercise) that confounded findings. A subsequent prospective trial found no reduction in rates of breast cancer. Preclinical evidence of reduced platelet aggregation suggests that risks may outweigh potential benefits. Patients may experience scurvy symptoms after abrupt withdrawal of chronic megadoses. Two randomized controlled trials of high-dose intravenous vitamin C in cancer patients found no benefits.^{253,254}

Vitamin D

Vitamin D is one of four fat-soluble vitamins and is traditionally linked with calcium metabolism and bone health. Vitamin D₂ (ergocalciferol) and vitamin D₃ (cholecalciferol) are precursors to calcitriol, the active form of vitamin D. Exposing skin to natural sunlight is the most common manner by which the body produces vitamin D. Growing evidence indicates the importance of vitamin D for immune processes. Additionally, studies in cancer populations indicate a possible worse outcome in those with vitamin D deficiency.^{255–257} Appropriate supplementation should be considered for those with documented deficiency or those at risk for bone fractures due to poor bone health (i.e., osteoporosis). Prolonged high-dose use of vitamin D may lead to hypercalcemia.

Vitamin E

Vitamin E (α -tocopherol) is a fat-soluble vitamin with antioxidant properties. Epidemiologic studies suggest a possible reduced breast, lung, and prostate cancer risk with intake. However, prevention trials report no reduction in risk of lung, breast, or colon cancers. Several reviews and meta-analyses have also found a higher mortality rate in doses of 400 IU or less daily.^{258–261} Additionally, a large randomized trial among head and neck cancer patients investigated vitamin E and beta-carotene and found that these agents were associated with decreased survival among subjects taking both. Some have hypothesized that the agents may have acted as an antioxidant and thus reduced the efficacy of the radiation treatment, leading to increased recurrence rates and, ultimately, decreased survival. Several studies have evaluated the potential to protect against chemotherapy-induced peripheral neuropathy with such agents as platinum and taxanes with positive results.^{262–266} However, these studies were not designed to assess for alterations in chemotherapy effectiveness. Preclinical evidence of reduced platelet aggregation has been shown.

Other Therapies

Other herbs and supplements that are used in cancer treatment without reliable evidence include aloe, antineoplastons, barley, bitter melon, bladderwrack, bromelain, calendula, chamomile, clay, danshen, dehydroepiandrosterone (DHEA), echinacea, evening primrose oil, eyebright, flaxseed, Gerson therapy and coffee enemas, ginseng, ginkgo, goldenseal, guggul, gymnema, hops, horsetail, kava, lactobacillus, laetrile, lavender, marshmallow, passion flower, pennyroyal, peppermint, propolis, red clover, sorrel, St. John's wort, sweet almond, white horehound, numerous types of mushroom extracts, and various combinations of Chinese herbal medicine.

Numerous therapies have also been used for cancer prevention, but they have not been well studied. These include aloe, black tea, bromelain, cranberry, eucalyptus oil, ginseng, grape seed extract, lactobacillus (colon cancer risk reduction), oleander, omega-3 fatty acids/fish oil, psyllium (colon cancer risk reduction), red clover, and spirulina.

Nonbiologically Based Therapies

Nonbiologically based therapies generally fall into the categories of mind–body techniques, massage, acupuncture, and energy techniques. These techniques are generally used to support overall well-being or specific treatment-related side effects.^{267–276}

Mind–Body Techniques

Background. Mind–body modalities, including meditation, hypnosis, relaxation techniques, cognitive–behavioral therapy, biofeedback, yoga, tai chi, qigong, and guided imagery, have increasingly become part of mainstream care over the years. Mind–body practices are defined as a variety of techniques designed to enhance the mind's capacity to affect bodily function and symptoms.¹

Clinical Studies. Techniques of stress management that may be helpful include progressive muscle relaxation,^{277,278} diaphragmatic breathing,^{279,280} guided imagery,^{281–283} social support,^{284,285} and meditation.^{286,287} Participating in stress management programs prior to treatment has enabled patients to tolerate therapy with fewer reported side effects.^{288–291} Supportive expressive group therapy has also been found to be useful for patients with cancer.^{292–294} Psychosocial interventions have been shown to specifically decrease depression and anxiety and increase self-esteem and active-approach coping strategies.^{295–298}

There is some evidence that when incorporated into cancer care, yoga, tai chi, and meditation may help to improve aspects of quality of life, including improved mood, sleep quality, physical functioning, and overall well-being.^{296,299–301} Hypnosis, and especially self-hypnosis, has been found to be beneficial for reducing distress and discomfort during difficult medical procedures.²⁸¹ A National Institutes of Health (NIH) Technology Assessment Panel found strong evidence for hypnosis in alleviating cancer-related pain.³⁰² Hypnosis effectively treats anticipatory nausea in pediatric³⁰³ and adult cancer patients,³⁰⁴ reduces postoperative nausea and vomiting,³⁰⁵ and improves adjustment to invasive medical procedures.^{306–308}

A meta-analysis of 116 studies found that mind–body therapies may reduce anxiety, depression, and mood disturbance in cancer patients and aid their coping skills.³⁰⁹ Newell et al.³¹⁰ reviewed psychological therapies for cancer patients and concluded that interventions involving self-practice and hypnosis for managing nausea and vomiting may be recommended. More recently, Ernst et al.³¹¹ examined the change in the state of the evidence for mind–body therapies for various medical conditions between 2000 and 2005 and found that there is now maximal evidence for the use of relaxation techniques for anxiety, hypertension, insomnia, and nausea due to chemotherapy.

Massage

Clinical Studies. Research to date suggests that massage is helpful for increasing relaxation and relieving pain, anxiety, fatigue, and distress.^{269,312–314} The obvious challenge in conducting massage therapy research is the difficulty achieving a placebo control group. It is, therefore, not clear what the exact mechanisms are for the benefits of massage in an oncology setting. Despite some of the imperfections in research design, the current findings are encouraging.

Safety. Massage therapy is generally safe when practiced by credentialed practitioners who have also had some training in cancer patient care. Serious adverse events are rare and tend to be associated with exotic types of massage or untrained or inexperienced practitioners.³¹⁵ In general, cancer patients should not receive deep tissue massage, and patients with bleeding tendencies should only receive a light touch. Obviously, areas that have recently had surgery or radiation should be avoided. A therapeutic benefit may

also be derived from simply receiving a massage to the feet, hands, and head, because these areas are especially sensitive to tactile stimulation and may result in providing relaxation and an increase in general well-being.³¹⁶

Acupuncture

Background. Acupuncture is a common treatment modality in many cultures. It is a form of traditional Chinese medicine (TCM) and has been practiced in China for thousands of years. Acupuncture is one of the most popular TCM therapies outside of China and is used in at least 78 countries.³¹⁷ According to traditional theory, the placement of needles, heat, or pressure at specific places on the body can help to regulate the flow of qi (vital energy). The most common form of acupuncture involves the placement of solid, sterile, stainless steel needles into various points on the body.^{318,319} Different techniques can be used to stimulate the needles, including manual manipulation or electrical stimulation.^{318–320}

Clinical Studies. There is good scientific evidence that acupuncture is effective for managing both postoperative and chemotherapy-related nausea and vomiting.^{44–47} An NIH consensus statement in 1998 supported this use, stating that the level of evidence was sufficient.³²¹ Further research has substantiated this

claim, and the American Cancer Society now states that clinical studies have found acupuncture may help treat nausea caused by chemotherapy drugs and surgical anesthesia. There is also good evidence that certain types of acupuncture are effective for both postoperative and chronic pain in cancer patients.^{321–323}

A growing number of clinical trials, both controlled and uncontrolled, suggest that acupuncture is beneficial for radiation-induced xerostomia, hot flashes, and aromatase-induced arthralgias.^{324–327} For the management of other treatment- or cancer-related symptoms, the evidence is not as strong. Nevertheless, there is some preliminary and anecdotal evidence to suggest that acupuncture may be useful in the treatment of anxiety, depression, fatigue, constipation, loss of appetite, peripheral neuropathy, insomnia, dyspnea, and leucopenia.^{328,329} However, the overall quality of the evidence for these symptoms remains weak, and further studies are needed.

Safety. When performed correctly, acupuncture has been shown to be a safe, minimally invasive procedure with very few side effects. The most commonly reported complications are fainting, bruising, and mild pain. Infection is also a potential risk, although very uncommon.^{330,331} Acupuncture should only be performed by a health-care professional with an appropriate license and preferably one who has had experience in treating patients with malignant diseases.
