Screening has not been particularly useful in the detection of bladder cancer and the most recent statement from the U.S. Preventive Services Task Force concludes that the current data are insufficient to make a definitive recommendation on screening for bladder cancer in asymptomatic adults.²⁷ The only test of proven usefulness is a urinalysis to detect microhematuria. If significant microhematuria is detected, then specific diagnostic studies are performed. When individuals are screened, 4% to 20% are found to have microhematuria. Of those with microhematuria, 0.5% to 8.1% have bladder tumors.^{28–30} In these particular studies, high-grade disease was identified in 2.4% to 3.5% of those presenting with dipstick microhematuria, and invasive disease was identified in 0.4% to 1%. Although one of these studies suggests that routine screening results in a reduced mortality from bladder cancer, the data are unconvincing due to a lack of randomization and likely significant selection bias.³⁰ Others have suggested that screening in high-risk populations increases the early detection rate of high-grade cancers. Early treatment of these would be expected to be associated with an increased survival, although this hypothesis in this group of patients has not been substantiated. Screening does not generally improve the detection rate of low-grade tumors because the methods used for screening have a large number of false-negative findings for low-grade tumors. When urothelial cancer is suspected, noninvasive screening may be performed using cytology, nuclear matrix protein, telomerase, or fluorescence in situ hybridization analysis, but the definitive diagnosis is made only by cystoscopy and biopsy.

Cytology has been regarded as the gold standard for noninvasive screening of urine for bladder cancer. It has a sensitivity of 40% to 60% and specificity in excess of 90%. Nuclear matrix protein³¹ fibrin or fibrinogen degradation products,³² urinary bladder cancer antigen,³³ and basic fetoprotein³⁴ have all been compared with cytology in bladder cancer screening studies. Other methods used include fluorescence in situ hybridization,³⁵ microsatellite analysis of free DNA,³⁶ and telomerase reverse transcriptase determination.³⁷ Unfortunately, all of these tests have a sensitivity that ranges from only 40% to 75% with a specificity of 50% to 90%, thus making it impossible to eliminate the need for cystoscopy by the use of these tests.³⁸ These urinary biomarkers have not been studied yet for sensitivity and specificity in detecting upper tract TCCs.

Cytology remains the preferred bladder tumor marker for specificity³⁹; however, many of the other bladder tumor markers have a better sensitivity.⁴⁰

Pathology

More than 90% of the TCCs throughout the lining of the urinary tract occur in the urinary bladder and of the remaining 10%, most are in the renal pelvis and fewer than 2% are in the ureter and urethra. Squamous cell carcinomas, defined by the presence of

keratinization, account for 5% of bladder tumors. Other, even less common bladder tumor types include adenocarcinoma and undifferentiated carcinoma variants such as small-cell carcinoma, giant-cell carcinoma, and lymphoepitheliomas.^{41–43} A TCC histology can also demonstrate areas of a variant subtype within a tumor, including micropapillary, squamous, glandular, or sarcomatoid differentiation. These are considered variants of TCC, and stage for stage, they do not portend a worse prognosis,^{44,45} likely with the exception of sarcomatoid carcinoma, which presents with a higher stage and more distant metastases than conventional TCC.⁴⁶ Pure adenocarcinoma of the bladder may also arise in the embryonal remnant of the urachus on or above the bladder dome. Other adenocarcinomas may closely resemble intestinal adenocarcinoma and must be distinguished from direct spread to the bladder from an intestinal primary by careful clinical evaluation. Rarely, these demonstrate a signet ring cell or clear cell histology.

Primary Tumors of the Bladder

The differential diagnosis of TCC usually does not pose a diagnostic difficulty for experienced pathologists, but tumors that are grade 1 and invasive are occasionally difficult to distinguish from von Brunn nests.⁴⁷ Also, rarely, an invasive TCC may be overdiagnosed when the glandular component of a nephrogenic adenoma is mistaken for TCC with glandular differentiation or for a pure adenocarcinoma. When invasion of the lamina propria has occurred, the pathologist must report whether muscularis propria is present in the submitted tissue and whether there is invasion of the muscularis propria. If muscularis propria is not present in the submitted tissue, this should be noted by the pathologist. Identification of invasion of the muscularis propria by the tumor may occasionally be difficult, because it may be confused with involvement of the muscularis mucosa, which is in the lamina propria.⁴⁸ More than two-thirds of newly diagnosed cases of bladder tumors are exophytic papillary TCCs that are confined to the epithelium (stage T_a) or invade only into the lamina propria (stage T₁). These tumors are generally managed endoscopically and, in some cases, with the addition of intravesical therapy (discussed in the following paragraphs). Approximately one-half to two-thirds of patients with such tumors have a recurrence or a new TCC in the bladder within 5 years.

Bladder tumors are also classified by their cytologic characteristics as low grade (G1) or high grade (G2, G3).⁴⁵ Low-grade tumors may also be referred to as papillary tumors of low malignant potential (PNLMP). Tumor grade is clinically more significant for noninvasive tumors because nearly all of the invasive neoplasms are high grade at diagnosis. Papillary carcinomas of low grade are considered to be relatively benign tumors that histologically resemble the normal urothelium. They show only very slight pleomorphism or loss of polarity and rarely progress to a higher stage. On the contrary, CIS is cytologically synonymous with high-grade disease and carries a high risk of progression to invasive disease. Primary CIS (stage T_{is}) that presents without a concurrent exophytic tumor constitutes only 1% to 2% of newly detected cases of bladder cancer, but CIS is found accompanying more than half of bladders presenting with multiple papillary tumors. CIS, in this instance, is either adjacent to or involves mucosal sites remote from papillary lesions.⁴⁹ CIS is believed to be an important precursor of invasive cancer and, if untreated, will develop into muscularis propria–invasive disease within 5 years from the initial diagnosis in more than 50% of patients.

Upper Tract Tumors

Like bladder tumors, 90% of upper tract tumors are TCCs with similar morphology.⁵⁰ Squamous cell carcinomas account for most of the remaining carcinomas, with adenocarcinoma representing, at most, 1% of upper tract malignancies. The cytologic characteristics for the classification of TCC by grade are the same for upper tract TCCs as they are for those in the bladder.

Molecular Tumor Markers

Because the natural history of superficial urothelial tumors is that of recurrence, an area of controversy is if tumors that occur at separate sites or at separate times in the urothelial tract are derived from the same clone or are polyclonal in origin. A report by Sidransky et al.⁵¹ demonstrated the clonality of multiple bladder tumors from different sites. Miyao et al.⁵² showed concordant genetic alterations in asynchronous tumors from individual patients. These studies suggest that urothelial TCCs appearing at different times and sites can be derived from the same neoplastic clone. Moreover, many studies have reported an increasing frequency of specific genetic abnormalities in bladder tumors of more advanced stages.⁵³⁻⁵⁶ Many tumor suppressor gene modifications, including those of *p53*, *pRB*, *p16*, *p21*, thrombospondin-1, glutathione, and factors controlling the expression and function of the epidermal growth factor receptor (EGFR), have been shown in retrospective analyses to be adverse prognostic factors in patients with TCC after various treatments.⁵⁸⁻⁶² However, even in the most intensively studied tumor suppressor gene in advanced TCC, the *p53* gene, retrospective analyses give. There is conflicting retrospective data on the association of *p53* mutation status and responsiveness to chemotherapy or radiation^{59,60} led to a phase III trial that randomized 114 postcystectomy patients with *p53* alteration to three cycles of adjuvant methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) or observation. Neither *p53* status nor MVAC adjuvant chemotherapy impacted the risk of recurrence.⁵⁷

The enthusiasm engendered by the development of novel biologic agents targeted against tumor-specific growth factor pathways or against angiogenesis has been fortified by positive studies in a variety of solid tumors. Two classes of agents that have received great attention are inhibitors of EGFR, including EGFR1 and EGFR2 (or HER2/neu), and inhibitors of vascular endothelial growth factor (VEGF) or its receptors. Ample preclinical evidence has shown that (1) many, if not most, bladder tumors express products of the EGFR family, (2) overexpression correlates with an unfavorable outcome, and (3) inhibition of these pathways may have an anti-tumor effect.⁶⁴⁻⁶⁹

Evidence suggests that *p53*, *p16*, and *pRB* altered expression are of no prognostic significance in patients treated with chemoradiation, but that overexpression of *HER2* correlated with a significantly inferior complete response rate. The recently closed Radiation Therapy Oncology Group (RTOG) 0524 protocol evaluated the addition of trastuzumab to chemoradiation for *Her2* overexpressing tumors. EGFR overexpression, which occurred in only 19% of the patients, was associated with improved disease-specific survival.⁷⁰

Another potential therapeutic avenue is the inhibition of angiogenesis. Several studies have correlated elevated VEGF levels or cyclooxygenase-2 (COX-2) expression with disease recurrence or progression, often as an independent prognostic factor by multivariate analysis.^{69,71}

Preclinical data support the concept that COX-2 inhibitors may inhibit the development of non-muscle-invasive bladder cancer. A randomized, double-blind, placebo-controlled trial sought to determine whether celecoxib, a COX-2 inhibitor, could reduce the time-to-recurrence of superficial tumors. No benefit was observed in patients receiving daily celecoxib.⁷²

The major challenge for clinical and translational investigators is to design appropriate trials that will identify which molecular tumor markers will be prognostic of outcome and also be predictive of whether a patient will do better treated by surgery, radiation, chemotherapy, molecular targeted therapy, or a combination of these. An example of recent encouraging results include the identification of MRE11, a protein involved in DNA damage double-strand break repair, as a predictive marker of disease specific survival following radiation or chemoradiation for muscle invasive bladder cancer.^{73,74} Only when such molecular biomarkers are validated and incorporated into clinical decision making will

physicians be able to make better treatment choices on behalf of their patients.

CANCER OF THE BLADDER

Cancers of the bladder can be grouped into three general categories by their stages at presentation: (1) those that do not invade the muscularis propria, (2) muscularis propria-invasive cancers, and (3) metastatic cancers. Each differs in clinical behavior, primary management, and outcome. When treating non-muscularis-invasive tumors, the aim is to prevent recurrences and progression to a stage that is life threatening. With muscularis propria-invasive disease, the main issue is to determine which tumors require cystectomy, which can be successfully managed by bladder preservation using combined modality therapy, and which tumors, by virtue of a high metastatic potential, require an integrated systemic chemotherapeutic approach from the outset. Combination chemotherapy is the standard for treating metastatic disease. Despite reports of complete responses (CR) in more than 40% of cases, the duration of response and overall cure rates remain low.

Clinical Presentations and Staging

Bladder cancer is rarely incidentally discovered at autopsy. Indeed, almost all cases show symptoms in the premortem period. The most common presentation is gross painless hematuria. Unexplained urinary frequency and irritative voiding symptoms should alert one to the possibility of CIS of the bladder or, less commonly, muscularis propria-invasive cancer.

Workup

The workup of suspected bladder cancer should include urine cytology, a cystoscopy, and an upper tract study. The preference for the upper tract study is a renal computed tomography (CT) urogram because both ureters and renal pelvis as well as the relevant lymph nodes and the kidney parenchyma can be particularly well visualized.

Careful staging is important, because treatment depends on the initial stage of the disease. The clinical stage of the primary tumor is determined by transurethral resection of the bladder tumor (TURBT). This resection should include a sample of the muscularis propria for appropriate diagnosis, particularly if the tumor appears sessile or high grade. Once the specimen has been resected, the base of the resected area should be separately biopsied. Any suspicious areas in the remainder of the bladder should be biopsied, and many advocate additional selected biopsies of the bladder mucosa and a prostatic urethral biopsy as well. Urethral biopsies are clearly indicated in patients with risk factors for urethral involvement, as previously discussed, and in those who have persistent positive cytologies in the absence of a demonstrated bladder lesion. Patients who have T1, G3 tumors on biopsy without muscularis propria in the specimen require a second biopsy in order to obtain muscularis propria to reduce the risk of understaging. Indeed, the authors rebiopsy all patients with T1, G3 disease, because it has been shown that even if muscularis propria is in the initial specimen, a significant number of patients will be upstaged (T2) on the second biopsy.

5-Alpha amino levulinic acid installation into the bladder, resulting in porphyrin-induced fluorescence of vascular lesions when viewed with blue light, and narrow band imaging, which increases the contrast between vascular lesions and normal mucosa, have been recommended by some to increase the yield of positive biopsies. Several studies have shown a slight advantage to these techniques in reducing disease recurrence, but it remains difficult to differentiate inflammatory lesions from urothelial carcinomas with either technique, and not all well-designed clinical trials have shown a benefit.⁷⁵⁻⁷⁸

Staging

The primary bladder cancer is staged according to the depth of invasion into the bladder wall or beyond (Table 65.1).^{70,79} The urothelial basement membrane separates non-muscularis propria bladder cancers into Ta (noninvasive) and T1 (invasive) tumors. Stage T2 and higher T-stage tumors invade the muscularis propria, the true muscle of the bladder wall. If the tumor extends through the muscle to involve the full thickness of the bladder and into the serosa, it is classified as T3. If the tumor involves contiguous structures such as the prostate, the vagina, the uterus, or the pelvic sidewall, the tumor is classified as stage T4 (nonstromal invasive urothelial tumors of the prostate are not classified as T4, because the prognosis in this group is quite good). In a fragmented TURBT specimen, in contrast to a cystectomy specimen, it is relatively infrequent for the pathologist to be able to make an accurate assessment as to the depth of invasion of the tumor into the muscularis propria. Thus, the primary pathologic substages of the TNM (tumor, nodes, metastasis) staging system shown in Table 65.1, such as pT2a and pT2b, cannot be determined from TURBT specimens. Of note, significant rates of clinical-pathologic stage discrepancy and clinical (TURBT) understaging have been described.¹³⁸ CT scans or magnetic resonance images (MRI), even those done prior to the TURBT, are not reliable for staging of

Figure 65.1 A computed tomography scan of a patient with a muscularis propria–invasive bladder cancer performed before a transurethral tumor resection, unequivocally showing an extravesical extension of tumor (stage T3). The tumor projecting into the bladder lumen (black arrow); portion of the tumor extending into the ureter outside the bladder (white arrow).

TABLE 65.1

American Joint Committee on Cancer 2009 TNM Bladder Cancer Staging

Primary Tumor (T)	
Tis	Carcinoma in situ
Ta	Noninvasive papillary tumor
T1	Tumor invades the lamina propria, but not beyond
T2	Tumor invades the muscularis propria
pT2a	Tumor invades superficial muscle (inner half)
pT2b	Tumor invades deep muscle (outer half)
T3	Tumor invades perivesical tissue
pT3a	Microscopically
pT3b	Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostatic stroma, uterus, vagina, pelvis, or abdominal wall
T4a	Tumor invades prostate, uterus, vagina
T4b	Tumor invades pelvic or abdominal wall
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node in primary drainage region
N2	Metastasis in multiple lymph nodes in primary drainage region
N3	Common iliac lymph node involvement
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

the primary tumor. Neither scan can differentiate a Ta/T1 tumor from a T2/T3 tumor because neither can visualize the depth of invasion of the primary tumor into the bladder wall. These scans are helpful, however, when they show unequivocal tumor extension outside the bladder (stage T3) (Fig. 65.1). CT scans or MRIs following a TURBT also are not reliable for staging of the primary tumor because either surgically induced edema in the resected portion of the bladder wall or postsurgical extravesical inflammatory stranding may be confused with extravesical tumor extension. For this reason, it is preferable and recommended to perform a staging CT or MRI prior to TURBT.

Patients who have documented muscularis propria–invasive bladder cancer require an additional set of studies: a chest x-ray or CT scan, liver function studies, creatinine and electrolytes level studies, and a CT evaluation of the pelvic and retroperitoneal lymph nodes. A bimanual examination is also performed at the time the tumor is transurethraly resected to evaluate for possible extravesical extension of the tumor and to determine mobility of the pelvic contents. An MRI lymphangiography, using a lymphotropic iron nanoparticle administered intravenously, shows potential.⁸⁰ Nodes that appear to be enlarged on a CT may be differentiated by this technique as to whether they are inflammatory or malignant. The sensitivity and specificity of the test are quite high.

If there is a history of functional bowel abnormality, a barium study of the segment of bowel to be used for the diversion should be performed. It is the authors' practice when using colon in the reconstruction of the urinary tract to obtain a barium enema or colonoscopy so that there are no surprises at the time of surgery. Finally, patients with muscularis propria–invasive bladder cancer must have a prostatic urethra and bulbous urethra biopsy to determine whether an orthotopic bladder may be placed or whether the procedure should encompass the urethra—that is, a cystoprostate-urethrectomy in males or a cystourethrectomy and anterior exenteration in females.

Treatment of Non-Muscularis Propria–Invasive Bladder Cancer (Ta, Tis, T1)

Of patients with bladder cancer, 70% have disease that does not involve the muscularis propria at presentation. Approximately 15% to 20% of these patients will progress to stage T2 disease or greater over time. Of those presenting with Ta or T1 disease, 50% to 70% will have a recurrence following initial therapy. Low-grade tumors

(G1 or G2) and low-stage (Ta) disease tend to have a lower recurrence rate at about 50% and a 5% progression rate, whereas high-risk disease (G3, T1 associated with CIS, and multifocal disease) has a 70% recurrence rate and a 30% to 50% progression rate to stage T2 disease or greater. Less than 5% of patients with non-muscularis propria-invasive bladder cancer will develop metastatic disease without developing evidence of muscularis propria invasion (stage T2 disease or greater) of the primary lesion.

Patients who are at significant risk for developing progressive or recurrent disease following TURBT are generally considered candidates for adjuvant intravesical drug therapy. This includes those with multifocal CIS, CIS associated with Ta or T1 tumors, any G3 tumor, multifocal tumors, and those whose tumors rapidly recur following TURBT of the initial bladder tumor. A number of drugs have been used intravesically, including bacillus Calmette-Guérin (BCG), interferon (IFN) and BCG, thioTEPA, mitomycin C, doxorubicin, and gemcitabine. Complications generally include frequency, dysuria, and irritative voiding symptoms. Over the long term, bladder contracture may occur with these agents. Other complications, which are specific for each drug, are as follows: BCG administration may result in fever, joint pain, granulomatous prostatitis, sinus formation, disseminated tuberculosis, and death; thioTEPA may cause myelosuppression; mitomycin C may cause skin desquamation and rash; and doxorubicin may cause gastrointestinal upset and allergic reactions. The proposed benefit of intravesical chemotherapy is to lessen the rate of recurrences and reduce the incidence of progression. Unfortunately, it cannot be clearly stated that any of these drugs accomplish these goals over the long term.

The use of electromotive installation as an adjunct to intravesical therapy remains controversial. A randomized trial sought to clarify the benefit of electromotive installation of mitomycin. Patients were randomized to TURBT alone (n = 124), immediate post-TURBT mitomycin (n = 126), or pre-TURBT electromotive mitomycin (n = 124). Trial results demonstrated that intravesical electromotive installation of mitomycin before TURBT reduced recurrence and improved the disease-free interval compared with intravesical mitomycin after TURBT and TURBT alone.⁸¹

Intravesical BCG therapy is typically initiated with an induction course of 6 weekly instillations, followed by a cystoscopic evaluation 1 month after induction. In cases in which CIS is present or suspected, only a biopsy can differentiate this from inflammatory change secondary to treatment. For those who respond to induction, maintenance BCG therapy for up to 3 years is a standard of care, although patients frequently discontinue therapy early due to bladder toxicity.⁸²

A European Organisation for Research and Treatment of Cancer (EORTC) phase III trial in over 1,300 patients sought to evaluate whether a third of a dose versus a full dose and a 1-year treatment versus a 3-year treatment could suffice.⁸³ The trial thus had four different doses and schedules of BCG maintenance therapy. No meaningful differences in toxicity, progression, or survival were observed across dose and schedules. However, the recurrence rate was lowest in high-risk patients treated with the full dose therapy for 3 years, supporting current treatment recommendations.

A number of studies have compared one intravesical chemotherapeutic agent with another. For the most part, BCG in these comparisons has a slight advantage in reducing recurrences.⁸⁴ However, when the follow-up is more than 5 years, it appears that there is minimal overall effect at reducing the recurrence rate when compared with no treatment. BCG and epirubicin are the most commonly used agents in this setting and both are considered effective for the treatment of superficial bladder cancer. However, superiority of one over the other is unknown. A meta-analysis of over 1,100 patients treated with either drug reported that intravesical BCG was more efficacious, although also more toxic.⁸⁵

BCG failure is a clinical concern and a treatment dilemma with limited truly effective nonsurgical options. The precise definitions of BCG failure are well outlined by the 2005 International

Consensus Panel on T1 bladder cancer and include four subtypes of BCG failure.⁸⁶ BCG refractory T1 disease should be of paramount concern and raises the concern for understaged diseases. Options for further intravesical treatment after BCG failure include BCG plus IFN α -2B, gemcitabine, valrubicin, docetaxel, and other novel agents.⁸⁵⁻⁹² Unfortunately, however, no single agent has yet proven to be more reliably or durably effective than another, and a true consensus on continued intravesical treatment in this setting remains to be determined.

Approximately 70% of patients with high-grade disease will experience recurrence whether or not they are treated with intravesical therapy. Moreover, there is no well-documented evidence that the use of these agents prevents disease progression, for example, from stage Ta/T1 disease to stage T2 or greater disease. One-third of patients who are at high risk for disease progression (those with G3, T1 disease) will progress to stage T2 or greater disease whether or not they are treated with BCG.⁹³ One-third of patients at 5 years who have disease progression and undergo a cystectomy die of metastatic disease. Thus, approximately 15% of patients with superficial disease at high risk for disease progression (CIS with associated Ta or T1 disease, rapidly recurrent disease, or G3 disease), irrespective of treatment modality, will die of their disease.⁹⁴ If definitive therapy (cystectomy) is performed when the disease is found to progress into the muscularis propria (T2 or greater), there is no difference in cure rate when these patients are compared with those who present primarily with T2 or greater disease. These statistics have encouraged some to perform a preemptive cystectomy in those patients at high risk for progression before muscularis propria invasion is documented. Ten-year cancer-specific survivals of 80% are given as justification for this approach, as compared with 50% in patients in whom the cystectomy is performed when the disease progresses to involve the muscularis propria.⁹⁵ Unfortunately, this approach subjects approximately two-thirds of these patients who are included in the 80% cancer-specific survival figure to a needless cystectomy, making it questionable as to whether there is in fact any survival advantage whatsoever. Although cystectomy remains the gold standard for recurrent BCG refractory T1 disease, there is an open protocol RTOG 0926 evaluating chemoradiation for such patients who opt for an attempt at bladder preservation or are otherwise not good cystectomy candidates.⁹⁶

Treatment of Muscularis Propria-Invasive Disease

Surgical Approaches

The standard of care for squamous cell carcinoma, adenocarcinoma, TCC, and sarcomatoid or spindle cell carcinoma that invade the muscularis propria of the bladder is a bilateral pelvic lymph node dissection and a cystoprostatectomy, with or without a urethrectomy in the male. In the female, an anterior exenteration is performed, which includes the bladder and urethra (the urethra may be spared if uninvolved and an orthotopic bladder reconstruction is performed), the ventral vaginal wall, and the uterus. A radical cystectomy may be indicated in non-muscularis propria-invasive bladder cancers when G3 disease is multifocal or associated with CIS or when bladder tumors rapidly recur, particularly in multifocal areas following intravesical drug therapy. When the prostate stroma is involved with TCC or when there is concomitant CIS of the urethra, a cystoprostatectomy is the treatment of choice.⁹⁷ If the urethra needs to be removed, the type of urinary reconstruction is limited to an abdominal urinary diversion. In selected circumstances in the male, the neurovascular bundles coursing along the lateral side of the prostate caudally and adjacent to the rectum more cephalad may be preserved, sometimes preserving potency. Partial cystectomies may rarely be performed in selected patients, thus preserving bladder function and affording in the properly selected patient the same cure rate

as a radical cystectomy.⁹⁸ Patients who are candidates for such procedures must have focal disease located far enough away from the ureteral orifices and bladder neck to achieve at least a 2-cm margin around the tumor and a margin sufficient around the ureteral orifices and bladder neck to reconstruct the bladder. Practically, this limits partial cystectomies to those patients who have small tumors located in the dome of the bladder and in whom random bladder biopsies show no evidence of CIS or other bladder tumors.

Survival

The probability of survival from bladder cancer following a cystectomy is determined by the pathologic stage of the disease. Survival is markedly influenced by the presence or absence of positive lymph nodes. Some have argued that the number of positive nodes impacts survival in that, when resected, there is a potential for cure provided there are less than four to eight positive nodes.^{99,100} Positive perivesical nodes have a less ominous prognosis when compared with involvement of iliac or para-aortic nodes. Pathologic type may also impact outcome, but in most series, survival is more dependent on pathologic stage than on the cell type of the cancer. Most large series of survival statistics following treatment include all patients regardless of cell type. These series are generally constituted as to histologic type as follows: TCC, 85% to 90%; combination of TCC and either squamous cell or adenocarcinoma, 6%; pure squamous cell carcinoma, 3%; pure adenocarcinoma, 3%; small-cell and sarcomatoid or spindle cell carcinoma, 2% (Table 65.2).

Types of Urinary Diversion

Urinary diversions may be divided into continent and incontinent. Incontinent urinary diversions or conduits involve the use of a segment of ileum or colon and, less commonly, a segment of jejunum. The distal end is brought to the skin, and the ureters are implanted into the proximal end. The patient wears a urinary collection appliance. The advantages of a conduit (ileal or colonic) are its simplicity and the reduced number of immediate and long-term

Figure 65.2 An intravenous urogram of a patient with an orthotopic bladder after a radical cystoprostatectomy. The orthotopic bladder was constructed of the right colon and distal ileum.

postoperative complications. In most series, 13% of patients who undergo a cystectomy and urinary diversion of this type will have a significant complication that impacts on hospital stay or recovery. Generally, the distal ileum is used for the urinary conduit or reservoir; however, if it has been irradiated or is otherwise involved, one may select the right colon or a short segment of jejunum. The latter is the least desirable choice because electrolyte problems may be significant. On occasion, during exenterative surgery when an end colostomy is created, a segment of distal bowel is used, thus obviating the need for an intestinal anastomosis.

Continent diversions may be divided into two types: abdominal and orthotopic. Abdominal diversions require a continence valve, whereas an orthotopic neobladder depends on the urethral sphincter for continence. The reservoir is made of bowel that is fashioned into a globular configuration. In the abdominal type of continent diversion, the stoma is brought through the abdominal wall to the skin. The patient catheterizes the pouch every 4 hours. Orthotopic urinary diversions entail the use of bowel brought to the urethra, thus allowing the patient to void by Valsalva (Fig. 65.2). Patients must have the facility to catheterize themselves, because it is mandatory in the abdominal continent diversion and occasionally necessary in the orthotopic reconstruction. The advantage of continent diversions is the avoidance of a collection device. The advantage of an orthotopic bladder over all other types of continent diversions is that it rehabilitates the patient to normal voiding through the urethra, often without the need for intermittent catheterization or the need to wear a collection device. Postoperative and long-term complications of continent diversion are increased over the conduit types of diversions. Indeed, in some series, postoperative complications range from 13% to 30%. Long-term metabolic complications are also increased.

Complications of Cystectomy and Urinary Diversion

The complications of all types of urinary diversion may be divided into three groups: metabolic, neuromechanical, and surgical.

TABLE 65.2

Survival After Radical Cystectomy According to Pathologic Stage at 10 Years

Pathologic Stage	Disease-Specific Survival (%)	Overall Survival (%)
pTa, Tis, T1 with high risk of progression	82	—
Organ confined, negative nodes (pT2, pN0)	73	49
Non-organ confined (pT3–4a or pN1–2)	33	23
Lymph node positive (any T, pN1–2)	28, 34	21

Metabolic Complications of Urinary Intestinal Diversion.

When the intestine is interposed in the urinary tract, there is the potential for a number of metabolic complications.¹⁰⁴ These may involve electrolyte abnormalities and altered drug metabolism, which may result in altered sensorium, infection, osteomalacia, growth retardation, calculi both within the reservoir as well as in the kidney, short bowel syndrome, cancer, and altered bile metabolism.

Depending on the segment used, different specific electrolyte abnormalities may occur. When the ileum and colon are used, hyperchloremic metabolic acidosis may result; when jejunum is used, hypochloremic or hyperkalemic metabolic acidosis may follow.

Hypokalemia is more common when the colon is used, whereas hypocalcemia is more common when the ileum and colon are used, and hypomagnesemia is more common when the ileum and the colon are used.

The most pervasive detrimental effect created by all urinary intestinal diversions is due to acidosis. Acidosis may result in electrolyte abnormalities, osteomalacia, growth retardation, altered sensorium, altered hepatic metabolism, renal calculi, and abnormal drug metabolism. In general, patients with normal renal function as well as normal hepatic function are less prone to acidosis and its complications.

Treatment for the metabolic acidosis is straightforward and can be accomplished with bicarbonate or with Bicitra solution, which is sodium citrate and citric acid. Polycitra, which is a combination of potassium citrate, sodium citrate, and citric acid, may also be employed. It has the advantage of supplying potassium, which, on occasion, is deficient. Chlorpromazine and nicotinic acid have been used to block the chloride bicarbonate exchanger, and thus lessen the potential for the acidosis.

Decreased renal function is seen in a majority of patients in the decade following a radical cystectomy, and choice of diversion does not predict the decline. Postoperative hydronephrosis, pyelonephritis, and uretero-enteric strictures represent factors that, if addressed, may mitigate the loss of function.¹⁰⁵

Patients with conduits may have a 3% to 4% incidence of renal calculi over the long term. Those with reservoirs have up to a 20% incidence of calculi within the reservoir. The pathogenesis may be a metabolic alteration or infection, whereas reservoir stones are most commonly due to a surgical foreign body or mucus serving as a nidus.

There is a high incidence of bacteriuria in patients with either conduits or pouches, and the incidence of sepsis is 13%. There appears to be diminished antibacterial activity of the intestinal mucosa, with the immunoglobulins, which are normally secreted by the mucosa, being altered. In addition to this, when the bowel is distended, there can be a translocation of bacteria from the lumen into the bloodstream.

Because the intestine is interposed in the urinary tract, drugs that are eliminated unchanged from the body through the kidney and have the potential to be reabsorbed by the gut can in fact result in significant alterations in metabolism of that drug. Patients with a urinary diversion, when given systemic chemotherapy, have a higher incidence of complications and are more likely to have their chemotherapy limited when compared with patients without diversion who receive the same drugs and dose.¹⁰⁶

The loss of the distal ileum may result in vitamin B₁₂ malabsorption, which then manifests itself as anemia and neurologic abnormalities. Bile salt malabsorption may occur and result in diarrhea. Loss of the ileocecal valve may result in diarrhea with bacterial overgrowth of the ileum and malabsorption of vitamin B₁₂ and fat-soluble vitamins A, D, E, and K. Loss of the colon may result in diarrhea and bicarbonate loss.

Neuromechanical Complications. Neuromechanical complications may be of two types: atonic, resulting in an atonic segment with urinary retention, and hyperperistaltic contractions. The latter is relevant in continent diversions, as this may result in incontinence and a low-capacity reservoir.

Surgical Complications. There are a number of complications that occur following any major surgical procedure, which include thrombophlebitis, pulmonary embolus, wound dehiscence, pneumonia, atelectasis, myocardial infarction, and death. Complications specific to cystectomy and urinary diversion are divided into short term and late. The short-term complications include acute acidosis (16%), urine leak (3% to 16%), bowel obstruction or fecal leak (10%), and pyelonephritis (5% to 15%). The longer term complications include ureteral or intestinal obstruction (15%), renal deterioration (15%), renal failure (5%), stoma problems (15%), and intestinal stricture (10% to 15%).^{107,108}

The morbidity of salvage cystectomy for a recurrence following bladder sparing chemoradiation has also been described and appears acceptable when compared to primary cystectomy series.¹⁰⁹

Selective Bladder-Preserving Approaches

The treatment options for muscularis propria-invasive bladder tumors can broadly be divided into those that remove the bladder and those that spare it. In the United States, a radical cystectomy with pelvic lymph node dissection remains the standard method used to treat patients with this tumor. Several reports from North America and Europe have described long-term results using multimodality treatment of muscularis propria-invasive bladder cancer, with appropriate safeguards for early cystectomy should this treatment fail. For bladder-conserving therapy to be more widely accepted, this treatment approach must have a high likelihood of eradicating the primary tumor, must preserve good organ function, and must not result in compromised patient survival. It does appear that, for selected patients, bladder sparing therapy with salvage cystectomy reserved for tumor recurrence represents a safe and effective alternative to immediate radical cystectomy.¹¹⁰

Successful bladder-preserving approaches have evolved during the past 3 decades. They began with the use of radiation therapy but expanded when the National Bladder Cancer Group first demonstrated the safety and efficacy of cisplatin as a radiation sensitizer in patients with muscle-invasive bladder cancer that was unsuitable for cystectomy.¹¹¹ The long-term survival with stage T2 tumors (64%) and stage T3 to T4 tumors (22%) was encouraging. This was validated by the National Cancer Institute-Canada randomized trial of radiation (either definitive or precystectomy) with or without concurrent cisplatin for patients with T3 bladder cancer, which showed a significant improvement in long-term survival with pelvic tumor control (67% versus 47%) in the patients who were assigned cisplatin.¹¹² Additional single-institution studies showed that the combination of a visibly complete TURBT followed by radiation therapy or radiation therapy concurrent with chemotherapy safely improved local control.^{113,114} These findings led the RTOG to develop protocols for bladder preservation beginning with a TURBT of as much of the tumor as is safely possible, followed by the combination of radiation with concurrent radiosensitizing chemotherapy. One key to the success of such a program is the selection of patients for bladder preservation on the basis of the initial response of each individual patient's tumor to therapy. Thus, bladder conservation is reserved for those patients who have a clinical CR to concurrent chemotherapy and radiation. A prompt cystectomy is recommended for those patients whose tumors respond only incompletely or who subsequently develop an invasive tumor (Fig. 65.3). Up to 30% of the patients entering a potential bladder-preserving protocol with trimodality therapy (initial TURBT followed by concurrent chemoradiation) will ultimately require a salvage radical cystectomy.

For over 2 decades, the Massachusetts General Hospital (MGH), the RTOG, and several centers in Europe have evaluated in phase II and III protocols concurrent chemoradiation plus neoadjuvant or adjuvant chemotherapy (Table 65.3). Radiosensitizing drugs studied in these series, either singly or in various combinations, include cisplatin, carboplatin, paclitaxel, 5-fluorouracil (5-FU), mitomycin C,

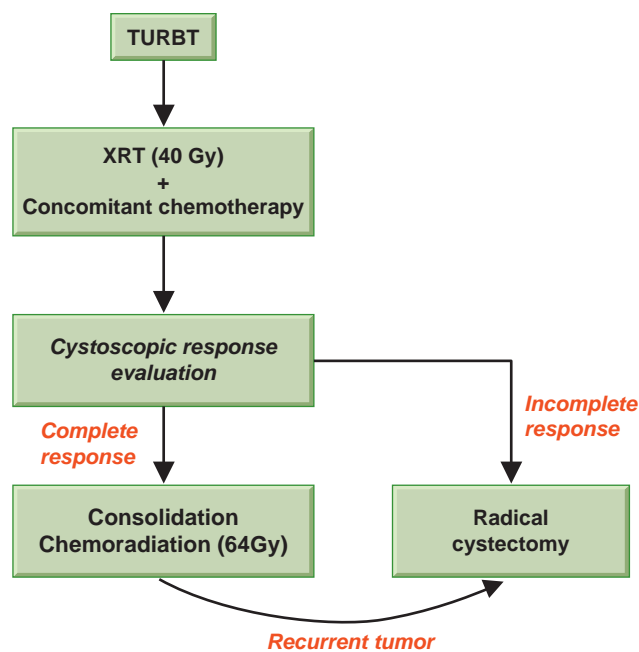

Figure 65.3 Schema for trimodality treatment of muscularis propria-invasive bladder cancer with selective bladder preservation. XRT, radiation therapy.

and gemcitabine.¹¹³ The first RTOG study of patients treated with once-daily radiation treatment and concurrent cisplatin yielded a 5-year survival of 52% (42% with intact bladder).¹¹⁵ RTOG studies 8802 and 8903 used methotrexate, cisplatin, and vinblastine (MCV) chemotherapy as neoadjuvant treatment.¹¹⁶ In the latter study, the neoadjuvant therapy was tested in a randomized fashion.¹¹⁷ No improvement was seen in survival or in local tumor eradication as a result of neoadjuvant therapy, although the trial was closed early and underpowered to give a definitive answer. The toxicity of the MCV arm was considerable, with only 67% of patients able to complete the planned treatment. The use of contemporary neoadjuvant

chemotherapy (dose-dense methotrexate, vinblastine, adriamycin, cisplatin [ddMVAC] or gemcitabine and cisplatin [GC]) regimens with appropriate supportive therapy in well-selected bladder-sparing patients may warrant further investigation.

Other studies from Paris and Germany have reported their large experience with bladder sparing.^{118,119} The CR rate in the German study was 72%, and local control of the bladder tumor after the CR without a muscle-invasive relapse was maintained in 64% of the patients at 10 years. The 10-year disease-specific survival was 42%, and more than 80% of these survivors preserved their bladder. This series reported the sequential use of radiation with no chemotherapy (126 patients), followed by concurrent cisplatin (145 patients), then concurrent carboplatin (95 patients), and finally concurrent cisplatin with 5-FU (49 patients). The CR rates in these four protocols were 51%, 81%, 64%, and 87%, respectively.^{120,121} The 5-year actuarial survival with an intact bladder in these studies was 38%, 47%, 41%, and 54%, respectively. These results strongly suggest that radiochemotherapy, when given concurrently, is superior to radiation therapy alone; that carboplatin is less radiosensitizing than cisplatin; and that cisplatin plus 5-FU may be superior to cisplatin alone.

The RTOG protocols have subsequently explored both twice-daily radiation therapy and novel radiosensitization using cisplatin with or without 5-FU or paclitaxel.^{62,122, 123,124} Complete response and bladder preservation rates are consistently high, with no one regimen clearly superior.⁶²

Gemcitabine has been also tested in bladder-treatment protocols. In a phase I trial from the University of Michigan, 23 patients, mostly T2, were treated with gemcitabine and concurrent daily radiation. At a median follow-up of 5.6 years, an impressive 91% CR rate was observed, and the 5-year actuarial estimates of survival include a bladder-intact survival of 62%, an overall survival of 76%, and a disease-specific survival of 82%.¹²⁵ A phase II study from the United Kingdom of 50 patients treated with concurrent weekly gemcitabine and hypofractionated radiation reported an 88% complete endoscopic response rate, a 3-year overall survival of 75%, and cancer-specific survival of 82%.¹²⁶ Twice weekly low-dose gemcitabine was recently evaluated as a radiosensitizer with daily radiation in protocol RTOG 0712.

Cisplatin is not always an ideal drug for bladder cancer patients, because it may cause impaired renal function in many. A British group observed high response rates using the combination of 5-FU

and mitomycin C with pelvic radiotherapy.¹²⁷ These results led to the phase III Bladder Cancer 2001 (BC2001) trial, in which 360 patients with muscle-invasive bladder cancer were randomized to either radiotherapy alone or to radiotherapy with concomitant 5-FU and mitomycin C chemotherapy. Local–regional disease-free survival was superior for those patients receiving chemotherapy (67% versus 54% at 2 years; hazard ratio [HR] 0.68, $p = 0.03$ with median follow-up of 70 months). Survival at 5 years was higher with chemoradiotherapy (48% versus 35%), but did not reach statistical significance (HR 0.82; $p = 0.16$).¹²⁸

Predictors of Outcome

A common feature of all the RTOG protocols was early bladder tumor response evaluation and the selection of patients for bladder conservation on the basis of their initial response to TURBT combined with chemotherapy and radiation.¹³⁰ Bladder conservation was reserved for those who had a complete clinical response at the midpoint in therapy (after a radiation dosage of 40 Gy). Complete responders to induction therapy then received consolidation with additional chemotherapy and radiation to a total tumor dose of 64 to 65 Gy. Incomplete responders were advised to undergo a radical cystectomy, as were patients whose invasive tumors persisted or recurred after treatment. The current schema for trimodality treatment of muscle-invasive bladder cancer is provided in Figure 65.3. Other tumor presentations associated with successful bladder-sparing therapy include: solitary T2 or early T3 tumors (typically <6 cm in size), no tumor-associated hydronephrosis, tumors allowing a visibly complete TURBT, invasive tumors not associated with extensive carcinoma in situ, and urothelial carcinoma histology (because alternative histologies have not been rigorously evaluated in bladder sparing protocols).

In the MGH series,¹³⁰ the median follow-up for all surviving patients was 7.7 years. Of patients, 72% (78% with stage T2) had CR to induction therapy. The 10-year actuarial overall survival was 35% (T2, 43%; T3–T4a, 27%) and the 10-year disease-specific survival was 59% (T2, 67%; stage T3–T4a, 49%) (Figs. 65.4 and 65.5). The clinical stage and achieving a CR were significantly associated with both overall survival and disease-specific survival. A nomogram predicting response has been developed from this data.¹²⁹ The use of neoadjuvant chemotherapy with MCV, however, was not associated with survival or incidence of metastases, although this may warrant further investigation in the modern era.

The 10-year disease-specific survival rate for the 102 patients (29%) undergoing a cystectomy was 44%, illustrating the very

Figure 65.5 Massachusetts General Hospital Selective Bladder Preservation Series 1986 to 2002 disease-specific survival reported by intention to treat.

important contribution of prompt salvage cystectomy. The 10-year disease-specific survival with an intact bladder was 45% (T2, 52%; T3–T4a, 36%). No patient required a cystectomy due to bladder morbidity. The overall survival and disease-specific survival for all 348 patients and for some clinically important subgroups are shown in Table 65.4. The value of complete TURBT in bladder-sparing therapy is demonstrated in this report. Of the 348 patients followed, 227 underwent a complete TURBT and 116 had an incomplete TURBT. Patients who underwent a complete TURBT had improved CR, overall survival, disease-specific survival, and lower rates of cystectomy (22% versus 42%) compared to those with an incomplete TURBT. In a review of the patients who were complete responders after induction therapy, 55% developed no further bladder tumors, 29% subsequently developed a superficial occurrence, and 16% developed an invasive tumor.¹³² Most patients with superficial recurrence were treated successfully by TURBT and intravesical chemotherapy. For these individuals, the overall survival was comparable to those who had no failure. However, one-quarter of these patients ultimately required a salvage cystectomy.

Notably, age is not a contraindication to successful bladder sparing therapy, and indeed, results are favorable in patients aged 75 years or older.¹³⁰ This is an important consideration given that the elderly generally appear to be undertreated for invasive bladder cancer in the United States.¹³¹ Bladder-sparing chemoradiation remains a good option for those patients who are not cystectomy candidates and, often, such patients would be treated with daily radiation and appropriate concurrent chemotherapy without a break.

Radiation Treatment

The most common approach with external-beam irradiation reported from North America and Europe involves the treatment of the pelvis to include the bladder, the prostate (in men), and often, the low external and internal iliac lymph nodes for a total dose of 40 to 45 Gy in 1.8- to 2.0-Gy fractions during 4 to 5 weeks. Subsequently, the target volume is reduced to deliver a final boost dose of 20 to 25 Gy in 15 fractions to the primary bladder tumor. Some protocols call for partial bladder radiation as the boost volume if the location of the tumor in the bladder can be satisfactorily identified by the use of cystoscopic mapping, selected mucosal biopsies, and imaging information from CT or MRI. Figure 65.6 is an isodose color wash of a partial bladder boost in a three-dimensional–conformal plan. Plans using conventional fractionation that result in a whole bladder dose of 50 to 55 Gy and a bladder tumor volume dose of 65 Gy in combination with concurrent

cisplatin-containing chemotherapy have been widely used. The available information suggests that higher doses per fraction may lead to a higher rate of significant late complications. Data looking at toxicity from urodynamic and quality-of-life studies indicate that lower dose per fraction irradiation given once or twice a day concurrent with chemotherapy results in excellent long-term bladder function and low rates of late pelvic toxicity.^{133,134}

Because the bladder is not a fixed organ, its location and volume can vary considerably from day to day. This results in a number of

logistic problems to ensure adequate coverage of the bladder. Studies have identified substantial movement of the bladder during the course of external-beam radiation therapy, and as a result of these findings, many have recommended that the bladder be emptied when simulated and prior to each treatment to maximize reproducibility and avoid a geographic miss. Forms of image-guided delivery (including daily cone-beam CT and fiducials) have also been employed for accurate localization. Another acceptable approach often employed in the United Kingdom, is for radiation to be delivered to 55 Gy in 20 fractions or 64 Gy in 32 fractions to the whole bladder without a tumor boost and without fields to specifically cover the pelvic lymph nodes.¹³⁵

Brachytherapy is another technique to deliver a higher dose of radiation to a limited area of the bladder within a short period. This approach has been reported from institutions in the Netherlands, Belgium, and France. It is reserved for patients with solitary bladder tumors and as part of combined modality therapy with transurethral resection and external-beam radiation therapy as well as interstitial radiation therapy. External-beam doses of 30 Gy are used in combination with an implant tumor dose of 40 Gy. These groups report that for patients with solitary clinical stage T2 to T3a tumors less than 5 cm in diameter, local control rates at 5 to 10 years range from 72% to 84% with disease-specific survivals of approximately 75%.¹³⁶

Comparison of Treatment Outcomes of Contemporary Cystectomy Series with Contemporary Selective Bladder-Preserving Series

Comparing the results of selective bladder-preserving approaches with those of radical cystectomy series is confounded by selection bias and the discordance between clinical (TURBT) staging and pathologic (cystectomy) staging. Clinical staging will understage the extent of disease 40% of the time with regard to penetration into the muscularis propria or beyond when compared to pathologic staging.^{137,138} The University of Southern California and Memorial Sloan-Kettering Cancer Center have reported their large cystectomy experience,^{102,136,139} and the national phase III protocol by Southwest Oncology Group (SWOG), Eastern Cooperative Oncology Group, and Cancer and Leukemia Group B (CALGB)

has also reported valuable prospective data.¹⁰³ The overall survival rates from these contemporary cystectomy series are comparable to those reported from single-institution and cooperative group results using contemporary selective bladder-preserving approaches with trimodality therapy and prompt salvage cystectomy for the minority of patients who recur (Table 65.5). An attempt to compare cystectomy to bladder-sparing therapy in a randomized fashion in the United Kingdom failed to accrue.

Bladder-Preservation Treatments with Less than Trimodality Therapy

It has been argued that trimodality therapy might represent excessive treatment for many patients with invasive bladder cancer and that comparable results could be obtained by TURBT, either alone or with chemotherapy. Herr¹⁴⁰ reported the outcome of 432 patients initially evaluated by repeat TURBT for muscle-invasive bladder tumors. In that series, 99 patients (23% of the original 432 patients) initially treated conservatively without immediate cystectomy had a 34% rate of progression to a recurrent muscle-invasive tumor at 20 years. In series combining TURBT and MVAC chemotherapy, only 50% of those found to have a clinical CR proved to be tumor-free at cystectomy.¹⁴¹ By comparison, one of the clearest examples of the improved success of trimodality treatment was reported in the study from the University of Paris.¹⁴² TURBT followed by concurrent cisplatin, 5-FU, and accelerated radiation was used by this group initially as a precystectomy regimen. In the first 18 patients, all of whom demonstrated no residual tumor on cystoscopic evaluation and rebiopsy (a CR) but who all underwent a cystectomy, none had any tumor in the cystectomy specimen (100% had a pathologic CR). Comparing approaches by TURBT plus MVAC chemotherapy alone with trimodality therapy, the 5-year survival rates are comparable (50%), but the preserved bladder rate for all patients studied ranged from 20% to 33% when radiation therapy was not used and from 41% to 45% when radiation therapy was used.¹⁴² Thus, trimodality therapy increases the probability of surviving with an intact bladder by 30% to 40% compared with the results reported with TURBT and chemotherapy alone.

Herr¹⁴³ reported on 63 patients who had achieved a complete clinical response to neoadjuvant chemotherapy with a cisplatin-based regimen, who then refused to undergo a planned cystectomy. He reported that the most significant predictor of improved survival was complete resection of the tumor before starting chemotherapy. Over 90% of surviving patients had small low-stage

invasive tumors that were completely resected. Thus, he concluded, selected patients with T2 bladder cancers may do well after a transurethral resection and chemotherapy.

Systemic Chemotherapy with Radical Therapy

Neoadjuvant Chemotherapy

The advantage of neoadjuvant chemotherapy is its potential to downsize and downstage tumors and to attack occult metastatic disease early, especially given the frequent postoperative complications and prolonged recovery that can delay or derail plans for adjuvant chemotherapy. Moreover, although trials described as follows suggest a survival advantage for neoadjuvant chemotherapy, there have been no contemporary studies supporting a benefit with adjuvant chemotherapy. The disadvantages of neoadjuvant therapy include the inherent difficulties in assessing response, the fact that clinical rather than pathologic criteria must be relied on, the debilitating effects of chemotherapy in some patients, increasing the risks of surgery and possibly complicating or delaying full recovery from surgery, and the possibility of the deleterious effects of the delay in cystectomy or radiation associated with neoadjuvant chemotherapy.¹⁴⁴

Although downstaging of the primary tumor has been demonstrated, randomized studies using single-agent neoadjuvant chemotherapy have failed to demonstrate a survival benefit. Studies in patients with measurable metastatic disease clearly showed the superiority of MVAC over single-agent cisplatin on survival, inspiring further studies of multiagent neoadjuvant therapy.¹⁴⁵

The study by Grossman et al.¹⁴³ randomly assigned patients with muscularis propria–invasive bladder cancer (stage T2 to T4a) to radical cystectomy alone or three cycles of MVAC followed by radical cystectomy. During an 11-year period, 317 patients were enrolled. The authors reported that MVAC can be given before radical cystectomy, but the side effects are appreciable. One-third of patients had severe hematologic or gastrointestinal reactions, but, on the positive side, there were no drug-related deaths and the chemotherapy did not adversely affect the performance of surgery. The authors concluded:

1. The survival benefit associated with MVAC appeared to be strongly related to downstaging of the tumor to pT0. Of the chemotherapy-treated patients, 38% had no evidence of cancer at cystectomy, as compared with 15% of patients in the cystectomy-only group. In both groups, improved survival was associated with the absence of residual cancer in the cystectomy specimen.

- The median survival was 77 months for the chemotherapy-treated patients compared with 46 months for the cystectomy-only group.
- The 5-year actuarial survival was 43% in the cystectomy group, which was not significantly different from 57% in the chemotherapy-treated group.

Stratification by tumor stage indicated greater improvement in median survival with chemotherapy in subjects with T3–T4a disease (65 versus 24 months, chemotherapy versus observation) than in subjects with T2 disease (105 versus 75 months). The authors point out that their study is different from seven previous negative studies that used either single-agent cisplatin (demonstrated to be inferior to MVAC in measurable metastatic disease) or a two-drug combination. They also acknowledged problems of interpretation created by slow accrual and a lack of pathologic review.

The Medical Research Council and the EORTC performed a prospective randomized trial of neoadjuvant cisplatin, methotrexate, and vinblastine in patients undergoing cystectomy or full-dose external-beam radiotherapy for muscularis propria–invasive bladder cancer.^{146,147} In the initial report with a median follow-up of 7.4 years, the difference in 5-year survival between those who received chemotherapy (49%) and those who did not (43%) just reached clinical significance with a probability value of 0.048.¹⁴⁷ However, the survival benefit did not reach the prespecified study goal. Long-term follow-up of the study with median follow-up of 8 years and more death events demonstrated that systemic chemotherapy plus local treatment improved overall 10-year survival by 6% and reduced the risk of bladder cancer death by 17% compared to local treatment alone. For patients whose local treatment included a cystectomy, the use of cisplatin, methotrexate, and vinblastine (CMV) resulted in a 26% reduction in the risk of death compared to surgery alone.¹⁴⁸ Based on their interpretation of the data as presented, Sharma and Bajorin¹⁴⁹ now recommend neoadjuvant chemotherapy, although others are concerned that the “number needed to treat” is very high.

A third randomized trial was the Nordic Cystectomy Trial 1.¹⁵⁰ Patients were treated with two cycles of neoadjuvant doxorubicin and cisplatin. All patients received 5 days of radiation followed by cystectomy. A subgroup analysis was performed and showed a 20% difference in disease-specific survival at 5 years in patients with T3 and T4 disease, but there was no difference in stages T1 and T2, nor a difference when all entered patients were compared.

The Nordic Cystectomy Trial 2 included only stage T3 or T4a patients in an attempt to confirm the positive results in Nordic 1 in this subgroup of patients.¹⁵¹ This trial eliminated radiation therapy and substituted methotrexate for doxorubicin in order to lower toxicity. In 317 patients studied, no survival benefit was noted in the chemotherapy arm. The authors concluded that despite substantial downstaging, no survival benefit was seen with neoadjuvant chemotherapy after 5 years of follow-up, although the choice of chemotherapy was unconventional by contemporary standards.

Raghavan et al.¹⁵² published a meta-analysis of all completed randomized trials of neoadjuvant chemotherapy for invasive bladder cancer (2,688 patients). They concluded that single-agent neoadjuvant chemotherapy is ineffective and should not be used; current combination chemotherapy regimens improve the 5-year survival by 5%, which reduces the risk of death by 13% compared with the use of definitive local treatment alone (from 43% to 38%).

Additional meta-analyses have been published^{144,153–155} that showed a 4% to 6% absolute increase in 5-year survival. Many phase II studies are now investigating alternative neoadjuvant combinations including cisplatin/gemcitabine and dose-dense or accelerated MVAC, and time will tell whether any have superiority.^{156–162}

In the 2014 National Comprehensive Cancer Network *Clinical Practice Guidelines in Oncology: Bladder Cancer*, neoadjuvant chemotherapy is a category I recommendation for localized stage T2–T4a disease. According to the National Cancer Data Base in the United States, only 11.6% of patients underwent any

perioperative chemotherapy, with most in the adjuvant setting.¹⁶² In the future, gene profiling may identify those most likely to respond to chemotherapy.¹⁶³

Adjuvant Chemotherapy

The advantage of adjuvant, as opposed to neoadjuvant, chemotherapy is that pathologic staging allows for a more accurate selection of patients. This approach facilitates the separation of patients in stage pT2 from those in stages pT3 or pT4 or node-positive disease, all at a high risk for metastatic progression.

Adjuvant chemotherapy has been studied in two major clinical settings: (1) following bladder-sparing chemoradiation and (2) following a radical cystectomy. In the former case, there is no guidance from pathologic staging, but experience has shown that up to 50% of those with invasive cancers have, in truth, a systemic disease.¹⁶⁴ Respecting this, the RTOG studies have added adjuvant chemotherapy at first with MCV, later using cisplatin plus gemcitabine, and more recently adding paclitaxel.¹⁶⁵ The results thus far do not indicate whether adjuvant chemotherapy is affecting survival.

The place of adjuvant chemotherapy after cystectomy has been studied more thoroughly, but again, the results are not clear. Investigators generally agree that in the face of positive nodes, and even with negative nodes and high pathologic stage of the primary tumor, adjuvant chemotherapy is likely to be important in improving survival. In reviewing existing reports of adjuvant trials in bladder cancer, there are five randomized trials using adjuvant chemotherapy.^{166–170} Three studies found no difference between adjuvant chemotherapy and cystectomy alone, but all three were seriously flawed in design or accrual.¹⁴⁹ Two of the five studies^{169,170} showed a survival benefit for cystectomy and adjuvant chemotherapy over cystectomy alone, but both are subject to criticism for both method considerations and small accrual.

Nonetheless, in a follow-up report by Stockle et al.¹⁷¹ an analysis of 166 patients, including the 49 initially randomized patients, a difference was noted in the 80 patients who received adjuvant chemotherapy as compared with 86 patients who underwent cystectomy alone. The extent of nodal involvement proved important, and when patients were stratified by the number of nodes involved, adjuvant chemotherapy was most effective in patients with N1 disease.

In an important review of the current status of adjuvant chemotherapy in muscle-invasive bladder cancer, the Advanced Bladder Cancer Meta-Analysis Collaboration examined 491 patients from six trials, representing 90% of all patients randomized in cisplatin-based combination chemotherapy trials. They concluded that there is insufficient evidence on which to base reliable treatment decisions, and they recommended further research.¹⁷²

More recent studies have used different adjuvant chemotherapy regimens or molecular stratification. A randomized trial performed in Italy randomized patients after cystectomy either to four courses of gemcitabine plus cisplatin (n = 102) or to the same treatment at time of relapse (n = 92). There was no difference in the 5-year overall survival across treatment arms. However, due to poor accrual, the study was insufficiently powered to detect a survival difference.¹⁷³

As described earlier, p53 alteration status was hypothesized to be both prognostic for recurrence after cystectomy and predictive for a survival benefit conferred by adjuvant chemotherapy. A phase III trial separated patients based on p53 status, with all p53-negative patients followed with observation alone. Patients with p53 alteration (n = 114) were randomized postcystectomy to three cycles of adjuvant MVAC or observation. Neither p53 status nor MVAC adjuvant chemotherapy impacted risk of recurrence.⁵⁷

Gallagher et al.¹⁷⁴ studied adjuvant, sequential chemotherapy in a nonrandomized design, using as a basis the improvement in survival in breast cancer when sequential adjuvant chemotherapy was used. In this study and others similarly designed,^{175,176}

adjuvant, sequential chemotherapy for patients with high-risk urothelial cancer did not appear to improve disease-specific survival over that observed with surgery alone.

Dricker,¹⁶¹ in reviewing the published literature, made the case for adjuvant chemotherapy as the standard of care given the lethality of radical cystectomy alone in muscle-invasive bladder cancer, but he acknowledges that “suboptimal trial design, insufficient numbers of patients, and lack of standardization of the chemotherapy regimens used have plagued adjuvant studies.”

Combined Modality Treatment of Local-Regionally Advanced Disease

The place of combined modality therapy for advanced disease has not been settled. Several series have suggested an improvement in long-term survival in selected patients undergoing resection of persistent cancer deposits after MVAC or CMV.^{164,177}

In our experience, carefully selected patients with locally advanced unresectable bladder cancer, including some patients with pelvic nodal masses, may experience long-term survival with the combination of chemotherapy and radiation. To be selected for this combined modality treatment, patients must have (1) an excellent performance status, (2) locally advanced measurable disease, (3) normal kidney function tests, and (4) no evidence of distant metastases beyond the common iliac lymph nodes. The initial treatment consists of four to six cycles of combination chemotherapy. If a significant regression of tumor is achieved, radiation treatment is administered in combination with radiosensitizing chemotherapy. These patients were carefully selected, but in the majority of patients so treated, excellent tumor shrinkage and long-term survival were achieved in patients who would otherwise have been expected to succumb rapidly if treatment had consisted of chemotherapy alone.

Quality of Life After Cystectomy or Bladder Preservation

Evaluating the quality of life in long-term survivors of bladder cancer has been difficult, and only recently have attempts been made to assess this in an objective and quantitative fashion.^{134,178-191} A number of problems arise in the interpretation of the published studies. Tools to assess quality-of-life variables were developed early for common prostate and gynecologic cancers, but until very recently no such instruments existed for bladder cancer. The instruments in use for bladder cancer have thus been adaptations of uncertain validity. The published studies are all cross-sectional and patients have follow-ups of varying lengths. This matters in a surgical series in which functional outcome improves with time and in a radiation series in which it may deteriorate. Despite these limitations, some conclusions can now be drawn.

A radical cystectomy causes changes in many areas of quality of life, including urinary, sexual, and social function, daily living activities, and satisfaction with body image.^{166-171,192} During the past decade, researchers have concentrated on the relative merits of continent and incontinent diversions. Available data have been mixed with some groups, surprisingly, reporting few differences between the quality of life of those with an ileal conduit and those with continent diversions. Hart et al.¹⁸² have compared outcome in cystectomy patients who have either ileal conduits, cutaneous Koch pouches, or urethral Koch pouches. Regardless of the type of urinary diversion, the majority of patients reported good overall quality of life, little emotional distress, and few problems with social, physical, or functional activities. Problems with their diversions and with sexual function were most commonly reported. After controlling for age, no significant differences were seen among urinary diversion subgroups in any quality-of-life area. It might be anticipated that those receiving the urethral Koch

diversions would be the most satisfied, and the explanation why this is not so is unclear. It may be that the subgroups were too small to detect differences, but perhaps it is more likely that each group adapts in time to the specific difficulties presented by that type of diversion. Somani et al.¹⁸⁴ reviewed 40 published studies that evaluated overall quality of life, reporting on 3,645 patients. Only two studies reported a better quality of life for those who had neobladder and only two reported a better body image.¹⁸⁴ Another prospective study reported by Mansson et al.¹⁸⁵ suggested that there may be a large cultural component to the response with big differences seen between Egyptian and Swedish men followed prospectively through trials of chemotherapy and cystectomy.

Porter and Penson¹⁸³ attempted a systematic review of the literature, testing the premise that continent diversions result in improved health-related quality-of-life outcomes. They concluded that, whatever our assumptions, there is no literature to support the use of one urinary diversion over another. Reviews by Gerharz et al.¹⁸⁷ and Somani et al.¹⁸⁴ came to the same conclusion. It appears that women have more problems with continent diversions, particularly the need to catheterize, than do men.¹⁸⁶

Zietman et al.¹⁸⁸ have performed a study on patients treated with chemoradiation for muscle-invasive bladder cancer. Patients underwent a urodynamic study and completed a quality-of-life questionnaire with a median time from therapy of 6.3 years. This long follow-up is sufficient to capture the majority of late radiation effects. Seventy-five percent of patients had normally functioning bladders by urodynamic studies. Reduced bladder compliance, a recognized complication of radiation, was seen in 22%, but in only one-third of these was it reflected in distressing symptoms. The questionnaire showed that bladder symptoms were uncommon, especially among men, with the exception of control problems. These were reported by 19%, with 11% using incontinence products (all women). Distress from urinary symptoms was half as common as their prevalence. Bowel symptoms occurred in 22% with only 14% recording any level of distress. The majority of men retained sexual function. Global health-related quality of life was high. A study reported by Herman et al.¹⁸⁹ showed that when low doses of gemcitabine are used as an alternative radiation-sensitizer to cisplatin, then treatment is also very tolerable. Thus, the great majority of patients treated by trimodality therapy retain good bladder function.

Two cross-sectional questionnaire studies, one from Sweden and one from Italy, have compared the outcome following radiation with the outcome following cystectomy.^{190,191} The questionnaire results for urinary function following radiation were very similar to those recorded in the MGH study. More than 74% of patients reported good urinary function. Both studies compared bowel function in irradiated patients with that seen in patients undergoing cystectomy. In both, the bowel symptoms were greater for those receiving radiation than for those receiving cystectomy (10% versus 3% and 32% versus 24%, respectively), but in neither was this statistically significant.

Data on the assessment of sexual function are limited to men. The majority in the MGH series report adequate erectile function (full or sufficient for intercourse). These findings are in line with those obtained in the Swedish and Italian series in which three times as many men retained useful erections as compared with cystectomized controls.

A Bladder Cancer Index has now been developed and validated.¹⁹³ It has been shown to have high internal and retest consistency and can be used regardless of local treatment type and across the genders. This is the first such tool developed and it holds great promise for comparative treatment studies in the future.

Metastatic Bladder Cancer

An estimated 12,500 deaths per year in the United States are due to metastatic bladder cancer.¹⁹⁴ Through lymphatic and hematogenous means, bladder cancer metastasizes to distant organs, most

commonly the lungs, bone, liver, and brain. The prognosis of metastatic bladder cancer, as with other metastatic solid tumors, is poor, with a median survival on the order of only 12 months. Nevertheless, since the discovery that platinum-containing agents have significant antitumor effect in bladder cancer, there has been great interest in the use of chemotherapy for advanced disease.

Compared with other solid-tumor malignancies, transitional cell cancer is chemosensitive. In phase II clinical trials, radiographic response rates may be as high as 70% to 80%, and in phase III clinical trials, response rates are often on the order of 50%. Moreover, a small but substantial minority of responding patients manifest a CR, and among these patients some long-term, durable responses are observed. Overall, however, the duration of response in TCC is short, with a median of 4 to 6 months, and therefore, the impact of chemotherapy on survival has been disappointing. As newer targeted agents come into clinical practice, the hope is that their incorporation into treatment regimens will lengthen the duration of response and, ultimately, will translate into a real change in survival.

Cisplatin

In 1976, a series of 24 patients with bladder cancer treated with single-agent cisplatin was reported.¹⁹⁵ The investigators observed eight partial responses in addition to four minor responses. Subsequent studies confirmed the activity of cisplatin in TCC, although the response rate to single-agent cisplatin has been lower than that of cisplatin-containing combination therapy.^{196,197} Thus, most subsequent studies have explored combination regimens.

Cisplatin-Based Combination Chemotherapy

The standard chemotherapy regimen for advanced bladder cancer for more than a decade was MVAC.^{198,199} MVAC is administered in 28-day cycles, with starting doses of methotrexate 30 mg/m² (days 1, 15, and 22), vinblastine 3 mg/m² (days 2, 15, and 22), doxorubicin 30 mg/m² (day 2), and cisplatin 70 mg/m² (day 2). Another commonly used regimen has been CMV, which omits the doxorubicin and has somewhat less toxicity.²⁰⁰ The MVAC regimen has superior activity to cisplatin alone^{196,197} and to other cisplatin-containing regimens.²⁰¹ The response rate to MVAC is 40% to 65%,^{197,198,202} and there is improved progression-free and overall survival compared with either single-agent cisplatin or cisplatin, cyclophosphamide, and doxorubicin. Complete response is seen in 15% to 25% of patients, with an expected median survival of 12 months (Table 65.6).^{196–201}

On the negative side, MVAC is associated with substantial toxicity, and most patients require dose adjustment at some point in their treatment. Toxic effects of MVAC in notable numbers of patients include neutropenia, anemia, thrombocytopenia, stomatitis, nausea, and fatigue.^{136,149,202} The rate of chemotherapy-induced fatality among patients with metastatic disease may be as high as 3%, most often due to neutropenic sepsis.²⁰²

The doublet of gemcitabine and cisplatin showed encouraging results in phase II studies, with response rates of 42% to 66% and CR rates of 18% to 28%.^{203,204} Primary toxicity was hematologic and was generally easily managed, with rare hospitalizations for febrile neutropenia and no toxic deaths. Based on these encouraging results, GC was compared with MVAC in a multicenter phase III study.^{202,205} MVAC was administered as previously described, and GC was administered in 28-day cycles with gemcitabine 1,000 mg/m² (days 1, 8, and 15) and cisplatin 70 mg/m² (day 2). In the study, 405 patients were randomized to one of the two treatment arms, and the two groups exhibited similar characteristics. Median survival was 14 months with GC and 15.2 months with MVAC, which were statistically comparable.²⁰⁵ Patients treated with GC, however, had significantly less toxicity and improved tolerability. Patients receiving GC gained more weight, reported less fatigue, and had better performance status than patients who received MVAC. As a result of this study, GC is generally considered the current standard of care for metastatic bladder cancer.

Taxane- and Platinum-Containing Regimens

The addition of taxanes to cisplatin-based regimens has been the subject of numerous phase II trials in bladder cancer (Table 65.7). The doublets of cisplatin and paclitaxel and cisplatin and docetaxel appear to have response rates comparable to that of GC.^{211–214} Trials with carboplatin suggest that this agent has good activity, although likely not the same level of activity as cisplatin.^{207,221}

Many patients with bladder cancer cannot receive cisplatin due to medical comorbidities. The EORTC reported a randomized phase III study comparing an historic standard of care in Europe, the three-drug regimen of methotrexate, carboplatin, and vinblastine (M-CAVI), to the doublet gemcitabine and carboplatin in patients who were felt to be unfit for cisplatin-based therapy. All had previously untreated locally advanced or metastatic urothelial cancer. Severe toxicity was greater in patients receiving the three-drug regimen. Responses were greater in the two-drug regimen, but this did not translate into a difference in survival between the two arms. The authors recommended gemcitabine plus carboplatin as the

Gemcitabine/paclitaxel	94	54–60	14.4	218–220

new standard of care based on a better safety profile in this patient population.²⁰⁸

A phase III trial compared MVAC with carboplatin and paclitaxel.²⁰⁹ The study failed to reach its accrual goal, with only 85 patients randomized, although no significant differences in efficacy were seen. It is of note that the MVAC group exhibited a trend toward higher response rate (36% versus 28%), progression-free survival (8.7 versus 5.2 months), and overall survival (15.4 versus 13.8 months).

To date, there has been no consensus regarding those patients who should not receive cisplatin-based chemotherapy. A review of trial eligibility shows marked variation across studies. To address this concern, criteria for trials for “cisplatin-ineligible” patients were reviewed, and a set of criteria for all future studies was proposed by an international group of investigators.²¹⁰

The complete omission of platinum has been studied as well. The doublet of gemcitabine and paclitaxel appears to have good activity, with phase II studies suggesting that this regimen has response rates and survival comparable to GC, with minimal toxicity.^{218–220,222} Gemcitabine with paclitaxel may be a reasonable regimen to consider in patients unfit for platinum therapy. Gemcitabine and docetaxel demonstrated a response rate of 33% and median survival of 12 months in a trial of 27 patients with advanced TCC.²²³

Triplet Chemotherapy

Because of the activity of each of these agents in TCC, investigators then asked whether triplet combinations of platinum, taxanes, and gemcitabine might have increased activity over the doublets. In phase II trials, three such combinations, including cisplatin/gemcitabine/paclitaxel,¹⁶⁸ carboplatin/gemcitabine/paclitaxel,²²⁴ and cisplatin/gemcitabine/docetaxel,²¹⁷ demonstrated high CR rates of 28% to 32%, and overall response rates of 66% to 78%, although the number of patients with visceral metastases was relatively low. A second study of carboplatin/gemcitabine/paclitaxel showed a more modest response rate of 43% and overall survival of 11 months in a more typical population of metastatic TCC.²¹⁶ A triplet of paclitaxel, cisplatin, and infusional high-dose 5-FU with leucovorin has also been studied. The response rate was 75%, with 28% CRs, and a median overall survival of 17 months. Significant toxicity included frequent myelosuppression, gastrointestinal disturbances, infections, and two treatment-related deaths.²²⁵

A randomized phase III trial compared the standard GC regimen with GC plus paclitaxel (PCG).²¹⁵ Preliminary results and updated data are available. Despite a response rate that was superior in the three drug arm (55.5% versus 43.6%, $p = 0.0031$) and a median overall survival that was slightly longer in patients receiving the third drug (15.8 months versus 12.7 months), the HR for survival did not achieve statistical significance (HR, 0.85; $p = 0.075$). Thus, the standard of care remains the doublet of gemcitabine plus cisplatin.²²⁶

Biologic Agents

The enthusiasm engendered by the development of novel biologic agents targeted against tumor-specific growth factor pathways or angiogenesis has been fortified in recent years by positive studies in a variety of solid tumors. Two classes of agents that may be of interest in TCC are inhibitors of EGFR, including EGFR1 and EGFR2 (HER2/neu), and inhibitors of VEGF or its receptors. There is ample preclinical evidence that many bladder tumors express members of the EGFR family, that overexpression may correlate inversely with prognosis, and that inhibition of these pathways may have an antitumor effect.^{63–69} A number of groups are conducting studies with inhibitors of EGFR1 and HER2/neu in the treatment of advanced bladder cancer. Similarly, the utility of angiogenesis inhibitors in TCC is currently being explored in a cooperative group trial in metastatic TCC studying GC with or without the addition of bevacizumab.

Second-Line Therapy and Beyond

There is no U.S. Food and Drug Administration (FDA)-approved therapy or regimen for second-line chemotherapy for progressive bladder cancer. One phase III trial randomized 370 patients with advanced TCC who had received prior platinum-based chemotherapy 2:1 to single-agent vinflunine or best supportive care. Median survival favored the vinflunine population (6.9 versus 4.6 months), but the difference was not statistically significant ($p = 0.287$).²²⁶ These findings were confirmed at longer follow-up.²²⁸ The lack of benefit combined with adverse effects have not led to broad approval of vinflunine worldwide or approval by the FDA in the United States. In practice, treatment beyond first-line chemotherapy typically employs doublet regimens described previously, single-agent chemotherapy, or clinical trials, where available.

CANCERS OF THE RENAL PELVIS AND URETER

The majority of tumors of the upper urinary collecting system are TCCs. However, these are uncommon, with fewer than 3,000 cases diagnosed annually in the United States. The incidence has remained constant, but there has recently been a slight stage migration toward a higher proportion of earlier stage tumors.²²⁹ Because of the challenge in gaining access to them, initial diagnosis and staging are less accurate than for cancer of the bladder. Histologically, 90% of upper tract tumors are TCC. Squamous cell carcinoma accounts for nearly all of the remainder. There is a predilection for these tumors to arise in the renal pelvis; primary tumors of the ureter occur only half as frequently as do tumors of the renal pelvis.²³⁰ Men develop upper tract TCC two to three times more often than women, with the peak age of development

of these tumors in the 7th and 8th decades of life.²¹¹ Women, however, are more likely than men to have a more advanced and higher grade tumor at nephroureterectomy.²³¹ As discussed in the first section of this chapter, the majority of these tumors arise as a result of, or at least in association with, environmental exposures and stresses.^{7-13,25}

Clinical Presentation, Diagnosis, and Staging

Gross hematuria is the presenting symptom in 75% to 95% of all patients who present with tumors of the renal pelvis and ureter. Hematuria may be accompanied by colicky flank pain if the tumor or blood clots cause obstruction of the upper urinary tract. Patients often describe the passage of vermiform clots, which are unusual in bleeding from a lower tract source. Hydronephrosis may also be a presenting sign. Urinary cytology is an important part of the workup for an upper tract tumor. Voided urine cytology, however, has only 10% to 40% sensitivity in the detection of low-grade TCC lesions. Cytology is far more useful for high-grade tumors, for which the sensitivity may be as high as 70%.^{232,233}

Improvements in endoscopic technology allow the urologist to view directly and to obtain tissue in many of the TCCs of the upper tract. A pathologic confirmation may be obtained prior to treatment. Also, the grade may be a useful predictor of advanced stage disease.^{234,235}

Historically, intravenous urography was the mainstay of a radiographic evaluation of upper tract tumors, but now, in most major centers, a CT urogram is preferred (Fig. 65.7).²³⁶ An MRI urography may also be useful in patients when sensitivity to iodinated contrast prevents the use of that agent.^{237,238} When a patient is found or judged to have a TCC more aggressive than a G1 stage I tumor, additional staging of the patient is indicated, including CT scans of the chest, abdomen, and pelvis. Because standard therapy is radical excision of the kidney and the ipsilateral ureter, an evaluation of the total remaining renal function prior to a proposed nephrectomy is indicated. Isotope renal scanning can accurately estimate the function of the uninvolved kidney.

The current American Joint Committee on Cancer TNM staging for tumors of the upper urinary tract is shown in Figure 65.8 and in Table 65.8. The staging is determined by the extent of invasion by the primary tumor and by microscopic evaluation of the regional lymph nodes.

Figure 65.7 Abdominal computed tomographic scan of a stage T3 transitional cell carcinoma of the right renal pelvis, with intravenous contrast showing a large filling defect in the right renal pelvis (arrow).

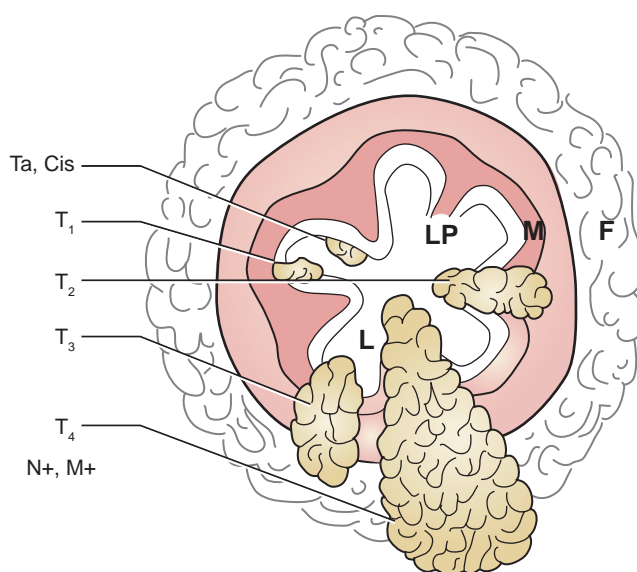

Figure 65.8 Schematic diagram of the American Joint Committee on Cancer TNM (tumor, necrosis, metastasis) staging of cancers of the renal pelvis; LP, lamina propria; M, muscularis propria; F, peripelvic fat; L, lumen.

Surgical Treatment

The standard surgical treatment for patients with transitional cell cancer of the upper urinary tract of all grades and stages is radical nephroureterectomy. This involves a complete removal of the kidney with its surrounding perirenal fat contained within Gerota fascia and en bloc removal of the ureter down to, and including, the portion of ureter within the urinary bladder (the ureteral orifice and the intramural ureter).²³⁹ A retroperitoneal lymph node dissection along the ipsilateral great vessel (the vena cava for right-sided tumors; the aorta for left-sided tumors) is performed for more complete surgical staging, especially for higher grade and invasive cancers (Fig. 65.9). A lymphadenectomy and complete bladder cuff excision may not be necessary in cases of upper tract TCC, particularly at a low stage and grade.²⁴⁰ When TCC of the renal pelvis invades the renal vein or the vena cava, an extensive surgical procedure, including thrombus extraction or partial vena cava dissection, may be required. A nephroureterectomy may be performed via open or laparoscopic surgical techniques. Common open approaches employ either a single extended midline abdominal incision or nephrectomy via a thoracoabdominal incision and a separate incision in the lower abdomen to accomplish the distal ureterectomy with a cuff of the contiguous urinary bladder.

Open surgical approach had long been the standard of treatment for the majority of patients with tumors of the renal pelvis and ureter, although morbidity may be reduced by using a laparoscopic technique.^{241,242} The operative time and blood loss with the laparoscopic technique may be substantially less and the hospital stay shorter than those of an open surgical technique. With proper technique in resecting the distal ureter, laparoscopic or robotic-assisted nephroureterectomy is equally oncologically effective.^{243,244} Invasive TCC may seed the abdomen if spilled, allowing tumor implantation, and this has led to concern among surgical oncologists about the laparoscopic approach. One group has reported three cases of laparoscopic port-site recurrence; however, in all three of these cases, the tumor was spilled from the operative specimen, allowing growth of the tumor tissue at the trocar sites.²⁴⁵

In patients in whom radical excision of the tumor would result in severe renal insufficiency that required dialysis (such as patients with a solitary kidney or in a patient with substantially diminished renal function), other surgical therapies may be considered. Endoscopic resection techniques have been developed and shown

to be effective when done selectively and in experienced hands.²⁴⁶ Endoscopic ablation via laser or electrocautery may be used to treat small tumors of the ureter and renal collecting system. However, the success of focal resection can be thwarted by the multicentricity of these tumors and the common concurrent existence of CIS.²⁴⁷ Furthermore, although small, low-grade tumors can often be effectively treated endoscopically, high-grade tumors are often understaged by endoscopic assessment only, and therefore, may be treated inadequately without nephroureterectomy.²⁴⁸

Percutaneous endoscopic surgery of renal pelvic and calyceal TCC with access via the flank has been developed as a treatment option in highly select patients who have poor renal function or who medically could not withstand an open surgical procedure.²⁴⁹ Using standard endoscopic tools, it is possible to resect tumors in the fashion similar to that which is used for bladder tumors. All limited resection endoscopic procedures require vigilant follow-up with an endoscopic reevaluation on a regular schedule because recurrence is quite common. In one study, 33% of patients ultimately required nephroureterectomy and 11% of patients died of TCC.²⁵⁰

Although endoscopic management of high-grade tumors can result in undertreatment and poorer oncologic outcomes, a

TABLE 65.8

**American Joint Committee on Cancer 2009
TNM Staging of Renal Pelvis and Ureter
Cancers: Definition of TNM**

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Papillary noninvasive carcinoma
Tis	Carcinoma in situ
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades the muscularis
T3	(For renal pelvis only) Tumor invades beyond muscularis into peripelvic fat or the renal parenchyma
T3	(For ureter only) Tumor invades beyond muscularis into periureteric fat
T4	Tumor invades adjacent organs or through the kidney into the perinephric fat
Regional Lymph Nodes (N) ^a	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node more than 2 cm but not more than 5 cm in greatest dimension or multiple lymph nodes; none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node, more than 5 cm in greatest dimension
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Figure 65.9 Diagram of the kidneys, ureters, bladder, and retroperitoneal lymph nodes to demonstrate that a nephroureterectomy for upper tract transitional cell carcinoma requires a complete excision of the distal ureter, including the portion within the wall of the bladder. The bladder here is open to reveal the distal ureter, which tunnels within the wall of the bladder.

kidney-sparing approach to appropriately selected isolated ureteral tumors using surgical resection is becoming a more accepted alternative to nephroureterectomy with similar oncologic outcomes.^{251,252} This involves segmental resection of the ureter incorporating the tumor and the entire ureter distally, including the ureteral orifice/bladder cuff, and appropriate lymphadenectomy. Because recurrences and urothelial atypia are usually distal in the ureter to the index lesion, it is reasonable to spare the kidney without undue risk of recurrent disease. Surgically, it is possible to remove approximately half of the distal ureter and reimplant it in the bladder. For upper ureteral tumors, replacement of the ureter with a segment of the ileum may be considered. Although segmental resection is becoming more accepted for mid and distal ureteral tumors, radical nephroureterectomy does remain the gold standard, especially for tumors in the proximal ureter and tumors with extensive ureteral involvement.

Results of Surgical Therapy

The success rate of surgical procedures is primarily influenced by the pathologic stage of the disease at the resection (Table 65.9). Tumors lower in the urinary tract have a better prognosis when matched by stage with tumors higher in the ureter and pelvis.²⁵⁴ Within the upper tract, the location of the tumor in the ureter versus the renal pelvis does not seem to affect the prognosis.^{255,256} In a report with a long follow-up from the University of Texas Southwestern Medical Center, of 252 patients treated surgically for upper tract TCC, disease-specific and overall survival were strongly influenced by the pathologic stage of the primary tumor.²⁵³ The

TABLE 65.9

Five-Year Disease-Specific Survival by Primary Tumor Pathologic Stage After Surgical Resection of Transitional Cell Carcinoma of the Upper Urinary Tract

Tumor Stage	Number of Patients	Percentage (%)
pTa/pTis	38	100
pT1	99	92
pT2	34	73
pT3	53	41
pT4	19	0

From Hall MC, Womack S, Sagalowsky AI, et al. Prognostic factors, recurrence, and survival in transitional cell carcinoma of the upper urinary tract: a 30-year experience in 252 patients. *Urology* 1998;52:594–601, with permission

5-year actuarial disease-specific survival rates by primary tumor pathologic stage were 100% for noninvasive tumors (Ta and Tis), 92% for pathologic stage T1, 73% for pathologic stage T2, and 41% for pathologic stage T3. There were no long-term survivors for those with stage T4 tumors (Table 65.9). The type of open surgical procedure used (nephroureterectomy in 77% of the patients compared with a kidney-sparing approach used in 17%) was evaluated by a univariate and multivariate analysis. Patients undergoing nephroureterectomy were found to have a significantly improved recurrence-free and disease-specific survival on multivariate analysis but not on the univariate analysis. However, as discussed previously, in other more recent series, patients with ureteral cancers who were appropriately selected for kidney-sparing resections did not have a poorer outcome.

Adjuvant Topical Therapy Following Local Excision Only

In cases in which endoscopic resection is performed, topical immunotherapy or topical chemotherapy may be important in preventing or delaying local tumor recurrence. BCG appears to be useful in treating carcinomas of the upper tract that are stage Tis.²⁴⁷ Adriamycin given prophylactically following conservative resection of upper tract TCCs, using an antegrade infusion, also has been judged to be of some benefit in reducing recurrence.²⁵⁷ The risk of systemic absorption of BCG or the chemotherapeutic agents is substantially higher than in treatment of the bladder and should be considered in therapeutic decision making.

Adjuvant Combined-Modality Therapy: Advanced Primary Tumors

The most appropriate treatment for invasive transitional cell cancers of the upper urinary tract is nephroureterectomy. Despite aggressive surgery, cure rates are low when the disease has spread beyond the muscularis, with 5-year survival rates varying between zero and 34%.^{257–262} Whether these low survival rates can be improved by adjuvant therapy depends on the pattern of failure and the efficacy of the available treatment. Metastatic relapse appears to predominate over local relapse when systemic cisplatin-based chemotherapy has been used, extrapolating from the experience with locally advanced bladder cancer. The true rate of local–regional failure is, however, unknown because many of the published series are old and employed pre-CT methods of intra-abdominal evaluation. The available data suggest an overall local–regional failure of 2% to 27%, although these figures may be underestimated.^{263–265} Cozad et al.²⁶⁶ report local failure rates of 50% in stage T3 disease,

rising to 60% if the tumors were high grade. Brookland and Richter²⁶⁷ have reported local–regional recurrence in 45% and 62%, respectively. Most series report a close association between local failure and distant metastasis, although whether the association is causal or simply synchronous cannot be determined from the small numbers in the series.

Radiation has been employed as an adjuvant therapy with mixed results reported in the literature (Table 65.10). Several small phase II studies have suggested a local control and perhaps survival advantage for adjuvant radiation.^{267–273} One study reported no benefit, although their treated population was diluted with 30% early stage patients. Another study showed no advantage to radiation, but the radiation doses given were inadequate. In others, chemotherapy was given in addition. Therefore, it is difficult to determine the true benefit of adjuvant radiation, if any. However, in a recent retrospective report by Chen et al.,²⁷³ a survival advantage was seen in patients with T3/T4 disease of the renal pelvis or ureter receiving postoperative radiation with a median dose of 50 Gy to the tumor bed.

At the MGH, a more aggressive approach has been taken during the past 20 years in which patients with high-risk disease were treated first with adjuvant radiation alone and then more recently with concomitant radiation-sensitizing chemotherapy and, if tolerable, further combination chemotherapy.²⁷¹ Although the authors' series of 31 patients is nonrandomized and small, local failure was lower if chemotherapy was combined with radiation and the survival rate at 5 years was higher (see Table 65.10). Kwak et al.²⁷² also suggested that cisplatin-based adjuvant chemotherapy may reduce the rate of relapse and death from disease at 5 years. The small size of these two series and the biases inherent in this kind of retrospective review make it difficult to draw conclusions.

Very little published data exist to guide physicians managing patients with a local relapse following a nephroureterectomy. If the relapse is bulky and metastases are present elsewhere, then palliation with chemotherapy would be the most appropriate course. When the relapse appears isolated and the patient relatively vigorous, consideration can be given to an aggressive approach that holds out the chance for cure. The first step would be to downsize and perhaps improve the respectability of the recurrence using external radiation to a modest preoperative dose of 30 to 45 Gy along with sensitizing chemotherapy. An attempt could then be made at resection or debulking and, if the facility were available, intraoperative radiation could then be given directly onto the tumor bed or onto an unresectable mass, with the bowel and other critical organs displaced out of the field. Such an approach allows for the delivery of high doses of radiation to the target without the risk of bowel injury that is present when managing such disease using external radiation treatment alone (Fig. 65.10).

Advanced Transitional Cell Carcinoma of the Upper Tract

Most patients with upper tract TCC have superficial disease, with a favorable prognosis.^{274,275} However, patients with disease that invades beyond the muscularis propria have a significantly worse prognosis. The most consistent prognostic variables for the outcome of patients with upper tract TCC, including renal pelvic and ureteral carcinomas, are tumor stage and grade.^{276–279} Molecular markers are being studied, and a poor outcome may be predicted by overexpression of p53 and a higher Ki-67 labeling index.^{280–282}

In a series of 252 patients with mostly localized disease, relapse occurred in 67 patients (27%) after a median of 12 months.²⁶⁵ Survival was highly stage specific, with 5-year disease-specific survival of 92% for T1, 73% for T2, 41% for T3, and zero for T4. In a series of 126 patients with nonmetastatic but more advanced renal pelvic or ureteral tumors, relapsed disease was noted in 81 patients (64%) after a median of 9 months.²⁶⁸ Overall, 5- and 10-year survival rates

were 29% and 19%, respectively. The most common sites of distant metastases were liver, bone, or lung. Utilization of postoperative radiation therapy did not impact on local or distant relapse. Factors that influenced survival outcomes in a multivariate analysis were initial tumor stage, residual postsurgery tumor, and the location of the initial tumor, with renal pelvic cancer being more favorable than ureteral cancer. The role of adjuvant chemotherapy in reducing relapse has not been explored in randomized fashion in this uncommon disease.

The biology of upper tract TCC is considered to be identical to that of bladder TCC. Consequently, the chemotherapy regimens recommended for advanced or metastatic upper tract TCC are the same as that for bladder cancer, as previously described. Standard treatment is cisplatin-based combination therapy, such as gemcitabine and cisplatin or methotrexate, vinblastine, doxorubicin, and cisplatin. As with bladder cancer, upper tract TCC is highly responsive to chemotherapy but has a short median duration of response.

Coronal pretreatment

Coronal posttreatment

Figure 65.10 Sequential coronal MRI of a patient with an unresectable ureteral tumor mass. The mass shown on the MRI on the **left** (arrows) was at the bifurcation of the aorta; it was initially judged unresectable because of involvement of the vessels. A partial resection, however, became possible as part of a combined-modality treatment approach that included preoperative conformal external-beam radiation. Intraoperative electron-beam radiation was given to the entire tumor bed after resection. On the **right** is the repeat MRI 1 year after treatment without any visible tumor.

66 Genetic Testing in Urinary Tract Cancers

Gayun Chan-Smutko

INTRODUCTION

Cancers of the urinary tract include renal cell carcinoma (RCC) and transitional cell carcinoma, or urothelial carcinoma (UC). About 64,770 cases of invasive cancer of the kidney and renal pelvis, 74,510 cases of urinary bladder cancer, and 2,860 cases of cancer of the ureter and other urinary organs are expected to be diagnosed in men and women in the United States in 2012.¹ The lifetime risk of cancer of the kidney and renal pelvis is 1.6%, with an average age at diagnosis (based on statistics from 2005 to 2009) of 64 years.² A family history of RCC is associated with a 2.2- to 2.8-fold increased risk for developing RCC.³ Most cases of RCC are sporadic, and approximately 4% are due to a hereditary susceptibility.

RCC is a heterogeneous disease, which has been divided into the following subtypes based on the World Health Organization 2004 classification system: Clear cell (80%), papillary types 1 and 2 (10%), chromophobe (5%), collecting duct (1%), and RCC unclassified (4% to 6%). Additional rarer types that collectively account for <2% of RCCs have been described as well.⁴ The molecular pathways driving tumorigenesis in hereditary syndromes such as von Hippel-Lindau (VHL) disease, Birt-Hogg-Dubé (BHD) syndrome, hereditary leiomyomatosis and RCC, and hereditary papillary renal cell carcinoma (HPRCC) have provided greater insight into the molecular mechanisms behind the four major subtypes of RCC. This understanding has led to targeted therapies aimed at specific molecular pathways such as the hypoxia-inducible factor (HIF) pathway. This review is devoted primarily to the discussion of renal neoplasms in the adult population and their associated hereditary syndromes (Table 66.1). Genetic testing for susceptibility to urothelial cancers of the upper urinary tract is also presented.

GENETIC SUSCEPTIBILITY TO RENAL CELL CARCINOMA

von Hippel-Lindau Disease

VHL disease is an autosomal dominant condition that affects approximately 1 in 36,000 live births worldwide. The *VHL* gene is located on the short arm of chromosome 3 (3p25) and is the only known susceptibility locus associated with the condition. It is a well-studied tumor suppressor gene that demonstrates loss of heterozygosity in RCCs of patients with VHL disease and sporadic clear cell RCC as well.

VHL disease is a multisystem condition, and an affected individual is at risk to develop any of the following lesions: (1) hemangioblastoma of the cerebellum, spine, or retina; (2) papillary cystadenoma of the epididymis, the adnexal organs, or the endolymphatic sac; (3) adrenal pheochromocytoma and occasionally extra-adrenal paraganglioma; (4) pancreatic cysts, serous cystadenomas, and neuroendocrine tumors (NET); and (5) multiple and/or bilateral RCC and cysts.

Although the penetrance of VHL disease is 100%, where individuals will develop at least one associated lesion by their sixth decade of life, the expressivity is highly variable even among individuals

sharing the same gene mutation. The disease is phenotypically categorized into type 1 and type 2 based on risk for developing pheochromocytoma, with the latter further divided into three subtypes (2A, 2B, and 2C) based on risk for developing RCC. The genotype/phenotype correlations within each type are described in Table 66.2.

Renal Lesions

RCCs of patients with VHL disease are of exclusively clear cell histology. The lifetime risk for developing RCC is 25% to 45%, and when renal cysts are included, the risk rises to 60%.⁵ Renal cysts and RCCs develop at an earlier age in patients with VHL in comparison to sporadic counterparts, with an average age of 39 years (range, 16 to 67 years).⁵ Cystic lesions are typically asymptomatic; however, complex cysts must be monitored closely with computed tomography (CT) or magnetic resonance imaging as they will harbor a visibly solid RCC component. RCC will often arise from noncystic parenchyma as well.

Nonrenal Clinical Features

With the exception of RCC and pancreatic NETs, the malignancy risk with VHL-associated tumors is very low. Renal lesions and hemangioblastoma of the cerebellum, spine, or retina are common presenting lesions in VHL. The risk for developing a single hemangioblastoma of the spine, cerebellum, and brainstem is 60% to 80%, and the average age is 33 years (range, 9 to 73 years),⁵ although most patients can develop multiple lesions at any point in their lifetime. Patients may remain completely asymptomatic, especially during periods of no growth or slow growth. Surgical resection is delayed until onset of symptoms.

Retinal hemangioblastomas (retinal angiomas) are usually multifocal and bilateral. These hypervascular tumors can lead to retinal detachment and vision loss. Retinal hemangioblastomas have been observed in 25% to 60% of patients with an average age of 25 years (range, 1 to 67 years). Approximately 5% of lesions are seen younger than 10 years, making genetic testing of at-risk children essential as affected children should undergo annual retinal examinations beginning at birth. Pheochromocytoma has also been observed in young children and can present as a hypertensive crisis. The average age at presentation is 30 years (range, 5 to 58 years), and the risk is 10% to 20%.⁵

Pancreatic manifestations include multiple simple cysts and serous cystadenomas (47% and 11%, respectively), which follow a benign course and are almost always asymptomatic in patients. Pancreatic NETs are less common (15%); however, approximately 2% undergo malignant transformation.⁶ A NET tends to be indolent and is seldom the initial presenting lesion; however, close monitoring is indicated for timing of surgical resection. A less common manifestation of VHL is a papillary cystadenoma of the endolymphatic sac, or inner ear, which is extremely rare in the general population but more prevalent in VHL disease (~11%). Papillary cystadenomas may also arise in the epididymis in men and less commonly in the adnexal organs in women.

TABLE 66.1

Genetic Susceptibility to Renal Cell Carcinoma

Syndrome	Acronym	Gene(s)	Phenotype	RCC Type	Genetic Testing Sensitivity
von Hippel-Lindau syndrome	VHL	<i>VHL</i>	Hemangioblastoma (cerebellum, spine, retina), pheochromocytoma, papillary cystadenoma (pancreas, epididymis, adnexal organs, endolymphatic sac pancreatic NET, and cysts)	Clear cell	Nearly 100% ^a
Birt-Hogg-Dubé syndrome	BHD	Folliculin, <i>FLCN</i>	Fibrofolliculoma, trichodiscoma, acrochordon, lung cysts, spontaneous pneumothorax	50% chromophobe/oncocytic hybrid, 34% chromophobe, 9% clear cell, 5% oncocytoma, 2% papillary	~88% ²⁰
Hereditary leiomyomatosis and RCC	HLRCC	<i>FH</i>	Cutaneous leiomyoma, uterine leiomyoma	Papillary type 2	~93% ²⁵
Hereditary papillary RCC	HRCC	<i>MET</i>	No additional features	Papillary type 1	Not well established as families are rare
Hereditary paraganglioma/pheochromocytoma	HPGL	<i>SDHB</i> , possibly <i>SDHD</i> and <i>SDHC</i>	Pheochromocytoma and paraganglioma	Not well defined, but clear cell and papillary types reported	Unknown in families with RCC and no paraganglioma or pheochromocytoma

RCC, renal cell carcinoma; NET, neuroendocrine tumor.

von Hippel-Lindau Molecular Genetics

The *VHL* gene was cloned by Latif et al.⁷ in 1993 and is the most well studied of the familial RCC syndromes. Loss of *VHL* function has been demonstrated to cause RCC formation in VHL disease as well as in the majority of sporadic clear cell RCCs.^{8,9} The *VHL* gene encodes the pVHL protein, which in normoxic conditions forms a complex with elongin B, elongin C, Cullin 2, and Rbx1. The VHL complex targets HIF-1 α and HIF-2 α for ubiquitin-mediated degradation. The HIF-1 α and HIF-2 α genes, along with HIF-3 α , encode the α subunit of the HIF heterodimer. In hypoxic conditions, the VHL complex does not interact with HIF-1 α and HIF-2 α , leading to an accumulation of these subunits and downstream transcription of HIF-dependent genes. Loss of VHL protein

function in renal tumors simulates low tissue oxygen levels, or “pseudohypoxia,” where HIF-1 α and HIF-2 α accumulate, causing upregulation of many genes involved in tumorigenesis such as vascular endothelial growth factor (proangiogenesis), epidermal growth factor receptor (cell proliferation and survival), and glucose transporter 1 (regulation of glucose uptake).

von Hippel-Lindau Genetic Testing

Genetic testing of the *VHL* gene is available on a clinical basis and involves full-gene sequencing and large gene rearrangement analysis. When both methods are used, the mutation detection rate is nearly 100% in patients with a clinical diagnosis of VHL.¹⁰ Approximately 80% of patients have a parent with VHL, and ~20% represent de

TABLE 66.2

von Hippel-Lindau Genotype Phenotype Correlations

VHL Phenotype	Pheo	RCC	HB	Predominant Mutation Type
Type 1	Rare or absent	High	High	Large deletions, nonsense, frameshift
Type 2A	High	Rare	High	Missense
Type 2B	High	High	High	Missense
Type 2C (uncommon)	High	Absent	Absent	Missense

Note: The majority of type 1 mutations are partial or complete deletions and protein truncating (nonsense and frameshift), whereas 96% of type 2 mutations are missense. Missense mutations that disrupt amino acid residues on the surface of the VHL protein confer a higher Pheo risk than missense mutations that disrupt protein structure.

VHL, von Hippel-Lindau; Pheo, pheochromocytoma; RCC, renal cell carcinoma; HB, hemangioblastoma.

Phenotypic expression in von Hippel-Lindau disease: Correlations with germline *VHL* gene mutations. *J Med Genet* 1996;33:328-332; and Ong KR, Woodward ER, Killick P, et al. Genotype-phenotype correlations in von Hippel-Lindau disease. *Hum Mutat* 2007;28:143-149.

novo cases where neither parent carries the mutation. Genetic testing is recommended for a proband with a personal and family history of VHL, as the identification of causative mutations aids in determining disease subtype (see Table 66.2). Disease subtype information along with a careful, detailed family history aids in guiding screening and surveillance of patients with VHL. In simplex cases, where a patient has two or more VHL-associated lesions and a negative family history, genetic testing is recommended to establish a diagnosis. When a mutation is identified in a proband, at-risk family members should be offered predictive testing. Since young children with VHL are known to be at risk for retinal lesions and pheochromocytoma, genetic testing should be offered any time after birth.

Birt-Hogg-Dubé Syndrome

In 1977, Drs. Birt, Hogg, and Dubé first described a multigenerational kindred showing autosomal dominant transmission of fibrofolliculomas with trichodiscomas and acrochordons.¹¹ The phenotype was later expanded beyond dermatologic manifestations to include lung cysts and pneumothorax and renal tumors.¹² The number of families with BHD syndrome described in the literature to date is small, and therefore, the exact incidence is unknown. Inherited mutations in the folliculin (*FLCN*) gene are associated with BHD syndrome.

Renal Lesions

An individual with BHD syndrome is at increased risk of developing multiple and bilateral renal tumors, frequently of more than one histologic type even within the same renal unit, and at younger ages compared with the general population. The lifetime risk is in the range of 27% to 45%,^{13,14} and the wide range may be a reflection of ascertainment bias introduced when families are recruited predominantly through dermatology clinics versus urology. The most common tumor pathology found in patients is a hybrid oncocytic RCC, which contains a mixture of oncocytic and chromophobe cells. Furthermore, radical nephrectomy specimens of patients have demonstrated oncocytosis where tiny nodules of cells similar to the larger hybrid tumors are diffusely scattered throughout the renal parenchyma. A retrospective study by Pavlovich et al.¹⁵ examined 130 tumor specimens from 30 patients (25 males, 5 females) in 19 different BHD families. The authors found that hybrid oncocytic (50%) and chromophobe (34%) were the more common histologic findings, followed by clear cell (9%), benign oncocytoma (5%), and papillary (2%). The average age at first tumor was 50.7 years, and patients averaged 5.3 tumors each (range, 1 to 28). Other studies reporting histologic subtypes of BHD syndrome–related renal tumors have similar findings.

Nonrenal Manifestations

Skin findings associated with BHD syndrome are benign and consist of fibrofolliculoma, trichodiscoma (which are histologically and clinically indistinguishable from angiofibroma), perifollicular fibroma, and acrochordons. Fibrofolliculoma is highly specific for BHD syndrome, whereas trichodiscomas and acrochordons are not. Onset for skin lesions is typically at older than 25 years, and a dermatologic diagnosis of BHD syndrome can be made on the basis of the presence of five or more facial or truncal papules with at least one histologically confirmed fibrofolliculoma.

Approximately 83% to 89% of patients with BHD syndrome will have multiple pulmonary cysts^{14,16,17} identified upon chest CT. The lifetime risk of spontaneous pneumothorax is 24% to 32%,^{14,18} and the majority of patients have their first event by age 50 years. The presence of lung cysts is strongly associated with risk of pneumothorax,¹⁷ but the mechanism behind this is not known. A possible association between BHD syndrome and parotid oncocytoma has also been reported in a small number of cases.¹⁴

FLCN Molecular Genetics

The *FLCN* gene is located on chromosome 17p11.2 and was cloned by Nickerson et al.¹² in 2002. The gene has 14 exons and encodes the protein folliculin. The role of *FLCN* and tumorigenesis has not been fully established, but animal studies and loss of heterozygosity studies in renal tumors provide some evidence that it is a tumor suppressor gene. Folliculin binds with folliculin-interacting proteins (FNIP1 and FNIP2) and then binds AMP-activated protein kinase, which is part of the cellular energy and nutrient sensing system. AMP-activated protein kinase also helps regulate mTOR activity (mTORC1 and mTORC2). Studies of renal tumors from heterozygous BHD knockout mice and renal tumors from patients with BHD syndrome show mTOR activation. Therapeutic agents inhibiting mTOR activity in sporadic chromophobe tumors are currently under investigation and may have implications for patients with BHD syndrome–related renal tumors.¹⁹

The mutation detection rate for *FLCN* clinical testing is approximately 89%, and nearly all of the mutations described to date have been truncating point mutations (frameshift and nonsense). Splice-site mutations have also been reported in a small number of BHD families, and one missense mutation in a patient with bilateral renal tumors has been reported as well.²⁰ A mutational hotspot in a polycytosine tract in exon 11 has been suggested.¹⁴

Hereditary Papillary Renal Cell Carcinoma

HRCC is inherited in an autosomal dominant manner with reduced penetrance where patients with HRCC are at risk of developing multiple and/or bilateral papillary RCCs at a young age. The phenotype is limited to the risk of papillary RCC alone, particularly papillary type 1, although the distinction between type 1 and type 2 is not always made on initial pathology review.

Germ-line mutations in the *c-met* or *MET* proto-oncogene on chromosome 7q31.2 have been associated with HRCC.²¹ This is a comparatively uncommon condition, and few families with a *MET* mutation have been reported to date. Missense mutations found in HRCC families occur in exons 16, 17, 18, and 19 of the *MET* proto-oncogene, which encodes the tyrosine-kinase domain of the protein product. These mutations have been shown to be activating or gain-of-function mutations, unlike most hereditary cancer susceptibility syndromes, which are associated with loss-of-function mutations in tumor suppressor genes. Papillary tumors obtained from patients with HRCC typically show duplication of chromosome 7, as do their sporadic counterparts.²² Furthermore, HRCC-associated tumors show nonrandom duplication of the chromosome 7 copy harboring the mutation *MET* allele,^{22,23} suggesting that overexpression of *MET* may lead to cellular proliferation, although the exact mechanism has not yet been elucidated.

Analysis by Lindor et al.²⁴ of 59 apparently sporadic patients with papillary type 1 tumors, including 13 cases with multifocal or bilateral disease, found no germ-line mutations in *MET*. This suggests differing etiology in sporadic versus papillary type 1 cancers. The rarity of the disease and low likelihood of identifying mutation carriers in isolated cases poses a challenge for genetic counseling of these patients. In the setting of a positive family history, *MET* genetic testing should be offered to patients with papillary type 1 RCC. A negative genetic test result, however, does not exclude the possibility of a hereditary susceptibility.

Hereditary Leiomyomatosis and Renal Cell Carcinoma

Susceptibility to papillary type 2 RCC has been associated with hereditary leiomyomatosis and RCC (HLRCC) syndrome demonstrating autosomal dominant transmission. Most individuals

with HLRCC-associated renal lesions present with unilateral, solitary tumors; however, bilateral and multifocal disease has also been observed.²⁵ The tumors tend to be highly aggressive with poor prognosis, which has implications for screening and early detection in at-risk patients. Although papillary type 2 is the predominant histology, collecting duct RCC and mixed cystic, papillary, and tubulopapillary RCC have also been reported. The incidence of RCC in individuals with HLRCC is approximately 25% to 40%.^{25,26}

Cutaneous leiomyomatosis and uterine leiomyomatosis are additional features of the disease. Leiomyomas of the skin appear as firm skin-colored to light brown papules and can be distributed anywhere along the trunk, extremities, head, or neck. Uterine leiomyomas (fibroids) are common in the general population; however, HLRCC-associated burden tends to be greater in women with HLRCC. Compared with the general population, the average age at onset is younger where many women become symptomatic before the age of 30 years, significantly impacting their childbearing years. The fibroids tend to be multiple (ranging from 1 to 15 in one series of 22 women from 16 families studied) and large (1 to 8 cm), often requiring myomectomy or hysterectomy for treatment.²⁵ Not all individuals with HLRCC will have cutaneous manifestations, although it is worthwhile to note that the presence of cutaneous leiomyomas has a strong concordance with uterine leiomyoma. A very small number of cases have been reported of cutaneous and uterine leiomyosarcoma in HLRCC families. The fumarate hydratase gene, or *FH*, is the only gene associated with the disease to date. Fumarate hydratase functions in the Krebs cycle to convert fumarate to malate. Alteration of the *FH* gene results in accumulation of fumarate, which inhibits HIF- α prolyl hydroxylase enzymes (HPH). HIF- α is hydroxylated by HPH in normoxic conditions, but when HPH is inhibited, HIF- α levels rise, leading to increased transcription of downstream genes involved in tumorigenesis.¹⁹

Hereditary Paranglioma and Pheochromocytoma Associated with SDHB

Several genes have been implicated in hereditary paraganglioma with and without pheochromocytoma, such as the succinate dehydrogenase complex genes (*SDHB*, *SDHD*, and *SDHC*), as well as *TMEM127*, *SDHAF2*, *VHL*, *MEN2*, and others. The reader is referred to Chapter 88 “Genetic Testing in the Endocrine System” in this book for a detailed discussion of these genes.

Earlier reports of families with mutations in *SDHB* also noted renal tumors in a minority of these families with a paraganglioma/pheochromocytoma phenotype.²⁷ Different renal tumor histologic findings have been reported including clear cell, chromophobe, carcinoma not classifiable, papillary type 2, or oncocytoma.^{27–31} Gill et al.³² examined five renal tumors from four families with an *SDHB* mutation and suggest that *SDHB*-associated renal tumors share common morphologic features such as bubbly eosinophilic cytoplasm with intracytoplasmic inclusions and indistinct cell borders.

Genetic testing of *SDHB* should be considered in patients presenting with early-onset and/or multifocal/bilateral RCC and a family history of paraganglioma or pheochromocytoma. Testing can also be considered in familial RCC especially in multigeneration and early-onset families, although there are not enough data at this time to suggest whether many *SDHB* carriers will be identified in the absence of known paraganglioma or pheochromocytoma. Ricketts et al.²⁹ studied a cohort of 68 patients with RCC and no evidence of syndromic RCC susceptibility and identified three *SDHB* mutation carriers (4.4%). One had a personal history of RCC at 24 years and a positive family history; two had a history of bilateral disease, one at the age of 30 years and the other at the age of 38 years; none of the three cases had a personal or family history of paraganglioma or pheochromocytoma.²⁹

GENETIC SUSCEPTIBILITY TO UROTHELIAL CANCERS

Hereditary Nonpolyposis Colorectal Cancer, or Lynch Syndrome

Hereditary nonpolyposis colorectal cancer, or Lynch syndrome, is an inherited syndrome characterized by an increased risk for carcinoma of the colon, uterus, stomach, ovary, pancreas, and upper urinary tract. Inherited mutations in the DNA mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*) are associated with the syndrome. A detailed discussion of Lynch syndrome and genetic testing can be found in Chapter 59 “Genetic Testing in Colon Cancer (Nonpolyposis Syndromes)” of this book.

Upper urinary tract cancers are the third most common cancer in Lynch syndrome, with a 5% to 6% lifetime risk. The associated cancers are mainly UCs of the ureter and renal pelvis with a relative risk of 22 times higher than that of the general population and a median age at onset of 56 years, or 10 to 15 years earlier.³³ Upper urinary UC may be the initial presenting feature in some patients from Lynch families. Most of the reported cases are in families with *MSH2* mutations, but have been observed in smaller number of *MLH1* and *MSH6* families as well. Bladder UC has been reported in patients with Lynch syndrome, with some studies reporting a relative risk similar or slightly higher to that of the general population.³⁴ In a cohort of Dutch families with Lynch syndrome, the relative risk of bladder cancer compared with the Dutch population was higher: 4.2 for men and 2.5 for women. *MSH2* mutation carriers in this cohort showed an even higher risk of 7 for men and 5.8 for women.³⁵

Upper urinary tract cancers may be an underrecognized entity in Lynch syndrome, particularly in the urology specialty setting. Patients with UC of the ureter and renal pelvis may warrant a referral to genetics for risk assessment when presenting at young ages and/or synchronous or metachronous disease. Family history positivity for upper urinary tract cancers and other Lynch-associated tumors should be an indication for referral as well.

INDICATIONS FOR GENETIC TESTING

One or more of the indicators listed in the following should prompt a referral for evaluating a patient for genetic susceptibility to RCC. Possible entry points for the patient include a diagnosis of RCC, pheochromocytoma or paraganglioma, spontaneous pneumothorax, bilateral cystic kidneys, cystic pancreas, or suspicious cutaneous lesions. A proposed guide to making a differential diagnosis is depicted in Figure 66.1.

- Syndromic features: A thorough medical history and physical examination may provide supporting evidence of syndromic features. Review of available radiology examinations is warranted. Patients with suspicious cutaneous lesions should be referred to dermatology for biopsy and histologic confirmation.
- Personal diagnosis of RCC: Even in the absence of known family history, early-onset (<40 years) and/or presence of multifocal or bilateral lesions warrants referral.
- Family history: Obtaining and reviewing pathology reports on renal tumors from family members is essential. Patients should be queried for a positive family history of related tumors such as pheochromocytoma, skin findings, and colon cancer.

GENETIC TESTING AND COUNSELING

Genetic testing for *VHL*, *FLCN*, *MET*, *FH*, and *SDHB* is clinically available for approximately \$1,000 to \$1,200 per gene, although the per-gene cost is anticipated to decrease as the cost of sequencing technologies decreases and more multigene panels are offered.

Approach to diagnosis of familial RCC

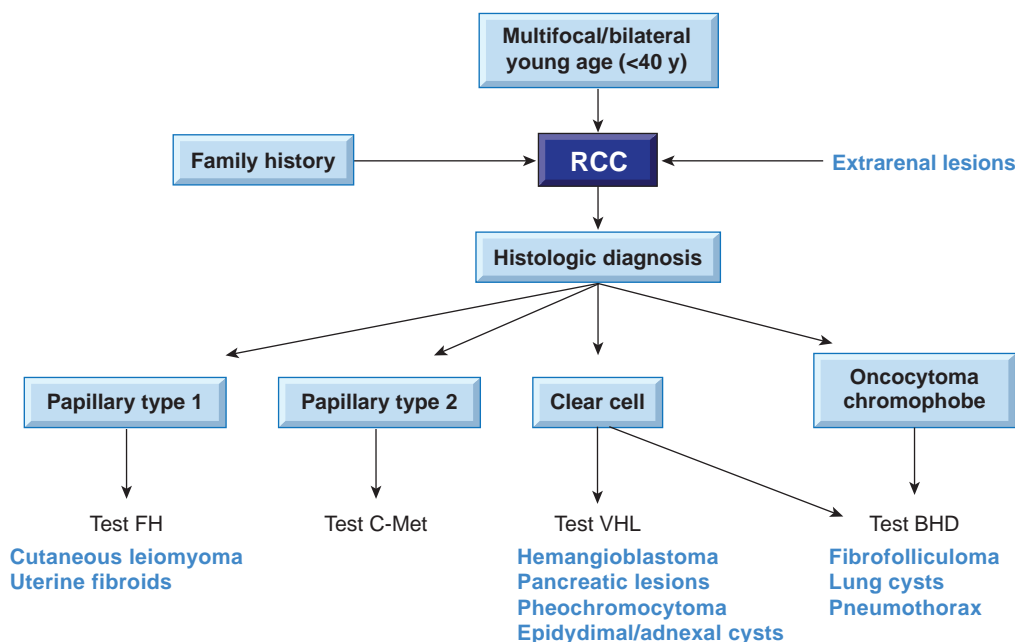

Figure 66.1 Proposed approach for evaluation and testing for inherited susceptibility to RCC. Family history, age at onset, extrarenal lesions, and renal histology guide testing. RCC, renal cell carcinoma; FH, fumarate hydratase; VHL, von Hippel-Lindau; BHD, Birt-Hogg-Dubé.

Lynch syndrome testing is also available; however, it is a genetically heterogeneous disease, and tumor screening with microsatellite instability analysis and immunohistochemistry of the DNA mismatch repair genes can help guide germline testing (see “Colon Nonpolyposis” section of this book). A summary of the mutation detection rates for each gene can be found in Table 66.1. Testing sensitivity is predictably highest in syndromic cases with uncommon tumors that are highly specific for the syndrome such as hemangioblastoma (VHL) and fibrolliculoma (BHD). Genetic testing is still warranted in less suspicious cases as a positive test result in a patient (i.e., germline mutation) prompts close monitoring in a rational, targeted manner. This includes screening for new renal tumors and nonrenal manifestations such as pheochromocytoma and paraganglioma. High-risk, aggressive papillary type 2 tumors are associated with HLRCC and warrant prompt intervention. Early detection and monitoring of nonpapillary type 2 renal lesions provide the patient and physician with information on disease burden, tumor size, and doubling time. Because patients with hereditary conditions such as VHL are at high risk of developing multiple RCC over their lifetime, close surveillance provides necessary clinical information for timing surgical intervention and increases the likelihood that nephron-sparing approaches can be used.

When a deleterious mutation is identified, at-risk family members should be offered predictive genetic testing. Genetic counseling regarding the natural history of the condition, the risk of carrying the mutation, age-appropriate screening, and the limitations of genetic testing is essential. In the case of BHD, HPRCC, and HLRCC, there is no consensus for a minimum age at which genetic testing should be considered. Timing of testing of asymptomatic relatives may be guided by ages at onset within the family. Each first-degree relative of a mutation carrier has an empiric risk of 50%. A negative test effectively rules out the disease and spares the individual from unnecessary imaging and screening. A positive test prompts close monitoring, such as regular imaging of the kidneys with CT or magnetic resonance imaging. With respect to limitations, it is important for patients to understand that a positive test result does not predict which tumors they will develop over their lifetime, age at onset of tumors, or severity of their disease.

VHL disease represents an exception where genetic testing should be offered anytime after a child is born. When a child tests negative for the familial VHL mutation, he/she is spared unnecessary screening; a child who carries the mutation must begin annual retinal examinations within the first year of life, with additional imaging examinations of the abdomen and brain around the onset of puberty. Multiple cases of retinal hemangioblastomas (angioma) in young children have been reported, and the morbidity of undiagnosed retinal tumors is high. Similarly, childhood-onset pheochromocytoma is also known to be associated with VHL and hereditary paraganglioma/pheochromocytoma syndromes.

Predictive testing of minors in their teenage years should be treated with a greater sensitivity to the minor’s intellectual and emotional capacity. Some parents include their child on the decision to test, depending on the age and emotional maturity of their child. This helps maintain trust between the child and the parent, and lays a foundation for greater comprehension of the test result and the implications, whether the results are positive or negative. In the setting of genetic predisposition counseling, the concept of risk and the struggle to cope with risk information is a tenuous position for any adult patient. This is no less stressful for a teenager and his/her parents demanding elevated sensitivity and awareness from the provider and genetic counselor caring for the family.

Not including an older child in the testing decision is also the parents’ prerogative; however, the health-care provider or genetic counselor working with the family should help parents consider the potential ramifications of initiating testing without the child’s knowledge. Questions to consider include when and how they would disclose the results to their child in an age-appropriate way. When we consider a teenaged minor who is intellectually capable of giving assent for genetic testing, the process of obtaining the minor’s assent involves the health-care professional who, together with the parents, provides age-appropriate information about the genetic disease, what is involved in carrying out the test, and how results will be disclosed. Parents may wish to test their teenage minor without his/her knowledge primarily because they are hoping for a “good news” scenario of a negative test result where both the teen and the parents can be worry-free. When parents

request testing for their teenager without his/her knowledge, the provider should help parents anticipate that they may be putting their child's trust in them (and their child's trust in the medical community) at risk, particularly if it results in a positive diagnosis.

The role of the genetic counselor and health-care provider is to support the patient and family with a focus on improving their understanding of their disease and on helping the family find a common language with which to communicate their fears, concerns, and needs. Families often benefit from participating in multidisciplinary practices staffed by a combination of medical oncology, advanced practice nursing, genetic counseling, urology, and other practitioners.³⁶ These disease specialty clinics are geared toward meeting the medical and informational needs of the patient and family, which are expected to evolve with age and with major life transitions.

SUMMARY

The genetic basis of heritable susceptibility to cancers of the urinary tract is a complex problem composed of many different genes and molecular pathways. Careful inspection of family medical history, tumor histology, and physical findings such as cutaneous lesions provide the opportunity for a stepwise approach to genetic risk assessment of the patient with cancer. Genetic testing of cancer susceptibility genes has downstream implications for surveillance and treatment of disease, and identification of causative mutations provides valuable information for patients and their at-risk family members. Genetic counseling of patients and their family members allows for enhanced understanding of the disease and treatment.

67 Molecular Biology of Prostate Cancer

Felix Y. Feng, Arul M. Chinnaiyan, and Edwin M. Posadas

INTRODUCTION

Prostate cancer is the most common malignancy and the second leading cause of cancer death in men in the United States.¹ It also poses a global problem, with recent significant increases in incidence outside the Western world.² This malignancy is marked by extremely clinical and biological heterogeneity, which creates the opportunity for resistant clones to emerge, leading to eventual relapse and disease progression, and thus presenting problems for both patients and their physicians.

A major limitation in the management of this disease has been in the nomenclature used to describe the nature of each patient's underlying disease. The currently employed staging system and the histopathologic scores established by Gleason reflect neither our current understanding of prostate cancer biology, nor the implications of this biology for outcomes and management. There has remained a need to further refine the pathologic classification of prostate cancers to account for the various families of molecular aberrations that exist within this disease. It is hoped that this refinement of classification may allow for more precise or "personalized" management of prostatic adenocarcinomas.

Systemic therapy for this disease begins with the reduction of circulating testosterone levels by medical or surgical castration. In most cases, this results in clinical benefit. However, progression to castration-resistant prostate cancer (CRPC) eventually occurs. A number of effective CRPC therapies have recently emerged. Regrettably, none are curative and all have a limited benefit, as shown in clinical trials. Refining our understanding of the molecular nature of this disease will hopefully lead to better characterization and, ultimately, more effective assignment of treatments to improve outcomes for patients.

OVERVIEW OF THE GENOMIC LANDSCAPE OF PROSTATE CANCER

The advent of next-generation sequencing technology has significantly broadened our understanding of the genomic landscape of prostate cancer. Recent studies have characterized the complete prostate cancer genome from 75 patients and have reported on the exomes of hundreds of additional cases.³⁻⁷ In combination with gene expression and copy number data previously interrogated from thousands of tumors, these studies provide a relatively comprehensive profile of the prostate cancer genome and transcriptome. Like other epithelial tumors, prostate cancers harbor genomic lesions, such as amplifications and deletions; point mutations; and translocations, as well as transcriptional changes leading to overexpression of oncogenes and underexpression of tumor suppressor genes.

Subsets of tumors have been shown to harbor recurrent amplifications and deletions ranging from focal alternations (one to a few genes) to others that span entire chromosomal arms (Fig. 67.1). These alterations tend to increase in prevalence with higher grade and stage. The most common deletions occur on chromosomes 8p,

10q, and 13q, and include genes such as *NKX3-1*, *PTEN*, and *RB1*. Metastatic tumors harbor amplifications of chromosome X and 8q, which include the androgen receptor (*AR*) and *MYC* oncogenes (see Fig. 67.1). Although the prostate cancer genome exhibits an overall low mutation rate (~1 per MB), the landscape of prostate cancer can also be defined by copy number and mutational alterations along several key oncogenic and tumor suppressor pathways, which are commonly involved when the individual genes in each pathway are considered collectively. Three of these pathways—the *AR* pathway, the phosphatidylinositol 3-phosphate kinase (*PI3K*)/*AKT* pathway, and the retinoblastoma (*RB*) pathway—are altered in more than one-third of primary cancers and in the vast majority of metastatic lesions.³⁻⁷ Frequent alterations in these pathways suggest that, in prostate cancer, different individual genes in the pathway may be targeted to activate or suppress a common pathway lesion (Fig. 67.2).

In addition to pathway-based analyses, prostate cancer can be defined by recurrent lesions of single genes. Approximately 50% of prostate-specific antigen (PSA)-screened prostate cancers harbor gene fusions involving E26 transformation specific (*ETS*) transcription factors, which represent oncogenic drivers.^{8,9} Strikingly, *ETS* fusions and certain other lesions, such as mutation of the E3 ubiquitin ligase *SPOP* and fusions involving *RAF*, appear to be mutually exclusive, suggesting a framework for molecular subtyping of prostate cancer.^{5,10,11} The sections that follow further describe the altered pathways and recurrent genetic lesions most validated in prostate cancer.

ANDROGEN RECEPTOR BIOLOGY AND THERAPY

Introduction to the Androgen Receptor

AR has remained one of the most important and most studied proteins in prostate cancer. The dependence of most prostate cancers on *AR* activation has served as a basis for important therapeutic approaches, such as luteinizing hormone releasing hormone (*LHRH*) analogs, antiandrogens, and androgen biosynthesis inhibitors.

AR is a 110-kb steroid receptor transcription factor, located on Xq12.¹² Upon binding to an androgen, *AR* mediates the transcription of a number of genes involved in survival and differentiation of prostate epithelial cells, starting at development of the normal gland. Expression of *AR* is high in the luminal epithelial cells but lower in the basal epithelial cells that define glandular structure.¹³

In conjunction with *NKX3.1* and *FOXA1*, *AR* plays a critical role in normal prostate organogenesis and disease progression.¹⁴ *NKX3.1* is an *AR*-regulated prostatic tumor suppressor gene that is located on chromosome 8p and present through development.¹⁵ It is the earliest marker of organogenesis and is involved with ductal morphogenesis and secretory function.¹⁶ Mutations are infrequent in human cancers, but loss of heterozygosity in 8p becomes more frequent during cancer progression, with 86% loss in prostate cancers (see Fig. 67.1).¹⁷ Loss of *NKX3.1* has been associated with

Figure 67.1 Copy number alterations found in prostate cancer. Genomewide copy number profiles were plotted from four publicly available datasets including 545 prostate cancers, using the OncoPrint DNA Copy Number Browser (Life Technology). Each chromosome is color coded (see legend), and the locations of key genes harboring recurrent copy number gains/losses or mutations are labeled. The y axis indicates the sum of the log₂ copy number for each segmented sample, as plotted in genomic order.

activation of the TMPRSS2-ERG gene fusion, which promotes tumorigenesis.¹⁸ FOXA1 is a member of the forkhead transcription factor family that opens compacted chromatin to facilitate AR recruitment.¹⁹ It is known to play a pivotal role in AR and steroid receptor function.²⁰ It is now recognized that mutation and overexpression of FOXA1 can promote progression to CRPC (see Fig. 67.2).^{3,5}

Polymorphisms of AR as well as CYP17 and SRD5A2 are low penetrant risk factors for prostate cancer development in some but not all studies.²¹ AR-pathway alterations exist in 60% of primary tumors and nearly 100% of metastatic tumors. NCOA2 (also called SRC2) is the most commonly altered member of this pathway (see Fig. 67.2) and is an AR coactivator that potentiates transcriptional output. Several other AR coactivators, including NCOA1, TNK2, and EP300, are upregulated in metastatic disease, whereas AR corepressors, including NR1P1, NCOR1, and NCOR2, are downregulated (see Fig. 67.2).

Targeting Androgen Receptor Activity: GnRH-Targeting Therapies and Androgen Biosynthesis Inhibitors

The inhibition of androgen synthesis has been used as a means of suppressing AR activity. Gonadotropin-releasing hormone-luteinizing hormone (GnRH) agonists or antagonists represent the first-line approach for inhibiting androgen synthesis (Fig. 67.3). These therapies work by suppressing the hypothalamic–pituitary–gonadal axis by eventually causing luteinizing hormone (LH) levels to fall, thereby minimizing testicular production of testosterone and its subsequent conversion to dihydrotestosterone (DHT) by 5- α reduction. DHT is the most potent activator of AR and binds to the AR, resulting in translocation to the nucleus and activation of transcription (see Fig. 67.3).

These strategies, although initially highly effective, are often overcome during tumor progression. Alternative sources of DHT and alternative means of AR activity have been identified as mechanisms of resistance. GnRH-targeting agents have no impact on

nongonadal androgen synthesis (i.e., suppression of adrenocorticotropic hormone [ACTH] and, hence, adrenal androgen synthesis) (see Fig. 67.3). The adrenal glands can synthesize adequate levels of androgens to promote cancer growth. CYP17 is a key P450 enzyme in the androgen biosynthesis pathway that generates dehydroepiandrosterone (DHEA) and androstenedione in the adrenal glands. These weak androgens can be further converted into testosterone or alternative steroid substrates that are reduced to DHT.^{22,12} This step is recognized as a particular bottleneck in androgen production. The specific inhibition of CYP17 decreases androgen synthesis, with less effect on the production of other essential steroids. Abiraterone acetate is a pregnenolone derivative that is a high-affinity, irreversible inhibitor of CYP17, and results in decreased adrenal androgen synthesis. At higher doses, this agent inhibits other DHT synthetic pathways such as 3 β -hydroxysteroid dehydrogenase.²³

Intratumoral androgens may be increased in CRPC.²⁴ Measurements of intratumoral androgens showed that CRPC tumors have more testosterone than primary tumors in untreated men.²⁵ Expression profiling studies comparing CRPC with primary tumors have shown that androgen synthesis enzymes are upregulated in CRPC.^{26,27} Patient samples at all stages of disease contain an abundance of AKR1C3 and SRD5A1, which are necessary for the conversion of androstenedione to DHT. However, the samples lacked high expression of enzymes necessary for de novo steroidogenesis.²⁸ These data suggest that autocrine androgen synthesis may allow tumors to grow despite low serum androgen levels, but that this process may, in part, be dependent on adrenal precursors.

Targeting Androgen Receptor Activity: Antiandrogens

Antiandrogens compete with endogenous androgens for the ligand binding pocket of AR (see Fig. 67.3). Older agents promote translocation of AR from the cytoplasm into the nucleus and DNA binding, but induce conformational changes that prevent optimal transcriptional activity. In the United States, there have been

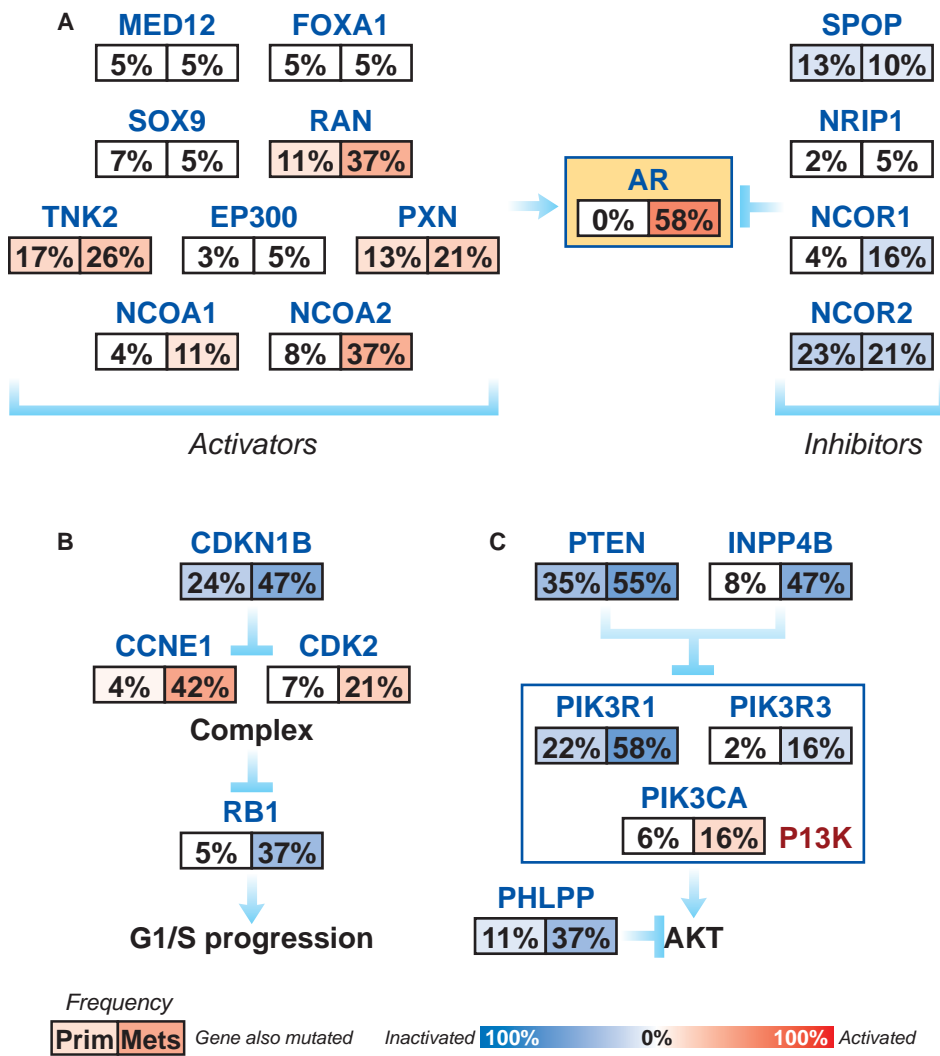

Figure 672 Alterations in common pathways dysregulated in prostate cancer. The androgen receptor (*AR*) (**A**), retinoblastoma (**B**), and phosphatidylinositol 3-kinase (*PI3K*) (**C**) pathways are altered in more than one-third of primary cancers and in the vast majority of metastatic lesions. This schematic depicts alteration frequencies for individual genes and for the entire pathway in primary and metastatic tumors. Alterations are defined as those having significant up- or downregulation compared with normal prostate samples, or by somatic mutations, and are interpreted as activation (red) or inactivation (blue) of protein function. (Figure adapted from the 9th edition of Devita, Hellman, and Rosenberg's *Cancer: Principles and Practice of Oncology*.)

three historic nonsteroidal antiandrogens (NSAA): flutamide, bicalutamide, and nilutamide. Each has been associated with an antiandrogen withdrawal effect, whereby treated patients experiencing disease progression on treatment derive clinical benefit when the antiandrogen is stopped.²⁹ Although this was initially believed to be related to AR mutation, later studies have shown this is due to AR activation by these NSAAs.^{30,31}

Newer NSAAs have now been developed that lack agonist effects on the AR. Enzalutamide (MDV3100) was approved by the U.S. Food and Drug Administration (FDA) in 2012.³² Other next-generation NSAAs are in development, including ARN-509.

Finally, new approaches are being taken to inhibit AR at the amino terminus.³³ As opposed to interrupting ligand binding, agents such as EPI-001 interfere with transcriptional activity of AR. These agents are still in early development, but appear very promising because they display activity even when the ligand-binding domain of AR has been altered.

Alterations in the Androgen Receptor During Prostate Cancer Progression

Prostate cancers eventually progress to a more lethal state: castration resistance. The time to development of resistance and the molecular pathways to CRPC differ from patient to patient. Progression of CRPC is usually accompanied by the restoration of PSA secretion, indicating a reactivation of AR activity in these cases.¹²

Gene amplification and increased protein expression represent the most common mechanisms of means of reactivating AR signaling in the face of castration therapy. These changes allow cancer cells to respond to subphysiologic concentrations of androgen.³⁴ AR mutations are detected in up to 10% of CRPC cases and allow for activation by alternative ligands.³⁵ Overexpression of AR is seen in approximately 30% of cases of CRPC.³⁶ Alternative splicing of AR mRNA can lead to a truncated protein missing the ligand-binding domain. These increase in number in the face of many second-line NSAAs.^{37,38} Some of these variants have constitutive transcriptional activity in the absence of androgens. Overexpression of these variants can confer castration resistance in preclinical models.³⁹ More recent studies show that these variants impact sensitivity to taxanes⁴⁰ and even next-generation antiandrogens such as enzalutamide.⁴¹

ADDITIONAL PATHWAYS FREQUENTLY ALTERED DURING DISEASE PROGRESSION

The Phosphatidylinositol 3-Phosphate Kinase (*PI3K*) Pathway

Progression to CRPC is characterized by gain of function in AR and activation of the phosphatidylinositol 3-phosphate kinase

Figure 67.3 The androgen-signaling axis and its inhibitors. Testicular androgen synthesis is regulated by the gonadotropin-releasing hormone-luteinizing hormone (GnRH-LH) axis. Pharmacologic inhibitors are labeled in *red* at respective steps. GnRH-driven activity can be inhibited by both GnRH agonists and antagonists, as well as estrogens. Adrenal androgen synthesis is regulated by the corticotrophin-releasing hormone (CRH)-adrenocorticotrophic hormone (ACTH) axis. CYP17 is a critical enzyme in androgen synthesis inhibited by abiraterone, orteronel, and galeterone. CYP17 inhibitors decrease synthesis of androgen from the adrenal glands, testes, and (in advanced disease) the tumors themselves. 5-Alpha reductase inhibitors prevent reduction of testosterone and other androgen intermediates to DHT. Antiandrogens such as enzalutamide and ARN-509 block activation of AR by inhibiting the binding of androgens to androgen receptors. DHEA-S, dehydroepiandrosterone sulfate; ARE, androgen-response element.

(PI3K) pathway. Cross-talk between these pathways has been proposed^{42,43} because a loss of *PTEN* and subsequent PI3K activation is associated with repression of androgen responsive genes. Conversely, AR inhibition results in the upregulation of PI3K activity.^{42,43} As such, combination therapy with PI3K and AR inhibition are currently being evaluated in clinical trials.

The PI3K signaling cascade is one of the most commonly altered pathways in human malignancy. *PTEN* is a tumor suppressor that deactivates PI3K signaling. *PTEN* deletions are present in nearly 30% of primary prostate cancers, and inactivating mutations of *PTEN* occur in another 5% to 10%; both are more common in advanced disease (see Fig 67.2).^{3,5,7,44,45} Functional studies across multiple preclinical model systems of prostate cancer consistently reinforce the role of *PTEN* in suppressing tumorigenesis and prostate cancer progression.^{46,47} Dysregulation of *PTEN* represents a poor prognostic factor. There is significant evidence that *PTEN* deletion is associated with higher stage, higher Gleason grade, and higher rates of progression, recurrence after therapy, and disease-specific mortality.^{48,49}

Amplification and point mutations in *PIK3CA*, encoding a catalytic subunit of PI3K, also result in overactivation of the pathway and are enriched in metastatic versus localized prostate cancer (see Fig 67.2).^{3,50} Activating *PIK3CA* lesions and inactivation of *PTEN* are usually mutually exclusive, supporting a similar endpoint in driving downstream signaling.

Recent studies have also identified the presence of rarer events that affect PI3K signaling. These lesions include the rearrangement of *MAGI2*, the deletion of *PHLPP1*, mutations in *GSK3B*, and point mutations and genomic deletions of *CDKN1B*.^{3,4,44,47,51} Recurrent alterations in multiple nodes along the PI3K pathway emphasize its critical importance in the pathogenesis of prostate cancer and support the rationale for therapies targeting this pathway.

The Retinoblastoma Pathway

Another tumor suppressor pathway that is frequently inactivated in epithelial malignancies is the RB pathway (see Fig. 67.2). The p130 RB protein regulates cell cycle progression by binding to E2F family members and repressing E2F-mediated gene transcription. RB is inactivated via phosphorylation by cyclin-dependent kinases (CDK), resulting in

E2F-mediated cell cycle progression.⁵² The absence of RB signaling results in aberrant cell cycle progression and tumor proliferation.

Similar to *PTEN* deletion, the loss of RB is enriched in prostate cancer metastases compared to primary disease (see Fig. 67.2).⁵³ Within preclinical prostate cancer models, the inactivation of RB confers castration-resistant tumor growth via E2F1-mediated activation of AR gene transcription.⁵³ RB status is currently being explored as a stratification variable for treatment strategies on ongoing clinical trials.

E26 TRANSFORMATION SPECIFIC (ETS) GENE FUSIONS AND THE MOLECULAR SUBTYPES OF PROSTATE CANCER

E26 Transformation Specific (ETS) Gene Fusions

In addition to pathway-based analyses, prostate cancer can be defined by recurrent lesions of single genes. The most common molecular abnormality in prostate cancer is a gene fusion involving an ETS transcription factor.^{8,9} These genetic rearrangements, found in approximately 50% of prostate cancers, occur when genes encoding an ETS transcription factor are translocated downstream of the regulatory, usually androgen-responsive, element of a second gene.^{8,9,54} These fusions result in AR-driven overexpression of an ETS transcription factor, causing transcriptional dysregulation of downstream oncogenic pathways, increased invasion, and carcinogenesis in preclinical models of prostate cancer.^{8,9,54,55} The most prevalent ETS gene rearrangement involves either chromosomal deletion or insertion of chromosome 21, resulting in fusion of the 5' untranslated region of the androgen-regulated gene *TMPRSS2* with the ETS family member *ERG*. Over 90% of ETS rearrangements involve *ERG*, whereas the remaining ETS fusions include *ETV1* (chromosome 7), *ETV5* (chromosome 3), or *ETV4* (chromosome 17) as common 3' partners (Fig. 67.4). Although *TMPRSS2* is the most common 5' partner for *ERG*, over 10 androgen-regulated genes, including *SLC45A3* and *NDRG1*, have been identified as 5' fusion partners in ETS rearrangements (see Fig. 67.4).

Several studies have investigated the prognostic value of ETS fusion status, with conflicting results likely stemming from the heterogeneity of study cohorts, screening practices, and management

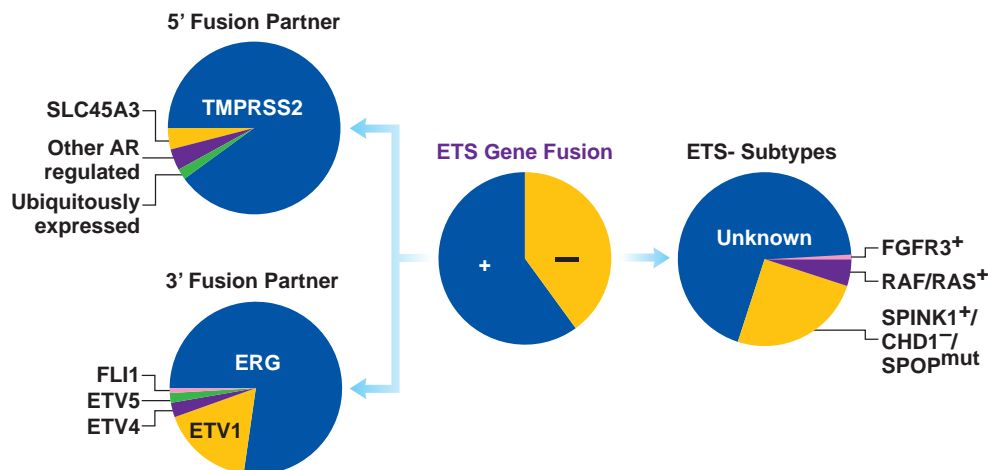

Figure 67.4 The molecular subtypes of prostate cancer subtypes. The approximate distribution of prostate cancer subtypes, as defined by driving molecular lesions, is presented for PSA-screened Caucasian populations. Approximately 50% to 60% of all prostate cancers harbor ETS gene fusions (*central pie chart*). ETS gene fusions are nearly mutually exclusive with other alterations, such as *FGFR3* fusions, *RAF* fusions, *SPOP* mutations, *CHD1* deletions, and *SPINK1* overexpression (*right pie chart*). The predominant 5' fusion partner in ETS fusions is the androgen-regulated promoter of the *TMPRSS2* gene (*top left pie chart*). The primary 3' fusion partner is *ERG*, though other genes encoding ETS transcription factors, such as *ETV1*, *ETV4*, *ETV5*, and *FLI1*, are involved at lower frequencies (*bottom left pie chart*).

strategies, as well as the variability in tumor sampling, disease multifocality, and measured clinical outcomes. In the context of non-PSA-screened populations managed conservatively, population-based studies have demonstrated a significant association between ETS fusion status and adverse clinicopathologic predictors, metastases, or disease-specific mortality.^{56,57,58} However, in the context of patients treated with radical prostatectomy, the prognostic impact of ETS fusions is uncertain, with some studies demonstrating an association between ETS fusion status and features of aggressive prostate cancer, and other studies finding no such associations. The largest report, a prospective cohort study involving over 1,100 patients treated with radical prostatectomy, found that ETS related gene (ERG) rearrangement or overexpression was associated with tumor stage, but not recurrence or mortality.⁵⁹ Overall, ETS fusions are associated with poorer prognosis in population-based studies of watchful waiting cohorts, but are of uncertain prognostic value in radical prostatectomy patients.

The Molecular Subtypes of Prostate Cancer

Although the prognostic value of ETS fusions remains unclear, the molecular characterization of prostate cancer often begins with the determination of ETS fusion status, by either fluorescence in situ hybridization or immunohistochemical approaches. Transcriptomic, genomic, and epigenetic profiling studies have demonstrated that ETS fusion-positive prostate cancers are biologically distinct from ETS fusion-negative disease.^{4,60} For example, certain lesions, such as deletions or mutations of the *PTEN* or *TP53* tumor suppressors, are significantly enriched in ETS-positive cancers.^{4,44,61} Strikingly, other alterations, such as *RAF* fusions, *SPOP* mutations, *CHD1* deletions, and *SPINK1* overexpression, occur exclusively in ETS-negative cancers,^{3,5,62} (Fig. 67.4) providing evidence that these alterations define distinct biologic subsets of prostate cancer and may provide a framework for defining molecular subtypes of prostate cancer.^{3,10,11} The potential subtypes are described in the following paragraphs.

Gene fusions and known activating mutations in *RAF* and *RAS* family members have also been identified in approximately 1% to 2% of all prostate cancers (see Fig. 67.4).^{3,5,11} *RAF* encodes for a serine/threonine-specific protein kinase, and *RAS* encodes for a GTPase. *RAF-RAS*⁺ tumors are exclusively negative for ETS fusions, *SPOP* mutations, *CHD1* deletions, and *SPINK1* overexpression. Both *RAF* and *RAS* serve as signaling intermediates in the mitogen activated protein kinase (MAPK) pathway, and activation of *RAF* and *RAS* may enhance the transcriptional activity of the androgen receptor.⁶³ Of note, activating events in the *RAF/RAS/MAPK* pathway may be targetable by existing kinase inhibitors.

SPOP mutations represent the most prevalent point mutations in localized prostate cancer, occurring at a frequency of 10% to 15%.^{3,4} *SPOP* codes for the substrate-recognition component of a Cullin3-based E3-ubiquitin ligase. Recurrent mutations are located exclusively within the region of *SPOP*, which forms the substrate-binding cleft, suggesting that they prevent substrate binding.^{3,64} Previous studies have suggested that *SPOP* substrates include AR and its coactivator SRC-3,^{65,66} and that *SPOP* mutations result in increased androgen signaling. *SPOP*-mutant prostate cancers have a distinct genomic profile; in addition to occurring only in ETS-negative cases, *SPOP* mutations are also mutually exclusive with *TP53* mutations/deletions, and generally lack PI3K pathway alterations. Additionally, *SPOP* mutations are significantly associated with deletions of the *CHD1* gene, which is a DNA binding protein that functions in remodeling chromatin states. Of note, cases with *CHD1* deletions are significantly enriched in the number of genomic rearrangements that they harbor, compared to other prostate cancers.^{67,68} Thus, *SPOP* mutations and *CHD1* deletions appear to define a distinct ETS fusion-negative subtype of prostate cancer.

SPINK1 is a secreted protease that is overexpressed in approximately 10% of prostate cancers.⁶² Although *SPINK1* overexpression is present in only ETS fusion-negative cases, *SPINK1* overexpression can co-occur with *SPOP* mutations and *CHD1* deletions, suggesting that multiple aberrations can define this subset of ETS-negative prostate cancer (see Fig. 67.4). *SPINK1* interacts with epidermal growth factor receptor (EGFR) to mediate its neoplastic effects, suggesting that *SPINK1*-positive prostate cancers may be targeted via EGFR inhibition.⁶⁹

Lastly, a recent study has identified a potential new subset of ETS-negative prostate cancers, defined by the presence of a fibroblast growth factor receptor (FGFR) fusion, in which the *FGFR2* gene is translocated downstream of an androgen-regulated promoter, resulting in androgen-driven overexpression of *FGFR2*.⁷⁰ Although these *FGFR* fusions are rare, they have, to date, not been found to co-occur with the other subtypes described previously. In total, results described previously suggest the presence of molecular subtypes of prostate cancer, several of which are mutually exclusive and represent biologically distinct diseases. As the biology underlying these subtypes is elucidated and as therapeutic approaches are further investigated for each subtype, the hope is that physicians will eventually be able to utilize a simple molecular barcode (i.e., *ETS/SPINK1/SPOP/CHD1/RAS-RAF/FGFR* status) to better personalize therapy.

EMERGING AREAS IN PROSTATE CANCER BIOLOGY AND THERAPY

Our growing understanding of prostate cancer biology has opened a variety of potential therapeutic venues (Fig. 67.5) These opportunities range from kinase inhibition to immunotherapy, which impact both the tumor and microenvironment.

Kinase Targeting in Castration-Resistant Prostate Cancer

Multiple kinase signaling pathways beyond those listed previously have been implicated in CRPC. Examples of these pathways and targets include mesenchymal epithelial transition factor (MET) and the Src-family kinases (SFKs). MET is a transmembrane receptor tyrosine kinase activated by hepatocyte growth factor that plays a crucial role in the development of the normal prostate as well as in the progression of cancer. Activation of MET has been associated with increased proliferation, survival, motility, invasiveness, and angiogenesis in several tumor models, as well as clinical aggressiveness.^{71,72} AR blockade also appears to promote the expression of MET.⁷³ These findings have led to a series of clinical studies exploring the utility of MET as a therapeutic target for CRPC with agents such as cabozantinib (see Fig. 67.5).

SFKs have also been implicated in the progression to CRPC. SRC, FYN, and Lck-Yes novel tyrosine kinase (LYN) have all been associated with prostate cancer progression.^{74,75} In particular, SRC has been implicated as playing a role in tumorigenesis,⁷⁶ whereas FYN and LYN have been implicated in the progression of metastatic and castration-resistant disease.^{74,77} Initial therapeutic trials with SFK inhibitors such as dasatinib have been difficult to interpret because the appropriate means of manipulating SFK biology in CRPC remain under investigation (see Fig. 67.5).

Targeting Chromatin Regulatory Pathways in Castration-Resistant Prostate Cancer

Recent studies have demonstrated that chromatin regulation and remodeling leads to disease progression across a wide range of human cancers. Overexpression of the Enhancer of Zest Homolog 2 (*EZH2*) gene, which encodes a histone methyltransferase,

Figure 67.5 The tumor microenvironment (TME) and agents targeting the tumor–TME interaction. The TME is a complex biome of interactions between the prostate cancer tumor cell and various environmental components, including cancer-associated fibroblasts (CAF) and mesenchymal stem cells (MSC) in the local prostatic stroma, as well as bone stromal cells and MSCs in the metastatic TME in areas such as bone. The TME also includes neovasculature and the immune microenvironment. Inhibitors are shown in red at respective sites of action. Events in the TME that promote metastasis include osteomimicry by cancer cells, transformation of normal fibroblasts to protumorigenic/prometastatic CAFs, and alternations of endothelial cell function allowing for vascular invasion and hematogenous dissemination of tumor cells. β -M, beta-2 microglobulin; DC, dendritic cells; EMT, epithelial-to-mesenchymal transition; NAF, normal fibroblast; RANKL, receptor-activated nuclear factor κ B (Ligand); Treg, T-regulatory cells.

is associated with aggressive and metastatic disease in prostate cancer.⁷⁸ Studies have shown that EZH2 may function via silencing gene expression, or alternatively, by activating AR and other transcription factors.^{79,80} EZH2 inhibitors are currently being developed as a potential therapeutic strategy for advanced prostate cancer.

Tumor Microenvironment

It has become increasingly clear that the tumor microenvironment (TME) plays a crucial role in disease initiation and progression.^{81–83} Reactive stroma, including fibroblasts, endothelial cells, osteoblasts, osteoclasts, and mesenchymal stem cells, have been associated with prostate cancer development and tumorigenesis (see Fig. 67.5).^{84,85} Studies of human prostate cancers have revealed a loss of transforming growth factor beta type receptor 2 (TGFβRII) in cancer-associated fibroblasts. In a murine model, stromal TGFβRII knockout alone results in the development of spontaneous prostate cancers.⁸⁶

The TME has become a target for newer therapies because host stromal cells do not exhibit the same high level of genetic instability as the tumor.⁸⁷ Considerable work has been done in the area of angiogenesis. A greater emphasis is now placed on stromal and mesenchymal cells and their influence on epithelial differentiation and even the prostate cancer cell of origin.^{88,89} As an example, osteoclast inhibition with bisphosphonates and receptor-activated nuclear factor κB (RANKL) inhibitors has been shown to yield clinical benefit. With the emergence of therapies active on the immune microenvironment, this field is continues to expand (see Fig. 67.5).

Immunotherapy

Unlike other forms of anticancer therapy, immune-based treatments have the capacity to adapt to changes in the tumor. This biological advantage bears particular importance given the emerging recognition of progressive temporal-spatial heterogeneity and chromoplexy in cancer.^{6,90} The dendritic cell–based therapy, sipuleucel-T, was the first successful demonstration of immunotherapy in prostate cancer. This relatively nontoxic treatment used prostate alkaline phosphatase as a primary target and provided a survival benefit for men with asymptomatic metastatic CRPC (mCRPC).⁹¹ A number of alternative immunotherapy strategies have gone into advanced development, such as the PSA-directed prime and boost vaccinia/fowlpox ProstateVax approach developed by the National Cancer Institute (NCI).⁹² This approach uses PSA as an antigen and employs three costimulatory molecule transgenes: *B7.1*, *ICAM-1*, and *LFA-3*. CTLA-4 and suppression of the PD-L1/PD-1

interaction have also been identified as potentially useful immune strategies in metastatic CRPC.^{93,94} Although these approaches have great appeal, there remains an absence of biomarkers to measure the degree of benefit that such therapies may provide.

Neuroendocrine Prostate Cancer

The use of more potent suppressors of AR activation has raised concerns over neuroendocrine prostate cancer. There is growing concern that AR suppression may foster the development of this particularly aggressive subtype of prostate cancer. The approach to these cancers has been hampered by a lack of consensus on nomenclature. The term *neuroendocrine* has been used to describe those cancers that are pure small-cell carcinomas to those clearly differentiated with biochemical features suggesting some level of neuroendocrine differentiation (e.g., expression of synaptophysin or chromogranin A).

Small-cell carcinoma composes only 0.5% to 2% of all primary tumors.⁹⁵ This is a pathologic diagnosis histologically marked by small round cells with no glandular architecture. Molecularly, this disease is characterized by the deletion of *RBI*,⁹⁶ increased *MET* and *RANKL* activation,⁹⁷ and amplification of *AURKA* and *MYCN*.⁹⁸ Non–small-cell neuroendocrine cancers are also clinically identified. The importance of these findings and their impact on therapeutic approaches remains an area where research is needed.

Noncoding RNAs

Recent data from the ENCODE sequencing consortium has suggested that, although up to 70% of the genome is transcribed into RNA, only 1.5% of the genome represents protein-coding genes.⁹⁹ Thus, the majority of the RNA in each cell represents *noncoding* RNAs. Of all the different noncoding RNA species, genes encoding long noncoding RNAs (lncRNAs) are most similar to protein-coding genes, based on common features, such as transcription by RNA polymerase II, polyadenylation, the presence of multiple exons, similar splicing patterns, and similar epigenetic signatures.¹⁰⁰ Recent sequencing efforts have resulted in the discovery of lncRNAs that are enriched in prostate cancer compared to normal tissue. These differentially expressed lncRNAs include prostate cancer associated transcript 1 (PCAT-1), which downregulates *BRCA2* to confer *BRCAness* and sensitivity to *PARP1* inhibitors in preclinical models of prostate cancer,¹⁰¹ as well as second chromosome locus associated with prostate 1 (*SChLAP1*), which promotes metastases by antagonizing the Switch/Sucrose NonFermentable (*SWI-SNF*) epigenetic complex.¹⁰² As RNA targeting strategies improve, it is likely that future biomarker and therapeutic strategies will begin to focus on these noncoding RNA elements.

68 Cancer of the Prostate

Howard I. Scher, Peter T. Scardino, and Michael J. Zelefsky

INTRODUCTION

The approach to prostate cancer diagnosis and treatment has changed dramatically across the spectrum of the illness. Recognizing the need to reduce overdiagnosis and overtreatment of clinically insignificant cancers, new diagnostic algorithms have become available to identify which men have a higher likelihood of having a clinically significant cancer and benefit from early detection and early treatment. New clinical and biologic biomarkers are being validated to determine, once localized prostate cancer is diagnosed, which tumors can be optimally treated using an active surveillance (AS) approach that closely monitors the cancer—based on the likelihood that the tumor will or has metastasized, putting the patient at risk for an impaired quality of life (QOL) and a shortened life expectancy. The techniques of surgery have evolved and more patients are being treated with robot-assisted approaches with the aims of reducing morbidity and shortening hospital stays without compromising cancer control. The ability to deliver higher doses of radiation safely has improved disease control rates without compromising long-term QOL. The past 4 years have also seen unparalleled progress in the treatment of castration-resistant metastatic tumors, as five agents with different mechanisms of action were proven to prolong life. At the same time that more patients and physicians recognize there are effective treatments for metastatic disease, these agents are also being tested earlier in minimal disease settings where they have the potential to provide even greater benefit.

In contrast to other tumor types, the paradigm of early detection leading to increased cure rates must be cautiously applied to prostate cancer. The widespread use of prostate-specific antigen (PSA)-based detection strategies has resulted, unfortunately, in increased treatment of clinically insignificant cancers, to the point where the morbidity and mortality associated with making a diagnosis and the therapy utilized to treat it can exceed that of the cancer itself. The high prevalence of prostate cancer in the general population, coupled with a natural history that can range from a few years to decades, mandates a different framework than that provided by the more traditional tumor, node, and metastasis (TNM) staging. There are also many prostate cancers from which a relapse after primary treatment does not require any intervention because the probability is low that the cancer will become metastatic, symptomatic, or lethal.

Many of these issues are addressed by describing the spectrum of the disease as a series of clinical states, ranging from pre-diagnosis to the lethal metastatic castration-resistant phenotype (Fig. 68.1).¹ Each state represents a milestone in the disease that is easily recognizable by patients and physicians, enabling them to define therapeutic objectives based on the manifestations present at a particular point in time or the likelihood that specific disease manifestations might occur in the future. The utility of specific diagnostic tests needed to maximally inform a treatment decision for a specific context of use at a particular point in time is considered analogously; in short, how the performance and the result of the test guide management. This chapter will refer throughout to this clinical states model.

INCIDENCE AND ETIOLOGY

Incidence and Mortality

In 2014, some 233,000 men in the United States are expected to be diagnosed with prostate cancer and 29,480 to die of the disease,² accounting for 14% of all new cancers in men and women³ and 11% of male cancer deaths.⁴ Over the past decade, men in the United States had a 15.4% chance of being diagnosed with prostate cancer and a 2.7% chance of dying of it.² Worldwide, there were an estimated 899,100 new cases and 258,100 deaths from prostate cancer in 2008.⁵ Histologic cancers, found in the prostate at autopsy in men who die of other causes, are even more common, and their age-adjusted frequency varies relatively little from country to country, about 2.4-fold.⁶ In contrast, the mortality rate from prostate cancer varies by 10.8-fold among different countries, suggesting different mechanisms of carcinogenesis and progression, and supporting the concept of distinct “indolent” and “aggressive” forms of the disease.^{6–8} There are significant age, ethnic, racial, geographic, and familial differences in incidence and mortality rates.⁹

Risk Factors

Age

Clinically detected prostate cancer is rare before age 40, but then the incidence increases with age faster than that of any other cancer, and continues to rise through the ninth decade of life. Histologic evidence of invasive cancer can be found in the prostates of men as early as the third decade of life, and its prevalence increases dramatically with age to reach 50% to 60% by age 90. As life expectancy increases throughout the world, morbidity and mortality from prostate cancer will impose increasing burdens in developing countries.⁵

Family History and Genetic Susceptibility

A family history of prostate cancer increases the risk that a man will develop the disease. The level of risk when a family member is affected is similar in breast and prostate cancers. Men with a first-degree relative with prostate cancer have a 2- to 3-fold increased risk, and those with two or more first-degree relatives affected have a 5- to 11-fold increased risk compared with the general population.¹⁰ Nevertheless, familial factors have been thought to play a role in only 11% of prostate cancers, although studies of twins suggest that inherited factors may be involved in as many as 42% of all cases.¹¹ While over 70 risk alleles (single nucleotide polymorphisms [SNP]) have been associated with prostate cancer in genome-wide association studies, few are associated with the risk of aggressive or lethal cancer. Many such SNPs are in genes that code for PSA or related kallikreins, blood levels of which are widely used for diagnosis.¹² For these SNPs, the increased risk is for a diagnosis of prostate cancer, not metastases or death from the disease. Several high-penetrance mutated genes have been identified, such

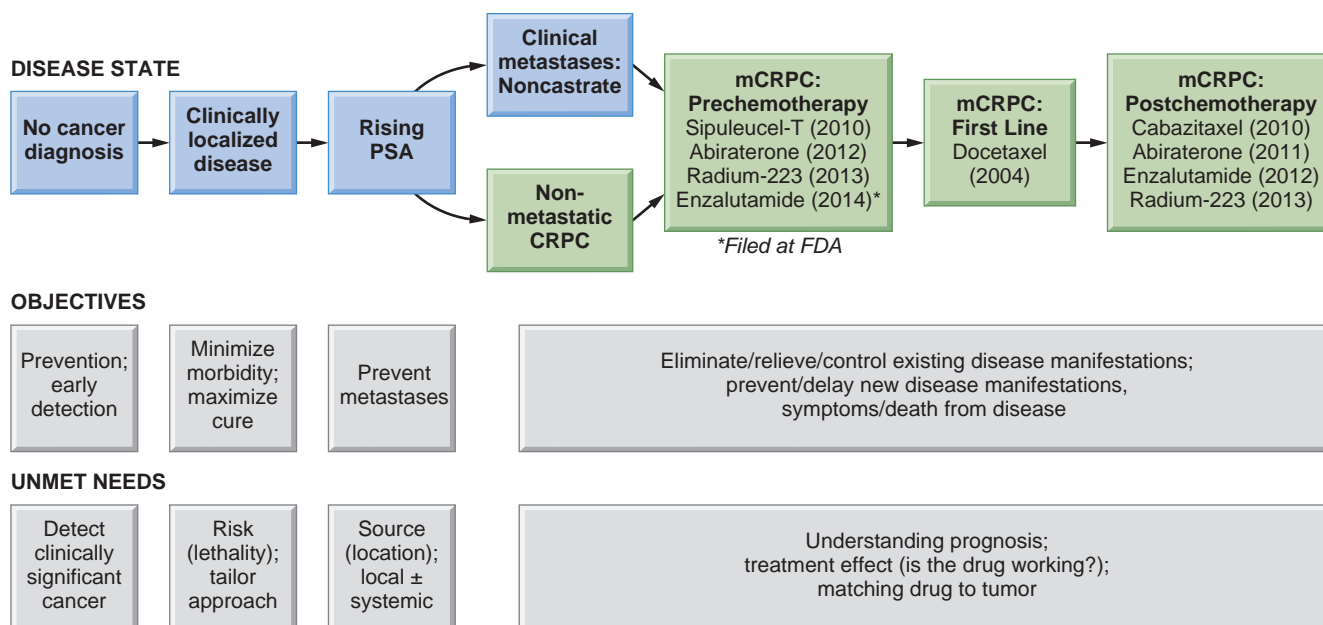

Figure 68.1 Clinical states model of prostate cancer progression. Green boxes indicate castration-resistant prostate cancer (CRPC) and blue indicate noncastrate disease. PSA, prostate-specific antigen; mCRPC, metastatic castration-resistant prostate cancer. (Modified from Scher HI, Heller G. Clinical states in prostate cancer: towards a dynamic model of disease progression. *Urology* 2000;55:323–327.)

as HOX13B, which are more common in patients with early-onset and familial disease, but this variant is rare (occurring in 0.1% of the population) and it is not associated with the lethal form of the disease.¹⁵ In contrast, men who carry BRCA2 mutations are more likely to develop early-onset prostate cancer, which is more likely to be aggressive and lethal.¹⁴

Race and Ethnicity

The incidence and frequency of diagnosed clinical cancers are similar in most Western countries, with the highest age-adjusted mortality rates in Scandinavia and significantly lower rates in non-Western countries. Both genetic susceptibility and exposure to causative environmental factors contribute to these variations.

Men of African ancestry in the United States and Caribbean have the highest incidence of prostate cancer in the world, with striking differences in incidence (1.8-fold) and mortality (2.4-fold) relative to American men of European descent. African American men are diagnosed at a younger age and have higher tumor burdens within each stage category,¹⁵ a two-fold higher frequency of metastatic disease at presentation,¹⁶ and lower survival rates.¹⁷ Incidence and mortality rates are significantly lower for Americans of Asian descent and somewhat lower for those of Hispanic descent.

Environmental factors also affect mortality risk.⁷ Asians who immigrate to the United States have a higher incidence of and mortality from the disease than in their countries of origin, which increases with each succeeding generation, but remains below the rates in men of African or European descent.¹⁸

Other Risk Factors

Diet, Supplements, and Lifestyle Factors. The increased incidence and mortality from prostate cancer evident in immigrants moving from low- to high-risk countries supports an important role for environmental in addition to genetic risk factors. Many epidemiologic studies support an association between high fat intake and breast, colon, and prostate cancer incidence and mortality.^{19,20} Adult obesity has been associated with aggressive prostate cancer, adverse outcomes after therapy, and increased mortality.^{11,21,22} The risk of death from prostate cancer has been reported to increase

15% to 20% for each 5 kg/m² increase in body mass index (BMI).²³ Among men diagnosed with prostate cancer, the risk of death from the disease is significantly associated with increased BMI (1.5-fold for overweight men and 2.7-fold for obese men).²⁴ Physical activity may reduce the risk of mortality from prostate cancer; the data are inconsistent for development of the disease, but convincing once the diagnosis has been established.²⁵ Smoking has not been shown to alter incidence rates, but it may be associated with the risk of prostate cancer death, especially when assessed in men after diagnosis.²⁵

Despite many indications that certain micronutrients, minerals, and vitamins have a protective effect on the development of prostate cancer or mortality from the disease, firm evidence is sparse. In the large Selenium and Vitamin E Cancer Prevention Trial (SELECT), vitamin E and selenium, alone or in combination, failed to reduce the incidence of prostate cancer. In fact, men who took vitamin E alone may have had a greater risk of the disease,²⁶ although there is some suggestion that aggressive, potentially lethal cancer may be reduced among smokers taking vitamin E supplements.²⁷ There is no evidence that ingestion of calcium or administration of vitamin D affects incidence or mortality from prostate cancer. Diets rich in tomato-based products, which contain high amounts of carotenoids and lycopene, may reduce the risk of advanced prostate cancer.^{28,29}

Alcohol use, blood group, body hair distribution, sexual activity, urban versus rural residence, and vasectomy do not affect risk.³⁰ There are no data supporting a viral origin of prostate cancer.³¹

Prevention

While the evidence is incomplete and there are no large intervention trials addressing the role of diet and exercise in preventing prostate cancer, it is reasonable to recommend a low-fat diet, regular exercise, and maintenance of a normal BMI as likely having a modest effect in reducing the risk of developing prostate cancer. More evidence suggests there may be some benefit for such lifestyle changes after the diagnosis of prostate cancer is established.^{11,21,22}

Finasteride, a competitive inhibitor of type II 5 α -reductase (5 α RI) that blocks the conversion of testosterone to dihydrotestosterone (DHT) within prostatic cells, is a safe and effective drug

that reduces the size of the prostate and relieves voiding symptoms in men with benign prostatic hyperplasia (BPH). Hence, it was logical to test the hypothesis that finasteride, or other 5 α RI, could prevent prostate cancer. The Prostate Cancer Prevention Trial (PCPT) randomly assigned 18,882 men, age 55 years or older, who had a normal digital rectal examination (DRE) and PSA, to receive finasteride or placebo over a 7-year period.³² Finasteride reduced by 25% the risk of detecting prostate cancer on biopsy (either end-of-study biopsy or one ordered during study “for cause”). Toxicity was low, but there were more high-grade cancers (Gleason score ≥ 7) in the finasteride group.³³ Many subsequent analyses strongly suggested that the small increase in high-grade cancers was probably a detection artifact resulting from the 20% shrinkage of the prostate by the drug,³⁴ and there were no differences in long-term survival in either arm.³⁵

In a separate randomized trial (REDUCE), the dual 5 α RI dutasteride also reduced the detection rate of cancer by 23%.³⁶ However, the US Food and Drug Administration (FDA) conducted an extensive review of the data from the PCPT trial and a reanalysis of the biopsy specimens from the REDUCE trial after Gleason grades were reassigned using contemporary criteria.³⁷ The FDA reviewers agreed that while both 5 α RI reduced the risk of a prostate cancer diagnosis, the effect was seen only among low-grade cancers (Gleason score ≤ 6), and there was a small (0.5%) but significant absolute increase in the risk of the highest-grade cancers (Gleason score 8 to 10). The FDA concluded that the tradeoff for using a 5 α RI in healthy, asymptomatic men would be the occurrence of one additional high-grade cancer for every three or four low-grade cancers (of uncertain clinical potential) prevented, and recommended against the approval of these drugs for chemoprevention of prostate cancer.³⁴

Other agents, such as statins, metformin, and resveratrol, may have protective effects,³⁸ but to demonstrate their benefit will require studies focusing on populations at high risk of developing clinically significant cancers.³⁸ PSA levels at midlife hold great promise for identifying men most likely to benefit from aggressive prevention strategies (see “Prostate-Specific Antigen: A Powerful Tool For Risk Stratification”).

ANATOMY AND PATHOLOGY

The prostate is an exocrine organ weighing 20 g to 25 g, which consists of lobular tubuloalveolar glands that secrete fluid through ducts that empty into the prostatic urethra. The fluid comprises

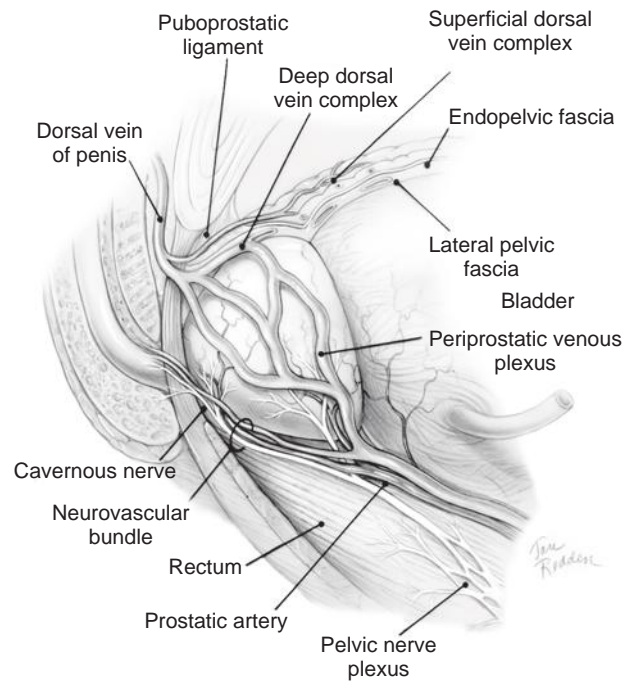

Figure 68.2 Lateral view of normal anatomy of the pelvis. (Redrawn from Ohori M, Scardino PT. Localized prostate cancer. *Curr Probl Surg* 2002;39: 833–957.)

the bulk of seminal emissions and is rich in PSA. The prostate is located deep in the pelvis between the bladder and the external urinary sphincter, anterior to the rectum and below the pubis (Fig. 68.2).³⁹ The cavernous nerves, which control blood flow to the penis and hence erectile function, run from the pelvic plexus lateral to the rectum along the posterolateral prostate and external urinary sphincter to enter the corpora cavernosa. Because the prostate is located at this critical anatomic juncture, cancers of the prostate and the treatment of these cancers place urinary, sexual, and bowel function at risk.

The prostate has three anatomic zones and an anterior fibromuscular stroma (Fig. 68.3). The central zone surrounds the ejaculatory

Figure 68.3 Zonal anatomy of the prostate.

(A) Young male with minimal transition zone hypertrophy. Note that preprostatic sphincter and periejaculatory duct zone (central zone of McLean) are clearly defined. (B) Older male with transition zone hypertrophy, which effaces the preprostatic sphincter and compresses the periejaculatory duct zone. SV, seminal vesicle; CZ, central zone; PZ, peripheral zone; TZ, transition zone; AFS, anterior fibromuscular stroma. (From McLaughlin PW, Troyer S, Berri S, et al. Functional anatomy of the prostate: implications for treatment planning. *Int J Radiat Oncol Biol Phys* 2005;63:479, with permission.)

ducts, the transition zone surrounds the urethra, and the peripheral zone makes up the bulk of the normal gland. The posterior peripheral zone lies against the rectum and is the area that is palpable by DRE. These zonal boundaries are indistinct in the prostate of a normal postpubescent male, but as men age the transition zone enlarges from nonmalignant growth (BPH). The frequency of malignancy in the different zones is disproportionate to the glandular tissue present. Very few cancers originate in the central zone, and only 15% originate in the transition zone; most originate in the peripheral zone.

Patterns of Spread

Localized prostate cancer is typically multifocal, in 85% of patients. Most cancers arise near the capsule in the peripheral zone; the surrounding capsule is invaded early and frequently, in up to 80% of cancers detected clinically. Local extension occurs through the capsule (termed “focal” or “established” extracapsular extension [ECE], depending on extent, when observed in a radical prostatectomy [RP] specimen), but may also extend through defects in the capsule where the neurovascular structures and ejaculatory ducts enter the gland, or in the region of the bladder neck. Local invasion can progress to involve the seminal vesicles or the bladder, or to invade the levator muscles. Rarely does tumor invade through Denonvilliers’ fascia to reach the rectal wall. Lymphatic dissemination can involve the hypogastric, obturator, external iliac, presacral, common iliac, or retroperitoneal nodes, with no consistent sentinel landing zone. Hematogenous spread most commonly involves the bones of the axial skeleton and, less commonly, the lung, liver, and other soft tissue organs. The predilection for bone seems to result from a unique bidirectional interaction between tumor cells and the marrow stroma.

Histopathology

Two main growth-related diseases develop in the prostate: BPH, which affects both the epithelial and mesenchymal components, and cancer.⁴⁰ There is no direct etiologic relationship between BPH and cancer; they are related only by their close anatomic site of origin and high incidence in men over 40 years of age. More than 95%

of malignant tumors of the prostate are adenocarcinomas that arise in acinar and proximal ductal epithelium. Grossly, carcinoma appears as pale yellow or gray flecks of tissue coalesced into a firm, poorly defined mass that is difficult to distinguish from surrounding normal tissue. Adenocarcinomas are often multifocal, heterogeneous, and follow a papillary, cribriform, comedo, or acinar pattern. Immunohistochemistry may assist the diagnosis when atypical areas, suspicious for carcinoma, are present in a biopsy sample, particularly in the differentiation of high-grade prostatic intraepithelial neoplasia (PIN) and atypical adenomatous hyperplasias from low-grade carcinoma. A hallmark of prostate cancer is the loss of basal cells, highlighted by negative staining for basal cell markers (high molecular weight/basal-specific cytokeratin) and p63, and positive staining for alpha-methyl-CoA racemase, which is upregulated in cancer.⁴¹

Pathogenesis

Prostate cancers develop from the accumulation of genetic alterations that result in an increase in cell proliferation relative to cell death, arrest differentiation, and confer the ability to invade, metastasize, and proliferate in a distant site. Histologic changes can be found in the prostates of men in their 20s, yet the diagnosis is typically made three to four decades later, which suggests that the development of the disease is a multistep process resulting from a variety of genetic and epigenetic alterations.⁴² The accumulation of changes acting synergistically seems to be more critical than the order in which the alterations occur. Identifying and understanding the events has implications for control of the disease at the earliest stages of transformation, for progression to an invasive tumor, for prognostication, and for points of therapeutic attack. Men who are castrated or who become hypopituitary before the age of 40 rarely develop prostate cancer.⁴³ The evolution of the tumor is heavily influenced by hormonal factors; it is also influenced by environmental, infectious/inflammatory factors, and given the long history once the diagnosis is established, the response to specific treatments.

Premalignant Lesions

The phenotypic alterations that occur during prostate carcinogenesis and progression are shown in Figure 68.4. The earliest precursor lesion is the subject of debate, as is the cell type that

Figure 68.4 Proliferative inflammatory atrophy is hypothesized to be a precursor to prostatic intraepithelial neoplasia, which in turn is the precursor of prostate cancer. (From Nelson WG, De Marzo AM, Isaacs WB. Prostate cancer. *N Engl J Med* 2003;349:366, with permission.)

is actually transformed. Recognizable changes begin with proliferation of cells within glands, termed PIN, often found adjacent to areas of proliferative inflammatory atrophy.⁴⁴ PIN is defined by the presence of cytologically atypical or dysplastic epithelial cells within architecturally benign-appearing acini, and is subdivided into low- and high-grade. Only high-grade PIN is considered a precursor for some invasive carcinomas.^{45,46} Because high-grade PIN develops preferentially in the peripheral zone where most cancers originate, it precedes the development of cancer by 10 years or more,⁴⁷ and prostates with extensive high-grade PIN tend to have multifocal tumors. With subsequent loss of the basal cell layer surrounding prostatic glands and the development of anaplastic cellular morphology with nuclear pleomorphism and prominent nuclei, the tumor invades the basement membrane, spreads locally, and begins to metastasize. Not all lesions progress to invasive prostatic cancer during the lifetime of the host. Foci of small atypical acini that display some but not all features diagnostic of adenocarcinoma are referred to as atypical small acinar proliferation, a significant predictor of invasive cancer on subsequent prostate biopsy.^{48,49} Atypical adenomatous hyperplasia, on the other hand, is not considered a malignant precursor lesion.

Gleason Grade

For adenocarcinomas, the degree of differentiation has prognostic significance and pathologists judge biopsy specimens using the Gleason grading system, which assesses the architectural details of malignant glands under low to medium magnification.^{50–52} Cytologic features under high magnification are not considered.^{53,54} Five distinct patterns of growth from well- to poorly differentiated were originally described by Gleason using a scale from 1 to 5 (Fig. 68.5). Pattern 1 tumors were considered the most differentiated with discrete glandular formation, while pattern 5 lesions were the most undifferentiated with strands of disorganized, free-floating cells and complete loss of the glandular architecture. Prostate cancers tend to be heterogeneous, with two or three patterns occurring within a typical prostate. So the final Gleason score is the sum of the grades of the primary (largest) and secondary patterns, ranging from 2 (1 + 1) to 10 (5 + 5).

The prognostic importance of Gleason's scoring system has been difficult to improve on, but the system has been modified several times, most recently by a consensus of expert pathologists, to reflect current data and best practices.^{55,56} In biopsy specimens, patterns 1 and 2 are almost never recognized, so Gleason 3 + 3 = 6 cancers are the earliest, most well-differentiated tumors currently reported by pathologists. Careful reassessment of the histologic criteria for assigning Gleason pattern 3 has resulted in reclassification

of many grade 3 cancers as grade 4, and some grade 4 variants are now considered grade 3. As a result, there has been "grade inflation" over the last decade, and the prognosis for both Gleason 3 + 3/well-differentiated cancers and for 3 + 4/moderately differentiated cancers is better than in historical series.

If three Gleason patterns are seen within a single biopsy, the accepted approach is to designate the largest area as the primary grade and the highest grade as the secondary grade to arrive at a score. So a biopsy with a large area of pattern 3, a smaller area of pattern 4, and an even smaller area of pattern 5 would be designated 3 + 5 = 8. Multiple cores are typically taken during each biopsy session, and the Gleason score assigned to the patient is the score of the highest single core. In contemporary biopsy series, 25% to 50% of tumors are low-grade (Gleason 3 + 3 = 6 or less), 40% to 70% are intermediate grade (Gleason 3 + 4 or 4 + 3 = 7), and 5% to 10% are high grade (Gleason 8 to 10).⁵⁵

The Gleason grading system is also used to assign grade in RP specimens, with some modifications. When the pathologist inspects all areas of cancer within the prostate, it is not unusual to identify more than two Gleason patterns.⁵⁷ The original system ignored patterns that represented <5% of the cancer, but the presence of a small amount of high-grade tumor has subsequently been shown to worsen prognosis. The current recommendation is to report a tertiary grade (i.e., 3 + 4 = 7 with tertiary 5).⁴⁰ Transition zone cancers tend to have lower Gleason grades than peripheral zone cancers of comparable size, and they are less likely to extend to the seminal vesicles or lymph nodes (LN).⁵⁸ Despite its apparent complexity, the Gleason grading system has proven reliable and reproducible, it is strongly associated with prognosis, and it is accepted worldwide.

Other Histologic Types

Although other tumors and histologic variants of adenocarcinoma rarely develop within the prostate, the most notable include ductal carcinomas (now considered a variant of poorly differentiated adenocarcinoma), small cell or neuroendocrine tumors, and transitional cell carcinomas. Pure ductal carcinomas comprise <1% of prostate cancers, but ductal elements are present in ~5%. These tumors are biologically similar to high-grade prostate adenocarcinomas, are clinically aggressive, and are associated with lower PSA levels than comparable adenocarcinomas.⁵⁹ Small cell or neuroendocrine tumors of the prostate typically comprise small, round, undifferentiated cells.⁶⁰ Distinguishing these tumors from lymphomas or round cell sarcomas can be difficult without immunohistochemical analysis.⁴⁰ Neuroendocrine cells can be found in almost all adenocarcinomas, but they do not affect the biology of the tumor unless they are a large component, in which case the tumors tend to metastasize early and have a poor prognosis. The presence of neuroendocrine cells may raise serum levels of neuroendocrine markers such as chromogranin-A, and the tumors should be treated with immediate chemotherapy as well as androgen ablation (androgen deprivation therapy [ADT]). Transitional cell carcinoma of the prostate is most frequently associated with and may be an extension of bladder cancer. When found in isolation, as a primary tumor on prostate biopsy without an associated bladder cancer, transitional cell carcinoma may be confined to periurethral ducts, but often invades stroma. Treatment may require cystoprostatectomy. Malignant mesenchymal tumors make up <0.3% of prostatic neoplasms, of which rhabdomyosarcomas are most common in younger patients and leiomyosarcomas in older patients. Carcinosarcomas are defined by the coexistence of adenocarcinomas of the epithelial cells, along with malignant mesenchymal elements that have differentiated into identifiable chondrosarcoma, osteosarcoma, myosarcoma, liposarcoma, or angiosarcoma.⁶¹ These tumors may be found in previously irradiated patients and are highly resistant to therapy. Metastatic tumors to the prostate include lymphomas, leukemias, adenocarcinomas of the lung, melanoma, seminoma, and malignant rhabdoid tumors, whereas tumors of the bladder and colon may sometimes involve the gland by direct extension.

Gleason Pattern

SCREENING

Screening and Early Detection

The clinical states model (see Fig. 68.1) can also be applied to men without a cancer diagnosis by considering an individual's need for screening or other diagnostic tests designed to detect cancer on the likelihood that he already has or will develop a clinically significant prostate cancer. Operationally, a "clinically significant" cancer can be defined as one that, left untreated, would lead to symptoms, metastases, or a premature death from cancer—but for each individual, these risks must be balanced against his competing risks of noncancer-related morbidity and mortality, and the risk of suffering harm from overtreatment or unnecessary treatment.

PSA level and DRE are commonly used for screening and early detection, although both are limited by low specificity: only one-quarter of men with an abnormal DRE or a PSA level >3 ng/ml are found to have cancer on biopsy.^{62,63}

Prostate-Specific Antigen: A Powerful Tool for Risk Stratification

PSA is a 28 kDa protein of the kallikrein family, a group of serine proteases whose genes are found on chromosome 19q13. PSA is abundant in seminal fluid, at concentrations up to 3 mg/ml, a million times higher than in serum.⁶⁴ The enzymatic activity of PSA induces liquefaction of seminal fluid and the release of mobile spermatozoa. PSA is synthesized in the ductal and acinar epithelium and is secreted into the lumina of the prostate gland. PSA is organ-specific but not cancer-specific; normal prostatic tissue (and BPH) produces more PSA per gram than cancer, and well-differentiated cancer produces more PSA than poorly differentiated cancer.⁶⁵ Under pathologic conditions, PSA is thought to reach the circulation through the disrupted epithelial basement membranes. Circulating levels of PSA are inherently variable, fluctuating spontaneously by 15% from year to year.⁶⁶ When cancer is present, each gram of tumor raises the serum PSA level above background by approximately 3 ng/ml, whereas each gram of BPH contributes an average of only 0.3 ng/ml. Thus, there is considerable overlap in values between patients with cancer and those with benign conditions such as BPH and prostatitis. Acute urinary retention, urethral catheterization, urinary tract infection, and prostatic manipulation by needle biopsy, or transurethral resection of the prostate (TURP) may raise serum PSA levels dramatically. Performance of DRE does not.

A commonly used threshold for a normal PSA level in adult men is 4.0 ng/ml. But there is no "normal" level; the risk of cancer rises directly with PSA levels as a continuum.⁶⁷ PSA levels in healthy men vary with age. The population median PSA at age 45 to 50 is 0.6 ng/ml (interquartile range, 0.4 to 1.0), at age 60 the median is 1.1 (interquartile range, 0.6 to 2.0), and at age 70, 1.6 (interquartile range, 0.9 to 2.6).^{68–70}

PSA levels at midlife predict with remarkable accuracy the risk that a man will develop advanced prostate cancer or die of the disease.^{68,70,71} For example, in the Malmö Preventive Medicine cohort of 60-year-old men followed to age 85, stored blood samples from 1981 were retrieved and analyzed for PSA. Ninety percent of deaths from prostate cancer were in men in the top quartile of PSA levels (>2 ng/ml). In contrast, the risk of death from prostate cancer was only 0.2% by age 85 for those with a PSA below median (<1.1 ng/ml) at age 60.⁷⁰ PSA levels in men as young as 44 to 50 years were also prognostic, with 81% of advanced cancers diagnosed within 30 years occurring in men with PSA levels above the median (0.65 ng/ml).⁶⁸

In fact, PSA levels at midlife are more informative than family history or ethnicity (Table 68.1), and can be used to stratify the intensity of screening over the next two to three decades of life, an approach that could substantially reduce false-positive test results without delaying detection of potentially lethal cancers.^{17,72}

TABLE 68.1

Proportion of Prostate Cancer Deaths in Men Defined as at High Risk by Family History, Race, or Prostate-Specific Antigen in Middle Age

Risk Factor (scenario)	% High Risk/ % Death	Risk Group Size/ No. Risk Group Deaths
Prostate-specific antigen	10/44	4.4
Family history	10/14	1.4
African American	12.6/28	2.2

Prostate-Specific Antigen for Screening

Although PSA has proved to be a valuable test for early detection, prognosis, and monitoring the response to therapy, its use for population-based screening for prostate cancer remains controversial. The widespread adoption of PSA testing in the United States shifted the stage at diagnosis away from metastases in 20% of patients in the 1980s to 5% in the 1990s, with a corresponding increase in frequency of early-stage cancers that are potentially curable with surgery or radiation. Over the last two decades, the age-adjusted mortality rate for prostate cancer in the United States has declined by 42% from its peak in 1992, a more rapid decline than in any other country.² In the largest randomized trials, PSA screening reduced the risk of dying from prostate cancer by 21% to 44% (29% to 56% among men actually screened).^{71,73} With long-term follow-up, the number needed to screen to prevent one prostate cancer death declined from 1,410 at 9 years to 293 at 14 years, and is estimated in models to be 98 over the lifetimes of men screened at ages 55 to 69.^{63,71,74} The number of men who need to be diagnosed or treated (40% were managed expectantly on AS) was estimated to be 48 at 9 years, but falls to 12 at 14 years and 5 over the lifetime of men screened.^{63,71,74} These numbers compare favorably with other screening programs. With mammography screening from age 50 to 70, 111 to 235 women need to be screened and 10 to 14 diagnosed to avert one death from breast cancer.^{75–77} For colorectal cancer screening, 850 need to be screened with flexible sigmoidoscopy to prevent one colorectal cancer death.⁷⁸

Nevertheless, PSA has low specificity: three of four men who have a biopsy for a PSA >3 ng/ml are not found to have cancer,⁶³ and 10% to 56% of those in whom cancer is found would probably have lived out their lives with no symptoms from the disease, and are therefore considered "overdetected."⁷⁹ An additional consideration is that the prostate biopsy itself carries a risk of bleeding and infection in 3% to 4% of those undergoing the procedure, which increases with the number of cores obtained. In cases where "saturation" biopsies are performed, in which upwards of 24 to 30 cores are sampled in the same session, the risk is higher and mortalities have resulted. Most cancers detected have been treated immediately with radical surgery or radiation,⁸⁰ with substantial risk of adverse effects on bowel, urinary, and sexual function.

In screening large populations, the lack of specificity of PSA leads to overdiagnosis, the discovery of incidental, clinically insignificant cancers that pose little or no immediate threat to life or health,⁸¹ which often leads to overtreatment with accompanying morbidities that may be permanent and compromise QOL. With rare exceptions, low-risk cancers managed expectantly, as well as intermediate-risk cancers in older men, have a good prognosis when carefully observed on an "AS" protocol, rather than proceeding to immediate treatment.^{82–86} AS is treatment that is designed

to detect changes in the cancer that indicate it has become more aggressive and therefore requires more definitive intervention(s).

But most men with low-risk prostate cancer are treated, especially in the United States,⁸⁰ with all the attendant risks of bothersome side effects and altered QOL. These findings led the US Preventive Services Task Force (USPSTF) to conclude that “there is moderate or high certainty that this service has no net benefit or that the harms outweigh the benefits” (grade D recommendation).⁸⁷ Rather than screening all men or no men, a risk-adapted approach is clearly preferable (see “Clinical States Model”).

Screening Trials

Two large, prospective randomized trials of screening for prostate cancer have been published, with conflicting results.^{79,88} Both studies were recently updated.^{89,90} The European Randomized Study of Screening for Prostate Cancer (ERSPC) compared screening with PSA every 2 to 4 years to no screening in a core group of 162,243 men age 55 to 69 years in seven European countries. At a median of 9 years, prostate cancer was diagnosed more often in the screened (8.2%) than in the control (4.8%) group (relative risk [RR] = 1.63), while the risk of dying of prostate cancer was reduced by 20% (RR = 0.80; $p = 0.04$). The number of men needed to be screened to prevent one death from prostate cancer was 1,410 (1,068 among those actually screened), comparable to the data for breast cancer and colorectal cancer screening.⁷⁵⁻⁷⁸ However, the number needed to diagnose to prevent one death

was high, 48, probably because the full impact of prostate cancer on mortality was not manifest within 9 years, and because some of the cancers detected were indolent. With further follow-up, the reduction in prostate cancer mortality at a median of 11 years was 21% in the screening arm ($p < 0.0001$), and 29% among those actually screened. The number needed to be screened fell to 1,055 and the number needed to diagnose to 37.

The Göteborg randomized population-based prostate cancer screening trial was planned and initiated independently of the ERSPC in 1995, although the investigators subsequently agreed to include a subset of participants in the ERSPC. In Göteborg, 20,000 men ages 50 to 64 were randomly assigned to be screened with PSA every 2 years up to age 69, or to a control group with no screening. After a median of 14 years, cancer was detected in 12.7% of the screened group and 8.2% of the controls (RR = 1.64), and the risk of death from prostate cancer was reduced by 44% (RR = 0.56; $p < 0.002$) in the screening group (56% among the 76% who were actually screened at least once, RR = 0.44) (Fig. 68.6). At 14 years, the number needed to be screened fell to 293, while the number needed to diagnose to prevent one death from prostate cancer was only 12. (Forty percent of the men diagnosed with cancer were monitored expectantly and not treated.)⁷³

In contrast, screening with PSA and DRE in a US cohort did not reduce mortality from prostate cancer.^{88,89} The Prostate, Lung, Colorectal and Ovarian Cancer (PLCO) Screening Trial enrolled 76,685 men ages 55 to 74 in a prospective randomized trial from 1993–2001, comparing annual PSA for 6 years and DRE for 4 years

Figure 68.6 (A) Cumulative incidence of prostate cancer in the screening group and in the control group. **(B)** Cumulative risk of death from prostate cancer using Nelson-Aalen cumulative hazard estimates. (From Hugosson J, Carlsson S, Aus G, et al. Mortality results from the Goteborg randomised population-based prostate-cancer screening trial. *Lancet Oncol* 2010;11:725–732, with permission.)

with opportunistic screening. At the most recent (13-year) follow-up, the cancer detection rate was slightly higher (RR = 1.12) in the screened arm, but there was no difference in the risk of dying of prostate cancer.

The difference in outcomes of the US and European trials largely stems from the very different contexts in which the trials were conducted. The American trial was initiated in the 1990s, when PSA screening had already become widespread in the United States. In fact, 44% of the PLCO study subjects had had at least one PSA test before randomization, which would have excluded many men with potentially lethal cancers. The mortality rate from prostate cancer in both arms of the PLCO trial (1.7 and 2 per 10,000 person-years in the control and screened arms) was much lower than in the ERSPC (3.9 and 3.2, respectively), suggesting a heavily prescreened population. Many men (45% to 85%) in the PLCO control arm had at least one PSA test after randomization, compared with <20% in the ERSPC control arm, further diluting the potential for a difference between the arms.

Screening Recommendations

The USPSTF's recent recommendation against screening^{87,91} has been understandably criticized as based on a one-time analysis of a rapidly changing field.⁹² The USPSTF justifiably raised concerns about the high level of overdiagnosis and overtreatment inherent in PSA screening, which can lead to the immediate risks of harm from invasive prostate biopsies and subsequent radical therapy when cancer is found. But the potential harms from PSA screening can be greatly reduced by risk-adjusting screening so that it focuses on men at high risk of otherwise dying of prostate cancer; incorporating into screening newer, more specific biomarkers; and avoiding radical treatment of low-risk cancers.⁹³ In a recently published computer simulation model of PSA screening, prostate cancer mortality was reduced by 28% over the lifetime of men screened annually from ages 55 to 69. Over the lifetime of this population of 1,000 men, only 98 men would need to be screened and five cancers detected (three treated and two managed expectantly) to prevent one death from prostate cancer.⁹⁴

In response to the changes in the USPSTF recommendations, a number of professional organizations have revised their guidelines for prostate cancer screening. The American Society of Clinical Oncology recommends that men with a life expectancy >10 years have a discussion with their physician about whether screening for prostate cancer is appropriate, including a clear statement that screening may save lives but is associated with harms, including complications from unnecessary biopsies, surgery, or radiation treatments. Men with a shorter life expectancy should not be screened.⁹⁵ The American Urological Association recommends that men ages 55 to 69 years engage in shared decision making with their physicians and proceed based on each man's values and preferences. For men younger than 55 years at higher risk (e.g., African American men, or those with a positive family history), the decision about screening should be individualized.⁹⁶

The American Cancer Society recommends that men have an opportunity to make an informed decision with their health-care providers about whether to be screened. This decision should be made after the patients have received information about the uncertainties, risks, and potential benefits of screening; men should not be screened unless they have received this information. The American Cancer Society further recommends that discussion about screening should take place at age 50 for men who are at average risk of prostate cancer and are expected to live at least 10 more years, and at age 45 for men at high risk of developing prostate cancer (e.g., African American men and those with a first-degree relative diagnosed with prostate cancer at an early age [<65 years]). This discussion should occur at age 40 for men at even higher risk, that is, those with more than one first-degree relative who had prostate cancer at an early age.⁹⁷

DIAGNOSIS, RISK ASSESSMENT, AND STATE ASSIGNMENT

Signs and Symptoms

The most common symptoms arising from the prostate in men over 40 years are bladder outlet obstruction, including hesitancy; nocturia; incomplete emptying; and a diminished urinary stream. The occurrence of these symptoms, although more commonly related to BPH, should prompt a careful DRE and a PSA determination. The acute development of pelvic or perineal pain, erectile dysfunction, or hematuria should prompt further evaluation of the prostate. Today, men rarely present with symptoms of metastatic disease such as bone pain, pathologic fracture, anemia, or pancytopenia from bone marrow replacement, or disseminated intravascular coagulation.

Digital Rectal Examination

The physical examination should focus on a thorough DRE of the prostate, although palpable nodes can sometimes be detected in the inguinal or supraclavicular areas. Special attention should be paid to detect areas of induration within the prostate, extension through the capsule, or involvement of the seminal vesicles. If there is bladder outlet obstruction, the bladder may be palpable. Although not uniformly accurate or reproducible, DRE results are associated with pathologic stage and prognosis, and are the principal basis for assigning the clinical T stage of the cancer.⁹⁸

Prostate-Specific Antigen and Related Biomarkers

PSA levels are best considered as a continuum: the higher the level, the greater the likelihood that any cancer, or high-grade cancer, will be found on biopsy. The most commonly used threshold for recommending a biopsy is 3 ng/ml.⁷² A level this high is found in only 5% to 10% of men age 45 to 69 years. As PSA levels vary,⁶⁶ a rise in PSA to a newly "elevated" level should be verified 2 to 3 months later, after the patient has been evaluated by a medical history, DRE, and appropriate laboratory tests to exclude causes other than cancer for the "rise." The likelihood of finding cancer is about 15% to 20% in men with a normal DRE and a PSA level between 2.5 to 4 ng/ml. Among men with a PSA level of 4 to 10 ng/ml, 20% to 30% will have cancer. If the PSA level is >10 ng/ml, 60% of men will have cancer on biopsy. Many of these cancers will be low risk and can be managed conservatively without radical therapy.

Higher circulating PSA levels prior to treatment are associated with larger, more extensive cancers, although there may be a wide range of levels within any clinical T, N, or M category.^{99,100} Although poorly differentiated cancers produce less PSA per gram than well-differentiated cancers, higher PSA levels indicate a more extensive cancer and a poorer prognosis across all Gleason scores. Rare, highly aggressive, poorly differentiated cancers are found in men with low PSA levels (<2 ng/ml), but patients with these cancers usually present with rapidly progressive voiding symptoms and palpably abnormal DRE.

PSA levels rise with age because of age-related increases in prostate volume due to BPH. Adjusting the upper limit of normal for age, PSA should be <2.5 ng/ml for men age 40 to 49 years, <3.5 for men aged 50 to 59, <4.5 for men aged 60 to 69, and <6.5 for men aged 70 to 79.¹⁰¹ The utility of *age-specific PSA levels* has been challenged in screening trials because sensitivity is lost for a small increase in specificity in older men.¹⁰²

PSA levels can also be adjusted for the volume of the prostate gland. *PSA density* (PSAD) is the ratio of PSA to gland volume,

measured in ng/ml per cm³.¹⁰³ As more PSA is released into the serum by cancer (3 ng/g) than by BPH (0.3 ng/g),¹⁰⁴ PSAD can help to discriminate cancer from BPH. Because DRE correlates poorly with gland volume, an imaging study (transrectal ultrasound [TRUS] or magnetic resonance imaging [MRI]) is required to measure PSAD accurately, so PSAD is generally useful only in men who have had an ultrasound during a biopsy. PSAD has proved to be more valuable in prognosis than in detection, where it has been largely replaced by the *free/total PSA ratio*. The percent-free PSA in serum is higher in men with BPH than in men with cancer and can be used to discriminate cancer from BPH. Percent-free PSA values <10% are more indicative of cancer in men with values in the 4 to 10 ng/ml range.^{62,105}

PSA levels rise more rapidly over time in men with cancer than in those without cancer, even within the normal range.¹⁰⁶ The rate of change, termed *PSA velocity*, may indicate the presence of cancer, but normal biologic variations in PSA levels over time create many more false positives and lessen the accuracy of the calculated results.¹⁰⁷ Once a man's PSA level is known, PSA velocity contributes no additional information to predict the presence of a cancer,¹⁰⁷ except in the rare case of an unusually aggressive, high-grade cancer that produces little PSA.

Panels of Kallikrein Markers

The major limitation of PSA for screening and early detection of prostate cancer is the high proportion of false-positive tests: 70% to 80% of men with a PSA >3 ng/ml and a normal DRE do not have cancer on biopsy. The specificity of PSA testing can be increased substantially at any given level of sensitivity by incorporating additional kallikreins into a panel of markers. There are two commercially available panels: the 4Kscore test (OPKO Lab, Nashville, TN) and the *phi* (Prostate Health Index; Beckman Coulter, Brea, CA). To baseline measurements of PSA and free-PSA levels the 4Kscore adds "intact" PSA and hK2, and the *phi* adds -2(pro) PSA.¹⁰⁸⁻¹¹¹ All three of these kallikreins are elevated in cancer, relative to BPH. Both the 4Kscore and *phi* panels increase specificity, reducing the indication for biopsy among men with an elevated PSA level. In published studies, the number of biopsies was reduced by 40% to 50% while missing few high-grade cancers. The 4Kscore preserves sensitivity for high-grade (Gleason ≥7) cancer while reducing the number of negative biopsies and biopsies finding only low-grade (Gleason ≤6), small-volume cancer.^{110,111}

Urinary Molecular Biomarkers

Prostatic fluid may contain shed cells from prostate cancer that can be recognized by measuring the level of RNA for prostate cancer antigen-3 (PCA-3) relative to that for PSA in urinary sediment using reverse transcription-polymerase chain reaction technology. Urinary PCA-3 has been approved by the FDA to determine the likelihood of cancer in men with an elevated PSA level and a previously negative biopsy,¹¹² but is also useful in comparable men with no previous biopsy to avoid unnecessary biopsies. The test requires collection of urine after a prostatic massage by DRE, and the levels of PCA-3 do not reflect the volume, grade, and extent of cancer,¹¹³ limiting its clinical utility, especially when the goal is to avoid biopsy in men with only low-risk cancers. Other urinary assays for molecular markers are being explored, including one for the TMPRSS fusion gene, which may be more prognostic than PCA-3.¹¹³

Biopsy

Because prostate cancer is rarely curable when it causes symptoms, and rises in incidence with age, detection has focused on evaluating asymptomatic men between the ages of 50 and 70. The principal indications for biopsy are either an abnormal DRE or, more commonly, an elevated PSA level. Any palpable induration

TABLE 68.2

Probability of a Positive Prostate Biopsy Based on the Results of the Digital Rectal Examination and Serum Prostate-Specific Antigen Level

DRE Status (%)	PSA (ng/ml)			
	0-2	2-4	4-10	>10
DRE-	1	15	25	>50
DRE+	5	20	45	>75

PSA, prostate-specific antigen; DRE, digital rectal examination; DRE-, normal findings on the digital rectal examination; DRE+, findings on digital rectal examination suspicious for prostate cancer. Modified from Thompson IM, Pauler DK, Goodman PJ, et al. Prevalence of prostate cancer among men with a prostate-specific antigen level < or = 4.0 ng per milliliter. *N Engl J Med* 2004;350:2239-2246; Catalona W, Richie J, deKernion JB, et al. Comparison of prostate specific antigen concentration versus prostate specific antigen density in the early detection of prostate cancer. *J Urol* 1994;152:2031-2036.

should be evaluated further, but only about a third of men with an abnormal DRE prove to have prostate cancer. Similarly, a normal DRE does not exclude the presence of cancer. The likelihood that cancer will be found on biopsy depends on the results of the DRE and PSA test (Table 68.2).^{67,114}

The diagnosis of prostate cancer is typically established by TRUS-guided transrectal needle biopsy. TRUS is most useful for identifying the regions within the prostate for needle biopsy and for determining prostate volume; it is not used routinely for screening. When cancers are seen on TRUS, they are typically hypoechoic relative to normal prostate tissue, but the sensitivity of detection is low and MRI has proven to be more accurate and is the preferred imaging modality for identifying suspicious lesions for TRUS-guided biopsies within the prostate.

A needle biopsy of the prostate is usually performed transrectally with an 18-gauge needle mounted on a spring-loaded gun directed by ultrasound. Any palpable abnormality on DRE should be targeted for biopsy using finger guidance. In addition, abnormal areas visible on TRUS or MRI should be sampled, along with a total of at least 10 systematic biopsies of the prostate taken from the left and right apex, middle, and base of the peripheral zone. Each core or group of cores from a single region should be identified separately as to location and orientation so that the pathologist can report the extent and grade of cancer in each region and the presence of any perineural invasion or extraprostatic extension. Higher Gleason scores are strongly associated with larger tumor volume, extension outside the prostate, probability of metastases, and duration of response to therapy.^{115,116} Biopsy results are used not only to assign a Gleason score to the cancer, but also to assess the volume and extent of the cancer by determining the number and percent of cores involved by cancer,^{117,118} the amount of cancer in each core, and the total length of cancer in all cores. Each of these features adds important additional staging and prognostic information.¹¹⁹⁻¹²²

Because patient selection for AS is critically dependent on the results of the prostate biopsy, some investigators have suggested more extensive biopsy strategies to better assess the true extent of cancer within the prostate. Transperineal "mapping" biopsies use a brachytherapy template, with needle cores taken at 5 mm to 10 mm intervals throughout the gland.¹²³ These template biopsies more accurately reflect the grade and extent of cancer. One study collected a median of 46 individual cores and found bilateral cancer in 55% of patients and an increased Gleason score in 23%. However, the risk of acute urinary retention, hematuria, and erectile dysfunction are increased with mapping biopsy, compared with standard transrectal needle biopsy. Further experience is needed before extensive mapping biopsies can be recommended

as routine. Today, more attention is being focused on targeted biopsies of suspicious lesions seen on MRI.¹²⁴

Imaging for Diagnosis and Staging

The overwhelming majority of men diagnosed with prostate cancer today do not have metastases at the time of diagnosis, so imaging studies to detect metastases are usually not indicated. Neither bone scans nor computed tomography (CT) are helpful for patients with clinically localized cancer unless they have a poorly differentiated tumor (Gleason score 8 to 10) or a PSA >20 ng/ml.¹²⁵ Consequently, most patients diagnosed with a clinically localized prostate cancer need no further studies to rule out metastases. Patients with very aggressive tumors (PSA >20 ng/ml and biopsy Gleason score >7), advanced local lesions (T3-4), or symptoms suggestive of metastatic disease should have imaging studies, including a bone scan and a CT of the chest, abdomen, and pelvis.

Magnetic Resonance Imaging

With current magnet strengths of 3 Tesla (3T), a multiparametric MRI, which provides T1- and T2-weighted images as well as diffusion-weighted and contrast images, permits excellent visualization of the prostate and surrounding tissues and the pelvic LN (in which case CT imaging of the pelvis is unnecessary).¹²⁶ The endorectal coil is helpful for enhanced visualization of the internal anatomy of the prostate when the magnetic strength is $\leq 1.5T$, but magnetic resonance spectroscopy is rarely used today despite early promising results. On T1-weighted images, the prostate should appear homogenous and low intensity; cancers are not visible, but high-intensity areas resulting from recent biopsy should be noted to avoid misinterpreting corresponding low-intensity areas on T2 images as malignant lesions. On T2-weighted images, cancers can be recognized by their low signal intensity relative to the normal peripheral zone.

Diffusion-weighted imaging is a promising MRI technique that takes advantage of the known variability of random movements of water molecules observed between normal tissues and tumors. The rate of diffusion of water molecules is more restricted within tumors than in normal tissues and allows for an important metric known as the apparent diffusion coefficient. In one study

comparing MRI with combined MRI and diffusion-weighted MRI, the sensitivity and specificity were 86% and 84%, respectively.¹²⁷ Dynamic contrast-enhancement MRI may also identify malignant lesions within the prostate.¹²⁸ In one study, the combination of T2-weighted imaging and dynamic contrast-enhancement MRI findings had sensitivity and specificity rates of 77% and 91% for detecting tumor foci that measured 0.2 cm^3 , but these values improved to 90% and 88%, respectively, when detecting tumors $>0.5 \text{ cm}^3$.¹²⁹⁻¹³¹

Opinions vary regarding the value of MRI in routine staging and imaging of the prostate, and a wide range in specificity and sensitivity has been reported for the detection of extraprostatic extension and seminal vesicle invasion (SVI). In general, multiparametric MRI permits excellent visualization of the prostate and is more sensitive than DRE, TRUS, and CT for identifying extraprostatic extension and SVI (Fig. 68.7). MRI also allows accurate estimates of the size and shape of the prostate, the proximity of cancer to the neurovascular bundles and the urethral sphincter, the presence of a large anterior tumor that may be invading the anterior fibromuscular stroma or bladder neck, and the length of the membranous urethral sphincter, making MRI a valuable adjunct to the preoperative evaluation of patients with apparently localized prostate cancer.¹³²

Computed Tomography

CT scans of the abdomen and pelvis are ordered far too frequently in the initial evaluation of men with prostate cancer, as they have limited capability to detect cancer within the prostate or the presence of extraprostatic extension or SVI. CT scans can detect LN metastases within the pelvis, but these can be detected equally well with pelvic/prostatic MRI, which provides more information about the primary tumor.

Bone Scan

A radionuclide bone scan is the standard imaging study used to identify the presence of osseous metastases,¹³⁰ but is not generally indicated in patients with clinically localized cancer because true positive results are much less common than false positives. In patients with a baseline PSA level <10 ng/ml, a bone scan identifies metastases in <1% of men who have no symptoms of bone pain.

Figure 68.7 Clinical stage T2a prostate cancer. On the transverse image (A), the patient was noted to have a dominant tumor at the right base with loss of normal contour and irregular bulging consistent with extracapsular extension (arrow). Image (B) indicates the evidence of seminal vesicle involvement (arrowheads) demonstrating mild enlargement of the seminal vesicles and low signal intensity tissue replacing normal thin walls and obliterating the lumen. (From Hricak H, Choyke PL, Eberhardt SC, et al. Imaging prostate cancer: a multidisciplinary perspective. *Radiology* 2007;243:28, with permission of the Radiological Society of America.)

For patients with PSA levels between 10 ng/ml and 50 ng/ml or >50 ng/ml, the probability of a positive bone scan is 10% and 50%, respectively.¹³¹ Bone scans are frequently used to assess the response to hormonal therapy and chemotherapy in men with metastatic disease.

Risk Assessment

Characterization of the Local Tumor

A thorough evaluation of the extent of the local tumor should include a diagram of the area of induration and a recording of the clinical T stage, which reflects the size, location, and extent of the cancer (determined by DRE and imaging), histologic grade (Gleason score) in the biopsy specimen, baseline serum PSA level, and systematic biopsy results. These factors are used to predict pathologic stage, assist in treatment planning, and determine prognosis.

Tumor, Node, and Metastasis Classification

At the time of initial diagnosis, prostate cancers are staged using the TNM classification developed by the American Joint Committee on Cancer and the Union for International Cancer Control.^{50-52,133,134} We recommend the use of the seventh edition published in 2010⁵¹ (Table 68.3). With the TNM system, designations for the primary tumor, regional nodes, and distant metastases are noted separately. A distinct category, T1c, is used to describe cancers that are neither palpable nor visible, but were detected by

a biopsy performed after an abnormal PSA test or for other reasons. Cancers that are not palpable but visible on imaging such as TRUS or MRI are classified appropriately along with palpable cancers in the T2-4 categories. However, the TNM system does not fully reflect prognosis because it does not include PSA levels, Gleason grade, or the extent of cancer in the biopsy specimen.

Staging Tables and Risk Groups

While individual prognostic factors can be informative, combining multiple factors together produces more accurate estimates of pathologic stage and prognosis. Partin et al.¹³⁵ developed a nomogram reported as a series of staging tables (Partin tables) that combine clinical tumor stage, biopsy Gleason grade, and PSA to predict pathologic stage. The accuracy of these tables has been widely validated.¹³⁶

As pathologic stage is only a proxy for prognosis, a classification scheme has been developed to predict the risk of recurrence after treatment of the primary tumor using the same key prognostic factors (clinical stage, Gleason grade, and PSA).¹³⁷ The D'Amico classification, now adopted by the American Urological Association, assigns patients to one of three logical (rather than empirical) risk groups according to their clinical T stage, Gleason grade, and PSA.¹³⁷ Although it is intuitive to group patients into such risk-group categories, each "group" actually contains a heterogeneous population.¹³⁸ For example, patients with a clinical stage T1c, Gleason grade 3 + 3, and PSA 9.9 ng/ml would be classified as low risk, but if the PSA were 10.1 ng/ml, the same patient would be considered intermediate risk. Using categorical values

TABLE 68.3

Comparison of the 1992, 1997, 2002, and 2010 American Joint Committee on Cancer/International Union Against Cancer Tumor, Node, Metastasis Staging System

Stage	1992 ⁵⁰	1997 ⁵²	2002 ¹³³	2010 ⁵¹
TX	Primary tumor cannot be assessed			
T0	No evidence of primary tumor			
T1	Clinically inapparent, not palpable or visible by imaging			
T1a	Incidental histologic finding, ≤5% of resected tissue			
T1b	Incidental histologic finding, >5% of resected tissue			
T1c	Tumor identified by needle biopsy, for any reason (e.g., elevated PSA)			
T2	Palpable or visible tumor, confined within the prostate ^a			
T2a	≤ Half one lobe	One lobe	≤ Half one lobe	≤ Half one lobe
T2b	One lobe	Both lobes	One lobe	> Half one lobe, not both
T2c	Both lobes	No T2c classification	Both lobes	Both lobes
T3	Tumor extends through prostate capsule ^b			
T3a	Unilateral ECE	ECE, unilateral or bilateral		ECE, unilateral or bilateral
T3b	Bilateral ECE	Seminal vesicle involvement		Seminal vesicle involvement
T3c	Seminal vesicle involvement	No T3c classification		No T3c classification
T4	Tumor is fixed or invades adjacent structures			Tumor is fixed or invades adjacent structures other than seminal vesicles, such as external sphincter, rectum, bladder, levator muscles, and/or pelvic wall
T4a	Invades bladder neck, external sphincter, or rectum			No T4a classification
T4b	Invades levator muscles or fixed to pelvic sidewalls			No T4b classification

PSA, prostate-specific antigen; ECE, extracapsular extension.

^a Tumor found in one or both lobes by needle biopsy, but not palpable or reliably visible by imaging, is classified as T1c.

^b Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is classified not as T3 but as T2.

(e.g., PSA 10 to 20 ng/ml) rather than continuous values, and assigning a patient to an increased risk group if any single variable is high (e.g., tumor stage cT2c, Gleason 8 to 10, or PSA >20 ng/ml), is inherently inaccurate. Predictions are much more accurate when nomograms are used to combine individual prognostic factors into a single prognostic score assigned to an individual patient. Consequent comparisons of the results of different treatments are also more accurate when patients are more precisely matched.

Nomograms

Nomograms now widely available to predict prognosis in men with prostate cancer combine clinical and pathologic prognostic factors as continuous rather than categorical variables.¹³⁹ The prognosis or probability of recurrence after definitive therapy of an apparently localized prostate cancer depends on the clinical stage and grade of the cancer, the number or percent of positive biopsy cores, as well as the PSA level before treatment. Nomograms have proved highly useful in clinical practice and have been developed for external beam radiation therapy (EBRT)¹⁴⁰ and brachytherapy as well as surgery.¹⁴¹ These nomograms may provide clues about the relative efficacy of different treatment modalities in patients with comparable tumors. All these nomograms are available at <http://www.mskcc.org/cancer-care/prediction-tools> (accessed June 13, 2014).

Molecular Profiles

Genomic testing has recently been introduced to characterize the level of aggressiveness of prostate cancer, and, as in breast cancer,¹⁴²⁻¹⁴⁴ can help to guide treatment decisions.¹⁴⁵ There are currently two commercially available genomic tests for risk-stratification of prostate cancer, the Cell Cycle Progression assay (Prolaris, Myriad Genetic Laboratories Inc., Salt Lake City, UT) and the Genomic Prostate Score assay (Oncotype DX, Genomic Health, Redwood City, CA).¹⁴⁶⁻¹⁴⁹ Both these tests use reverse transcription-polymerase chain reaction techniques to assay the expression level of a panel of genes that reflect the biologic activity of the cancer relative to the level of housekeeper genes. The Cell Cycle Progression-Prolaris assay was developed on a cohort of men with a wide spectrum of prostate cancer managed conservatively; the molecular profile added significantly to the ability of standard clinicopathologic features (stage, grade, PSA, and extent of cancer in biopsy specimens) to predict time to death from prostate cancer.¹⁴⁷ When needle biopsy specimens from men who were candidates for AS were assayed with Genomic Prostate Score-Oncotype DX, the assay independently predicted the risk of adverse pathology (extraprostatic extension or Gleason grade 4 + 3 or greater) in RP specimens. Both tests can successfully assay expression profiles from as little as 1 mm of cancer in an 18-g needle core obtained as long as 10 to 15 years previous to the assay, and both show a wide range of expression levels, and therefore prognoses, within any clinicopathologic risk group.

The clinical utility of these molecular profiles is under active investigation; today, the assays are largely used to recommend AS in men with low- or intermediate-risk, low-volume cancer and favorable expression profiles. Assay results tend to be concordant with the clinicopathologic risk classification in approximately 45% of patients, whereas it is higher or lower in the remaining 55%. In a recent study, 14% of patients considered low risk and suitable for AS were reclassified as higher risk patients for whom active intervention was warranted, and 7% of those with clinically aggressive tumors were reclassified as low-risk and suitable for AS by the Cell Cycle Progression-Prolaris assay.¹⁵⁰

Pathologic Stage

Several other indices have been developed that improve the biologic characterization of a given tumor. Pathologic stage, determined by examining the RP specimen, predicts recurrence much more accurately than clinical stage.¹⁵¹ Independent prognostic factors include the level of invasion through the capsule of the prostate, SVI, LN metastases, and positive surgical margins, as

well as the Gleason score in the RP specimen and the preoperative serum PSA level. Some investigators have considered tumor volume an important prognostic factor, but others have found that it has no independent prognostic significance. Stephenson et al.¹⁵² combined these independent prognostic factors into postoperative nomograms to predict biochemical recurrence (BCR)¹⁵³ 10 years after RP and 15-year cancer-specific survival.^{139,154} These nomograms are more accurate than the preoperative nomogram, because they incorporate the final Gleason grade and pathologic stage as well as preoperative PSA.¹⁵⁴

Stage Assignment

Clinical States Model

Given the range of prognoses among men within each of the TNM-defined stages at diagnosis, a risk-adapted approach to diagnosis and treatment is mandated. To facilitate this approach, a model was developed that divides the disease continuum from prediagnosis to advanced metastatic disease into a series of clinical states. Each state represents a distinct clinical milestone defined by the status of the tumor in the primary site, the presence or absence of metastatic disease on imaging, whether the testosterone levels in the blood are in noncastrate or castrate (<50 ng/dl) range, and prior therapy. This model differs from staging algorithms in that it applies to both the newly diagnosed, untreated patient and to the patient who has received treatment as his disease evolves. Unmet needs in diagnosis, defining treatment objectives, and assessing outcomes vary by clinical state (see Fig. 68.1). Applied clinically to men without a cancer diagnosis, this approach accommodates the need to assess an individual's cancer based on the risk of harboring or developing clinically significant disease.

In the clinical states model, an individual is assigned to only one state and he remains in that state until his disease has progressed. He can only move forward, never back, even if his disease has been eradicated completely. Each assessment is considered a new evaluation in which the patient's symptoms and overall tumor status are reviewed, and the decision to offer treatment, and the specific form of treatment, are based on the current state of the disease or the future risk posed by the cancer relative to comorbid conditions.

For example, the rising PSA states include patients who have a rising PSA following treatment of the primary tumor with either surgery or radiation, an indication that the disease has recurred. Issues for these patients include whether the recurrence is systemic or limited to the prostate bed (following surgery) or the prostate itself (following radiation). A more important consideration is whether any treatment is needed, based on the likelihood in the long term that the cancer will cause symptoms, local or distant, or shorten a patient's life. Patients with rising PSA who are considered to have disease in the prostate bed (or the prostate itself) are discussed in the sections of this chapter that review the primary treatment modalities for prostate cancer. Treatment objectives and the means to assess outcomes vary by clinical state and will be considered separately. The more rapidly the disease is progressing or the more advanced the disease state, the greater the need for treatment.

Principles of Treatment and Assessing Outcomes

Treatment is offered with therapeutic intent that considers (1) why the treatment should be administered, (2) the potential benefits it can provide relative to potential morbidity, and (3) financial cost. Changing established practice paradigms requires demonstrating that a new therapy or approach provides incremental clinical benefit relative to a previous standard (if one exists) or to a suitable control in prospective randomized trials. Clinical benefit in regulatory terms represents an improvement in the way a patient functions or feels, or in how long he survives.¹⁵⁵ Examples of clinical benefits

include prolonging life, relieving pain or other symptoms, and/or reducing toxicity relative to an established standard. It is also important to demonstrate that a new approach, whether it is a therapeutic procedure or a drug, is safe and well tolerated in an elderly population.

Assessing Treatment Effects

It has long been recognized that the most common manifestations of prostate cancer, which include disease in the primary site, a rising PSA, and metastasis to bone, are not evaluable by the traditional measures of tumor regression used to monitor disease status in other solid malignancies (Response Evaluation Criteria In Solid Tumors [RECIST] 1.1).¹⁵⁶ Changes in nodal and visceral sites that can be assessed reliably using RECIST occur less often. To address this unmet need, the Prostate Cancer Working Group (PCWG2) was formed to develop guidelines for clinical trial design in castration-resistant prostate cancer (CRPC) that also apply to earlier disease states.¹⁵⁷

In the clinical states framework, treatment objectives are divided into early outcomes representing the control, relief, or elimination of disease manifestations present when a treatment is being considered or initiated, and later outcomes representing the delay or prevention of future manifestations. Existing manifestations may include disease limited to the prostate (localized disease), a biochemical recurrence following local treatment (rising PSA), or cancer in the extrapelvic LN, bone, or viscera with or without a rising PSA (clinical metastases). Potential manifestations that might be delayed or prevented from occurring include growth in the primary site, BCR, growth in an existing site, new sites of spread, pain, or other complications of progressive osseous disease described as skeletal-related events (SRE),¹⁵⁸ and death from disease. SREs, first used in the regulatory filing of zoledronate, include fractures, pain requiring a change in therapy, epidural disease, and/or surgery to bone.¹⁵⁹

“Control/relieve/eliminate” outcomes representing “response” are reported individually by the change in each disease manifestation present—PSA level, soft tissue disease, bone disease, and/or symptoms when treatment was started—rather than by grouped categorizations, such as complete and partial remission, that include all sites of disease. For example, a key PSA-based outcome for patients treated with RP is the proportion of patients who achieve an undetectable PSA level postoperatively, whereas for patients with CRPC treated with a systemic approach, a waterfall plot showing the percent change from baseline for each patient treated, or the proportion of patients achieving a defined degree of decline (e.g., $\geq 50\%$), is more informative. “Delay/prevent” outcomes focusing on time-to-event progression are also measured individually. For a patient with localized disease, outcomes from surgery or radiation include a response measure that demonstrates whether the disease was eliminated completely (e.g., a negative biopsy of the prostate at a certain time after radiotherapy) or time-to-event outcomes that include time to PSA recurrence, metastases, symptoms, or death from disease. This approach to evaluating outcomes enables the physician to focus on the specific therapeutic objective for a single patient or group of patients in a given disease state, rather than on changes in other, less-relevant measures, and at the same time enables clinical trial investigators to explore the relation between changes in individual disease manifestations and other measures of clinical benefit such as overall survival.

MANAGEMENT BY CLINICAL STATES

Clinically Localized Disease

The clinical course of newly diagnosed prostate cancer is difficult to predict. Men with similar clinical stage, serum PSA levels, and biopsy features can have markedly different outcomes. Although

prostate cancer is unequivocally lethal in some patients, most men die with, rather than of, their cancer. The challenge to physicians is to identify those men with aggressive, localized prostate cancer with a natural history that can be altered by definitive local therapy, while sparing the remainder the morbidity of unnecessary treatment. Not all men with clinically localized prostate cancer require or benefit from therapy. Depending on the characteristics of their cancer, their age, and comorbidities, some men would benefit greatly by aggressive treatment, whereas others would suffer harm.

Well-established prognostic factors for clinically localized prostate cancer include age, PSA level, clinical stage based on DRE and imaging, Gleason grade, and extent of the cancer on biopsy. Prognosis can be estimated more accurately by combining these risk factors into nomograms⁹⁹ that calculate the probability of a clinically important endpoint, such as freedom from BCR 10 years after surgery¹⁵³ or cancer-specific survival 15 years after surgery.¹³⁹

Active Surveillance

AS is a planned treatment of monitoring a patient with a potentially curable prostate cancer based on the likelihood that the cancer will progress, delaying active treatment until signs of progression to a more aggressive, potentially lethal cancer are detected. AS attempts to avoid the adverse effects of treatment in the majority of men, intervening with curative therapy for selected men only for specific indications. AS is now widely recommended for most men with low-risk cancer, based on the lack of survival benefit of immediate surgery versus observation at 12 years in the PIVOT trial¹⁶⁰ and the low risk of prostate cancer death at 10 years in large phase 2 studies of AS.⁸⁴ In this and other AS trials, the risk of progression or treatment for men with low-risk cancer is about 20% to 40% within 5 years and 35% to 60% within 10 years, depending on the initial eligibility criteria and the indications for delayed intervention.

A recommendation for AS assumes that the risk posed by the cancer at diagnosis can be assessed accurately, that progression can be identified by regular monitoring, and that deferring treatment until it is necessary will offer cancer control and survival rates similar to immediate treatment. Achieving all of these goals has not yet been realized. Standard assessment at diagnosis includes PSA, clinical stage, Gleason grade, and extent of cancer in biopsy results. This limited evaluation underestimates the grade and extent of the cancer in 15% to 25% of patients.¹⁶¹ A multiparametric MRI of the prostate can detect large, more aggressive cancers in some patients, and these findings can be confirmed by biopsies targeting the suspicious lesions.¹⁶² Alternatively, one can depend on annual repeat biopsies¹⁶³ or PSA velocity⁸⁴ to detect progression in time for effective intervention. In either case, patients under AS must accept frequent, regular, detailed evaluations of the status of their cancer for as long as they are healthy and young enough to be candidates for definitive therapy. Patients under AS are generally monitored every 6 months with DRE and measurement of free and total PSA, with repeat imaging and biopsy every 2 to 3 years after the baseline evaluation. The goal is to detect progression of the cancer while cure is still possible.

Outcomes of Active Surveillance with Selective Delayed Intervention

There are few reports of long-term outcomes of AS for localized prostate cancer. Klotz et al.⁸⁴ conducted a prospective phase 2 study of AS in men with low-risk cancer (or those over 70 with Gleason 7 [3 + 4] and PSA <15 ng/ml). The indications for intervention were a short PSA doubling time (PSADT) or grade progression on repeat biopsy. At 8 years, overall survival was 85% and disease-specific and metastasis-free survival 99%. Some 25%

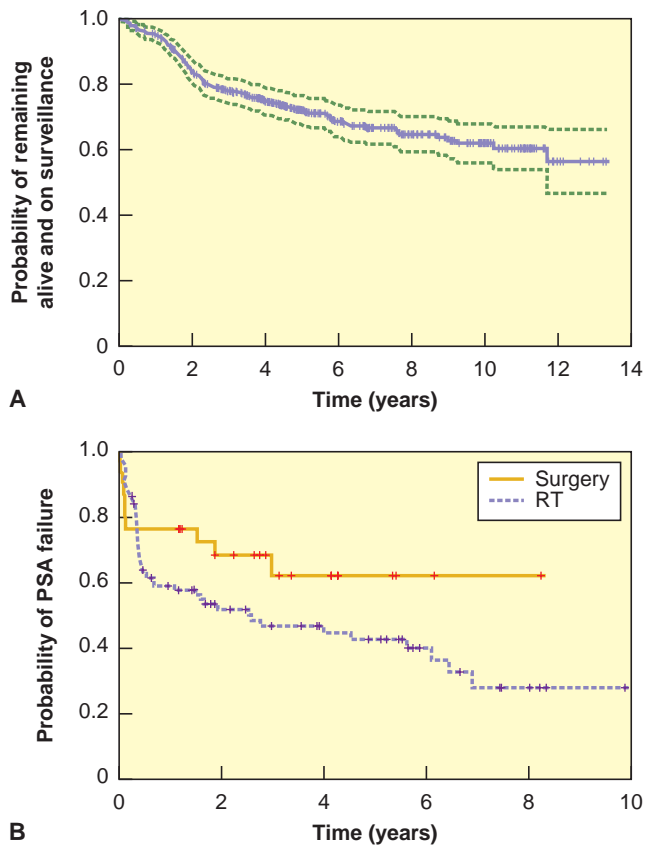

Figure 68.8 Long-term follow-up of active surveillance cohort with localized prostate cancer. **(A)** Likelihood of remaining alive and on surveillance in 450 patients. *Green lines* indicate 95% confidence intervals. **(B)** Prostate-specific antigen (PSA) failure in 117 patients treated with surgery or radiation after a period of surveillance. RT, radiotherapy. (From Klotz L, Zhang L, Lam A, et al. Clinical results of long-term follow-up of a large, active surveillance cohort with localized prostate cancer. *J Clin Oncol* 2010;28:126–131, with permission.)

of patients were treated within 5 years, and 40% by 10 years (Fig. 68.8). Delayed intervention was associated with a relatively low rate of cancer control, raising concerns that treatment for men with a short PSADT (<2 years) was too late.

Carter et al.⁹⁶ observed a cohort of 769 men with very-low-risk prostate cancer and low PSA density (<0.15) from 1 to 15 years after diagnosis with DRE, measurements of total and free PSA every 6 months, and an annual surveillance biopsy. Treatment was recommended based on biopsy changes (any Gleason pattern 4 or 5, more than two cores that were positive for cancer, or >50% of any one core that was involved with cancer) or if a patient requested a change in management, but not for changes in PSA alone. A total of 41% of patients had been treated at 5 years, and 59% at 10 years, and the median time to treatment was 6.5 years. Cancer control after delayed therapy was excellent. The large number of men who required delayed intervention suggested that many tumors were underestimated at baseline, and the high cure rates at delayed intervention call into question the clinical significance of the criteria for delayed intervention. Many physicians now recommend more comprehensive initial evaluation of candidates for AS with multiparametric MRI and/or early confirmatory biopsies.¹⁶⁴

These and other studies confirm that in appropriately selected men, AS is associated with an extremely low rate of progression to metastatic disease and/or death, and that the majority of patients do not require intervention over the first decade. Further follow-up

is necessary to determine the long-term risk of progression. The National Comprehensive Cancer Network recommends AS as the appropriate initial management strategy for patients with low-risk cancer and a life expectancy <10 years, as well as for patients with very low-risk cancer and a life expectancy <20 years.¹²⁵

Radical Prostatectomy

The modern anatomic technique for RP was developed nearly 35 years ago and has proven safe and effective in many large cohort studies and randomized clinical trials. The retropubic technique originally described by Walsh¹⁶⁵ for open surgery is equally suitable for laparoscopic and robot-assisted RP. Initially focused on patients with early-stage, organ-confined cancers, RP with pelvic LN dissection (PLND) is now recommended primarily for patients with aggressive cancers (intermediate- and high-risk), whereas low-risk tumors are generally managed with AS (see previous discussion). Because of the risk inherent in major surgery, RP should be reserved for patients without serious systemic comorbidity. Although the risk of recurrence after RP rises with higher clinical stage, Gleason grade, and serum PSA level, no absolute cutoff values exclude a patient as a candidate.

Surgical Technique. The goals of modern RP are to remove the entire cancer with negative surgical margins, minimal blood loss, no serious perioperative complications, and complete recovery of continence and potency. Achieving these goals requires careful surgical planning. Because no single test provides a reliable estimate of the size, location, and extent of the cancer, we rely on the results of DRE, serum PSA levels, and a detailed analysis of the amount and grade of cancer in each individually labeled biopsy core, along with multiparametric MRI. The results are used to plan the steps necessary to remove the cancer completely and to assess the likelihood that one or both of the neurovascular bundles will have to be resected partially or fully to minimize the risk of a positive surgical margin. The retropubic procedure is performed either through a suprapubic incision (open RP) or using a minimal access (laparoscopic or robot-assisted laparoscopic) approach. The operation should be exactly the same internally, regardless of the method of access.

Selecting Patients for Pelvic Lymph Node Dissection

Cancer that has spread to the pelvic LN carries a worse prognosis than when the nodes are negative, enhancing accurate staging. However, the therapeutic benefit of PLND is uncertain. Overall rates of pelvic LN metastases found at RP vary from 2% to 35% depending on the extent of the node dissection, whether the cancer was discovered after screening, and the stage and grade of the cancer.¹⁶⁶ Men with low-risk screen-detected cancer are rarely found to have nodal metastases (0.5% to 2%),^{166–168} so PLND is generally unnecessary, but it may be indicated if imaging studies or intraoperative findings suggest a more advanced cancer. The limited PLND commonly performed today, especially with robot-assisted RP, has underestimated the rate of nodal metastases.¹⁶⁹ In men with intermediate-risk prostate cancer, LN metastases are found in 5% (screen-detected) to 20%, whereas in men with high-risk cancer, the rates are 20% to 50%, respectively, when a full or extended PLND is performed.^{166,170–173} The incidence of LN metastases increases with increasing PSA, clinical stage, and Gleason score.¹⁶⁸ Our current practice is to restrict PLND at the time of RP to men with a $\geq 2\%$ risk of positive nodes according to a contemporary nomogram.¹⁷⁴ Even so, controversy persists concerning the role of PLND in patients with prostate cancer.

Limited Versus Extended Pelvic Lymph Node Dissection

No prospective studies have demonstrated the optimal anatomic limits of a PLND for prostate cancer. However, lymphatic drainage of the prostate is known to be highly variable and involves

regions not sampled during an external iliac–only PLND.¹⁶⁶ Some surgeons resect only the external iliac LN unless imaging suggests abnormal LN in other regions, whereas other surgeons routinely perform a more extensive dissection that includes the obturator, external iliac, and hypogastric areas.¹⁷⁵ No sentinel LN has been identified in prostate cancer. The more extensive the PLND, the greater the number of LN removed, and the greater the number of positive nodes.^{166,168,171–173} Nevertheless, the total number of positive LN is one in 50% of patients, two in 30%, and three or more in only 20% of patients who have an extended LN dissection.¹⁶⁶ A PLND that includes the external iliac, hypogastric, and obturator node packets is feasible in both open and minimally invasive RP, and carries no greater risk than a PLND limited to the external iliac nodes alone.

Therapeutic Benefit of Pelvic Lymph Node Dissection

Evidence from several surgical series of patients undergoing RP demonstrates a potential therapeutic benefit of extended PLND, particularly in men with only one or two positive nodes and Gleason score ≤ 7 in cancer identified in the RP specimen (Fig. 68.9).^{170–172,176–178} In a series of patients with positive LN treated at Johns Hopkins Hospital, men who had an extended PLND were less likely to develop BCR at 5 years, compared with men who underwent a limited PLND when 15% or fewer of the removed LN were involved.¹⁷⁰ In the Memorial Sloan Kettering Cancer Center (MSKCC) series, 25% to 30% of patients with positive nodes remained free of BCR 10 years after surgery with no additional therapy.¹⁷⁹

Radical Prostatectomy: Surgical Approach

RP is one of the most complex operations performed by urologists. The outcomes—cancer control, urinary continence, and erectile function—are exquisitely sensitive to fine details in surgical technique. No surgeon achieves perfect results, and outcomes vary dramatically among individual surgeons.^{180,181} Technical refinements have resulted in lower rates of urinary incontinence and higher rates of recovery of erectile function, less blood loss and fewer transfusions, shorter hospital stays, and lower rates of positive surgical margins. Laparoscopic and robot-assisted RP promised better cancer control and functional recovery, but numerous studies have confirmed that the only consistent advantages of “minimally invasive” surgery are shorter hospital stays and fewer blood transfusions.¹⁸² A thorough understanding of periprostatic anatomy and

vascular control by contemporary surgeons further increases the probability of a successful RP with reduced morbidity.

Open Radical Prostatectomy

Acute Postoperative Complications. Refinements in anesthesia, perioperative care, and surgical technique have decreased blood loss, length of hospital stay, complications, and mortality after open surgery.¹⁸³ The mortality rate ranges from 0.16% to 0.66% in modern series, rising with increasing age and comorbidity. Deep venous thrombosis and pulmonary embolism occur in approximately 2% of cases, with little evidence that anticoagulants or sequential pneumatic compression are preventive. Early ambulation and shorter hospital stays are likely responsible for the lower rate of thromboembolic events. Routine perioperative anticoagulation is not used because of the increased risks of bleeding and lymphocele. Rectal injuries are uncommon. Standardized treatment pathways have been shown to decrease the cost of radical retropubic prostatectomy without compromising quality of care. Hospital stays now average 2 days for open RP and 1 day for robot-assisted RP.

Robot-Assisted Radical Prostatectomy

Surgeons have demonstrated that robot-assisted RP (RALP) can be performed with excellent results in the hands of experienced surgeons. The initial enthusiasm for RALP was based on the idea that less bleeding and a magnified surgical image would markedly improve patient outcomes, which has not been borne out in carefully performed population-based studies.^{182,184,185} Open RP and RALP each have a number of theoretical advantages and disadvantages (Table 68.4).¹⁸⁶ No prospective randomized trials have yet compared the two techniques, and it is now clear that variations in outcomes among individual surgeons are much greater than variations between technologic approaches.¹⁸¹ Hu et al.¹⁸⁴ have suggested that the rapid increase in utilization of minimally invasive RP despite insufficient data demonstrating superiority over the well-established open operation may be a reflection of a society and a health-care system enamored of a new technology that has increased health-care costs but has yet to uniformly realize marketed or potential benefits during early adoption. As with open surgical techniques, laparoscopic RP and RALP outcomes, including surgical margin status, continence, and potency, reflect surgical technique (the actions and expertise of the surgeon) more than surgical approach. Current data suggest that the best way to improve outcomes after RP is to have the procedure performed by a skilled surgeon, regardless of the approach he or she uses.^{181,187}

Cancer Control with Radical Prostatectomy

Benefits of Surgery Relative to Active Surveillance. The most compelling evidence that selected patients with prostate cancer benefit from active treatment compared with watchful waiting comes from the Scandinavian randomized trial (SPCG-4) of 695 unscreened men with clinically localized prostate cancer.^{188,189} Over 23 years of follow-up, RP (compared with watchful waiting) reduced the risk of death from any cause by 29% and risk of death from prostate cancer by 44% (an absolute difference of 11%). The need for subsequent ADT was reduced by 51%, and clinical local recurrence was reduced by 66%. At 18 years of follow-up, the number needed to treat to prevent one death from prostate cancer was eight overall and four in men under age 65. This elegant study firmly documents the overall benefit of RP in patients with clinically localized prostate cancer diagnosed in the absence of systematic screening.^{188,189}

In a population of men subjected to widespread PSA screening, the benefit of surgery for prostate cancer was tested in the Prostate Cancer Intervention Versus Observation Trial (PIVOT).¹⁶⁰ This

Figure 68.9 Probability of freedom from biochemical recurrence (BCR) by number of positive nodes. Orange line, one positive node; blue line, two positive nodes; red line, three or more positive nodes. (From Touijer KA, Mazzola CR, Sjoberg DD, et al. Long-term outcomes of patients with lymph node metastasis treated with radical prostatectomy without adjuvant androgen-deprivation therapy. *Eur Urol* 2014;65:20–25, with permission.)

TABLE 68.4

Advantages and Disadvantages of Various Surgical Approaches to Radical Prostatectomy

Claims by Minimally Invasive Surgeons: Advantages	Rebuttal by Open Surgeons
Magnification improves visualization	Magnification achieved with surgical loupes
Less blood loss	Transfusion rates are similar
Improved visualization permits more precise dissection of the prostatic apex and neurovascular bundles	Outcomes fail to demonstrate any advantage in terms of continence and potency
Less pain and quicker recovery	Postoperative pain and recovery are comparable
Watertight anastomosis allows earlier catheter removal	No difference noted in most large series
Claims by Open Surgeons: Disadvantages	Rebuttal by Minimally Invasive Surgeons
Lack of proprioception compromises cancer control	Positive margin rates are equivalent
Complication rates are lower with open surgery	Complication rates with laparoscopic surgery decrease with experience
Mobilization of the neurovascular bundles with electrocautery compromises potency	Potency rates are similar
Significant learning curve	Proctoring reduces learning curve
Longer operative time	No rebuttal
Increased cost	No rebuttal

trial was conducted in the United States and randomly assigned 731 men with clinically localized prostate cancer to RP or observation. The mean age was 67, the median PSA level was 7.8 ng/ml, and approximately three-quarters of the men had a biopsy as a consequence of an elevated PSA; half had no palpable tumor (cT1c) and 70% had low-grade (Gleason ≤ 6) cancer on biopsy. With a median of 10 years of follow-up, 48% of the patients had died, but only 7% had died from prostate cancer. There were no differences in overall or cancer-specific mortality between the two arms of the trial. But there were clear indications that RP reduced the risk of dying of cancer in the subset of men who had aggressive cancers, including those whose PSA was >10.0 ng/ml and those with high-risk cancers.

Taken together, these two trials indicate that most men with cancers detected without screening and those with screen-detected intermediate- and high-risk cancers have less risk of metastases and of death from prostate cancer when treated with early RP than with observation alone. In contrast, men with screen-detected low-risk cancer can be managed safely with AS and do not need immediate surgery or radiotherapy. Life expectancy should be considered in

the choice of immediate therapy or AS, as the risks of RP increase and benefits decline progressively with age and comorbidity.¹⁹⁰ A UK-based trial (ProtecT) is currently assessing treatment versus no treatment in a PSA-screened population in $>1,500$ patients.¹⁹¹

Progression rates after RP depend on the clinical stage, biopsy Gleason score, and serum PSA level before surgery, as well as pathologic findings in the surgical specimen. After RP, the PSA level should become undetectable. Cancer control, as measured by freedom from BCR, is excellent after RP and is reproducible among many large series (Table 68.5).^{179, 192-196} Of 12,086 patients treated with RP between 1966 and 2003, 69% to 84% were free of progression at 5 years, and 47% to 78% at 10 years.^{179, 192-196}

Fifteen-year outcomes have been reported after RP based on preoperative and pathologic factors (Table 68.6). Bianco, Scardino, and Eastham¹⁷⁹ calculated the risk of recurrence in 1,743 consecutive patients with clinical stage T1-T3, N0 or X, M0 cancer treated with RP and followed with serum PSA levels for a mean of 72 months (range, 1 month to 240 months). Failure after RP was defined as a rising serum PSA >0.2 ng/ml, clinical evidence of local or distant recurrence, or the initiation of adjuvant radiotherapy or

^c Fourteen-year data.

hormonal treatment. At 5 years 84% of patients, at 10 years 78%, and at 15 years 73% were free of progression (see Table 68.5).

Of particular interest are patients with high-grade cancers (Gleason sum 7 to 10). Of patients with Gleason 3 + 4 = 7 cancers in the RP specimen, 68% were free of progression at 15 years. When the tumor was Gleason 4 + 3 = 7, 51% were free of progression at 15 years.¹⁷⁹ Even patients with Gleason sum 8 to 10 cancers fared well, with 27%

free of progression at 10 years. These progression rates are substantially lower than the 15-year cancer mortality rates reported for patients with Gleason sum 7 to 10 cancers managed with watchful waiting.¹⁹⁷

Once the prostate is removed, the most powerful prognostic factor is the pathologic stage (see Table 68.6). When the cancer is confined to the prostate (defined as cancer not extending into the periprostatic soft tissue), 92% to 98% of patients remain free of

progression at 5 years and 88% to 96% remain free 10 years after RP.¹⁹⁴ Focal penetration through the capsule into the periprostatic soft tissue alone, in the absence of SVI, results in a 73% 10-year nonprogression rate. Established (extensive) penetration through the prostatic capsule into the periprostatic soft tissue, in the absence of SVI, results in a 42% 10-year nonprogression rate. Even some patients with SVI (pT3cN0) can be cured with surgery, with 30% being free of disease recurrence at 10 years (see Table 68.6).

The slow clinical progression of prostate cancer after RP has led to the widespread use of PSA recurrence as the primary end point for evaluating treatment outcome. However, doing so ignores the fact that the prognosis of men in the rising PSA state is highly variable, and that the rising PSA by itself does not necessarily mean that a patient will develop metastatic disease, develop symptoms, or die of his cancer. For many, the threat posed to a man's duration and quality of survival is limited at best.

Reports of long-term, prostate cancer-specific survival rates after RP have clearly shown that many patients with PSA recurrence live out their lives free of cancer.^{179,193,194,196,198} The long-term risk of prostate cancer-specific mortality (PCSM) after RP for patients treated in the era of widespread PSA screening has

recently been estimated based on a multi-institutional cohort of 12,677 patients treated with RP between 1987 and 2005.¹³⁹ Fifteen-year PCSM and all-cause mortality were 12% and 38%, respectively. The estimated PCSM ranged from 5% to 38% for patients in the lowest and highest quartiles of nomogram-predicted risk of PSA-defined recurrence (Table 68.7). Only 4% of contemporary patients had a predicted 15-year PCSM of >5%.

Clearly, few patients will die from prostate cancer within 15 years of RP, despite the presence of adverse clinical features. It is not known whether this favorable prognosis is related to the effectiveness of RP (with or without secondary therapy) or to the low lethality of cancers detected by early screening. Although year of surgery, biopsy Gleason grade, and PSA level are associated with PCSM risk, an individual patient's risk cannot be predicted on the basis of clinical features alone. Further research is needed to identify novel markers specifically associated with the biology of lethal prostate cancer.

High-Risk Prostate Cancer

Monotherapy is often believed to be inadequate for high-risk cancers, and some clinicians are reluctant to consider RP in high-risk

patients. However, there are no standardized criteria to define high-risk before definitive treatment. Among 4,708 patients undergoing RP, high-risk patients were identified based on eight established definitions, and their pathologic characteristics and PSA outcomes were examined (Table 68.8). Depending on the definition used, high-risk patients composed 3% to 38% of the study population. Among patients defined as high-risk, 22% to 63% of tumors proved to be confined to the prostate on pathologic examination. Although high-risk patients had a 1.8- to 4.8-fold increased hazard of PSA relapse, their 10-year relapse-free probability after RP alone was 41% to 74% (see Table 68.8).¹⁹⁹ Disease-specific survival at 12 years was between 78% to 94% (Table 68.9).²⁰⁰ Of the high-risk patients who relapsed, 25% (across all definitions) relapsed more than 2 years after surgery, and in 26% to 39% the PSADT at recurrence was \geq 10 months. These results show that the commonly used definitions of high risk have the potential to deny patients potentially curative treatment. New criteria are needed to identify those patients who need the integration of systemic therapy to improve outcomes beyond what can be achieved with monotherapies directed to the prostate itself.²⁰¹

Impact of the Surgeon on Outcomes After Radical Prostatectomy

Recent research has focused on the ways in which surgical volume and the individual surgeon influence results after RP. Begg et al.²⁰² used the Surveillance, Epidemiology, and End Results–Medicare-linked database to evaluate health-related outcomes after RP. The rates of postoperative complications, late urinary complications (strictures or fistulas 31 days to 365 days after the procedure), and long-term incontinence ($>$ 1 year after the procedure) were inferred from the Medicare claims records of 11,522 patients who underwent RP between 1992 and 1996. These rates were analyzed in relation to hospital volume and surgeon volume (the number of procedures performed at individual hospitals and by

DSM, disease-specific mortality; CI, confidence interval; PSA, prostate-specific antigen; TNM, tumor, node, metastasis; GS, Gleason score; PFP, progression-free probability.

From Yossepowitch O, Eggener SE, Serio AM, et al. Secondary therapy, metastatic progression, and cancer-specific mortality in men with clinically high-risk prostate cancer treated with radical prostatectomy. *Eur Urol* 2008;53:950–959, with permission.

individual surgeons, respectively). Neither hospital volume nor surgeon volume was significantly associated with surgery-related death. Significant trends in the relation between volume and outcome were observed with respect to postoperative complications and late urinary complications. Postoperative morbidity was lower in very-high-volume hospitals than in low-volume hospitals (27% versus 32%; $p = 0.03$) and was also lower when the prostatectomy was performed by very-high-volume surgeons than when it was performed by low-volume surgeons (26% versus 32%; $p < 0.001$). The rates of late urinary complications followed a similar pattern. Results for long-term preservation of continence were less clear-cut. In a detailed analysis of the 159 surgeons who performed a high or very high volume of procedures, wide surgeon-to-surgeon variations in clinical outcomes were observed, and these variations were much greater than would have been predicted on the basis of chance or observed variations in the case mix. These findings suggest that, in general, high-volume surgeons have superior results compared with low-volume surgeons, in terms of early postoperative morbidity and urinary complications after RP. However, the much better than anticipated outcomes among the highest-volume surgeons suggest that individual surgical technique also influences clinical outcomes.

Individual patient data from four institutions was used to study the association between a surgeon's prior experience and BCR after RP (the principal reason that patients visit an oncologic surgeon).¹⁸¹ This relationship has often been termed the *learning curve* and probably reflects differences in surgical skill. A retrospective cohort study of consecutive patients treated from 1987 to 2003 was conducted at four academic, tertiary referral centers in the United States. In this study, 7,850 patients with localized prostate cancer received no neoadjuvant therapy and underwent open radical retropubic prostatectomy by 1 of 73 different surgeons.¹⁷⁹ For each patient, surgeon experience was coded as the total number of RPs conducted by the surgeon prior to the incident case, and cancer control was defined as a corroborated rising PSA level $>$ 0.4 ng/ml. The study demonstrated that cancer control improved with increasing surgeon experience (Fig. 68.10), and this relationship¹⁸¹ remained highly significant ($p < 0.001$) after adjustment for tumor characteristics and year of surgery. The learning curve for cancer control after radical retropubic prostatectomy was steep but did not begin to plateau until a surgeon had completed approximately 250 prior operations. Five-year probability of BCR was 17.8% for patients treated by surgeons in the early phase of their career (10 prior operations),

Figure 68.10 The surgical learning curve for cancer control after radical prostatectomy. Predicted probability (purple curve) and 95% confidence intervals (orange curves) for freedom from biochemical recurrence (BCR) at 5 years after radical prostatectomy are plotted against increasing surgeon experience. Probabilities are for a patient with typical cancer severity (mean prostate-specific antigen level, pathologic stage, and grade) treated in 1997 (approximately equal numbers of patients were treated before and after 1997). (From Vickers AJ, Bianco FJ, Serio AM, et al. The surgical learning curve for prostate cancer control after radical prostatectomy. *J Natl Cancer Inst* 2007;99:1171–1177, with permission.)

compared with 10.9% when surgeons had performed 250 operations (absolute risk difference, 6.9%; 95% confidence interval [CI] = 4.3% to 9.5%) (see Fig. 68.10). We saw no evidence that patient risk attenuates the learning curve: there was a statistically significant association between BCR and surgeon experience in all analyses. The relative risk for a patient receiving treatment from a surgeon with 10 rather than 250 prior RP was 2.5, 1.8, and 1.3 for low-, medium-, and high-risk patients, respectively.

Radiotherapy for Localized Prostate Cancer

Radiotherapy given by external beam or brachytherapy techniques is a second treatment option for men with clinically localized prostate cancers. With the availability of sophisticated treatment planning systems and image-guided approaches, there have been significant advances in radiotherapy enabling higher doses to be delivered more safely, and concomitant improvements in disease-free survival outcomes. Intensity-modulated external beam radiotherapy (IMRT) has become a standard mode of treatment delivery and has facilitated the application of higher radiation dose levels of ≥ 80 Gy, with lower risks of late rectal and urinary toxicities. Such treatments coupled with image guidance have enabled the routine use of tighter margins, incorporating less normal tissue within the high-dose region and leading to further decrements in late toxicities. Brachytherapy using permanent or temporary radioactive implants within the prostate alone or combined with IMRT is another commonly used radiotherapeutic approach. This approach has also improved with more accurate image guidance and intraoperative real-time planning for brachytherapy, resulting in more highly conformal dose distributions, which in turn has resulted in better outcomes and lower toxicity rates, relative to what has been previously reported. In some cases, ADT is used in several contexts: to improve local eradication of locally advanced tumors by reducing tumor size, to eliminate tumor clonogens inherently resistant to radiotherapy by impairing DNA repair pathways, and/or reducing prostate volumes by 30% to 40%, which improves the ability to deliver maximal radiation dose levels without exceeding the tolerance for the surrounding normal tissue. Hormone therapy also has a favorable effect on micrometastatic disease that may be present at the time of diagnosis in men with high-risk tumors.

Although there are no randomized trials comparing modern, sophisticated high-dose EBRT to brachytherapy for the treatment of localized prostate cancer, there are several criteria used to help select the most appropriate form of therapy for the patient. For patients with low-risk disease in whom AS may not be considered—owing to PSA velocity, the presence of a dominant lesion on imaging studies, or a larger volume of disease determined by biopsy—high-dose IMRT alone (in the range of 80 Gy) or brachytherapy alone are excellent treatment options.

Larger prostate volumes, the presence of urinary obstructive symptoms, and medical comorbidities may influence the selection away from a brachytherapy-based treatment. In contrast, brachytherapy may be the preferred choice for patients without these factors because of its excellent ablative capabilities (leading to long-term PSA relapse-free survival outcomes) and its convenience (as a treatment accomplished in a single outpatient setting). For patients with intermediate- and higher-risk disease, combined modality treatments including brachytherapy and supplemental IMRT are preferred to allow for the delivery of a high and concentrated dose of radiation to the prostate. Ultrahypofractionated EBRT regimens have generated increasing interest as another therapeutic option for patients with localized disease; however, the long-term results of this approach are not available, and the results of ongoing trials are awaiting more mature follow-up.

External Beam Radiotherapy

Intensity-Modulated Radiotherapy and Image-Guided Techniques

IMRT, a type of conformal radiotherapy (CRT), has become a standard mode of treatment planning for patients with localized prostate cancer and takes advantage of inverse-planning methods to optimize dose distribution. Inverse planning is part of a mathematical optimization algorithm that creates a treatment plan based on predefined, desired dose-distribution parameters for the target and dose constraints imposed on the normal tissues. The highly conformal radiation beam is produced with the ability to vary the intensities of the X-rays from each treatment field over the entire cross-section of the beam.

More recently, image-guided approaches have enhanced IMRT delivery. Acquisition of CT images or kilovoltage images on the treatment machine immediately before the radiation treatment allows for visualization of the target and correction of its position, which can fluctuate on a daily basis, related to bladder or rectal filling. Linac-based kilovoltage image guidance systems have become commercially available; they possess capabilities for kilovoltage two-dimensional projection imaging (radiographs), fluoroscopy, and three-dimensional cone beam CT, and are thus ideally suited for monitoring inter- and intrafractional motion. The use of image-guided radiotherapy and enhanced target localization could lead to a further reduction of safety margins and a decrease in morbidity related to ultrahypofractionated regimens. A recent retrospective report demonstrated reduced urinary-related treatment toxicities and improved tumor control outcomes among patients with clinically localized prostate cancer treated with image-guided approaches, compared with patients not treated with image-guided therapy.²⁰³ Among a cohort of patients treated to dose levels of 86.4 Gy, the incidence of late grade 2 urinary toxicities was 20% for those treated with daily image guidance, compared with 10% for patients treated with daily image guidance and target positional corrections ($p = 0.02$).

Definition of Target Volume

The multifocal nature of prostate cancer and the well-documented risk of microscopic ECE, even for patients with early clinical stages of disease, are important considerations that influence the

design of the target volume for radiation treatment planning. The clinical target volume (CTV) includes the entire prostate gland and immediate periprostatic tissues, as well as the seminal vesicles, as visualized on CT. For patients with low-risk disease with unremarkable imaging studies, the CTV may exclude the seminal vesicles, owing to the low likelihood of disease involvement. The planning target volume places an additional margin around the CTV to take into account patient setup uncertainties and organ motion. With the use of image-guided approaches, the margin can be safely reduced to 5 mm to 6 mm around the CTV, except at the prostate-rectal interface, where an even tighter margin (3 mm to 5 mm) is used.

Role of Dose Escalation in Patients with Clinically Localized Disease

Findings from several randomized phase 3 trials (Table 68.10)²⁰⁴⁻²⁰⁸ and the long-term results of single-institution studies²⁰⁹⁻²¹² demonstrate a significant improvement in treatment outcomes with higher radiation doses in patients with clinically localized disease. As shown in Table 68.10, these studies have generally demonstrated a 10% to 20% improvement in 5- to 10-year PSA survival outcomes when higher doses of 78 Gy to 80 Gy are applied, compared with dose levels of 70 Gy, and such benefits have been observed for low-, intermediate-, and high-risk cohorts. Although overall survival benefits have not been demonstrated with dose escalation, improvements in distant metastases-free survival are emerging with longer follow-up, suggesting that survival benefits will be seen as these studies mature. In one report, a reduction in death due to prostate cancer was noted at 10 years for intermediate- and high-risk patients treated with doses of 78 Gy, compared with those treated at 70 Gy.²¹³

For patients with intermediate- and especially high-risk disease, doses beyond 80 Gy may be required to achieve optimal tumor control outcomes. To do so requires ultra-high-dose IMRT, which

constrains the dose delivered to normal tissues, such as the bladder and the rectum. In a recent update of the long-term outcomes of ultra-high-dose IMRT at MSKCC, 1,002 patients treated with 86.4 Gy, using a five- to seven-field IMRT technique, had 7-year PSA-relapse-free survival rates of 99%, 86%, and 68% for low-, intermediate-, and high-risk patients, respectively. The incidence of distant metastases for these respective risk groups was 0.5%, 6%, and 18% at 7 years, and incidence of grade 3 rectal and urinary toxicities was 0.7% and 2.2%. The median follow-up was 5.5 years.²¹⁴

Sequelae of External Beam Radiotherapy

Complication rates after EBRT vary as a function of the dose, the volume of normal tissues irradiated at particular dose levels, and the treatment field. Acute symptoms typically appear during the third week of treatment and resolve within days to weeks after its completion. Acute intestinal symptoms, especially those associated with whole pelvic irradiation, are most commonly relieved with dietary manipulations. Otherwise, medications such as loperamide hydrochloride (Imodium; McNEIL-PPC, Inc., Fort Washington, PA) or diphenoxylate hydrochloride and atropine sulphate (Lomotil; Pfizer, New York, NY) are appropriate to relieve symptoms. Internal and external hemorrhoids, which may become inflamed during the course of therapy, are often best treated with sitz baths and hydrocortisone suppositories. Patients may also experience changes in the consistency of their bowel movements or an increase in mucous discharge. Acute urinary symptoms are treated with phenazopyridine hydrochloride (Pyridium; Warner Chilcott, Rockaway, NJ), nonsteroidal anti-inflammatory agents, or alpha-blockers, such as tamsulosin hydrochloride (Flomax; Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, CT). Alpha-blockers have been reported to be significantly more effective than nonsteroidal anti-inflammatory agents, resulting in significant resolution of urinary symptoms in 66% of patients and moderate improvement in 22%.²¹⁵

TABLE 68.10

Phase 3 External Beam Radiotherapy Dose Escalation Studies

Study (Ref.)	No. of Patients	Median Follow-Up	Treatment Arms	PSA Relapse-Free Survival Outcome	P Value
Beckendorf et al. ²⁰⁴ / GETUG 06	306	5 y	80 Gy vs. 70 Gy	At 5 y: Overall results High dose, 72% Low dose, 61%	0.039

Late rectal toxicities attributed to radiotherapy typically manifest 12 months to 18 months after completion of treatment and may persist for several years thereafter; the development of rectal complications after 5 years is rare. Late rectal toxicities may include rectal bleeding, mucous discharge, and mild incontinence of stool. The more-severe toxicities, including ulcer development and fistula formation, are observed in $\leq 1\%$ of patients. Grade 2 rectal bleeding can be effectively treated with steroid suppositories, sitz baths, and an increase in dietary fiber. Because of the increased risk of further trauma to the rectal mucosa and the risk of fistula formation, deep rectal biopsies and cauterization procedures should be avoided unless absolutely necessary. For radiation-induced proctitis not responsive to conservative measures, argon-beam plasma laser coagulation can decrease the frequency of rectal bleeding episodes.²¹⁶ Hyperbaric oxygen treatments, at a pressure of 2.4 atmospheres for a median of 36 sessions (90 minutes per session), may be helpful; in one study, they were associated with a complete resolution of rectal bleeding in 48% of patients and a reduction in bleeding episodes in 28% of patients.²¹⁷ It is assumed that hyperbaric oxygen improves the delivery of oxygen to ischemic rectal mucosa, promoting angiogenesis and advancing mucosal healing and fibroblast proliferation.

Late urinary toxicities include chronic urethritis, which occurs in approximately 10% to 15% of patients, and urethral strictures, which occur in 2% to 3%. Hemorrhagic cystitis is uncommon with conformal radiation techniques, which reduce the dose to the bladder. Current treatment approaches for hemorrhagic cystitis include intravesical formalin therapy and selective embolization of the hypogastric arteries. For patients refractory to such measures, hyperbaric oxygen therapy can be considered for radiation-induced hemorrhagic cystitis. In one report, 49 of 57 patients (86%) experienced complete resolution or marked improvement of hematuria following hyperbaric oxygen treatment.²¹⁸

Whereas any form of radiotherapy can increase the risk of developing a secondary cancer, the incidence after prostate radiotherapy appears to be lower than expected. One report comparing the risks of secondary cancers among patients treated with RP, EBRT, and brachytherapy did not find the therapeutic intervention to be a significant predictor of secondary cancer at 10-year follow-up.²¹⁹ Longer follow-up will be required to determine whether any significant differences eventually develop between the treatment arms. Nonetheless, given the risk of secondary cancer with any form of radiotherapy, close monitoring is important. Colonoscopy every 5 years and careful evaluation of patients who present with hematuria after radiotherapy are recommended to rule out the possibility of a secondary bladder cancer.

IMRT is also associated with a reduced risk of rectal-related toxicities after high-dose radiotherapy. In the initial cohort of patients treated with 81 Gy, late rectal and urinary complications were significantly reduced with IMRT relative to conventional three-dimensional CRT (Fig. 68.11). In 561 patients treated with IMRT (81 Gy) at MSKCC,²²⁰ the 8-year actuarial likelihood of developing grade 2 rectal bleeding was 1.6% with no grade 4 events and late grade 2 and 3 (urethral strictures) urinary toxicities were 9% and 3%, respectively. Among patients who were potent before IMRT, 49% developed erectile dysfunction.²²⁰

Factors predictive of late urinary toxicities after high-dose IMRT included a lower baseline urinary symptom score (International Prostate Symptoms Score) ($p = 0.006$) and an increased maximal dose beyond the prescribed dose to the bladder trigone region ($p = 0.003$).²²¹ When high-dose radiotherapy is used, efforts should be made to restrict the high-dose region from receiving $>15\%$ to 20% of the prescription doses for the urethra and, in particular, for the bladder neck and the region of the bladder trigone. These and other data indicate that patients with significant urinary symptoms before treatment may be better served by surgery, rather than radiotherapy.

Figure 68.11 Incidence of grade 2 or greater genitourinary (GU) and gastrointestinal (GI) toxicities for patients receiving intensity-modulated radiation therapy only for patients treated at Memorial Sloan Kettering Cancer Center. X-axis represents months from completion of treatment. Y-axis represents the percentage incidence of toxicity.

Potency Preservation with External Beam Radiotherapy

The reported rates of impotence at 3 years or longer after EBRT ranges widely from 36% to 68%,²²² a reflection of the differences in methodologies used to assess this end point and the heterogeneity of the EBRT patient population. Factors such as advanced age and the presence of medical comorbidities (coronary artery disease, diabetes, and use of antihypertensive medications) can have a profound effect on erectile function. Besides erectile dysfunction, aspects of sexual dysfunction that occur after radiotherapy include decreased volume of ejaculate, absence of ejaculate, decreased intensity of orgasm, and decreased libido.

Hypofractionated External Beam Radiotherapy

The administration of larger doses for each treatment fraction has potential radiobiologic advantages (hypofractionated radiotherapy) that can result in a greater degree of cell kill.^{223,224} One approach is stereotactic body radiosurgery, which has been used increasingly during the last several years. Unfortunately, most reports to date are uncontrolled single-center series of selected patients which, despite recognized limitations, are showing promising results using PSA-based outcomes.^{225–227} These treatments are delivered with a linear accelerator mounted with an image-guided device to achieve greater precision of the dose delivery. With tight margins used, high doses per fraction allow completion of the course of therapy in 1 week. A pooled analysis of 1,100 patients treated from 2003 to 2011 at eight institutions was recently reported.²²⁸ The median dose delivered for these patients was 36.25 Gy in five fractions. The median follow-up was 3 years; the 5-year PSA-relapse-free survival rates were 95%, 84%, and 81% for low-, intermediate-, and high-risk patients, respectively. Stereotactic radiosurgery appears promising, but this form of treatment cannot be considered an established form of radiotherapy delivery, and ongoing studies will define its role better in the years ahead.

The Role of Proton Therapy for Localized Prostate Cancer

Recently, there has been increasing interest in the use of proton therapy for clinically localized disease because of the known physical advantages of this charged particle—namely, the Bragg peak—by which the majority of the energy of the beam is deposited at the end of its track, creating a rapid falloff of dose beyond the target. The result is that exit dose beyond the target volume is eliminated, providing the potential to achieve greater sparing of normal tissues with dose escalation. Theoretically, physical advantages of the proton beam may also translate into

a reduced risk of second malignancies, owing to the reduced exposure of normal tissues to the radiation beam relative to photon therapy. A series by Mendenhall et al.²²⁹ examined the 5-year clinical outcomes of 211 prospectively treated patients who received proton therapy using an image-guided approach. Low-risk patients received 78 Gy, intermediate-risk 78 Gy to 82 Gy, and high-risk 78 Gy with concomitant docetaxel followed by ADT; the 5-year PSA-relapse-free survival rates were 99%, 99%, and 76%, respectively. The incidence of grade 3 rectal and urinary toxicities was 1% and 5.4%, respectively, comparable if not superior to those with high-dose IMRT. Randomized trials to confirm these findings are ongoing, including a multi-institutional trial comparing 80 Gy versus a similar dose of protons for low- and intermediate-risk patients; the end point is 2-year QOL and late toxicities.

Reports addressing the question of whether protons are associated with reduced long-term toxicities relative to high-dose photon therapy are conflicting. One recent study of 1,242 patients treated with either proton therapy at doses of 76 Gy to 82 Gy or IMRT at doses of 75.6 Gy to 79.4 Gy showed similar QOL scores for the bowel, urinary incontinence, urinary irritative symptoms, and sexual domains at the last follow-up evaluation. Further exploration of specific function outcomes showed that patients treated with proton therapy had less frequent bowel movements and rectal urgency, compared with patients treated with IMRT.²³⁰ However, an analysis of the relative toxicities of IMRT and proton therapy in patients with localized prostate cancer based on the Surveillance, Epidemiology, and End Results–Medicare-linked database showed that IMRT was associated with fewer gastrointestinal (GI)-related toxicities and hip fractures, whereas proton therapy was associated with a lower risk of erectile dysfunction.²³¹ It is anticipated that future improvements in intensity-modulated proton therapy will also improve the conformality of the proton beam, resulting in fewer complications with proton dose escalation. To date, however, there is no established evidence that proton therapy provides superior tumor control outcomes, compared with well-delivered high-dose IMRT or image-guided radiotherapy, for the treatment of prostate cancer.

Prostate Brachytherapy

Excellent long-term tumor control can be achieved with brachytherapy, and the approach is considered a standard treatment intervention associated with outcomes comparable to those with prostatectomy and EBRT for patients with clinically localized disease.^{232–237} By category, low-risk disease is managed with seed implantation alone (i.e., monotherapy), whereas intermediate- and selected high-risk disease is managed with a combination of brachytherapy (low-dose-rate [LDR] permanent interstitial implantation or high-dose-rate [HDR] brachytherapy via after-loading catheters) and EBRT. Whether the addition of EBRT is necessary in all patients with intermediate-risk prostate cancer is being studied in a phase 3 randomized trial (Radiation Therapy Oncology Group [RTOG] 0232).

Technical Aspects of Prostate Brachytherapy

Transperineal ultrasound-guided approaches have facilitated image-guided placement of the seeds and are credited with improved long-term outcomes and reduced treatment-related complications. These approaches have further improved the accuracy and consistency of the dose delivery to the target, with a concomitant reduction of dose to the urethra and rectum. The use of adjunctive intraoperative CT scanning to verify the actual deposited seed coordinates may eliminate the need for postimplantation assessments and may allow for opportunities, if necessary, to correct suboptimal implanted regions within the gland before the reversal of anesthesia. Close collaboration between the radiation oncologist and the medical physicist in

the design of the pre- or intraoperative treatment plan is critical for a successful outcome.

The two most commonly used radioisotopes for permanent seed brachytherapy are iodine-125 (¹²⁵I) and palladium-103 (¹⁰³Pd). The half-life of ¹²⁵I is 60 days, with a mean photon energy of 27 KeV and an initial dose rate of 0.07 Gy/h. In contrast, the half-life of ¹⁰³Pd is 17 days, with a mean photon energy of 21 KeV and an initial dose rate of 0.19 cGy/h. The active periods for ¹²⁵I and ¹⁰³Pd are 10 months and 3 months, respectively. When ¹²⁵I is used, the typical prescription dose is 144 Gy; 125 Gy is routinely used for ¹⁰³Pd.

The quality of the implant and dose distributions are routinely evaluated using CT scans obtained on the day of the implant or 30 days later. Postimplantation CT scans are used to generate dose-volume histograms, which allow detailed analysis of the radiation dose distribution relative to the prostate and surrounding normal tissues. Dosimetric parameters include V100 for the target (volume of the prostate receiving 100% of the prescription dose), D90 of the target (dose delivered to 90% of the prostate), and the average and maximum rectal and urethral doses.²³⁸

Table 68.11 summarizes the published biochemical control outcomes after LDR interstitial seed implantation, according to prognostic risk groups.^{235,237,239–243} The size of the prostate gland should preferably be <60 cm³ and optimally <50 cm³. In larger gland sizes, the pubic arch may interfere with needle placement reaching the anterolateral portions of the gland, resulting in inadequate dose coverage of the target volume. Larger glands require more seeds and activity to achieve coverage of the gland with the prescription dose, which may result in an increase in the central urethral doses and potentially increase the risk of urinary morbidity.²⁴⁴ The size of the prostate can be effectively addressed with combined androgen-blockade therapy. An approximately 30% reduction in volume is commonly observed after 3 months of ADT. For patients who have imaging findings consistent with gross ECE or SVI not detected on rectal examination, monotherapy is not sufficient, and supplemental EBRT should be considered.

Patients with a significant degree of urinary obstructive symptoms are more prone to develop prolonged morbidity after brachytherapy and would be better suited to other treatment interventions. A previous TURP may increase the risk of urinary morbidity after seed implantation²⁴⁵; brachytherapy should be performed with caution in such patients. Careful attention to dose-volume considerations to the periurethral region and the area of the TURP defect should reduce the likelihood of long-term morbidities.

Seed implantation may be a more suitable intervention for patients with bilateral hip replacements, in whom CT-based treatment planning is technically difficult because of the substantial artifact created by the prosthesis, precluding adequate visualization of the target volume. Ultrasound-based seed implantation would be an appropriate alternative for such patients, as artifacts would not pose a difficulty with this imaging modality. In most cases, patients with hip prostheses are able to tolerate the extended dorsal lithotomy position for adequate perineal exposure during seed implantation. Patients with small bowel in close proximity to the prostate volume are also better suited to brachytherapy, owing to the lower doses to the bowel expected with brachytherapy. Brachytherapy may be safe for patients with a history of inflammatory bowel disease, a condition that represents a relative contraindication for EBRT. Of 24 patients with a history of inflammatory bowel disease who were treated with brachytherapy, none experienced grade 3 or higher rectal toxicities (median follow-up, 4 years), but late grade 2 rectal bleeding (19%) was significantly higher than among patients without a history of inflammatory bowel disease.²⁴⁶

Transient urinary morbidity related to radiation-induced urethritis or prostatitis represents the most common side effect following seed implantation. Symptoms include urinary frequency, urgency,

TABLE 68.11

Prostate-Specific Antigen Relapse-Free Survival Outcomes for Low-Dose-Rate Brachytherapy

Study (Ref.)	No. of Patients	Median Follow-Up (y)	Treatment	Five-Y Biochemical Outcome According to Risk Group	Comments
Stock et al. ²³⁹	1,377	4.2	MT/CMT	Low, 94% Intermediate, 89.5% High, 78%	Interactive real-time planning
Zelevsky et al. ²³⁷	2,693	5.2	MT	Low, 82% Intermediate, 70% High, 48%	D90 \geq 130 Gy 8-y PSA control, 93% D90 <130 Gy 8-y PSA control, 76%
Guedea et al. ²⁴⁰	1,050	2.5	MT	Low, 93% Intermediate, 88% High, 80%	—
Khaksar et al. ²⁴¹	300	4	MT	Low, 96% Intermediate, 89% High, 93%	—

MT, monotherapy; CMT, combined-modality therapy (implant + external beam); D90, the dose received by 90% of the prostate; PSA, prostate-specific antigen.

and dysuria, which usually peak 1 to 3 months after the implant procedure and gradually resolve during the subsequent months. The incidence of urinary symptoms persisting after 1 year is 15% to 25%; the risk of urethral strictures ranges from 1% to 12%. The incidence of grade 3 and 4 rectal or urinary toxicities, including urinary or rectal incontinence, is \leq 1% (Table 68.12).^{239,242,247–255}

The incidence of grade 2 rectal toxicity after prostate brachytherapy ranges from 2% to 5%^{247,256,257}; grade 3 or 4 rectal toxicity is unusual (<2%). These results are similar to late toxicities observed after high-dose EBRT. Meticulous attention to needle and seed placement, as well as to the intraoperative dose-volume histogram data on normal tissue, should reduce rectal doses and lower risks of toxicity to minimal levels.

Erectile Function After Brachytherapy

Impotence rates after prostate brachytherapy and EBRT are likely underestimated in the literature. With longer follow-up, observations and responses from patient surveys indicate that approximately 40% to 50% of patients maintain erectile function after prostate brachytherapy.^{258,259} Preimplant erectile function score and the dose to 50% of the proximal crura of the penis have been shown to be significant predictors of erectile dysfunction.²⁵⁸

Excellent responses have been observed with sildenafil citrate in the treatment of impotence after brachytherapy and EBRT. In one report,²⁵⁹ 80% of patients responded to the medication. With long-term follow-up, 37% of patients discontinued use of the medication. Similar responses have been reported for patients who developed erectile dysfunction after EBRT and were treated with sildenafil citrate. There has been increasing interest in the use of sildenafil before the development of erectile dysfunction to reduce the risk of erectile dysfunction after treatment. The RTOG randomized patients to receive sildenafil following radiotherapy but before the development of erectile dysfunction and found no

demonstrable benefit.²⁶⁰ However, a recent randomized trial from MSKCC showed improvements in sexual function parameters 12 months and 24 months after therapy among patients treated with prophylactic sildenafil, compared with those who received placebo.²⁶¹

Combined Brachytherapy and External Beam Radiotherapy

Combined brachytherapy and EBRT is considered to be a more suitable treatment option than implantation alone for patients with unfavorable intermediate- or high-risk disease. The combined approach effectively delivers an increased dose of radiation that has been estimated to have a biologic equivalent that well exceeds a 100-Gy dose of EBRT. Conventional or conformal-based techniques are used to deliver 45 Gy to 50 Gy of EBRT to the prostate and periprostatic tissues. If an LDR boost is used, the brachytherapy prescription dose is 90 Gy to 100 Gy for ¹⁰³Pd implants and 110 Gy for ¹²⁵I implants. In the absence of clinical trials comparing HDR brachytherapy boosts with LDR boosts or establishing the optimal sequence of therapy (brachytherapy boost preceding EBRT or vice versa) or the preferred isotope to be used for combined-modality therapy, there is no definitive evidence demonstrating the superiority of a particular treatment strategy over another.

The phase 3 trial RTOG 0232 is comparing permanent-source brachytherapy as monotherapy with EBRT followed by brachytherapy for patients with intermediate-risk prostate cancer. The study is ongoing but no longer recruiting patients. The primary end point of this study is survival; secondary end points include PSA-relapse-free survival, distant metastases-free survival, and QOL. Eligibility criteria for this study include clinical stage T1c–T2b and either Gleason score <7 with a PSA level of 10 ng/ml to 20 ng/ml, or Gleason score of 7 with a PSA level <10 ng/ml. The American Urological Association voiding symptom score should be \leq 15, and prostate volume should be <60 g.

High-Dose-Rate Brachytherapy

HDR brachytherapy has been used in combination with EBRT for the treatment of prostate cancer.^{262–266} Patients undergo ultrasound-guided transperineal placement of afterloading catheters in the prostate. After CT-based treatment planning, several high-dose fractions, ranging from 4 Gy to 6 Gy each, are administered during an interval of 24 hours to 36 hours using ¹⁹²Ir, followed by supplemental EBRT directed to the prostate and periprostatic tissues at a dose of 45 Gy to 50.4 Gy using conventional fractionation. The results of a randomized trial²⁶⁷ comparing hypofractionated EBRT at 55 Gy in 20 fractions with EBRT at 35.75 Gy in 13 fractions followed by an HDR brachytherapy boost of 17 Gy in two fractions delivered over 24 hours showed a 7-year likelihood of biochemical control of 66% in the combined-modality group versus 48% in the EBRT group ($p = 0.04$).

HDR brachytherapy offers several potential advantages over other techniques. Taking advantage of an afterloading approach, the radiation oncologist and physicist can more easily optimize the delivery of radiotherapy to the prostate, reducing the potential for underdosage (“cold spots”). This technique also reduces radiation exposure to the radiation oncologist and others involved in the procedure, compared with that from permanent interstitial implantation. Finally, HDR brachytherapy boosts may be radiobiologically more efficacious in terms of tumor cell kill for patients with increased tumor bulk or adverse prognostic features, compared with LDR boosts using ¹²⁵I or ¹⁰³Pd.

Selecting the Optimal Radiotherapeutic Approach for Localized Disease Adapted for Risk Group

For patients with low-risk disease who have significant volume of disease ($\geq 50\%$ cores involved by cancer on the diagnostic biopsy), increasing PSA velocity, or a dominant lesion noted on MRI, a treatment intervention would be often indicated. For such patients, brachytherapy as monotherapy or IMRT at dose levels of 80 Gy would be appropriate and associated with biochemical outcomes of approximately 90% at 10 years. In these cases, brachytherapy is preferred over IMRT, given the convenience of a single treatment accomplished in an outpatient setting. Patients with significant urinary obstructive symptoms or other medical comorbidities may be better suited to IMRT. Patients with enlarged prostate glands of 60 ml to 90 ml are best treated with ADT to reduce the size of the gland before brachytherapy which in most cases, will result in a 30% volume reduction in 3 to 4 months.

For patients with intermediate- or high-risk disease, doses higher than 80 Gy may be necessary to achieve further improvement in local tumor control. In the absence of randomized trials comparing the efficacy of various forms of radiotherapy to deliver high dose levels for patients with intermediate- and high-risk disease, it has been our preference to recommend for these patients brachytherapy in combination with image-guided EBRT. In a recent study from MSKCC comparing intermediate-risk patients treated with brachytherapy combined with supplemental

IMRT versus IMRT alone to levels of 86.4 Gy, the 7-year actuarial prostate PSA-relapse-free survival rates were 81.4% versus 92.0% ($p < 0.001$) and distant metastases-free survival rates were 93.0% versus 97.2% ($p = 0.04$) for IMRT alone versus brachytherapy combined with IMRT, respectively. Multivariate analysis demonstrated that brachytherapy combined with IMRT boost was associated with better PSA-relapse-free survival (hazard ratio [HR] = 0.40; 95% CI = 0.24 to 0.66; $p < 0.001$) and better distant metastases-free survival (HR = 0.41 [0.18 to 0.92]; $p = 0.03$). The trade-off was a higher rate of acute urinary grade 2 symptoms in the combined treatment arm, which in most cases gradually resolved with time. Late toxicity outcomes were 4.6% versus 4.1% for grade 2 GI toxicity ($p = 0.89$), 0.4% versus 1.4% for grade 3 GI toxicity ($p = 0.36$), 19.4% versus 21.2% for grade 2 genitourinary toxicity ($p = 0.14$), and 3.1% versus 1.4% for grade 3 genitourinary toxicity ($p = 0.74$) for the IMRT versus the combination RT groups, respectively.

Androgen Deprivation Therapy and Radiotherapy

ADT has been used as part of a combined modality approach with radiation, and randomized trials have demonstrated improved outcomes, including an overall survival benefit for this combination, compared with radiotherapy alone. The uses include neoadjuvant and concurrent; neoadjuvant, concurrent, and adjuvant; and concurrent and adjuvant. It is routinely recommended for patients with high-risk disease and selected patients with intermediate-risk disease when used in combination with EBRT. Reported trials, however, vary in the total dose of radiation used to the primary site, whether pelvic radiation was utilized, as well as the duration and timing of ADT. The end points also vary from PSA recurrence alone, whether a biopsy of the gland was performed to assess for local disease control, to the documentation of metastatic disease or death. For many, follow-up is simply too short to draw definitive conclusions. Recognizing these caveats, outcomes and indications for use in practice are summarized.

Randomized Trials for High-Risk Disease

Table 68.13²⁶⁸⁻²⁷⁰ summarizes the outcomes of randomized trials comparing radiotherapy alone to radiotherapy combined with ADT for patients with locally advanced high-risk prostate cancer. These trials have consistently demonstrated improved outcomes when ADT is combined with EBRT and the administered dose is ≥ 70 Gy (see Table 68.10).

Several trials have used adjuvant hormonal therapy for various durations after EBRT and demonstrated long-term disease-free survival benefits. In another important randomized trial, the European Organization for Research and Treatment of Cancer (EORTC) 22863, node-negative patients with clinical stage T3 disease or T1-T2 patients with high-grade disease received adjuvant ADT on the first day of radiotherapy (prescribed dose of 70 Gy) and continued for 3 years. Improved outcomes were observed for all parameters, including absolute survival (median follow-up, 9 years).²⁷¹ The 10-year overall survival was 58% versus 40% for patients treated with ADT plus EBRT and EBRT alone, respectively ($p = 0.0004$). In addition, the 10-year PCSM rates for these respective cohorts of patients were 10% and 30% ($p < 0.0001$).

The duration of ADT was addressed in RTOG 92-02, the first ADT trial performed with baseline PSA information available, which randomized patients with clinical T2-T4 disease with PSA baseline levels < 150 ng/ml to receive either neoadjuvant and concurrent ADT for a total of 4 months or the same therapy plus an additional 24 months of adjuvant ADT for a total of 28 months. The prescribed radiation dose levels used in this study ranged from 65 Gy to 70 Gy. At a median follow-up of 5.8 years, the results showed that all outcomes were improved for patients who received 28 months with the exception of overall survival. A subset analysis,

however, showed a 10% overall survival advantage for patients with Gleason scores of 8 to 10 who were treated with the longer course of ADT.²⁷²

RTOG 94-13 evaluated two sequencing regimens of adjuvant ADT as well as the role of pelvic radiotherapy in the setting of treatment with ADT in patients with T2c-T4 disease or those with an estimated LN risk $\geq 15\%$. The radiation dose administered was 70.2 Gy in 39 fractions. Patients were randomized to receive either 4 months of ADT before and during radiotherapy or 4 months of ADT as adjuvant therapy following the completion of EBRT. Patients were also randomized to receive either whole-pelvic radiotherapy or treatment directed to the prostate only. Neoadjuvant and concurrent ADT in conjunction with whole-pelvic radiotherapy was associated with a trend for an improved progression-free survival (PFS) compared to the other study arms (48% PFS for neoadjuvant ADT and whole-pelvic radiotherapy versus 40% for prostate only radiotherapy and adjuvant ADT; $p = 0.065$).²⁷³

Randomized Trials for Intermediate-Risk Disease

Recent studies have explored the role of ADT for patients with earlier stages of disease. D'Amico et al.²⁷⁴ reported the results of a randomized trial comparing 70 Gy of three-dimensional CRT alone or a similar dose of radiotherapy combined with 6 months of ADT (initiated 2 months before radiotherapy). Of note, most of the patients included in this study had intermediate-risk disease—namely, pretreatment PSA levels 10 ng/ml to 40 ng/ml or Gleason score > 7 with T1-T2 disease. Overall 5-year (median follow-up, 4.5 years) survival advantage was demonstrated for the combination-therapy regimen, compared with radiotherapy alone (88% versus 78%; $p = 0.04$). RTOG 9408²⁶⁹ compared radiation alone with radiation plus 4 months of ADT (starting 2 months before radiation) in 1,979 patients with stage T1b, T1c, T2a, or T2b prostate cancer and a PSA level ≤ 20 ng/ml. The total EBRT dose was 66.6 Gy, 46.8 Gy delivered to the pelvis (prostate and regional LN), followed by 19.8 Gy to the prostate (see Table 68.13). Low-risk disease was defined as a Gleason score ≤ 6 , PSA level ≤ 10 ng/ml, and clinical stage T2a or lower; intermediate-risk disease was defined as a Gleason score of 7, Gleason score ≤ 6 and PSA level from 10 ng/ml to 20 ng/ml, or clinical stage T2b; and high-risk disease was defined as a Gleason score of 8 to 10. The 10-year overall survival (median follow-up, 9.1 years) was 62% for EBRT + ADT, compared with 57% for EBRT alone ($p = 0.03$). The addition of ADT decreased 10-year PCSM from 8% to 4% ($p = 0.001$). The reduction in risk was primarily observed in intermediate-risk patients; no significant reductions in mortality were noted among low-risk patients. Conclusions from this trial are limited by the dose of radiation administered, which was far lower than contemporary standards. Nevertheless, this study provides further level I evidence that short-course ADT is associated with a survival benefit when combined with subtherapeutic doses of EBRT. A subsequent trial in a similar patient population showed that 8 months of ADT was not superior to 3 months of therapy. This multi-institutional phase 3 study from Canada²⁷⁵ randomized 378 patients to receive either 3 months or 8 months of total androgen blockade. Conventional radiotherapy at 66 Gy was initiated within 2 weeks of completion of the ADT regimen. In this trial, 31% of the patients were considered to have high-risk disease; the remaining patients had low- or intermediate-risk disease. No differences in any of the end points, including BCR-free survival, were observed.

The various trials have used different sequences to deliver ADT, and the eligibility criteria have not been consistent. Nevertheless, some broad conclusions can be drawn regarding the optimal integration of ADT with radiotherapy. For patients with high-risk cancers, and in particular high-grade cancers, ADT is indicated and adjuvant courses of hormonal therapy that extend ≥ 2 years

appear to be associated with disease-free survival improvements compared to shorter courses. The preliminary results of the EORTC phase 3 trial 22961,²⁷⁶ comprising 970 patients with locally advanced prostate cancer who were randomized to receive either 6 months or 3 years of ADT in conjunction with 70 Gy of EBRT, show that biochemical control and PFS were shorter for patients treated with the 6-month ADT regimen than for those treated with the longer course. No differences in survival have been noted so far between the two treatment arms. These data suggest that, for high-risk patients, longer courses of ADT may be critical in the setting of subtherapeutic doses of EBRT (i.e., 70 Gy). One cannot extrapolate from the published randomized trials whether 2-year or longer courses for high-risk disease are necessary when using modern dose escalated radiotherapy in the range of 78 Gy to 80 Gy. Nevertheless, longer courses of ADT are routinely used in clinical practice for high-risk patients in combination with dose-escalated radiotherapy. For patients with lower Gleason scores but with larger-volume disease, or for select patients with intermediate-risk disease, a shorter course of 6 months may be sufficient to provide a significant clinical benefit. In a meta-analysis of studies using various durations of ADT in conjunction with radiotherapy, a two-fold reduction in prostate cancer mortality was observed among patients treated with longer courses of ADT.²⁷⁷

As all of the previously mentioned trials used doses of radiotherapy ≤ 70 Gy, the role of ADT in the setting of an escalated dose of radiotherapy (≥ 75.6 Gy) remains uncertain. Higher doses of radiotherapy have been shown to improve local tumor control and may obviate the need for ADT. Nevertheless, in the absence of a randomized trial in this setting, it remains uncertain whether ADT should be avoided in the treatment of high-risk patients. Retrospective data from MSKCC showed that, among intermediate-risk patients treated with high-dose IMRT, short-course ADT (6 months) was associated with improved PSA-relapse-free survival, distant metastases-free survival, and PCSM, compared with high-dose radiotherapy alone.²⁷⁸ The 10-year incidence of distant metastases and PCSM rates were 6.5% and 2.4%, respectively, for patients treated with high-dose IMRT and ADT compared to 12.3% and 5%, respectively, for patients treated with IMRT alone ($p < 0.001$).

Definitive trials addressing the role of ADT in combination with brachytherapy are lacking, but its use is supported by basis extrapolating the results of randomized trials of patients treated with EBRT. Several reports^{262,279,280} have suggested that, in the setting of brachytherapy (LDR or HDR brachytherapy boosts), ADT may be less beneficial than EBRT, whereas others²³⁹ have suggested a benefit for higher-risk patients. It is possible that the primary role of ADT is to act as a radiosensitizer of EBRT when lower radiation doses, such as 70 Gy, are used. When higher radiation doses were used, or with the incorporation of brachytherapy boosts, several retrospective reports found no benefit of hormone therapy, except in high-grade, high-risk patients. In the absence of randomized trials in this setting, it is reasonable to recommend the use of ADT in high-risk patients, even when higher radiation doses are used. Many reports have not confirmed the role of ADT in conjunction with brachytherapy for intermediate-risk disease. The phase 3 RTOG 0815 trial will address the role of short-course ADT for intermediate-risk patients who receive dose-escalated radiotherapy and brachytherapy as well; 1,520 patients will be randomized to receive either 6 months of ADT with high-dose radiotherapy or radiotherapy alone. High-dose radiotherapy will be administered either at 79.2 Gy in conventional fractionation or as combined brachytherapy with EBRT.

Morbidities for Androgen Deprivation Therapy and Radiotherapy

Finally, there is a growing awareness that the use of ADT in conjunction with radiation therapy is not without cost, as outcomes suggest an increased risk of subsequent congestive heart failure

or myocardial infarction. Although most of the previously cited randomized trials did not report an increase in cardiac-related events, a meta-analysis of patients with unfavorable-risk prostate cancer with moderate to severe medical or cardiac-related comorbidities showed no survival difference between the two groups due to a relative increase in noncancer-related deaths in the ADT-treated group.²⁸¹ In a report of 12,792 men treated with brachytherapy, the use of a 4-month course of ADT was associated with an increased risk of all-cause mortality among those with a history of coronary artery disease-induced heart failure or myocardial infarction.²⁸² The effect of longer courses of ADT in patients with moderate or severe comorbidities is unclear. These data suggest that the use of ADT among favorable-risk patients, in whom its oncologic benefit is unproven, should be carefully considered (particularly in those with severe cardiac comorbidities), owing to its potential morbidity.²⁸³ Future, well-designed prospective studies will be needed to elucidate these issues.

Adjuvant Radiation Therapy for High-Risk Patients After Radical Prostatectomy

Adjuvant Radiotherapy

Randomized Studies

The long-term (median follow-up, 14 years) results of Southwest Oncology Group (SWOG) trial 8794, which included 425 patients with high-risk localized disease who were randomized to receive either 60 Gy to 64 Gy to the prostatic fossa or only observation, have demonstrated a survival benefit of adjuvant radiotherapy in high-risk patients after RP.²⁸⁴ The 10-year distant metastases-free survival and overall survival rates were 71% and 74% for the adjuvant radiotherapy arm, compared with 61% and 66% for the observation arm, respectively ($p = 0.01$; HR = 0.71 and 0.72, respectively). The differences between the treatment groups were detected only after 10 years, highlighting the importance of long-term follow-up in these patients (Fig. 68.12).

EORTC 22911 included 1,005 patients with positive surgical margins or pT3 (ECE and SVI) disease; these patients were randomized to receive either adjuvant EBRT (50 Gy to the prostatic

Figure 68.12 Overall survival advantage demonstrated for high-risk postoperative patients receiving adjuvant radiation therapy (RT) versus observation in the Southwest Oncology Group 8794 trial. (From Thompson IM, Tangen CM, Paradelo J, et al. Adjuvant radiotherapy for pathological T3N0M0 prostate cancer significantly reduces risk of metastases and improves survival; long-term followup of a randomized clinical trial. *J Urol* 2009;181:956–962, with permission.)

fossa and periprostatic tissue plus a 10-Gy to 14-Gy boost to the prostatic fossa only) or no immediate treatment.²⁸⁵ A published update of this study (median follow-up, 10.6 years) showed that adjuvant radiotherapy improved the biochemical PFS rate from 40.1% to 60.6% ($p < 0.0001$); the 10-year rate of locoregional relapse was 7.3% for the adjuvant radiotherapy group and 16.6% for the control group. There was no difference in prostate cancer mortality (HR = 0.78; $p = 0.34$): 10-year prostate cancer mortality was 3.9% for the adjuvant irradiation group versus 5.4% for the observation group.²⁸⁶

The results of adjuvant radiation therapy trials show improvements in shorter term end points, including PSA PFS and locoregional relapse free survival, as anticipated. A meaningful improvement in PCSM has not been shown. Noteworthy as well is that PCSM rate in the nonadjuvant radiation therapy group was only 5.4%,²⁸⁶ reinforcing that preventing a BCR alone does not necessarily translate into a significant survival benefit and that deferring treatment until the disease has declared itself as being more aggressive is an option.

Similar results were observed in a phase 3 trial from Germany (ARO 96-02) which randomized 388 patients with pathologic T3 prostate cancer with undetectable postoperative PSA levels to receive either adjuvant radiotherapy or observation. The 10-year PFS was 56% for the adjuvant radiotherapy group and 35% for the observation group ($p < 0.0001$) with no survival benefit.²⁸⁷

These trials provide evidence that adjuvant postprostatectomy radiotherapy reduces the risk of BCR and in one trial, an improvement in distant metastases-free survival. Yet it remains unproven that deferring radiotherapy until manifestation of an early biochemical relapse would compromise the outcome of patients, compared with subjecting all high-risk patients to salvage radiotherapy. To address this issue, the RADICALS (NCT00541047) trial is randomizing patients to receive either immediate radiotherapy or salvage radiotherapy on detection of PSA during follow-up observations. In this trial, patients with positive margins after RP or pathologic stage T3 disease with a postoperative PSA ≤ 0.2 ng/ml would be randomized to receive early adjuvant radiotherapy or deferred radiotherapy on manifestation of a PSA relapse (defined as a detectable and rising PSA > 0.1 ng/ml or three consecutive rising PSA values). The primary end point of this study is distant metastases-free survival. A second randomization will evaluate the role of ADT with salvage radiotherapy and will randomize patients to be treated with RT alone versus RT with concomitant/adjuvant ADT for 6 months; a third arm will be treated with RT and concomitant/adjuvant RT for 24 months. For this second randomization, the primary end point is disease-free survival.

The Clinical State of Rising Prostate-Specific Antigen

Management of the Patient with Rising Prostate-Specific Antigen After Definitive Local Therapy

The most frequent manifestation of a potential relapse after definitive local therapy is a rise in PSA with no detectable disease on imaging. Here, the need is to determine whether the PSA rise is from a locally recurrent tumor or micrometastatic disease outside the pelvis, and, once determined, to assess whether an intervention is needed to prevent morbidity or mortality from cancer.

The former may benefit from additional local therapy, whereas the latter would require a systemic approach. Patients who develop a rising PSA following RP may be candidates for potentially curative salvage radiation, particularly those who have an undetectable PSA after surgery and develop the rising PSA later (see "Salvage Radiotherapy for the Patient with Rising Prostate-Specific Antigen After Prostatectomy"). Patients who develop a rising PSA after radiation therapy may be candidates for salvage RP, salvage cryotherapy, or

brachytherapy, assuming the sole source of the PSA is the gland itself. Here we consider salvage local therapy. Systemic options are considered later.

Salvage Therapies

Salvage Radiotherapy for the Patient with Rising Prostate-Specific Antigen After Prostatectomy

Numerous nonrandomized studies have shown improved biochemical control outcomes with salvage EBRT, yet the overall PSA-relapse-free survival outcome at ≥ 5 years is approximately 50%.²⁸⁸⁻²⁹² Prognostic factors associated with relapse include surgical Gleason score, the presence of SVI, absolute preradiotherapy PSA level, and preradiotherapy PSADT. Improved outcomes are achieved with salvage radiotherapy when preradiotherapy PSA values are ≤ 0.5 ng/ml.²⁹⁰

At MSKCC, 285 patients with increasing PSA levels after prostatectomy²⁹¹ were treated with either salvage three-dimensional CRT or IMRT. The median dose delivered to the prostate fossa was 70.2 Gy. Neoadjuvant and concurrent ADT were used in 31% of treated patients. The 7-year (median follow-up, 5 years) PSA-relapse-free survival and distant metastases-free survival rates were 37% and 77%, respectively. Multivariate analysis demonstrated that predictors of postradiotherapy failure included the presence of vascular invasion, negative surgical margins, presalvage PSA level > 0.4 ng/ml, and radiotherapy alone (i.e., without ADT). Patients treated without any adverse prognostic features had a 5-year PSA-relapse-free survival of 70%, compared with 30% for those with any adverse feature. In a multi-institutional cohort of 472 patients treated with salvage radiotherapy for a BCR after prostatectomy,²⁹² the overall PSA-relapse-free survival at 5 years (median follow-up, 4 years) was 73%. Variables significant as predictors of biochemical tumor control included Gleason score, surgical margin status, and preradiotherapy PSA level. Although it is difficult to compare retrospective series, it would appear that this latter multi-institutional cohort comprised a more favorable group with fewer adverse pathologic features.

The efficacy of salvage EBRT alone for clinically palpable local disease or imaging evidence of disease within the prostatic bed is suboptimal in part due to the inability to deliver full therapeutic doses of radiation safely.^{293,294} Here, ADT can be used to improve local tumor eradication by reducing the size of a mass, by the concurrent elimination of tumor clonogens inherently resistant to radiotherapy, or both. The 30% to 40% size reduction also increases the ability to deliver maximal radiation dose levels without exceeding the tolerance of the surrounding normal tissue. As such, it is our policy that neoadjuvant and concurrent ADT should be considered in patients with palpable local recurrence, imaging evidence of recurrent disease, especially if biopsy proven, or an immediate detectable PSA after surgery, extrapolating from randomized trials showing the benefit of ADT in patients treated with the prostate intact. Further studies are needed in this setting.

There is limited information on the role of ADT in combination with salvage radiotherapy in the postprostatectomy setting. RTOG 0534 is accruing patients with an increasing PSA level after prostatectomy to receive either radiotherapy alone to the prostate bed, radiotherapy to the prostate bed plus 4 to 6 months of ADT, or radiotherapy to the pelvis and prostate bed plus 6 months of ADT. The previously mentioned RADICALS study incorporates a second randomization of all patients that will explore the role of ADT in the setting of salvage or adjuvant therapy.

The American Society for Radiation Oncology and American Urological Association guidelines recommend that, among patients with adverse pathologic features after prostatectomy (such as positive surgical margins and SVI), adjuvant radiotherapy should be used to reduce the risk of biochemical failures and clinical progression, although its impact on overall survival is unclear. The

level of evidence grade was C. The guidelines also recommend that salvage radiotherapy should be offered to patients with an increasing PSA level or with evidence of local recurrence in the absence of metastatic disease. The recommended definition of biochemical failure after surgery is a detectable or rising PSA level >0.2 ng/ml, with a second confirmatory increase >0.2 ng/ml. Once documented, earlier administration of salvage radiotherapy is appropriate, as disease control is improved when salvage radiotherapy is administered at lower PSA levels.²⁹⁵

Salvage Therapy for Locally Recurrent Disease After Radiation

Patients with persistent disease in the prostate after radiation therapy can be considered for salvage local therapies including a salvage RP, brachytherapy, or cryosurgery. Patient selection requires a performance status of 80 or more, histologic confirmation of disease in the gland, and no evidence of metastatic disease by imaging.

Salvage RP is technically challenging. Reported short-term and long-term complication rates exceed those of standard RP, but with appropriate patient selection and surgical expertise, the procedure has become less hazardous. Despite these advances, complications including bladder-neck contractures and anastomotic strictures have continued to be problematic.²⁹⁶ Urinary incontinence rates remain high and in an MSKCC series,¹⁵² only 74% (95% CI = 54% to 94%) recover urinary control and 20% require a sling procedure or artificial urinary sphincters. The 15-year nonprogression rate was 29% and the 15-year cancer-specific survival rate was 64% after salvage RP. The 5-year actuarial nonprogression rate was 86% for patients with organ-confined cancer (pT2N0), 61% for those with ECE, and 48% for those with SVI.

Salvage Brachytherapy

Initial efforts to use brachytherapy in the salvage setting were restricted because of concerns about treatment-related complications. Improvements in imaging, dosimetry, and approaches (including HDR brachytherapy) have significantly lowered the risks of treatment-related complications to an acceptable level. After recurrent disease in the prostate is documented histologically, preferred candidates include those with no clinical or radiologic evidence of distant disease, adequate urinary function, age and overall health indicative of a >5 - to 10-year life expectancy, prolonged disease-free interval (>2 years) from primary radiotherapy, and a long PSADT (>6 to 9 months) at the time of recurrence. Salvage brachytherapy should be avoided in patients with evidence of SVI recurrence and extracapsular disease, as these patients are poorly treated in the conventional setting.

Therapeutic approaches include permanent interstitial seed implantation,^{297–299} with reported 5- to 10-year PSA-relapse-free survival rates ranging from 10% to 53%. In a second series of 37 patients with a median follow-up of 86 months, 10-year PSA-relapse-free survival and cause-specific survival rates were 54% and 96%, respectively. Improved biochemical tumor control was associated with a presalvage PSA level of ≤ 0.6 ng/ml in multivariate analysis.²⁹⁷ In another report, 69 patients were treated with salvage permanent seed implantation using ¹⁰³Pd with a planned D90 dose of 100 Gy as monotherapy of whom 90% received concurrent ADT. With a median follow-up of 5 years, 5-year PSA-relapse-free survival rates were 86%, 75%, and 66% for patients with low-, intermediate-, and high-risk disease, respectively. Grade 3 urinary toxicity was observed in 9% of patients.²⁹⁸

In 52 patients treated with salvage HDR brachytherapy after radiotherapy failure delivering 36 Gy in six fractions using two TRUS-guided HDR prostate implants, separated by 1 week, the 5-year PSA-relapse-free survival was 51% (median follow-up, 60 months). The incidence of grade 3 urinary toxicity was 2%,

and that of grade 2 rectal toxicity was 4%.³⁰⁰ A prospective phase 2 protocol at MSKCC assessed the safety and efficacy of salvage HDR brachytherapy after EBRT failure in 42 patients; the median dose was 81 Gy. The 5-year PSA-relapse-free survival and distant metastasis-free survival rates were 69% and 82%, respectively. Late grade rectal toxicity was 8%; grade 2 urethral toxicity was 7%. One patient developed urinary incontinence.³⁰¹

Caution and meticulous treatment planning are necessary when considering repeat irradiation, especially in the setting of previous high-dose EBRT. Given the radiation dose previously delivered to the prostate and nearby normal tissue structures, side effects can manifest, including chronic urinary retention, hematuria, rectal ulcers, rectal bleeding, and permanent sexual dysfunction. Yet in the absence of randomized trials, the nonrandomized published studies suggest salvage brachytherapy as potentially less toxic relative to salvage RP.

Salvage Cryotherapy

With the development of second- and third-generation probes, real-time TRUS for intraoperative monitoring, thermocouplers, and urethral warmers, cryotherapy is potentially less toxic and a feasible alternative for salvage local therapy after radiation failure. Case selection criteria include a prostate volume between 20 g to 30 g. The procedure is not advised for patients in whom the gland is ≥ 60 g. Patients with a prior TURP have an increased risk of urethral sloughing and urinary retention. Reported biochemical disease-free survival rates range from 34% to 98%.^{302–307} Reported long-term complications include erectile dysfunction (77% to 100%), rectal pain (10% to 40%), urinary incontinence (4% to 20%), urinary retention (0% to 7%), and urethral sloughing (0% to 5%).^{302–307} Rectourethral fistulas, the most serious complication following cryotherapy, are relatively uncommon (0% to 4%).

A second series of 187 patients with local follow-up³⁰⁶ showed that patients with precryotherapy PSA levels <4 ng/ml had 5- and 8-year (mean follow-up, 49 months) BCR-free survival rates of 56% and 37%, respectively, whereas those with precryotherapy levels ≥ 10 ng/ml had 5- and 8-year BCR-free survival rates of only 1% and 7%, respectively. A total of 17% of patients overall had a positive four-quadrant prostate biopsy after salvage cryotherapy.

Advanced Prostate Cancer: Rising Prostate-Specific Antigen and Clinical Metastases—Noncastrate and Castrate

The core principle of treatment of advanced prostate cancer is to deplete androgens or inhibit signaling through the androgen receptor (AR). The approach was first described in the 1940s by Huggins and Hodges,³⁰⁸ who showed that surgical removal of the testes or the administration of exogenous estrogen could induce tumor regressions, reduce the level of acid phosphatase in the blood, and palliate symptoms of the disease.^{308,309} Both remained the standard of care until the luteinizing hormone-releasing hormone (LHRH) agonists were introduced in the 1980s.^{310,311} The palliative role of surgical adrenalectomy for disease that was progressing following orchiectomy was first described in 1945,³¹² later replaced by the first-generation enzymatic inhibitors of adrenal steroid biosynthesis (aminoglutethimide and ketoconazole).^{313,314} Nonsteroidal antiandrogens were introduced in the 1980s.^{315,316} All these agents lower androgen levels, with the exception of the nonsteroidal antiandrogens that block the binding of androgens to the AR.

The “combined androgen blockade” era followed, during which various hormone combinations were explored in an attempt to increase the degree of AR signaling inhibition and thereby response. The first combined a LHRH agonist with flutamide,³¹⁷ others with adrenal androgen synthesis inhibitors; none of these meaningfully improved survival.^{318,319}

Other approaches to treating advanced prostate cancer include cytotoxic agents, biologic agents, and immunotherapy. In 1996, the first cytotoxic drug, mitoxantrone, was approved for the palliation of pain secondary to progressive osseous disease based upon a trial that was not specifically designed to show a survival benefit.³²⁰ But it was not until 2004 that the first systemic therapy, docetaxel, was shown to prolong the lives of men with progressive CRPC,^{321,322} setting a new benchmark for drug approvals that has not been exceeded by any docetaxel-based combination, several of which have proved inferior to docetaxel alone (Table 68.14).³²²⁻³³⁷

Efforts were also focused on better understanding of the biology of the disease. This effort has led to the approval of six new treatments with diverse mechanisms of action since 2010. Five were shown to prolong life (see Table 68.14), including a biologic agent (sipuleucel-T),³²³ a cytotoxic (cabazitaxel),³²⁵ a bone-seeking alpha-emitting radionuclide (radium-223),³²⁶ and two hormonal agents, the CYP17 inhibitor abiraterone acetate that inhibits androgen biosynthesis in combination with prednisone and a next-generation antiandrogen, enzalutamide, which is mechanistically unique from the first-generation compounds.^{327,328} The sixth agent, denosumab, a monoclonal antibody that binds the cytokine RANKL (receptor activator of nuclear factor- κ B ligand), was shown to reduce the morbidity associated with skeletal metastases relative to a previously established standard (zoledronate).³³⁸

Taken together, the results of these new treatments showed that survival could be prolonged by targeting different aspects of the

malignant process in addition to direct targeting of the tumor, and demonstrated the complexity of measuring success for these new agents. Separately, the success of hormonal agents that inhibit the AR and AR signaling confirmed that prostate cancers progressing despite castrate levels of testosterone are not uniformly hormone-refractory; instead, they are more accurately described as castration-resistant.

Efficacy End Points

Prostate cancer treatment outcomes are reported based on the changes in individual disease manifestations that are present when therapy is initiated and the prevention of development of subsequent manifestations. The appropriateness of one metric over another depends on the class and mechanism of the drug or therapy being used, the disease state of the patients being treated, and the clinical benefit or outcome the therapy is expected to achieve. Measurements of PSA levels alone are not sufficient to gauge efficacy for several classes of agents. For example, AR and AR signaling inhibitors may, in some patients, produce declines in PSA without affecting tumor growth. Conversely, bone-seeking radiopharmaceuticals may relieve pain without decreasing PSA levels. A drug that inhibits cell proliferation without inducing an apoptotic effect may lead to a prolonged period of disease stability or "nonprogression," preventing disease manifestations such as the development of new metastatic lesions or pain that were expected to occur. Such a drug might be beneficial independent of its effect on PSA. In contrast, a hormonal agent or cytotoxic drug that

does not produce a decline in PSA is likely to be inactive. Examples of agents that provide clinical benefit without PSA declines include the delay and prevention benefit of zoledronate¹⁵⁹ and denosumab³³⁸ on SREs, and separately, the survival benefit shown for sipuleucel-T³²³ and radium-223.³²⁶

It is for these reasons that the PCWG2 recommended focusing less on whether a treatment was “working” and more on when it was “not working,” and to carefully consider the potential significance of an apparent adverse change in PSA before stopping therapy.¹⁵⁷ Rather than discontinue treatment based on a PSA change alone, it is preferable to wait until there is evidence of radiographic or clinical progression. Figure 68.13 shows examples where (1) a significant initial rise in PSA or (2) a slow rise following an initial decline did not associate with radiographic or clinical progression for a considerable period of time (2 years and 3.5 years, respectively, in Fig. 68.13).³³⁹ In each case, reliance on the PSA change alone to guide management would have resulted in the premature discontinuation of therapy and denied the patient durable disease control.

Noncastrate Prostate Cancer (Rising Prostate-Specific Antigen and Noncastrate Metastases)

Hypothalamic-Pituitary-Gonadal Axis

The regulation of androgen production begins with LHRH being secreted from the hypothalamus, which acts on the pituitary gland to release follicle-stimulating hormone, which acts on Sertoli cells, and luteinizing hormone (LH), which acts on Leydig cells to control androgen synthesis and spermatogenesis in the testes (Fig. 68.14).³⁴⁰

Bilateral orchiectomy is an inexpensive standard treatment that reliably reduces testosterone levels to the “castrate” range (<50 ng/dL). Estrogens inhibit the production of LHRH, which decreases the release of follicle-stimulating hormone and LH, and reduces androgen levels in a dose-dependent manner. A dose of diethylstilbesterol (DES), 3 mg/d, generally achieves castrate testosterone levels.

Figure 68.14 The androgen-signaling axis and its inhibitors. Testicular androgen synthesis is regulated by the gonadotropin-releasing hormone (GnRH)–luteinizing hormone (LH) axis, whereas adrenal androgen synthesis is regulated by the corticotrophin-releasing hormone (CRH)–adrenocorticotropic hormone (ACTH) axis. GnRH agonists and corticosteroids inhibit stimulation of the testes and adrenals, respectively. Abiraterone inhibits CYP17, a critical enzyme in androgen synthesis. Bicalutamide, flutamide, and nilutamide competitively inhibit the binding of androgens to androgen receptors; enzalutamide also blocks the translocation of the ligand bound AR complex to the nucleus and from binding to DNA. DHEA, dehydroepiandrosterone; DHEA-S, dehydroepiandrosterone sulphate; DHT, dihydrotestosterone; AR, androgen receptor; ARE, androgen-response element. (Adapted from Chen Y, Clegg NJ, Scher HI. Anti-androgens and androgen-depleting therapies in prostate cancer: new agents for an established target. *Lancet Oncol* 2009;10:981–991, with permission.)

LHRH agonists produce an initial rise in LH that increases testosterone levels, followed 1 to 2 weeks later by downregulation of LH receptors that results in a medical castration.^{310,311} The initial rise in testosterone can flare the disease, precipitating or exacerbating symptoms such as pain, obstructive uropathies, and spinal cord compromise. These agents were first approved on the basis of trials showing an improved safety profile compared with oral estrogens, most notably the reduction in cardiovascular-related events such as edema, thrombosis and thromboembolism, myocardial infarction, and stroke.^{341–343} Several are approved for use in the United States, including leuprolide acetate (Lupron, given intramuscularly [AbbVie, North Chicago, IL]; Eligard, given subcutaneously [TOLMAR Pharmaceuticals, Inc., Fort Collins, CO]; Viadur, implanted subcutaneously [Bayer HealthCare Pharmaceuticals Inc.,

Montville, NJ]), goserelin acetate (Zoladex, given subcutaneously in the abdominal wall [AstraZeneca, London, England]), triptorelin pamoate (Trelstar, given intramuscularly [Actavis Pharma, Inc., Parsippany, NJ]), and histrelin acetate (Vantas, implanted subcutaneously [Endo Pharmaceuticals Inc., Dublin, Ireland]). These drugs are available as daily or monthly injections, and 3-, 4-, 6-, or 12-month depot injections.

In contrast, LHRH antagonists produce castrate levels of testosterone in 48 hours without the initial rise (Fig. 68.15), making them a compelling choice for the initial treatment of patients with symptoms. At present, degarelix, available as monthly subcutaneous injections, is the only LHRH antagonist that is approved in the United States. Reported outcomes suggest a comparable to slightly improved efficacy relative to the agonists/antagonists discussed

Figure 68.15 Testosterone levels following treatment with a luteinizing hormone–releasing hormone agonist and antagonist. Nadir is achieving castrate range.

previously.³⁴⁴ The tradeoff is the need for monthly injections and a higher frequency of injection-site reactions.

Antiandrogens

Antiandrogens block the binding of testosterone to the AR (see Fig. 68.14). There are two types: the steroidal type I agents such as cyproterone acetate have progestational properties that suppress LH levels and lower serum testosterone; these are not widely used. The nonsteroidal type II agents bind to the AR and act as competitive antagonists for ligands that might otherwise bind and activate the ligand-dependent transcriptional activity of the receptor. The three first-generation type II agents approved are flutamide, which has a short half-life requiring multiple daily doses, and bicalutamide and nilutamide, which have weekly half-lives and are administered once daily. All three were approved initially in combination with a LHRH analog: flutamide to prevent the flare that can result from the initial rise in testosterone that occurs with LHRH analogs,^{345,346} bicalutamide (50 mg daily) on the basis of an improved safety profile relative to flutamide,³⁴⁷ and nilutamide in combination with surgical orchiectomy based on greater efficacy relative to orchiectomy alone.³⁴⁸ Type II agents given as monotherapy do not inhibit LH synthesis in the hypothalamus or pituitary, and circulating testosterone levels rise. None of these antiandrogens are approved as monotherapy in the United States, although bicalutamide 150 mg is approved in the European Union.³⁴⁹

Enzymatic Inhibitors of Androgen Synthesis

All steroidal hormones are derived from pregnenolone and subsequently metabolized via several CYP450 class enzymes. Within the adrenal gland, CYP17 mediates the synthesis of weak androgens dehydroepiandrosterone (DHEA) and androstenedione (Fig. 68.16), whereas in the testes, the presence of 17-keto reductase generates testosterone that can be further converted to DHT in peripheral tissues by 5α -reductase. Ketoconazole is a nonspecific P450 inhibitor that, at a dose of 1,200 mg/d, produces castrate levels of testosterone in 24 hours through inhibition of adrenal and testicular steroidogenesis. The effect is not durable, limiting the drug's use as first-line treatment. It was useful for patients who presented with acute spinal cord compression or disseminated intravascular coagulation, when LHRH analogs are contraindicated and the risk of hemorrhage from surgery is significant.³¹⁴

Toxicities of Androgen Deprivation Therapy

The adverse effects associated with ADT include those associated with the hypogonadal state and others that are unique to

the specific drugs utilized. Symptoms associated with castration, whether medical or surgical, can be grouped under the “androgen deprivation syndrome,” and include hot flashes, a decrease in libido, erectile dysfunction, impotence, fatigue, anemia, weight gain and alterations in fat metabolism, loss of muscle mass and weakness, bone loss, a decrease in mental acuity, mood swings, personality changes, memory loss, depression, and insomnia. Consequently, to relieve patients' anxiety and minimize stress, it is essential to inform them of the goals of treatment and the potential adverse events that may occur. Many of the adverse effects of ADT can be relieved by exercise.^{350–352} Table 68.15 shows the frequency and methods of amelioration. Hot flashes occur in more than 80% of patients at any time, even during sleep, and may last for several seconds or an hour or more. They are bothersome in about 25% of cases, and if significant, can be reduced in frequency and intensity with estrogens at doses as low as 0.3 mg/d by patch³⁵³ or progestins (e.g., megestrol acetate or medroxyprogesterone acetate).³⁵⁴

Erectile dysfunction and loss of libido are almost universal. Penile and testicular size may diminish and facial and body hair decrease, but male-pattern baldness may improve. Fatigue, in part related to anemia, is also frequent, as 90% of men on ADT show a decrease in hemoglobin of 10%, and 25% show a decrease of 18% or more.³⁵⁵ Weight gain is also frequent (most of which is fat, as lean body mass decreases) and exceeded 6 kg on average at 12 months in one study.³⁵⁶ Other factors contributing to weight gain include an increase in appetite and sedentary lifestyle.

Metabolic changes include an increase in cholesterol in 10% of patients, increase in triglycerides in 26%, and incident diabetes,³⁵⁷ a consequence of insulin resistance. It is uncertain whether glucose intolerance results from an increase in weight or adiposity, a decrease in exercise tolerance, or a combination of these or other factors.

Osteopenia and osteoporosis are well documented, and in one prospective trial bone mass decreased by 2% to 5% after 1 year of ADT, leading to an increased rate of fracture,³⁵⁸ although few fractures occur in patients treated for <1 year (Fig. 68.17).³⁵⁹ Changes in bone can be monitored by bone densitometry and bone turnover markers such as urinary N-telopeptide (a breakdown product of collagen), bone-specific alkaline phosphatase, and osteocalcin.³⁶⁰ Bone loss and fracture rates can be reduced by bisphosphonates such as zoledronate³⁶¹ or denosumab, blocking osteoclast maturation, function, and survival,^{362,363} and toremifene, a selective estrogen receptor modulator.³⁶⁴ Supplemental calcium (1,000 mg/d to 1,500 mg/d) and vitamin D (400 international units) daily are also advised to prevent bone loss, but data to support their use are limited. Integral parts of the maintenance of bone integrity are exercise, reduction in caffeine, and smoking cessation.

Other adverse effects of ADT include depression, mood swings, emotional lability, decreased mental acuity, and memory loss.³⁶⁵ Psychological tests for cognitive dysfunction suggest that certain aspects of spatial reasoning and spatial ability,³⁶⁶ along with memory and attention, can be impaired by ADT.³⁶⁷

Cardiovascular issues are also a concern, given the multiplicity of risk factors that are worsened by ADT, including weight gain, increased adipose tissue, decreased exercise tolerance, hyperlipidemia, decreased insulin sensitivity, and glucose intolerance. The literature on the effects of ADT on cardiovascular mortality shows that this remains an area of controversy. A recent advisory panel from the American Heart Association concluded that links between ADT and cardiovascular mortality remain controversial, and that there is no reason at present to initiate cardiac testing in patients with cardiovascular disease before initiation of ADT.^{368,369}

Antiandrogen Toxicity

Antiandrogens do not lower serum androgens, and as a result, there is less loss of libido, fewer hot flashes, and potency may be spared, while muscle and bone mass are retained. Unique toxicities relative to testosterone-lowering approaches include GI events such as

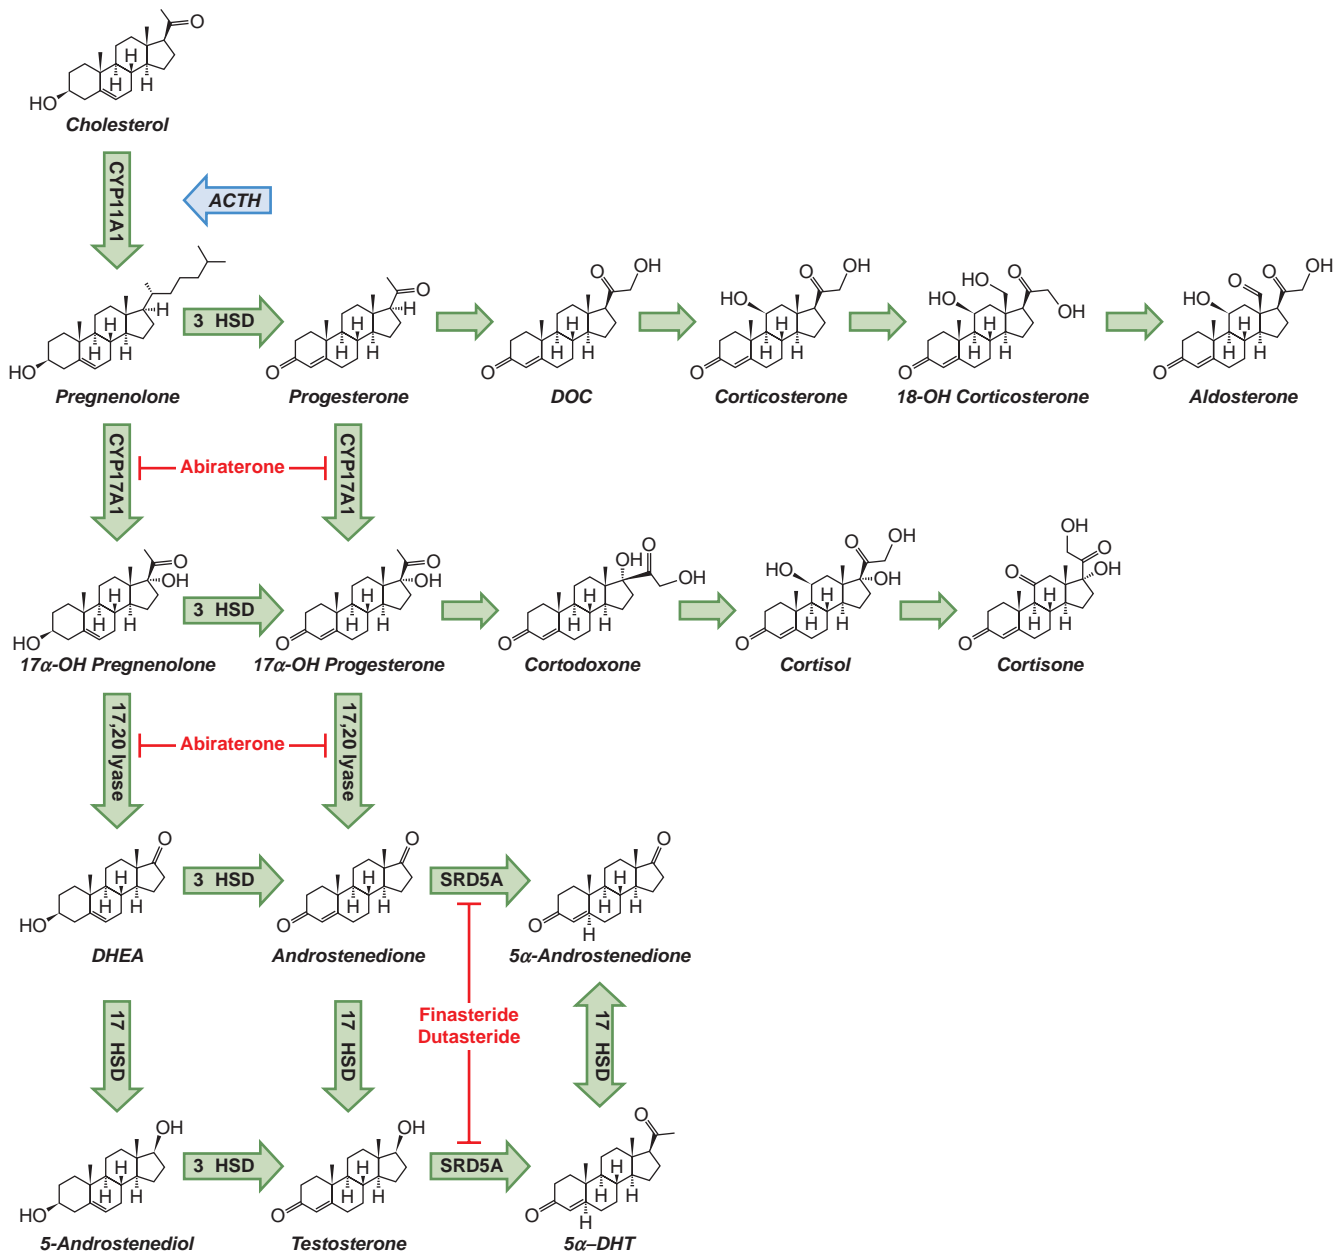

Figure 68.16 The effects of abiraterone acetate on steroid biosynthesis. ACTH, adrenocorticotrophic hormone; DOC, 11-deoxycorticosterone; DHEA, dehydroepiandrosterone; DHT, dihydrotestosterone.

elevations in hepatic enzymes, stomach upset and diarrhea,³⁴⁷ and pulmonary complications such as fibrosis; these toxicities are a rare class effect of the first-generation antiandrogens,³⁷⁰ which occur most frequently with nilutamide. Gynecomastia and/or breast tenderness may also develop, which, if severe, might require a reduction mammoplasty. Prophylactic breast irradiation can reduce the frequency and severity of these effects.^{350,351}

Contemporary Management

For the patient with metastatic disease and/or symptoms, or the patient in the rising PSA state for whom treatment is advised based on the absolute level of PSA or PSA kinetics, standard practice is to initiate therapy and monitor the disease with serial PSA measurements and imaging as appropriate until there are signs that the disease has started to progress, at which point it is considered “castration-resistant.” In most patients, this is manifested first by a rise in PSA despite castrate (<50 ng/dl) levels of testosterone.

Androgen deprivation and/or blockade produces declines in PSA, regression of measurable tumor masses if present, and a period of clinical quiescence or stability in which PSA levels and tumor size does not change, followed in a variable period of time by a rise in PSA, tumor proliferation, and clinically detectable changes on imaging. Applying the control/relieve–delay/prevent metric, approximately 60% to 70% of patients with an abnormal PSA will show a normalization to a value of ≤ 4 ng/ml, 30% to 50% of measurable tumor masses will regress by $\geq 50\%$, 30% to 40% of bone scans will improve while the majority remain stable, and $>60\%$ of patients with symptoms will show palliation, be the symptoms urinary or osseous in origin.

The complete elimination of disease in any site with ADT is rare, be it in bone or the prostate itself, although in many cases, LN disease that was present when hormone therapy is initiated does not recur. When ADTs are used as neoadjuvant therapy prior to surgery for upwards of 8 months, $<5\%$ of prostates removed subsequently are pathologically free of tumor,³⁷¹ which suggests that hormone therapy

TABLE 68.15

Adverse Effects of Androgen Deprivation, Approximate Frequency, and Potential Therapeutic Options for Amelioration^a

Effect	Approximate Frequency	Potential Corrective Actions
Libido loss	Universal	None known
Erectile dysfunction	Universal	None known
Hot flashes	50%–80%	Venlafaxine, estrogens, progestins
Muscle loss	Common, duration-dependent	Exercise
Weight gain	Common	Exercise/diet
Facial/body hair loss	Very common	None known
Fatigue	Not defined	Exercise
Emotional lability	Not defined	None known
Depression	0%–30%	Various antidepressants
Cognitive dysfunction	Not defined	None known
Gynecomastia	Up to 20%	Preemptive radiation
Breast tenderness	Not defined	Aromatase inhibitors
Osteoporosis	Common, duration-dependent	Exercise/bisphosphonates
Anemia	5%–13%	Erythropoietin not recommended
Hyperlipidemia	10%	Diet, statins
Diabetes	0.8%/year increase	Exercise, oral agents
Myocardial infarction	0.25%/year increase	Treatment of risk factors
Coronary heart disease	1%/year increase	Treatment of risk factors

^a A number of events are poorly defined in frequency as a consequence of a lack of controlled studies, quantitative assessments, and/or agreed on definitions.

alone does not cure the disease. Prognosis varies by the disease state, grade of the tumor, rapidity of growth, and extent of disease when hormone therapy was started. Adverse features from multiple series include a high Gleason score (8 to 10), low performance status, bone pain, low hemoglobin, high alkaline phosphatase, low testosterone level, and extensive as opposed to minimal disease.^{372,373} The number of metastases³⁴⁴ or percentage of the skeleton involved by tumor³⁴⁵ is also prognostic. In one series, 2-year survival times were 94%, 71%,

61%, and 40% for men with 0 to 5, 6 to 10, 19, and ≥ 20 lesions, respectively.^{374,375} Using a different classification, patients with minimal disease (involvement confined to the axial skeleton [pelvis and/or spine] and/or LN) and extensive disease (disease in long bones, skull or ribs, and/or viscera) had median PFS of 46 months and 16 months, respectively, and overall survival times of 51 months and 27.5 months, respectively.³⁷⁶

Prognosis can be estimated in part by the degree and rapidity of response determined by the posttreatment PSA nadir and the timing of the nadir. In a trial enrolling 1,345 patients, failure to achieve a PSA nadir of ≤ 4 ng/ml within 7 months was associated with a median survival of 13 months, whereas those with a nadir between 0.2 to 4.0 ng/ml had a median survival of 44 months, and patients with a nadir ≤ 0.2 ng/ml had a median survival of 75 months.³⁷⁷ With respect to the timing of the nadir, those who achieved a nadir in < 6 months had a median survival of 4.5 years versus 7.8 years for those with a nadir after 6 months from the start of treatment.³⁷⁸

Unfortunately, more contemporary natural history studies for patients with metastatic disease are lacking, in part because fewer men are presenting with metastatic disease, and because this approach has been the standard of care for over seven decades, fewer randomized trials are being conducted. As a result, comparing different treatments outside of dedicated trials is difficult due to the different methods used to determine and define disease extent, the posttreatment monitoring schema, and how outcomes were reported, leaving several basic questions in management incompletely resolved.

Is one form of monotherapy that suppresses testosterone levels superior to another? No. All single-therapy hormonal interventions that lower serum testosterone levels to castrate levels had similar overall survival times after 2 years of treatment.³⁷⁹ An EORTC study, powered for a 13% difference around the medians, showed similar outcomes between DES 1 mg and orchiectomy.³⁸⁰ In a meta-analysis of 10 randomized controlled trials that included

Figure 68.17 Fracture rate as a function of time after androgen deprivation therapy in men older than age 68 in the United States. Number of doses is the number administered within 12 months after diagnosis. GnRH, gonadotropin-releasing hormone. (From Shahinian VB, Kuo YF, Freeman JL, et al. Risk of fracture after androgen deprivation for prostate cancer. *N Engl J Med* 2005;352:154, with permission.)

LHRH agonists/antagonists, orchiectomy, DES, or choice of DES or orchiectomy, outcomes were similar.

Is more complete androgen suppression superior? Geller et al.³⁸¹ were the first to document elevated DHT levels in patients treated by orchiectomy, a finding validated later when more sensitive and specific mass spectroscopy-based assays became available,³⁸² and the demonstration of persistent PSA and TMPRSS2:ERG expression in posthormone treated RP specimens indicating continued AR signaling.^{383,384} This led to trials testing the hypothesis that more complete androgen suppression using a combination of an antiandrogen (flutamide, bicalutamide, or nilutamide) to inhibit adrenal androgens with a LHRH agonist/antagonist or orchiectomy would provide greater benefit.³¹⁷ Adrenal androgens can contribute 5% to 45% of the residual androgens present in tumors after surgical castration alone. Early results were promising,³⁸⁵ but subsequent meta-analyses have been conducted showing that the first-generation antiandrogens did not add significantly to the anti-tumor effects of surgical castration.^{319,341,386,387} One, summarizing 27 randomized trials with 8,275 patients, showed a 2% difference in mortality at 5 years: 72.4% for monotherapy versus 70.4% for the combined approach³⁸⁶; a second meta-analysis limited to trials of a nonsteroidal antiandrogen showed a 2.9% difference: 75.3% versus 72.4% at 5 years.³⁴¹ Other combinations explored to effect more complete androgen suppression included low-dose DES and megestrol acetate; an LHRH analog and ketoconazole plus hydrocortisone; an LHRH analog, antiandrogen and ketoconazole, plus hydrocortisone or aminoglutethimide and hydrocortisone.³⁸⁷ None proved meaningfully superior.

When should hormone therapy be initiated? Early versus late? This question is difficult to answer because of methodologic differences in the trials designed to address it. The differences include the clinical state of the patient group studied, whether the primary tumor has been treated and how (no treatment, surgery, or radiation including dose and treatment field), the specific hormones used, the duration they were administered, and the patient follow-up including the frequency of visits and the specific clinical, laboratory, and imaging assessments performed. Critical to the discussion as well is the “trigger” used to start treating patients randomized to the “no immediate treatment” arm of the study, which range from a predefined degree or level of PSA rise alone, the documentation of metastases, or the development of symptoms. Further confounding the issue is that in some studies, a significant proportion of patients in the “no immediate treatment” group were never treated.

A complete review of all of the trials designed to assess this question is beyond the scope of this chapter. In general, randomized trials

that address this question show “early” hormone therapy delays the time to metastases and symptoms, but the effect on overall survival is less clear. A key consideration in formulating a recommendation for patients at a particular point in the illness is to balance the likelihood that a patient would require treatment based on the development of metastatic disease or symptoms and when, with the likelihood that no treatment would ever be required based on these same metrics.

Trials in patients who did not receive treatment of the primary tumor were reported by the Veterans Administration Research Service Cooperative Urological Research Group, the Medical Research Council (MRC), and the Early Prostate Cancer Trials Group. The Veterans Administration Research Service Cooperative Urological Research Group trials enrolled 1,900 patients staged primarily by DRE and showed that DES or orchiectomy could delay the development of metastatic disease in patients with locally advanced stage C tumors,^{388,389} although overall survival was worse due to cardiovascular complications. There was also no overall survival benefit for patients with metastatic disease.

The MRC PR03 trial randomized 998 patients with locally advanced or asymptomatic metastatic prostate cancer to “immediate” treatment (orchiectomy or LHRH analog) or to the same treatment deferred until there was an “indication.” The trigger to initiate treatment was “clinically significant progression,” which was as frequent locally as metastatic. The trial showed that patients treated with early therapy were less likely to require a TURP or develop ureteral obstruction, progress from M0 to M1 disease ($P < 0.001$, two-tailed), to develop pain ($P < 0.001$), or to die of prostate cancer relative to those in whom therapy was “deferred.” Even so, survival times were similar between the two groups. An important caveat limiting the extrapolation of the results to the question of “early” versus “late” was that half of the men who died in the deferred arm never received therapy.³⁹⁰

The Early Prostate Cancer Trials Group trial ($n = 985$) randomized men with T0-4N0-2M0 prostate cancer who were not candidates for local therapy to immediate or to deferred treatment until symptomatic progression was documented. The results showed an increased risk of death in the deferred arm (HR = 1.25; 95% CI = 1.05 to 1.48), which remained after adjusting for baseline factors. Notable was that only 49.7% of men in the deferred arm began anticancer therapy during the median 7.8-year follow-up period, suggesting that a significant proportion of men on the immediate arm were overtreated. The median time to treatment for those who required it, however, was 3.2 years. Deaths were equally balanced between prostate cancer ($n = 193$, 18.8% of the population) and cardiovascular disease ($n = 185$) (Fig. 68.18).³⁹¹

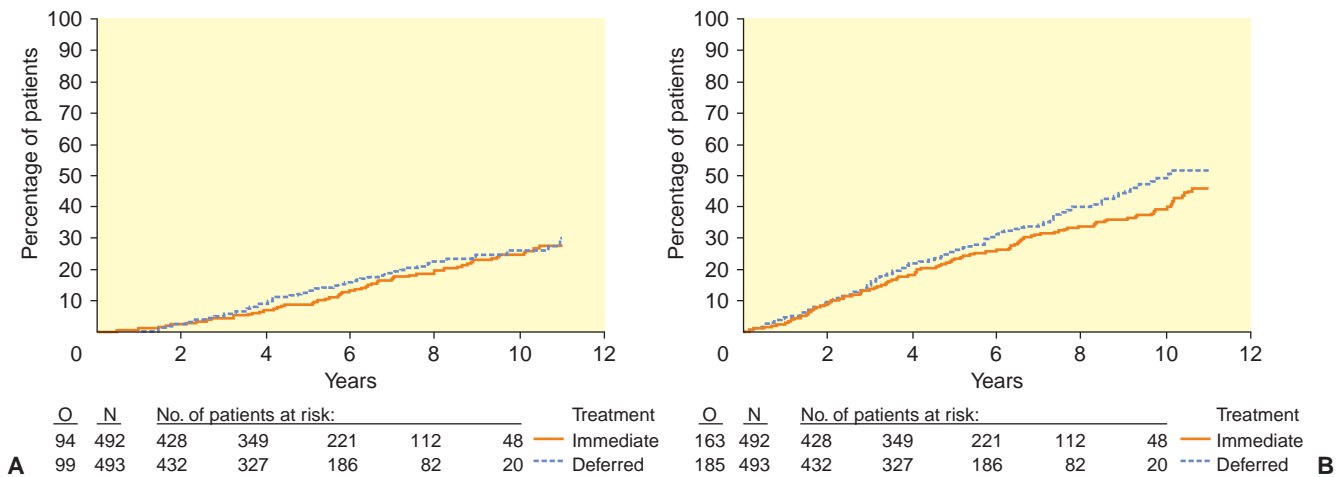

Figure 68.18 Immediate versus deferred hormonal therapy in patients with M0 prostate cancer who either refused local therapy or were deemed unsuitable for local therapy. (A) Prostate cancer-specific mortality. (B) Non-prostate cancer mortality. (From Studer UE, Whelan P, Albrecht W, et al. Immediate or deferred androgen deprivation for patients with prostate cancer not suitable for local treatment with curative intent: European Organisation for Research and Treatment of Cancer [EORTC] Trial 30891. *J Clin Oncol* 2006;24:1868, with permission.)

Rising Prostate-Specific Antigen (Extrapelvic Disease)

For the patient presumed to have microscopic nodal or more distant disease that would not respond or which cannot be addressed by additional treatment to the primary site, the optimal timing of ADT initiation is controversial. The first issue is to determine the risk of developing metastatic disease and in what time frame. One series that addressed this question included 1997 RP-treated patients, of whom 315 (15%) developed a rising PSA and were followed with annual imaging and PSA assessment until metastatic disease was documented. Of these patients, metastatic disease was subsequently documented in 103 at a median actuarial time of 8 years, of whom 44 (44%, or 2% of the 1997) died of disease.³⁹² Factors associated with the development of metastasis included the grade of the primary tumor, the time interval between the start of the treatment to the date of first recurrence, the absolute PSA value, and the rate that it was rising, typically expressed in terms of the PSADT.³⁹³ In a separate study, virtually all cancer-related deaths occurred in men who had PSADT ≤ 6 months, independent of whether the patient received radiation or surgery as primary treatment.³⁹⁴ In practice, many physicians consider treating patients when the PSADT is ≤ 12 months, although there remains no absolute PSA level mandating that treatment be started.

Strategies to Reduce the Toxicities Associated with Androgen Deprivation Therapy. Now, with the widespread use of PSA-based detection and monitoring, fewer men are diagnosed with or develop symptoms of advanced prostate cancer. For these individuals, the tolerance of castration is less than for men who receive treatment to relieve the symptoms of urinary obstruction or bone pain from osseous spread. This, coupled with the adverse events that can occur with longer use, has led to the evaluation of noncastrating approaches in an effort to improve patient tolerance without compromising efficacy.

Antiandrogen Monotherapy. Several randomized trials have compared antiandrogens alone to conventional testosterone-lowering forms of castration. Bicalutamide 50 mg daily, the dose approved for use in combination with an LHRH analog, was inferior to surgical orchiectomy.³⁹⁵ Bicalutamide 150 mg, which produces a higher frequency of PSA normalization than does the 50 mg dose (97% versus 73% of cases), showed mixed results: inferiority to castration for patients with metastatic disease but equivalence for patients with M0 disease (rising PSA values with no detectable metastases on imaging studies).³⁹⁶ Another approach is to begin with the antiandrogen alone and add a testosterone-lowering therapy when PSA levels rise. Unfortunately, only 30% of patients treated in this fashion respond to the addition of the LHRH analog.³⁹⁷ Nevertheless, some patients may be willing to accept this risk

rather than experience the impotence and other adverse effects of testosterone-lowering treatment, as long as symptoms of disease are controlled.

Intermittent Androgen Depletion/Blockade. A second approach that is now used widely is intermittent androgen deprivation (IAD). It evolved somewhat empirically in the era of estrogen therapy, pre-PSA, when it was recognized that patients in whom therapy was stopped for noncancer-related reasons would often respond when the treatment was resumed to control the disease.³⁹⁸ The central hypothesis, based on studies in murine tumors, is that by minimizing the exposure time to a castrate environment, the sensitivity to subsequent androgen depletion would be retained.^{399,400} An additional advantage is the potential for an improved QOL during the “off” intervals.

Applied today, the approach is considered for patients who respond well to ADT, typically defined as a PSA nadir ≤ 4 ng/ml for those with metastatic disease, and is restarted when PSA levels return to a predetermined level (typically 10 ng/ml to 20 ng/ml). Multiple phase 3 trials have been reported that differ in the patient population treated (BCR only, metastatic disease only, or both), the type and duration of treatment (3 months to 8 months), the criteria for discontinuation and for restarting it, and the primary end point. Most report a time to progression measure but do not use the same criteria. Few are powered for survival. Several large randomized trials have been reported recently: none showed the intermittent approach to be superior to continuous therapy in terms of cancer control, but most show a better QOL during the off intervals, which patients prefer.

In one trial enrolling 1,386 patients, median survival in the intermittent versus continuous arms was 8.8 years and 9.1 years, respectively, with more prostate cancer deaths in the intermittent arm and more deaths from other causes, including cardiovascular events, in the continuous arm. In this trial, a slight increase in cancer-related deaths in the intermittent arm was counterbalanced by an increase in nonprostate cancer deaths in the continuous arm.⁴⁰¹

In the largest trial reported to date, 3,040 men with noncastrate metastatic disease were enrolled, of whom 1,535 met the criteria for discontinuation. The trial was designed as a noninferiority study to show that the intermittent approach was no more than 20% inferior to continuous therapy. No significant difference in survival was observed overall, but for the subset of men with disease limited to the axial skeleton and no visceral disease at presentation, the median survival was 7.1 years for continuous therapy and 5.1 years for the intermittent group (HR = 1.23; 95% CI = 1.02 to 1.48); the study did not exclude IAD to be inferior.⁴⁰² Three meta-analyses were recently reported based on 8 trials enrolling a total of 4,664 patients,⁴⁰³ nine trials of 5,508 patients,⁴⁰⁴ and 13 trials

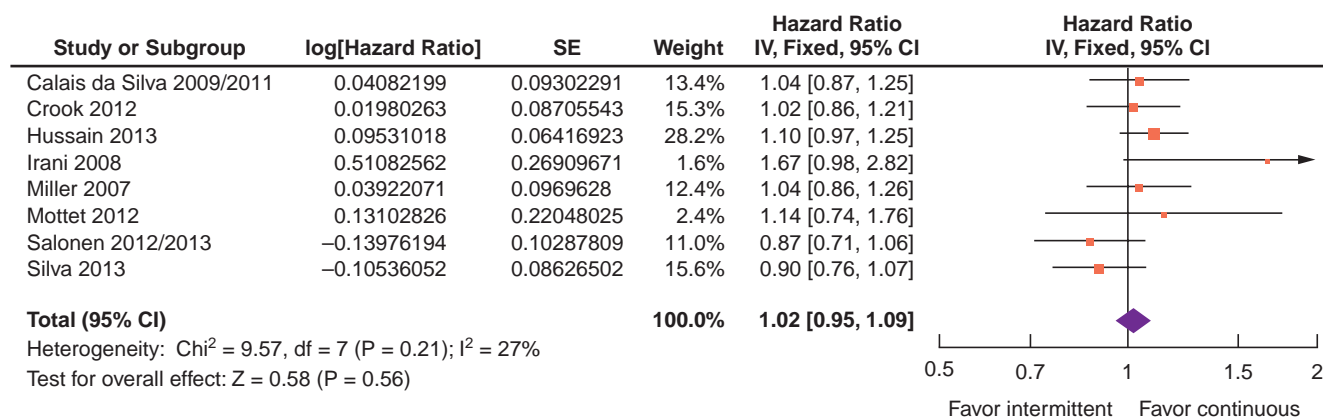

Figure 68.19 Overall survival with intermittent versus continuous androgen deprivation in prostate cancer. This figure is licensed under a Creative Commons Attribution 4.0 license. (From Botrel TE, Clark O, dos Reis RB, et al. Intermittent versus continuous androgen deprivation for locally advanced, recurrent or metastatic prostate cancer: a systematic review and meta-analysis. *BMC Urol* 2014;14:9.)

of 6,419 men⁴⁰⁵ (Fig. 68.19). All showed no difference in overall survival, two showed no significant differences in disease-specific survival,^{403,405} and one showed more deaths with IAD offset by more prostate cancer deaths with continuous therapy.⁴⁰⁴ IAD was superior with respect to overall QOL and sexual function with significantly reduced costs.

While some controversy remains whether a patient will accept the tradeoff of a potentially higher risk of a prostate cancer death in return for time off therapy, it is important to recognize that the approach should only be considered for patients who respond well to ADT. In the recently reported SWOG study, only 1,535 of the 3,040 enrolled patients (51%) reached the defined PSA nadir of ≤ 4 ng/ml.⁴⁰²

Castration-Resistant Disease: Metastatic and Nonmetastatic

A rising PSA despite castrate levels of testosterone represents the transition to a castration-resistant (CRPC) state, which is lethal for most men. Clinically, there are several phenotypes: nonmetastatic that includes a rising PSA or disease limited to the prostate or prostate bed, and metastatic which includes the patterns of osseous disease and no soft tissue disease, nodal spread and no bone or visceral spread, and visceral spread with or without osseous disease. In some cases, the pattern of spread is observed with no increase in PSA. Symptoms may or may not be present. Disease in other sites, including the adrenal glands, omentum, kidney, pancreas, or brain, is rare. Which pattern develops in a patient is influenced in part by the extent of disease at the time ADT was first initiated. The patient who initially received hormones for a rising PSA alone is likely to relapse with a rising PSA and negative imaging studies—the nonmetastatic-CRPC state. A therapeutic objective for these patients is to prevent the development of bone metastases, the likelihood of which is highly variable between patients. In the placebo arm of one metastasis prevention study evaluating denosumab, the median time to metastasis was 25.2 months,⁴⁰⁶ whereas in a second evaluating zoledronate, only one-third of patients had evidence of radiologic spread after 2 years of follow-up.⁴⁰⁷ In Smith et al.,⁴⁰⁸ men with a PSADT of ≤ 6 months had a median time to first bone metastases of 18.5 months.

In both trials, overall risk of developing visible metastases by imaging was most informed by the PSA level at baseline and the PSADT: men with higher PSA levels and faster PSADT had a shorter time to first bone metastasis. In contrast, the patient who first receives hormones for symptomatic osseous disease is more likely to develop recurrent symptoms and is at higher risk of death from prostate cancer. Considered by site of spread based on trials enrolling patients with progressing metastatic CRPC, 85% to 90% have osseous disease, 20% to 40% have measurable pelvic or retroperitoneal nodal disease, and 5% to 10% have visceral (lung and liver) spread.⁴⁰⁹⁻⁴¹¹

A unique pattern of spread being recognized with increasing frequency is one in which new metastases, predominantly in the lung or viscera, develop in the absence of a PSA rise. Histologically on repeat biopsy, these tumors may be pure small cell/neuroendocrine lesions similar to what is seen in other sites, or are classified more broadly as “anaplastic” tumors.^{409,410} These entities, when documented, are generally treated with platinum-containing chemotherapy regimens similar to what is used in small cell tumors that occur in the lung. The responses are similar: rapid improvements of short duration.⁴¹²

Patient Management

Patients with progressive disease with castrate levels of testosterone should continue LHRH agonist/antagonist therapies recognizing that no randomized trials have prospectively addressed this issue. Although not direct evidence, the survival benefits seen with the recently approved agents that inhibit AR signaling would

suggest that allowing testosterone levels to rise may adversely affect outcome. A retrospective analysis of 341 patients treated on four trials of secondary therapies suggested an improved survival for continuous androgen suppression when corrected for other factors,⁴¹³ but another did not.

The first consideration is to document castrate levels of testosterone. In rare cases, approximately 1% in prospective trials, LHRH analogs do not effect complete testosterone suppression.⁴¹⁴ The second is whether the patient has been on long-term antiandrogen therapy in combination with an LHRH analog or surgical orchiectomy, and if so, whether to discontinue the antiandrogen (continuing LHRH analog therapy) and to monitor the patient for a withdrawal response. The withdrawal response, consistent with the conversion of an antagonist to an agonist, was first reported in 1993 with flutamide discontinuation and later shown to occur with bicalutamide, nilutamide, cyproterone acetate, estrogens, glucocorticoids, and progestational agents.^{415,416} The onset of the withdrawal response, when it occurs, is directly related to the half-life of the drug: early for flutamide with its short half-life and 6 weeks to 8 weeks for agents such as bicalutamide, which has a 7-day half-life. The disease flare that can occur with megestrol acetate prescribed to increase appetite is consistent with an agonist effect.^{397,417-419}

Previously, if no withdrawal response was observed, patients were often treated with a different antiandrogen to which they had not been exposed, with limited benefit. The approaches included estrogens such as oral DES at a dose of 1 mg/d to 3 mg/d,⁴²⁰ Premarin (1.25 mg three times daily; Wyeth Pharmaceuticals Inc., Philadelphia, PA),⁴²¹ estramustine, the first agent with a formal indication in this setting,⁴²² and various parenteral formulations.⁴²³ All provided PSA decline rates in the 24% to 42% range, although durable responses were rare.^{422,424} Attempts to reduce the thromboembolic risk of estrogens by using transdermal estrogen delivery systems have been made; however, efficacy in these trials has generally been less than anticipated.^{425,426}

Ketoconazole, 600 to 1,200 mg/d in combination with hydrocortisone to minimize adrenal insufficiency, produces PSA declines by $\geq 50\%$ in up to 71% of patients,⁴²⁷ the response correlating with higher serum androgen levels at baseline.⁴²⁸ Absorption requires an acidic environment and so it is typically taken with juice. Proton-pump inhibitors and H₂ antagonists potentially interfere with absorption. Caution is urged with ketoconazole use as it is a potent inhibitor of CYP3A4. Cancer progression is associated with rises in androstenedione and DHEA sulfate,⁴²⁹ implying that steroidogenic compensatory mechanisms contribute to escape from ketoconazole.

Prednisone 10 mg daily was shown to palliate symptoms of the disease in one-third of patients by Tannock et al.⁴³⁰ in the pre-PSA era. Based on this, prednisone became an integral part of the “control” arms of many phase 3 trials in this disease. Similar results have been reported with hydrocortisone 30 mg/d to 40 mg/d and low-dose dexamethasone 0.5 mg to 2 mg daily in the PSA era, with reported decline rates ranging from 16% to 59% of patients.⁴³¹ These agents also lower serum androgen levels and, in a recent phase 3 trial in which patients were treated with prednisone 10 mg daily plus placebo, median survival times increased with each quartile increase in baseline serum androgen levels. PSA levels at baseline strongly associated with survival ($p < 0.0001$) in bivariate and multivariable analyses.⁴³²

Cytotoxic Therapy

Mitoxantrone. Building on the palliative benefits observed with prednisone alone, its combination with mitoxantrone 12 mg/m² every 3 weeks suggested superiority to prednisone monotherapy. The definitive phase 3 trial enrolling 160 patients, small by today’s standard, used a primary end point of pain palliation assessed with a patient-reported outcome scale and measuring daily analgesic consumption.³²⁰ The trial was not designed nor was it powered to show

a survival benefit. The results showed that a higher proportion of patients treated with the combination had a decrease in pain (29% versus 12%) and overall palliative response (38% versus 21%). Consistent with the findings was a decrease in analgesic consumption, improved bowel function, and increased patient mobility. Disease control shown by the duration of pain relief among mitoxantrone responders was 43 weeks versus 18 weeks for the control group. Similar results were obtained in a second trial,⁴³³ leading to the approval of mitoxantrone and prednisone for the treatment of CRPC in 1996 and establishing the regimen as the first cytotoxic-containing standard and the standard to which other treatments would be compared. Common toxicities with mitoxantrone at doses of 12 mg/m² every 3 weeks included nausea (61%), fatigue (39%), alopecia (29%), and anorexia (25%). Grade 3/4 neutropenia is reported in approximately 20% of patients, but febrile neutropenia is relatively unusual (2% of patients). Cardiac function is a concern; decreased cardiac function was reported in 5% to 7% of patients.

Docetaxel. Two pivotal trials were reported in 2004 showing that docetaxel plus prednisone could palliate symptoms, delay progression, and definitively prolong life relative to mitoxantrone and prednisone. TAX327 compared docetaxel 75 mg/m² every 3 weeks for up to 10 cycles (group 1), docetaxel 30 mg/m² weekly for 5 cycles (group 2), or mitoxantrone 12 mg/m² every 3 weeks for 10 cycles (group 3). Prednisone (10 mg daily) was added to all regimens. The primary end point was overall survival; secondary end points included changes in pain, PSA, and overall QOL. Median survival for the respective arms was 18.9 months, 17.4 months, and 16.5 months, respectively, which led to the approval of docetaxel plus prednisone for “androgen-independent (hormone-refractory)” disease. The 2.4-month difference in median survival (18.9 months versus 16.5 months) for the every-three-week docetaxel versus the mitoxantrone schedule established the every-three-week regimen as the de facto standard.³²²

SWOG 99-16 randomized 770 patients to estramustine (280 mg orally three times daily on days 1 to 5), docetaxel (60 mg/m² every 3 weeks), and dexamethasone (60 mg every 3 weeks) versus mitoxantrone and prednisone (5 mg twice a day) to a maximum of 12 cycles with no crossover at progression. The primary end point was overall survival. PSA declines, soft tissue response, and PFS were secondary end points. Here again, a 2-month difference in median survival was observed for docetaxel/estramustine (17.5 months versus 15.6 months), representing a 20% reduction in mortality (HR = 0.8). A higher incidence of neutropenia and fever, nausea, vomiting, and vascular events with docetaxel/estramustine was noted despite the lower dose of docetaxel. The results further supported docetaxel 70 mg/m² every 3 weeks as the standard regimen.³²¹

With docetaxel established as the first-line cytotoxic standard, drug development efforts focused on three discrete clinical contexts: the prechemotherapy space, the first-line cytotoxic chemotherapy space to build on the results of docetaxel, and the postchemotherapy space for which there was no standard of care at the time. Notable is that none of the docetaxel-based combination trials showed an improvement over single-agent therapy, whereas, in several trials, outcomes were inferior with the combination arm (see Table 68.14).³²⁹⁻³³⁷

Cabazitaxel is a next-generation taxane with an improved therapeutic index relative to docetaxel that is noncross-resistant with the parent compound in selected contexts.⁴³⁴ Following successful early phase trials showing antitumor activity in docetaxel-refractory metastatic CRPC, a randomized phase 3 trial comparing cabazitaxel plus prednisone ($n = 377$) to mitoxantrone plus prednisone ($n = 378$) was developed in this setting. At the final analysis, median survival and median PFS for the cabazitaxel and mitoxantrone cohorts was 15.1 months and 12.7 months (HR = 0.70; 95% CI = 0.59 to 0.83; $p < 0.0001$) and 2.8 months and 1.4 months (HR = 0.74; 95% CI = 0.64 to 0.86; $p < 0.0001$), respectively.³²⁵ In 2010, the FDA

approved cabazitaxel plus prednisone for the treatment of metastatic CRPC previously treated with a docetaxel-containing regimen.

Further progress was not achieved until there was a more complete understanding of the biology of the disease. Through profiling studies of prostate cancers representing different clinical states, a series of oncogenic changes in the AR signaling pathway were identified that showed CRPC remained hormone driven, while serving as points for therapeutic attack. These changes included amplification of a wild-type AR gene, overexpression of the enzymes involved in androgen synthesis, and alterations in the ligand-binding domain and co-activator/co-repressor protein interactions leading to promiscuous activation by other steroid hormones and antiandrogens.⁴³⁵ Consistent with the upregulation of the androgen biosynthetic machinery, and with the development of mass spectroscopy based assays for serum and tissue androgens,⁴³⁶ came the demonstration that intratumoral androgen levels in metastatic CRPC tumor samples could exceed those present in the prostates of men in a eugonadal state.⁴³⁷ This finding, coupled with overexpression of the receptor itself, enabled an intracrine signaling mechanism to sustain growth.

Abiraterone acetate plus prednisone: The cytochrome P450 (17) inhibitor abiraterone was developed to inhibit testicular and adrenal androgen production,⁴³⁸ and shown in a series of three dose-escalating studies to achieve androgen suppression in both noncastrate and castrate men.⁴³⁹ A subsequent phase 1 trial in men with CRPC who had not received chemotherapy showed a sustained decrease in testosterone to the 1 ng/dl to 2 ng/dl range as well as a reduction in estradiol, DHEA, and androstenedione, confirming the dependence of CRPC on ligand-activated AR signaling. Antitumor effects included significant declines in PSA, tumor regressions, and favorable changes in circulating tumor cell number. Adverse clinical and laboratory events consistent with mineralocorticoid excess including hypertension, fluid retention, and hyperkalemia were identified, which could be reduced by eplerenone or prednisone.⁴⁴⁰ A second phase 1 trial showed similar results in the same patient group and established a dose of 1,000 mg daily for phase 2 investigations.⁴⁴¹

Phase 2 trials of abiraterone acetate alone⁴⁴² or abiraterone acetate plus prednisone⁴⁴³ in postchemotherapy-treated CRPC followed based on the hypothesis that the decision to treat a patient with chemotherapy would not change the underlying biology of the disease significantly, and that if efficacy were shown, the track to approval would be shorter because the prognosis of these patients was inferior to that of patients who had not received prior chemotherapy. The unmet need for effective therapy was also greater in this population because there was no standard of care that had been shown to prolong life. Two phase 2 trials followed, one that excluded prior ketoconazole exposure⁴⁴² and one which did not⁴⁴³; both trials showed significant activity leading to the definitive phase 3 trial, Cougar AA-301, comparing the combination of abiraterone acetate (1,000 mg daily) plus prednisone (5 mg twice a day) to placebo plus prednisone (5 mg twice a day). The primary end point was overall survival, and secondary end points were radiographic PFS (rPFS), PSA response, time to PSA progression, and changes in QOL. Superiority of the combination relative to the placebo combination with respect to overall survival was shown in both interim (median 14.8 months versus 10.9 months; HR = 0.65; 95% CI = 0.54 to 0.77; $p < 0.001$) and final (15.8 months versus 11.2 months; HR = 0.74; 95% CI = 0.64 to 0.86) analyses. The drug was approved in 2011 for postchemotherapy-treated CRPC.^{327,444}

Subsequently, there was an abiraterone phase 3 trial in chemotherapy-naïve patients that used a coprimary end point of rPFS and overall survival. Notably, the rPFS end point included the PCWG2 definition of bone scan progression, which enabled 72% (166 of 229) of patients with apparent progression on a first follow-up to continue treatment because no additional new lesions were documented on the confirmatory scan. In the final analysis with a median follow-up period of 27.1 months, rPFS was

8.3 months in the placebo arm and not yet reached in the abiraterone arm (HR = 0.43; 95% CI = 0.35 to 0.52; $p < 0.0001$). Improvement in overall survival (35.3 months versus 30.1 months; HR = 0.78; 95% CI = 0.66 to 0.95; $p = 0.0151$) did not reach the prespecified statistical efficacy boundary but was supported by significant improvements in time-to-opiate-use and time-to-cytotoxic-chemotherapy end points.^{324,445} Abiraterone plus prednisone gained expanded approval for chemotherapy-naïve metastatic CRPC in 2012.³²⁴

Next-Generation Antiandrogens

Enzalutamide (previously MDV3100) was rationally designed with the aim of developing an antiandrogen active in prostate cancers with overexpressed AR, a setting in which the tumor is both resistant and growth is stimulated by bicalutamide, consistent with an antagonist-agonist conversion.

In the phase 1/2 enzalutamide clinical trial that enrolled patients with pre- and postchemotherapy CRPC treated with a variety of dose levels, there were PSA declines of $\geq 50\%$ in 71% and 37% of patients who were prechemotherapy or postchemotherapy treated, respectively, along with soft tissue regressions, and a posttherapy conversion of circulating tumor cell counts from unfavorable to favorable in 49% (25 of 51) of patients.⁴⁴⁶ The results led to the phase 3 AFFIRM trial in which 1,199 men with progressive postchemotherapy-treated CRPC were randomized in a 2:1 ratio to enzalutamide 160 mg daily ($n = 800$) or placebo ($n = 399$). The primary end point was overall survival and at the first interim analysis, a statistically significant reduction in mortality was seen (HR = 0.63; 95% CI = 0.53 to 0.74; $p < 0.001$), with a median overall survival of 18.4 months (95% CI = 17.3 to not yet reached) for enzalutamide versus 13.6 months (95% CI = 11.3 to 15.8) in the placebo group. All secondary end points favored enzalutamide including rPFS (8.3 months versus 2.9 months; HR = 0.40; $p < 0.001$), the time to the first SRE (16.7 months versus 13.3 months; HR = 0.69; $p < 0.001$), and QOL response rate (43% versus 18%; $p < 0.001$). The results led to FDA approval in 2012.³²⁸

More recently, the results of the prechemotherapy enzalutamide trial PREVAIL were reported; PREVAIL randomized 1,717 patients with prechemotherapy CRPC to enzalutamide 160 mg daily or placebo using the coprimary end points of rPFS and overall survival. This study was stopped by the data and safety monitoring board after 540 deaths based on the superiority of enzalutamide in delaying radiographic progression or death (HR = 0.19; 95% CI = 0.15 to 0.23; $p < 0.001$) and risk of death (HR = 0.71; 95% CI = 0.60 to 0.84; $p < 0.001$) relative to placebo. The benefit of enzalutamide was consistent for all secondary end points including rate of $\geq 50\%$ PSA decline (78% versus 3%), overall soft tissue response (59% versus 5%), time to PSA progression (HR = 0.17), time to initiation of cytotoxic chemotherapy (HR = 0.35), and time to first SRE (HR = 0.72) ($p < 0.001$ for all comparisons).⁴⁴⁷ These results have been submitted to the FDA, and an expanded indication is pending.

New antiandrogens in development include ARN-509 and galeterone. ARN-509 was more potent than enzalutamide in preclinical models,⁴⁴⁸ has shown significant activity in a phase 1 trial,⁴⁴⁹ and is now in phase 3 testing in nonmetastatic CRPC (NCT01946204). Galeterone (previously TOK-001) has multiple effects, including blocking and degrading AR,⁴⁵⁰ and will be entering phase 3 testing shortly.

Targeting the Tumor Microenvironment

Immunotherapy

Sipuleucel-T (Provenge; Dendreon Corporation, Seattle, WA) is an autologous active cellular immunotherapy that includes an acid phosphatase specific, replication-competent adenovirus that is cotransfected with granulocyte macrophage-colony-stimulating

factor. Mononuclear cells are harvested by leukopheresis, transfected with the viral construct, and maintained in culture under an adequate number of the defined mononuclear cell fraction has developed to enable re-infusion to the patient. A phase 1 dose-ranging study showed that injection of the primed cells into the prostates of patients with recurrent disease after radiation therapy was safe, and declines in PSA were observed that correlated with the administered dose of the virus.⁴⁵¹

A randomized phase 3 trial in which patients received either primed and unprimed mononuclear cells was then performed; the trial failed to meet the primary end point of PFS,⁴⁵² but with longer follow-up, an overall survival benefit was observed.⁴⁵³ A pivotal trial was then designed in which 512 patients with asymptomatic or minimally symptomatic metastatic CRPC were randomized to three doses of the biologic product or autologous cells that had been treated similarly but not exposed to the granulocyte macrophage-colony-stimulating factor/prostatic acid phosphatase fusion protein. The results showed a significant improvement in survival for the immunized patients (HR = 0.77; 95% CI = 0.61 to 0.97; $p = 0.02$), median 25.8 months in the sipuleucel-T arm and 21.7 months in the control arm. Adverse reactions were primarily related to the infusion of the activated cells and included chills (53%), fatigue (41%), fever (31%), back pain (30%), nausea (21%), joint aches (20%), and headaches (18%). Most of these reactions had resolved within 2 days of infusion. Grade 3–4 events were $< 3\%$ for each of these conditions. No improvement in PFS or response rate was seen in the large randomized trial, suggesting either that these parameters were not accurately measured or that slower kinetics of the disease were manifest after progression was initially measured. FDA approval was granted in 2010.³²⁴

PROSTVAC (Bavarian Nordic, Kvistgaard, Denmark) is a vaccinia and fowlpox immunization approach that includes the gene sequence for PSA and three costimulatory molecules (B7-1, ICAM-1, and LFA-3) collectively designated as TRICOM. In the phase 1 trial, patients received the recombinant vaccinia virus vaccine first, which was followed by a booster injection with recombinant fowlpox virus; all patients generated an immune response to vaccinia.⁴⁵⁴ A randomized phase 2 trial was then performed with a primary end point of PFS, which showed no difference between the groups, but 3 years post study, 30% (25 of 82) of the vaccine-treated versus 17% (7 of 40) of the placebo-treated patients were alive (median survival 25.1 months versus 16.6 months; HR = 0.56; 95% CI = 0.37 to 0.85).⁴⁵⁵ A phase 3 trial is ongoing.

Ipilimumab: Cytotoxic T-lymphocyte antigen-4 is a T-cell co-inhibitory and immune checkpoint molecule expressed by activated and regulatory T cells that plays a critical role in maintaining immune homeostasis and peripheral tolerance to self-antigens. In preclinical studies, cytotoxic T-lymphocyte antigen-4 blockade augmented T cell-mediated immune responses against tumors. This led to the development of ipilimumab, a fully humanized immunoglobulin G₁ monoclonal antibody to cytotoxic T-lymphocyte antigen-4 in malignant melanoma, renal cell carcinoma, prostate cancer, and other tumors. Two phase 3 trials demonstrated an overall survival benefit in malignant melanoma leading to FDA approval, and of particular note is the durable, complete remission of over 4 years in approximately 20% to 25% of patients.^{455,456} Antitumor activity was shown in a phase 1/2 trial of ipilimumab alone or in combination with EBRT in prostate cancer,⁴⁵⁷ which led to a phase 3 trial in patients with CRPC who had received prior treatment with docetaxel of radiation therapy alone versus radiation therapy plus ipilimumab.⁴⁵⁸ This study failed to meet the primary overall survival end point but did show evidence of activity at later time points. A second trial in prechemotherapy treated CRPC has fully accrued.

There are two randomized, double-blind, phase 3 registration trials in metastatic CRPC, which have fully accrued. One trial, comparing the efficacy of ipilimumab versus placebo in asymptomatic or minimally symptomatic patients with chemotherapy-naïve metastatic CRPC (NCT01057810), fell short of the primary

end point. Results from preclinical studies and early clinical trials suggest synergistic effect of ipilimumab and next-generation drugs targeting the AR signaling axis, cytotoxics and other immune modulators (poxvirus).

Cabozantinib (previously XL-184) is an orally bioavailable tyrosine kinase inhibitor with potent activity against MET and vascular endothelial growth factor receptor 2 shown in preclinical bone metastatic CRPC models to inhibit osteoblasts and osteoclasts function. In the clinic, the drug produced dramatic improvements in radionuclide bone scans which were associated with relief of pain. In a subsequent phase 2 randomized discontinuation study (nonrandomized extension),⁴⁵⁹ 122 patients with postdocetaxel CRPC with measurable disease received cabozantinib 100 mg daily for 12 weeks and were then randomized based on response: subjects with response by modified RECIST criteria continued open-label cabozantinib, subjects with progressive disease discontinued therapy, and subjects with stable disease were randomized to either placebo or continued cabozantinib (primary end point: PFS). The results showed improvements on bone scan in 68% of patients, including complete resolution in 12%, declines in total alkaline phosphatase and plasma cross-linked C-terminal telopeptide of type I collagen of $\geq 50\%$ in 57% of patients, and 67% showed reductions in pain. Notable was that improvements in pain and changes in PSA were in 40% of patients.

A subsequent nonrandomized extension was conducted in 85 patients evaluable for bone scan response, and 51 (60%) had a partial resolution, 24 (28%) stable disease, 5 (6%) progressive disease, and 5 (6%) discontinued prior to follow-up scan. Measurable disease was reduced in 21/30 patients (70%). Of the 33 patients with a Brief Pain Inventory score ≥ 4 , 16 (49%) had pain reduction durable for ≥ 6 weeks; 46% had decreased narcotic use, including 27% who discontinued use completely.

The results led to the design of two, currently ongoing, phase 3 trials of cabozantinib in patients with metastatic CRPC who have progressed on docetaxel-containing chemotherapy and abiraterone or enzalutamide. In COMET-1 (NCT01605227), the effect of cabozantinib on overall survival is being compared to prednisone. COMET-2 (NCT01522443) explores the effect of cabozantinib versus mitoxantrone plus prednisone on pain response and bone scan response.

Tasquinimod (formerly ABR-215050) is a quinoline carboxamide that binds to the immunomodulatory protein S100A9 with antiangiogenic activity in xenograft models through a vascular endothelial growth factor-independent mechanism.⁴⁶⁰⁻⁴⁶² A randomized placebo-controlled phase 2 trial of 201 men with chemotherapy-naïve CRPC showed improvement in median PFS (7.6 months versus 3.3 months; HR = 0.57; 95% CI = 0.39 to 0.85; $p = 0.0042$)⁴⁶³ and a trend toward improvement in median overall survival (33.4 months versus 30.4 months; $p = 0.49$).⁴⁶⁴ The results led to a phase 3 trial (10TASQ10) in men with asymptomatic to mildly symptomatic metastatic CRPC. Other ongoing studies include the phase 1 CATCH trial combining tasquinimod and cabazitaxel in postchemotherapy metastatic CRPC (NCT01513733) and a phase 2 trial evaluating the drug as a maintenance therapy for men with metastatic CRPC who are not progressing after first-line docetaxel-based therapy (NCT01732549).

PALLIATION

Bone-Directed Therapy

The high propensity for prostate cancers to metastasize to the skeleton puts patients at a high risk for significant morbidity from SREs. This can be complicated further by the bone loss associated with ADT itself, and the frequent use of corticosteroids for antitumor effects, to reduce the toxicities of anticancer agents such as the taxanes and CYP17 inhibitors, and for palliation of pain or

symptoms related to neurologic compromise. Targeting the bone microenvironment can provide palliation of symptoms, delay SREs, and prolong life.

Targeting Growth Factors and Cytokines

Bisphosphonates localize to the bone tumor interface and inhibit osteoclast activity to reduce bone turnover. The bisphosphonate zoledronate is the only FDA-approved agent for CRPC with bone metastases. In randomized trials, zoledronate (4 mg intravenously every 3 to 4 weeks) reduced the frequency of SREs (defined as pathologic fractures, radiation to bone, spinal cord compression, and/or surgery to bone) by 25% (33% with zoledronate versus 44%; $p = 0.021$). Time to first SRE was prolonged, whereas skeletal morbidity rate and the proportion of patients with an individual SRE were lowered. There was no effect on overall survival.¹⁵⁹ Bisphosphonates are also used in patients with prostate cancer to reduce the risk of osteoporosis, exacerbated by ADT, that increases the susceptibility to fracture or collapse of a vertebra in nontumor-bearing areas.¹⁵⁹ Nephrotoxicity can occur with these agents, and doses must be adjusted on the basis of renal function.

Denosumab is a monoclonal antibody that binds RANKL, inhibiting osteoclast function. Initial trials showed a decrease in bone loss and reduction in fracture rate for patients on ADT.⁴⁶⁵ A subsequent phase 3 trial enrolled 1,904 patients and compared denosumab (120 mg subcutaneous monthly) to zoledronate (4 mg every 3 weeks). The primary end point, delay in time to first SRE, showed a benefit in favor of denosumab (20.7 months versus 17.1 months; HR = 0.82; $p < 0.001$ for noninferiority and $p = 0.008$ for superiority). The denosumab arm had a slightly higher frequency of serious adverse events (63% versus 60%), Common Terminology Criteria for Adverse Events grade 3-4 adverse events (72% versus 66%; $p = 0.01$), and grade ≥ 3 hypocalcemia (5% versus 1%). There was no significant difference in the rate of serious adverse events, disease progression, or overall survival. The frequency of osteonecrosis of the jaw was similar (2% versus 1%). This relatively rare but serious side effect seems associated with bisphosphonate or denosumab use in combination with dental disease, dental surgery (e.g., tooth extraction), oral trauma, periodontitis, poor dental hygiene, glucocorticoid use, or chemotherapy use.³³⁸

Denosumab 120 mg every 4 weeks was also shown to delay the development of bone metastases relative to placebo in patients with nonmetastatic CRPC at a high risk of bone metastases (baseline PSA ≥ 8 ng/ml or PSADT ≤ 10 months). In this trial, bone metastasis-free survival was increased by a median of 4.2 months (median 29.5 months, 95% CI = 25.4 to 33.3 for denosumab versus 25.2 months, 95% CI = 22.2 to 29.5 for placebo). Denosumab also prolonged the time to first bone metastasis. Osteonecrosis was observed in 5% of patients receiving denosumab. Although statistically significant, denosumab's effect upon bone metastases was deemed insufficient for FDA approval.⁴⁶⁶

Pain

Optimal palliation of pain requires careful attention to the pain frequency, pattern, and precipitating factors. It also requires early performance of appropriate diagnostic studies to establish an etiology.

Critical for pain management is a low threshold for recommending an MRI if there should be any of the following: back pain suggestive of neurologic compromise of the spinal cord or cauda equina; diplopia, dysarthria, difficulty swallowing, or facial weakness suggestive of involvement of the base of the skull; or numbness in the jaw or chin suggestive of mental nerve compromise that may interfere with eating.⁴⁶⁶ If neurologic encroachment is documented in any of these areas, radiotherapy should be administered on an urgent basis to preserve function and to maximize the chance of recovery. Corticosteroids are also administered to provide more immediate palliation, and to reduce the risk of further compromise secondary to swelling that can occur after

radiotherapy is initiated.⁴⁶⁷ An MRI can also be recommended for patients with extensive bony disease in the absence of symptoms, as one series showed occult cord compromise in 11% of patients, which involved multiple locations in several patients.⁴⁶⁸ Metastases to the base of the skull leading to cranial nerve palsies can also severely compromise function unless diagnosed and treated expeditiously.

For one or more painful lesions that can be encompassed by a single or regional radiation port, EBRT offers excellent palliation. A variety of fractionation schemes and administered daily doses have been studied: 30 Gy administered as 300 cGy in 10 fractions is considered standard, although randomized trials have shown a single administered dose of 8 Gy in 1 fraction to be equivalent but not as durable. Patients treated with 30 Gy are less likely to require repeat treatment (18% versus 9%). High-dose hypofractionation regimens have also been studied, including 20 Gy or 24 Gy as a single dose, or 500 cGy to 800 cGy in three separate doses. A limitation of EBRT is that the disease is often diffuse and that lacking some form of systemic control, patients often experience recurrence in a relatively short interval after a first lesion is treated. In such cases of patients with recurrence of painful lesions outside of radiated areas, a systemic approach is preferred. Retreatment of a site previously irradiated is also necessary in approximately 25% of cases.⁴⁶⁹⁻⁴⁷¹

Radiopharmaceuticals

Therapies to control more diffuse pain include those directed at the tumor/bone interface with little effect on tumor, those directed at specific cytokines and growth factors produced by tumor cells and the host that contribute to the progression and survival of prostate cancer cells in the skeleton, and those directed at the tumor itself.

Bone-seeking radiopharmaceuticals are taken up rapidly at the tumor/bone interface with maximal deposition at the site of maximal bone turnover. The distribution of the isotope through the tumor is uncertain, making dosimetry difficult to calculate, but estimates are that the administered dose to the tumor itself is typically below that achieved with EBRT. Three such agents are currently approved in the United States on the basis of phase 3 trials.^{326,472-474}

Strontium-89 is a low-energy beta-emitter with a long (50-day) half-life. It was approved on the basis of a trial enrolling patients with symptomatic skeletal metastasis randomized to EBRT alone or EBRT plus the radiopharmaceutical, showing patients treated with strontium were less likely to have pain in new metastatic sites.⁴⁷⁴

Samarium (¹⁵³Sm) lexidronam,^{475,476} with a 2.9-day half-life, relies on the diphosphonate moiety for targeting, while the radionuclide simultaneously emits gamma energies that can be imaged and short-range beta energies that can be therapeutic. Technetium (^{99m}Tc) methyl diphosphonate bone imaging can identify tumors with high uptake.

¹⁵³Sm-EDTMP exhibits pharmacokinetic, toxicity, and pain response using an escalating dose schedule in treatment of metastatic bone cancer. This agent was approved on the basis of a trial that randomized patients to radioactive (¹⁵³Sm) versus nonradioactive (¹⁵²Sm) drug, showing a reduction in both opioid analgesic consumption and improvement in patient-reported visual analog scales and pain descriptor scales. The most common side effects were pain flare in approximately 10% of cases that could last for several days and myelosuppression which varies with the extent of disease and with the amount of bone marrow that has received radiation in the past.^{472,477} ¹⁵³Sm lexidronam has also been safely administered on a repetitive basis in combination with docetaxel.⁴⁷⁸

As beta-emitters, both strontium-89 and ¹⁵³Sm lexidronam have a penetration energy up to 2.4 mm in bone that disrupts normal hematopoiesis leading to myelosuppression and anemia. Tumor cell kill results from the inability to repair single-strand DNA breaks induced by the agent.

Radium-223 dichloride (radium-223) is a high linear energy transfer radiation that has a very short (<0.1 mm) range and

induces double-strand DNA breaks, rendering cellular repair mechanisms ineffective. Exposure of the surrounding tissues is minimized. After activity was shown in a phase 1 trial,⁴⁷⁹ a phase 3, randomized, double-blind, placebo-controlled study was completed that enrolled, in a 2:1 ratio, 922 patients with symptomatic bone metastases and no visceral disease who had either received, were not eligible to receive, or declined docetaxel. Patients were randomized to receive six injections of radium-223 (at a dose of 50 kBq per kg of body weight intravenously) or matching placebo; one injection was administered every 4 weeks. The primary end point was overall survival. Secondary end points included time to the first symptomatic SRE; time to bone-specific alkaline phosphatase progression, response, and normalization; PSA progression; and changes in several biochemical measures. Relative to placebo, radium-223 significantly improved overall survival (median, 14 months versus 11.2 months; HR = 0.66; 95% CI = 0.58 to 0.83; two-sided *p* = 0.00007). Assessments of all main secondary efficacy end points also showed a benefit for radium-223 compared with placebo, including the time to first SRE, which was prolonged from a median 9.8 months for placebo to 15.6 months (HR = 0.66; 95% CI = 0.52 to 0.83). Notable was that the drug was associated with low myelosuppression rates and fewer adverse events.³²⁶

FUTURE DIRECTIONS

The key to prostate cancer diagnosis and management is the assessment of risk based on the continuous reassessment of the disease at the current point in time and projecting the likelihood of disease-specific events in the future. Now, advances in our understanding of prostate cancer biology have changed diagnostic and treatment paradigms and improved the outcomes for patients across the clinical spectrum of the disease. The diagnostic algorithms used to detect disease are increasingly incorporating biologic determinants to better enable the detection of clinically significant cancers rather than all cancers. Many of the prognostic models used to define the metastatic and lethal potential of a tumor are also including molecular measures in addition to the standard clinicopathologic measures such as T stage (plagued by interobserver variability), PSA (lacks sensitivity and specificity), and Gleason score based on morphology. All prognostic models aim to ensure that only those tumors with the potential to cause symptoms, metastasize, or shorten patient survival are treated, while recognizing that for the tumors that are not treated, close monitoring using an AS approach is the "treatment."

Technologic advances in surgery and radiation therapy have resulted in better cancer control rates, particularly for "high-risk" patients, with fewer and lesser short- and long-term morbidities. In these cases, the focus of treatment centers on two objectives: control of the primary tumor and of metastatic disease. A range of biomarkers are in development to better inform prognosis (who needs treatment), prediction (what type of treatment), treatment efficacy (if it is working), and regulatory approval (providing clinical benefit). Missing in many biomarker studies is clinical utility—showing the incremental information provided by the "test" relative to what is currently available, a key factor in whether a test will be used in practice.

The same needs apply to patients who have experienced recurrence after primary therapy: to determine the likelihood that a tumor can be cured if still localized, independent of whether the primary treatment was surgery or radiation, and if not still localized, to guide the need for a systemic intervention based on the likelihood that metastatic disease might develop and when. Equally important is that we have learned that prostate cancer in an individual is more than one disease that can have different drivers of growth in different tumors as well as within one individual site of disease. The heterogeneity increases even further with the increasing number of drugs to which the cancer has been

exposed. To address this will require the continued characterization of disease biology. However, the necessary repeated tissue- or blood-based diagnostics to do so are presently not part of routine clinical practice.

Unfortunately, the field is still plagued by the use of end points of convenience that occur early as opposed to end points that take longer to observe but which more accurately reflect clinical benefit. Few reports include a clearly defined statistical design, and those that do rarely define a level of improvement to justify the development of a large-scale definitive trial to generate the evidence required to change practice standards.

The recent approval of several life-prolonging therapies as well as agents that reduce morbidity is particularly encouraging. However, it also presents an additional challenge because the use of effective treatments *after* a patient has been treated on a clinical trial reduces the trial's ability to show a survival benefit for an experimental drug. The failure to show a survival benefit in the phase 3 trials in CRPC with the Cyp 17 inhibitor orteronel⁴⁸⁰ and custirsen,⁴⁸¹ an antisense molecule that reduces the levels of the antiapoptotic protein clusterin, are recent examples. The latter represents another docetaxel-based combination that failed to show a survival benefit relative to docetaxel alone. Yet, both agents showed promising effects in phase 2 studies⁴⁸²⁻⁴⁸⁴ and show that it is essential to carefully consider the regulatory path to approval for any prostate cancer drug. Critical here is the discovery, validation, and qualification of predictive biomarkers of sensitivity. Such biomarkers will enable the enrollment of patients most likely to respond to the treatment being evaluated and will supply trial end points short of survival that could potentially lead to regulatory approvals.

A challenge now is to design trials that show how to maximize patient benefit with the available agents, used alone in sequence or in combination, and to understand cross-resistance and synergies. Strategies to improve outcomes with AR and AR signaling inhibitors include the development of new antiandrogens such as ARN-509 and galeterone (previously TOK-001). An analysis of the posttherapy PSA patterns of patients treated with AR and AR signaling inhibitors shows that a proportion of tumors are intrinsically resistant, a proportion show a pattern consistent with acquired resistance, and others show durable response followed later by progression.⁴⁸⁵ Studies in preclinical models have associated intrinsic

resistance with reciprocal feedback between the AR and phosphatidylinositol kinase signaling pathways,⁴⁸⁶ and AR splice variants,⁴⁸⁷ in particular the AR-V7 variant,⁴⁸⁸ whereas acquired resistance has been associated with an acquired mutation in the ligand-binding domain of the AR at position 876L.⁴⁸⁹ Cooptation of the AR by the glucocorticoid receptor⁴⁹⁰ and a number of new agents and combinations are being evaluated in the clinic based on activity demonstrated in these models.

The efficacy seen with newer agents in late-stage disease also suggests that the time is now to shift our paradigm from palliation to cure by evaluating available life-prolonging therapies in non-castrate settings with low disease burdens. Several trials exploring combinations of ADT and radiation therapy have been completed and have shown significant survival improvements. Such has not been the case with trials of ADT and RP as, to date, only one trial that enrolled patients with node-positive disease following RP showed a survival improvement.⁴⁹¹ More recently, another trial, CHARTED, showed that early use of docetaxel in combination with standard ADT conferred a 13.6-month improvement in median survival for patients with high-grade, high-volume, noncastrate disease.⁴⁹² Two ongoing randomized trials are awaited that will evaluate a similar combination in the high-risk neoadjuvant setting (NCT00430183) and in patients with a rising PSA with rapid PSADT (NCT01813370). An important consideration in the design of such studies is to demonstrate that the "experimental" treatment proposed has sufficient activity to justify large-scale testing. Here, neoadjuvant studies are particularly important because they ensure that adequate amounts of tumor material are available for analysis.⁴⁹³ One promising approach reported recently was a randomized trial in which abiraterone acetate and prednisone in combination with leuprolide acetate was shown to provide a higher pathologic complete response rate relative to leuprolide acetate alone.⁴⁹⁴ To test this further, the trial in patients with a rising PSA and rapid PSADT is comparing degarelix in combination with abiraterone acetate and prednisone to degarelix alone, with the end point of an undetectable PSA (NCT01813370). Trials of this type can be useful to support larger-scale studies to address whether even greater benefit can be provided to patients with potentially lethal disease if treated early, an approach that has been shown to be effective in many cancer types.

69 Cancer of the Urethra and Penis

Edouard J. Trabulsi and Leonard G. Gomella

INTRODUCTION

Penile and urethral carcinomas are uncommon malignancies, with a peak incidence in the 6th decade of life. Often overshadowed by more common genitourinary cancers, penile and urethral cancers represent difficult challenges for the treating physician. Squamous cell carcinoma is the most frequent type of cancer in the penis and the urethra. Carcinoma of the penis is a slow-growing tumor with a usually well-defined pattern of dissemination. This orderly spread allows definitive local-regional management of the primary tumor in most cases. In contradistinction, urethral carcinoma in men and women tends to invade locally and metastasize to regional nodes early. Depending on the site of the urethra involved and disease extent, a multimodal treatment approach may be required to treat this aggressive tumor.¹

CANCER OF THE MALE URETHRA

Carcinoma of the male urethra is uncommon. Chronic irritation and infection are the strongest risk factors. The incidence of urethral stricture in men with development of urethral cancer ranges from 24% to 76%, and most of these strictures involve the bulbomembranous urethra, also the most frequent site of cancer.² Human papillomavirus-16 (HPV-16) likely has a causative role in the development of squamous cell carcinoma of the urethra.³ No racial predisposition has been noted.

The onset of malignancy in a patient with a longstanding urethral stricture disease is often insidious, and a high index of suspicion is needed to diagnose these tumors early. The new onset of urethrorrhagia or urethral stricture in a man without a history of trauma or venereal disease should raise the possibility of urethral carcinoma. A palpable urethral mass associated with obstructive voiding symptoms is the most common presenting symptom.⁴ Pain associated with a periurethral abscess or urethral fistula may be the harbinger of a male urethral cancer.

Pathology

Overall, 80% of male urethral cancers are squamous cell, 15% are urothelial (transitional cell), and approximately 5% are adenocarcinomas or undifferentiated tumors.⁵ The anatomic location of urethral cancer largely determines the histologic type. Carcinomas of the prostatic urethra are urothelial in 90% and squamous in 10%; conversely, carcinomas of the penile urethra are squamous in 90% and urothelial in 10%. Adenocarcinomas of the urethra arise from metaplasia of mucosa or from periurethral glands, but direct invasion of rectal adenocarcinoma must be ruled out. Adenocarcinoma has the same prognosis, stage for stage, as the other histologies.⁴

The bulbomembranous urethra is most commonly involved (60%), followed by the penile urethra (30%) and the prostatic urethra (10%).⁴ The incidence of urethral involvement associated with carcinoma of the bladder has been estimated to be approximately 6%,⁶ and urethral recurrences after radical cystectomy occur in 4% to 17%.⁷

Male urethral cancer may spread locally to involve the corpus spongiosum or may metastasize to regional nodes. The lymphatics

of the anterior urethra drain into the superficial and deep inguinal lymph nodes and occasionally to the external iliac nodes. The lymphatics from the posterior urethra drain into the external iliac, obturator, and hypogastric nodes. Palpable inguinal nodes are found in approximately 20% and almost always suggest metastatic disease, in contrast to penile cancer, where 50% of palpable nodes are inflammatory. Bulbomembranous urethral cancer in particular spreads to the urogenital diaphragm, prostate, perineum, and scrotum. Hematogenous spread is rare except in advanced disease and in primary transitional cell carcinoma of the prostatic urethra.

Evaluation and Staging

The 2010 American Joint Committee on Cancer (AJCC) tumor, node, metastasis (TNM) staging system⁸ is based on the depth of invasion of the primary tumor and the presence or absence of regional lymph node involvement and distant metastasis (Table 69.1). The 2010 AJCC system subdivides T1 lesions into T1a (no lymphovascular invasion or poorly differentiated tumors) and T1b (the presence of lymphovascular invasion or poorly differentiated histology); prostatic invasion is now reclassified as T4 disease (previously T3). Examination under anesthesia is useful to evaluate the local extent of disease. Cystoscopy and transurethral or needle biopsy of the lesion, and of the prostate if indicated, are also performed at the time of examination under anesthesia. A complete blood count and serum chemistry analysis coupled with urine culture and cytology are routinely obtained. Cytology is particularly helpful in patients with transitional cell carcinoma. A computed tomography (CT) scan with contrast is useful in local staging with magnetic resonance imaging (MRI) scan with gadolinium the ideal staging modality for evaluating local soft tissue, lymph node, and bone involvement.⁹

Treatment

Surgery is the mainstay of treatment of carcinoma of the male urethra. In general, anterior urethral cancers are more amenable to surgical extirpation, and the prognosis is better than that of posterior urethral tumors, which are more often associated with extensive local invasion and distant metastasis.¹⁰ Radiation therapy is reserved for patients with early-stage lesions of the anterior urethra who refuse surgery. Although it preserves the penis, radiation may cause urethral stricture or chronic penile edema and may not prevent new tumor occurrence. Multimodal treatment combining chemotherapy and radiation therapy with surgical excision for locally advanced urethral carcinomas has yielded promising results (disease-free survival 60% in one series).¹¹ The median survival without treatment or with palliation is approximately 3 months.

Site-Specific Treatment

Carcinoma of the Distal Urethra. Superficial tumors (Ta, Tis, and T1) are usually treated with transurethral resection and fulguration with close follow-up. Tumors invading the corpus

spongiosum (T2) and localized to the distal half of the penis are best treated with a partial penile amputation with a 2-cm margin proximal to the visible or palpable tumor. If infiltrating tumor is confined to the proximal penile urethra or involves the entire urethra, total penectomy is indicated. Isolated reports of penile-sparing surgery (urethrectomy with corpora cavernosa sparing) have a high incidence of failure.¹² Ilioinguinal node dissection is indicated only in the presence of palpable adenopathy. Prophylactic groin dissection has no proven role in this site.

Carcinoma of the Bulbomembranous Urethra. Early superficial tumors (Ta, Tis, and T1) can be treated with transurethral fulguration or segmental resection with end-to-end anastomosis; however, such cases are rare. Invasive tumors (T2, T3) are best treated with radical cystoprostatectomy with en bloc penectomy and pelvic lymphadenectomy. Despite this aggressive approach, the prognosis remains dismal, with a 5-year disease-free survival of 26% in patients with invasive bulbomembranous carcinomas.¹³ Isolated reports of penile preservation surgery for invasive bulbomembranous cancers have used adjuvant radiation therapy (45 Gy) and concurrent chemotherapy with 5-fluorouracil (5-FU) and mitomycin C with acceptable results.¹⁴

Carcinoma of the Prostatic Urethra. Primary carcinoma arising from the prostatic urethra is rare. Adenocarcinomas and urothelial carcinomas are found. Although superficial lesions (Tis-pu, Tis-pd, T1) can be managed by transurethral resection, such tumors are rare. Invasive urothelial carcinoma of the prostatic stroma (T2) carries a poor prognosis despite aggressive surgical therapy. Extravesical extension of disease has a worse prognosis than intra-urethral disease, with a higher chance of nodal involvement and a 5-year survival rate of only 32%.¹⁵

Advanced carcinoma (T3-4N1 to N3) of the prostatic urethra is best treated with a combination of neoadjuvant chemotherapy (methotrexate sodium, vinblastine sulfate, doxorubicin hydrochloride [Adriamycin, Pharmacia S.p.A, Milan, Italy], and cisplatin [MVAC]) with consolidative surgery or irradiation. One series of five patients (with T2-4N0M0 lesions) treated with neoadjuvant

MVAC chemotherapy had a complete response rate of 60%.¹⁶ MVAC chemotherapy preoperatively was ineffective against non-urothelial carcinoma.

Radiation and Multimodal Therapy

Radiation therapy alone has poor results in male urethral carcinoma. Patients who receive radiation therapy followed by salvage surgery seem to fare worse than with surgery in an integrated fashion. The most common approach has been external-beam radiotherapy of 50 to 60 Gy with best results for *distal* urethral lesions. Multimodal therapy with chemoradiation has shown the efficacy of 5-FU, mitomycin C, and cisplatin with radiation for squamous cell carcinoma of the urethra.^{17,18}

CARCINOMA OF THE FEMALE URETHRA

Carcinoma of the urethra is the only genitourinary neoplasm that is more common in women than in men (four-to-one ratio). The peak incidence is in the sixth decade, more commonly in white women. Chronic irritation, recurrent urinary tract infections, and a host of proliferative lesions (caruncles, papillomas, polyps) are predisposing factors, and HPV may play a role. Leukoplakia of the urethra is considered a premalignant condition. In females, the urethra is approximately 4 cm long, mostly buried in the anterior vaginal wall, and divided into the distal one-third (anterior urethra) and the proximal two-thirds (posterior urethra). The most common presenting symptom (greater than 50%) is urethrorrhagia. Urinary frequency, obstructive voiding, a foul-smelling discharge, and a palpable urethral mass are other modes of presentation. Initially, it may be difficult to distinguish fungating tumors of the urethra from those of the vagina or vulva.

Spread of urethral carcinoma follows the anatomic subdivision: lymphatics of the anterior urethra drain into the superficial and deep inguinal nodes and the posterior urethra into the external iliac, hypogastric, and obturator nodes. At presentation, one-third of patients have inguinal lymph node metastases and 20% have pelvic node involvement. Palpable inguinal nodes in patients with urethral cancer invariably contain metastatic carcinoma. The most common sites of distant spread are the lungs, liver, and bone.¹⁹

An epidemiologic survey of female urethral cancer identified over 700 women in the Surveillance, Epidemiology, and End Results database.²⁰ No other study approaches this one in number of patients analyzed. The median overall survival in this large cohort was 42 months, with 5- and 10-year overall survival rates of 43% and 32%, respectively. The median cancer-specific survival was 78 months, and the 5- and 10-year cancer-specific survival was 53% and 46%, respectively. On multivariate analysis of nonmetastatic patients, variables predicting for worse cancer-specific survival were African-American race, stage T3 through T4 tumors, node-positive disease, nonsquamous cell histology, and advanced age.

Pathology

Stratified squamous epithelium lines the distal two-thirds of the female urethra, and transitional epithelium (urothelium) lines the proximal one-third. The majority (60%) of neoplasms of the female urethra are squamous cell carcinomas. Less common types are urothelial carcinoma (20%), adenocarcinoma (10%), undifferentiated tumors (8%), and melanoma (2%). Clear cell carcinoma is a distinctive clinical entity that has generated considerable interest with respect to its prognosis and relationship to urethral diverticulae.²¹ Histology does not affect the prognosis, and all are treated similarly. In general, anterior urethral carcinomas are low grade and stage; carcinomas involving the proximal or entire urethra are of a higher grade and stage.

Evaluation and Staging

The workup for women with suspected urethral carcinoma includes a pelvic examination under anesthesia, cystourethroscopy, and biopsy. Radiographic evaluation includes a chest x-ray and CT of the pelvis and abdomen. MRI is particularly useful for staging of female urethral carcinoma. Although the 2010 AJCC TNM staging includes female urethral cancer,⁸ the practical usefulness is limited. Clinically, it is more useful to stage, treat, and prognosticate female urethral cancers by stratifying patients based on anatomic location (anterior versus posterior urethra versus entire urethra) and clinical stage (low stage versus high stage).²²

Treatment

The anatomic location and stage of the tumor are the most significant prognostic factors predicting local control and survival. Treatment is based on the stage at the time of initial presentation, with low-stage distal urethral tumors having a better prognosis than high-stage proximal urethral tumors. In one series, the 5-year disease-specific survival was 46%, with 89% survival for low-stage tumors and 33% for high-stage disease.²³

Local surgical excision is often sufficient in selected patients with low-stage distal urethra carcinoma. With proximal urethra and for bulky locally advanced tumors, more aggressive treatment with an anterior pelvic exenteration is often needed (en bloc total urethrectomy, cystectomy, pelvic lymphadenectomy, hysterectomy with salpingectomy, removal of the anterior vaginal wall). Bulky proximal urethral tumors that invade the pubic symphysis may require resection of the pubic symphysis and inferior rami. Anterior exenteration alone has been reported to produce a 5-year survival rate of <20% in patients with invasive carcinoma of the female urethra.²⁴ Radiation therapy (brachytherapy alone or with external-beam radiation) is an alternative to surgery in low-stage urethral carcinoma with cure rates up to 75%. The reported doses have ranged from 50 to 60 Gy for brachytherapy alone and 40 to 45 Gy external-beam radiation to the whole pelvis followed by a brachytherapy boost of 20 to 25 Gy over 2 to 3 days. Proximal urethral tumors with bladder neck invasion and bulky tumors require combined external-beam and brachytherapy. Large primary tumor bulk and treatment with external radiation alone (no brachytherapy) were independent adverse prognostic factors. Brachytherapy reduced the risk of local recurrence, possibly as a result of the higher radiation dose.²⁵ Complications from radiation therapy occur in about 20% and include urethral strictures and stenosis, urethrovaginal fistulas, incontinence, and bowel obstruction.

Combined modality treatment with neoadjuvant chemotherapy and preoperative radiation therapy, followed by surgery, is recommended for advanced female urethral carcinoma. A 55% survival rate has been reported with advanced urethral carcinoma treated with radiotherapy plus surgery, as compared with a rate of 34% with radiation alone.²⁶ Although long-term results from multimodal therapy are not yet available, combination chemotherapy, radiation, and surgery is believed essential for local control and cure with larger or locally advanced urethral cancer.²³ The prognosis for women with carcinoma of the urethra is poor, regardless of the treatment modality used, and the median time to local recurrence for invasive carcinoma is 13 months.

Distal Urethral Carcinoma

Small superficial (T_a, T_{is}, and T₁) tumors of the distal female urethra can be removed surgically with little risk of urinary incontinence. Spatulation of the urethra and approximation to the adjacent vagina preserve urinary continence and prevent meatal stenosis. For small invasive tumors of the distal urethra (T₂), brachytherapy alone is an excellent therapeutic option.

Proximal Urethral Carcinoma

Proximal female urethral carcinomas tend to be more aggressive and bulky. For advanced (T₃ and T₄) lesions, a multimodal approach is preferred. Surgery consists of a radical cystourethrectomy or an anterior exenteration, depending on the extent of the disease. Radiation therapy with a combination of brachytherapy and external-beam irradiation is usually required. Neoadjuvant chemotherapy with 5-FU and mitomycin C has been noted to enhance the therapeutic ratio of radiation therapy.

CANCER OF THE PENIS

Carcinoma of the penis is an uncommon malignancy in Western countries, representing 0.4% of male malignancies and 3.0% of all genitourinary cancers. Penile cancer constitutes a major health problem in many countries in Asia, Africa, and South America, where it may comprise up to 10% of all malignancies. The incidence of penile cancer has been declining in many countries, partly because of increased attention to personal hygiene.²⁷ It most commonly presents in the sixth decade but may occur in men younger than 40 years. Analysis of the Surveillance, Epidemiology, and End Results database data shows no racial difference in the incidence of penile cancer among African American men and white men, but significant disparities exist in the mortality of invasive penile carcinoma in the United States.²⁸ Significantly lower rates of invasive penile cancer are seen in Asian American men and significantly higher rates are seen in Hispanic American men. Regional and socioeconomic differences are also noted, with higher rates in the southern area of the United States and in lower socioeconomic populations.

Etiology

Penile cancer is associated with phimosis and poor local hygiene, with phimosis found in more than half the patients. The irritative effect of smegma, a byproduct of bacterial action on desquamated epithelial cells in the preputial sac, is well known, although definitive evidence of its role in carcinogenesis is lacking. Neonatal circumcision as practiced by religious groups virtually eliminates the occurrence of penile carcinoma. While circumcision can reduce the risk of various sexually transmitted diseases such as HIV, and possibly HPV and herpes virus, delaying circumcision until puberty or adult circumcision does not have the same benefit with respect to penile cancer.²⁹

HPV infection, particularly HPV-16, has been implicated in the development of invasive penile cancer, as has the number of sexual partners.²⁹ HPV infection accounts for about half of penile cancers, with HPV-16 and -18 the predominant subtypes.^{30,31} Evidence now indicates that penile cancer has two primary etiologies: approximately half are related to HPV infection, with the other half related to inflammatory conditions such as phimosis, chronic balanitis, and lichen sclerosis.³² The use of tobacco products is an independent risk factor.³³ Thus, avoidance of tobacco products and HPV infection, penile hygiene, and neonatal circumcision represent important preventive strategies against penile cancer. Vaccination of younger men against HPV is controversial but may change the incidence and burden of this disease.^{34,35}

Symptoms

Local symptoms and signs often draw attention to penile cancer. The clinical spectrum of penile cancer is varied: subtle areas of erythema or induration to a frankly ulcerated, fungating, foul-smelling mass. Penile cancer is commonly associated with concomitant infection, with infection playing an important role in the pathogenesis and ultimately in the presentation of the disease. Pain usually is not a prominent feature and is not proportional

to the extent of local destruction. The lesion primarily involves the prepuce and glans, often under a tight phimotic ring. In late stages, involvement and destruction of the shaft of the penis or urethra are seen. Urethral obstruction is rare. Instead, erosion of the urethra with multiple fistulas ("watering-can perineum") may be seen. Rarely, inguinal ulceration may be the presenting symptom, with the primary tumor concealed within a phimotic preputial sac.

Patients with penile cancer, more than with other types of cancer, delay seeking medical attention. Historically, up to 50% of patients delayed more than 1 year in seeking medical help; contemporary series, especially from the United States, fail to show such a trend.

Pathology

More than 95% of penile carcinomas are squamous cell. Non-squamous cell carcinomas consist of melanomas, basal cell carcinomas, lymphomas, and sarcomas. Nearly 18% of patients with acquired immunodeficiency syndrome-related Kaposi sarcoma have penile involvement.³⁶

Squamous cell carcinomas are graded using Broder classification. Low-grade tumors (grades I and II), typically confined to the prepuce and glans penis, constitute nearly 80% of penile cancers. Most lesions that involve the shaft of the penis are high grade (grade III), with grade and stage often correlated. The incidence of lymph node metastases from squamous cell carcinoma of the penis is related to histologic grade. Verrucous carcinoma, a particularly exuberant variant of squamous cell carcinoma, has low potential for lymph node spread and a good prognosis. Another important predictor of lymph node metastases and, hence, prognosis is the presence of vascular invasion.³⁷

Premalignant Lesions

The description of early and premalignant lesions has been complicated by the rarity of the disease and a proliferation of eponyms.

Leukoplakia

Leukoplakia is characterized by the presence of solitary or multiple whitish plaques involving the glans or prepuce in the setting of chronic or recurrent balanoposthitis. Surgical excision in the form of circumcision or local wedge resection is usually curative.

Balanitis Xerotica Obliterans

Balanitis xerotica obliterans (BXO) is an inflammatory condition of the glans and prepuce of unknown cause; it is a form of lichen sclerosis isolated to the penis. BXO is a scaly, indurated, whitish plaque that produces significant phimosis and meatal stenosis. Although selected reports suggest an association with penile cancer, treatment remains controversial and consists of topical steroids and surgical excision. Meatoplasty may be required, with early circumcision the most effective treatment for BXO.³⁸

Buschke-Löwenstein Tumor

The Buschke-Löwenstein tumor is a large exophytic mass involving the glans penis and prepuce; it is a giant condyloma acuminatum that has a good prognosis and does not metastasize. Except for unrestrained local growth, this lesion has malignant features. A viral etiology has been proposed, with identification of HPV-6 and -11 in some tumors. Treatment consists of local conservative resection. Recurrence is common. Systemic interferon- α therapy combined with neodymium: yttrium aluminum garnet (Nd:YAG) laser therapy is successful in some cases. Radiation therapy is contraindicated because rapid malignant degeneration has been described.

Diagnosis and Staging

The workup for penile cancer begins with physical examination of the genitalia and inguinal nodes to ascertain local extent of the

lesion and the presence of inguinal adenopathy. Nodal status is the most significant prognostic variable predicting survival. Approximately 50% of patients with penile cancer present with palpable inguinal nodes. Only half of these patients will have metastatic disease, with the remainder having inflammatory adenopathy secondary to infection of the primary lesion. Conversely, 20% of patients with clinically negative groin examination are found to have metastases on prophylactic node dissection. The most common distant metastatic sites are the lung, bone, and liver. The AJCC system (seventh edition) for staging penile cancer uses the TNM classification to determine the stage of the primary tumor and the extent of nodal metastases (Table 69.2).⁸ After biopsy confirmation of the lesion, no further radiologic workup is generally needed in patients with early-stage disease and the absence of inguinal adenopathy on examination or other worrisome symptoms. Ultrasound and gadolinium-enhanced MRI are recommended for high-grade and high-stage lesions suspected of involving the corporal bodies, especially if partial penectomy is contemplated. Abdominal and pelvic CT scanning is recommended in obese patients to evaluate the inguinal nodes. In patients with known inguinal metastases, CT-guided biopsy of enlarged pelvic nodes, if positive, may be an indication for neoadjuvant chemotherapy. The role of positron emission tomography scan in the staging of penile cancer is unclear, with conflicting data.³⁹⁻⁴¹

Treatment

Treatment of penile carcinoma depends on the local extent of the primary neoplasm and the regional lymph node status. For the primary lesion, a 2-cm proximal margin of resection is recommended. If an adequate margin can be obtained, a partial penectomy offers excellent local control. Leaving the patient with adequate penile length for hygienic upright micturition and sexual intercourse is the goal. Thus, depending on the extent of the primary tumor, resection may include a partial or total penectomy, with local recurrence rare.⁴²

In advanced cases (T4), more aggressive resections (emasculatotomy, hemipelvectomy, hemicorpectomy) have been reported with mixed results. Although surgery is the mainstay for treatment of the primary lesion, radiation therapy can be considered for a select group of patients. Radiation therapy allows preservation of the penis, obviating the psychosocial and physical morbidity caused

by partial or total penectomy. External-beam and brachytherapy techniques have been used for treatment of the primary cancer. Circumcision is generally recommended before radiation therapy is initiated. This allows for further evaluation of the tumor extent and reduces morbidity associated with radiation (swelling, maceration, secondary infection), all of which may eventually result in secondary phimosis. Local control and penile preservation rates approaching 70% at 10 years have been reported for carefully selected early (T1 to T2) lesions.⁴³ Treatment of more advanced penile cancers has a much higher risk of local recurrence and progression to nodal and systemic disease.⁴⁴ Thus, radiation therapy, although cosmetically attractive, has disadvantages, and the number of patients for whom this treatment is appropriate is small.

Of paramount importance in treatment is consideration of the lymphatic drainage of the penis. The inguinal lymph nodes constitute the first echelon of drainage. Superficial and deep inguinal nodes are involved in a stepwise manner. Bilateral drainage occurs as a result of free anastomoses and crossover at the base of the penis. Therefore, the pattern of nodal metastasis is not limited to one side. The superficial inguinal nodes are located in the deep portion of Camper fascia above the deep fascia of the thigh (fascia lata). The superficial lymphatics drain into the deep inguinal lymphatics, which surround the femoral vessels deep to the fascia lata. Secondary drainage is to the iliac nodes, although direct drainage to these nodes (skip metastases) can occur rarely.

Five-year disease-free survival rates for palpably negative adenopathy (cN0) or low volume palpable groin disease (cN1) are similar and favorable at 93% and 84%, respectively, with a markedly worse survival for palpably bulky disease (cN2 or cN3) of 32% and 0%, respectively.⁴⁵ When stratified by pathologic stage, low volume nodal involvement (pN1) had favorable and similar 5-year disease-free survival rates when compared to pathologically negative nodes (pN0) at 93% and 90%, respectively. Pathologically confirmed bulky adenopathy (pN2 and pN3) had very poor long-term outcomes with 5-year disease-free survival rates of 31% and 0%, respectively.

Based on the rarity of advanced penile carcinoma in the Western world, there is growing awareness that these men may receive better outcomes if they are directed to tertiary care centers with expertise in penile carcinoma and inguinal lymphadenectomy. In the United Kingdom, the National Institute for Clinical Excellence published guidelines in 2002 that included the treatment of penile carcinoma and advocated the creation of regional multidisciplinary teams.⁴⁶ These guidelines have increased the rate of penis-preserving procedures and inguinal lymphadenectomy, with decreased mortality.⁴⁷

Treatment of Primary Lesion

Surgery for penile carcinoma ranges from circumcision, conservative local resection, laser ablation, and Mohs micrographic surgery to partial and total penectomy. Radiation therapy can be used in selected patients with early superficial lesions.

Carcinoma In Situ (Tis). Penile squamous cell carcinoma in situ, also known as erythroplasia of Queyrat, is a red, velvety, well-margined lesion of the glans penis or the prepuce of uncircumcised men. After confirmatory biopsy, a conservative approach that spares penile anatomy and function is preferred. Preputial lesions are adequately treated with circumcision. Topical 5-FU cream and imiquimod have been used with excellent cosmetic results for glandular and meatal lesions (imiquimod 5% cream for 5 days per week for 4 to 6 weeks or 5-FU 5% cream every other day for 4 to 6 weeks). A prospective study of carbon dioxide and Nd:YAG lasers has shown good local tumor control and satisfactory cosmetic results.⁴⁸ Mohs micrographic surgery has been described as a less-deforming alternative, with local control rates up to 86% in selected patients with early penile cancer.⁴⁹ Radiation therapy can often eradicate these lesions with minimal morbidity.

Verrucous Carcinoma (Ta). Penile verrucous carcinoma is characterized by aggressive local growth and a low metastatic potential. Partial or total penectomy is usually overtreatment, and conservative therapeutic approaches are favored. Laser ablation or Mohs micrographic surgical technique has yielded acceptable results. Intra-aortic infusion with methotrexate has been reported with reasonable results.⁵⁰ Radiation therapy is contraindicated as it has been shown to cause subsequent rapid malignant degeneration and metastases.

Invasive Penile Cancer (T1, T2, T3, and N1). Distal penile lesions, in which a serviceable penis for upright micturition and sexual function can be achieved, are best treated with a partial penectomy. Extensive lesions that approach the base of the penis usually require total penectomy with corporal body excision and perineal urethrostomy. Local recurrence after a partial penectomy in properly selected cases is rare. Most relapses occur within the first 12 to 18 months after penectomy, and salvage surgery is beneficial.

The effectiveness of radiation therapy in the treatment of penile cancer is hindered by a lack of uniformity of radiation treatment in terms of type of delivery and doses. Radiation therapy is effective for local control of small, 2- to 4-cm, T1 and T2 lesions but also for more advanced T-stage tumors. Local recurrence is higher in those with T3 and T4 tumors, but a significant percentage can be salvaged by adjuvant surgical resection.⁵¹ Before treatment, patients should have a circumcision to allow direct inspection and staging of the tumor and to facilitate management of the acute side effects of radiation. External-beam and brachytherapy techniques have been used. External-beam radiotherapy can be delivered by a direct field method that uses a low-energy photon beam or an electron beam applied directly to the tumor, with a safety margin of 2 cm beyond the visible and palpable extent of the tumor. This approach is suitable only for very superficial tumors (Tis and T1). For T2 and T3 lesions, a parallel opposed field method is used. Using this approach, the entire thickness of the penis can be irradiated by encasing the lesion in a wax mold to ensure uniform dosage and to negate the skin-sparing effects of supervoltage beams with a total dose of 60 Gy recommended. A 65% to 80% local success rate has been reported with radiation therapy for small T1 and T2 tumors.⁴³ Brachytherapy involves placement of radioactive material (usually iridium-192 wire) within the tumor (interstitial brachytherapy) or molded around the tumor (plesio-brachytherapy) and is limited to T1 and T2 tumors. This form of therapy is not suitable for patients with bulky tumors, deeply infiltrating tumors, and obese patients with a short penis. Radiation therapy as primary treatment for invasive penile carcinoma has significant disadvantages: acute effects of skin edema, maceration, and dysuria may persist for 6 to 8 weeks. Telangiectasia and fibrosis are found in more than 90% of cases. The most serious late effects are urethral fistula, meatal stenosis, and penile necrosis. Postradiation fibrosis, scar, and necrosis may be difficult to distinguish from recurrent cancer. Infection is very often associated with penile cancer and reduces the therapeutic efficacy of radiation while increasing the risk of penile necrosis. Thus, in summary, radiation therapy for primary penile cancer should be considered only in a select group of patients: young patients with small (2 to 4 cm) superficial lesions of the distal penis who wish to maintain penile integrity, patients who refuse surgery, and patients with inoperable cancer or those unsuitable for major surgery.

Advanced Penile Cancer (T4, N2-3, and M1). Large proximal shaft tumors require a total penectomy with a perineal urethrostomy. For extensive, proximal tumors with invasion of adjacent structures, total emasculation (total penectomy, scrotectomy, and orchiectomy) is recommended. In extreme cases, a hemipelvectomy or even a hemicorporectomy has been described. Multimodal therapy with chemoradiation and salvage surgery has also been used in this setting.

Management of Regional Lymph Nodes

The presence and extent of inguinal lymph node metastases are the most important prognostic factors in penile cancer. Although 50% of patients with a penile lesion have clinically palpable inguinal nodes at presentation, in more than half of these the adenopathy is inflammatory. A 4- to 6-week course of antibiotics (e.g., first- or second-generation cephalosporin) after treatment of the primary lesion is recommended. Persistent palpable adenopathy after antibiotic therapy should be biopsied. Unlike many other genitourinary malignancies that require systemic chemotherapy, once lymph node metastases are discovered, inguinal metastases from penile cancer are potentially curable by lymphadenectomy alone. Inguinal lymphadenectomy therefore should be performed at the earliest suspicion of metastases.

Clinical Node Negative (N0). Although there is no controversy in the literature regarding management of the patient with clinically positive inguinal lymph nodes after a course of antibiotics, considerable controversy surrounds the management of the clinically N0 patient. Approximately 20% of these clinically negative groins harbor occult lymphatic metastases on prophylactic lymph node dissection. Stated another way, approximately 80% of patients with clinically negative groins would be subjected to the morbidity of inguinal lymph node dissection without benefit. To resolve this dilemma, a risk-based approach to management of the clinically negative groin has been recommended in most contemporary series. Analysis of histopathologic data from the primary penile cancer allows stratification of patients into high- and low-risk groups for lymph node metastases.⁵²

Low-Risk Group. Patients with carcinoma in situ (Tis), verrucous carcinoma (Ta), and T1 tumors who have grade 1 or 2 tumor histology have a <10% chance of developing lymph node metastases and are best served by surveillance and a low incidence of lymphovascular invasion, a risk for nodal metastasis.³⁷

High-Risk Group. Patients with invasive penile cancer (T2 and T3) with grade 3 tumors and the presence of vascular invasion have a >50% incidence of inguinal lymph node metastases in various series. Vascular invasion is strongly correlated with lymph node metastases. In pT2 patients, the incidence of lymph node metastases was found to be 75% in the presence of vascular invasion and only 25% when vascular invasion was absent.⁵² In this cohort of patients, a prophylactic lymphadenectomy is reasonable.

The timing of surgery in the clinically negative groin has been debated in the past. Most contemporary series favor *early adjunctive* lymphadenectomy, especially in the high-risk group, over surveillance and *delayed therapeutic* lymphadenectomy. Sentinel lymph node biopsy, originally described by Cabanas,⁵³ is no longer recommended in view of the high false-negative rate. Intraoperative lymphatic mapping using dynamic scintigraphy with technetium-labeled sulfur colloid have decreased the false-negative rate considerably.⁵⁴ Other approaches that use sentinel lymph node biopsy have also been advocated, including measurement of the size of the micrometastatic sentinel lymph node to determine whether to perform lymphadenectomy.⁵⁵ Sentinel node biopsy remains controversial, with recent studies demonstrating a much lower false negative rate,^{56,57} but further data are required.⁵⁸ Lymphotropic nanoparticle-enhanced MRI has been investigated to detect micrometastasis but awaits validation.⁵⁹

Inguinal lymph node dissection superficial to the fascia lata has been found to be adequate for the N0 patient. Superficial inguinal lymph node dissection should include a frozen section, and if positive, a modified complete dissection should be carried out. Creation of thicker skin flaps, control of infection, and preservation of the areolar fat superficial to the Scarpa fascia have greatly decreased the complications of flap necrosis, scrotal and extremity edema, lymphocele, and lymphorrhea.

Prediction Models. Ficarra et al.⁶⁰ and Kattan et al.⁶¹ have developed predictive nomograms to help determine an individual patient's risk of nodal involvement and cancer-specific survival. One nomogram to predict the probability of lymph node involvement uses eight clinical and pathologic variables (tumor thickness, growth pattern, grade, lymphovascular invasion, corpora cavernosal involvement, spongiosal involvement, urethral involvement, palpable lymph nodes).⁶⁰ Not surprisingly, clinically suspicious inguinal lymph nodes are a powerful predictor of pathologic nodal involvement. For cancer-specific survival of patients who undergo surgery for squamous cell carcinoma of the penis, two separate nomograms were created, depending on whether clinical or pathologic staging of inguinal lymph nodes was used.⁶¹ These nomograms may guide patients and clinicians alike on the appropriate treatment and can potentially avoid the risks of lymph node dissection in low-risk patients.

Clinical Node Positive (N1, N2, or N3). The modified inguinal lymph node dissection as described by Catalona⁶² has replaced the standard complete inguinal lymphadenectomy as the procedure of choice with clinically persistent nodes after antibiotics. It involves a smaller incision, limited field of inguinal dissection, and preservation of the saphenous vein in an effort to reduce the morbidity of the standard procedure while adhering to standard oncologic principles. Unlike superficial dissection, the deep nodes within the fossa ovalis are also removed. In the face of synchronous unilateral N+ disease, it is standard practice to proceed with a bilateral lymph node dissection in view of the high incidence of bilateral drainage. The exception to this rule is the patient with a clinically negative groin in whom metachronous unilateral inguinal lymphadenopathy develops sometime after treatment of the primary tumor. In these patients, a unilateral dissection of the clinically positive groin usually suffices. The value of pelvic lymphadenectomy in the presence of positive inguinal lymph nodes is for the purposes of staging and identifying patients who would be candidates for adjuvant chemotherapy and had little therapeutic efficacy (5-year survival with pelvic lymph node metastases is <5%).

Patients with advanced nodal disease or bulky fixed inguinal nodes (N3) may require neoadjuvant radiation or chemotherapy before any surgery. Groin lymph nodes adherent to or fungating through the skin require wide excision with myocutaneous flaps to cover the skin defect. The published literature unequivocally favors surgical resection as superior to radiation therapy for the treatment of inguinal lymph nodes. Clinical evaluation of the groin is difficult because of postradiation tissue changes, and the inguinal area tolerates radiation rather poorly. Radiation therapy can be used as a palliative measure in patients with fixed inoperable inguinal nodes or in those with advanced unresectable penile cancer in which the primary and the ilioinguinal region can be treated with radiation therapy.

Role of Chemotherapy and Multimodality Therapy

The role of chemotherapy in the management of penile carcinoma is evolving, and the exact role of chemotherapy has not been established. Data suggest that penile cancer is sensitive to chemotherapy.⁶³ Besides the use of 5-FU in the treatment of superficial penile cancer, single-agent chemotherapy with cisplatin, methotrexate, and bleomycin has modest activity in advanced penile cancer. The combination of methotrexate, bleomycin, and cisplatin is more active than cisplatin alone but is associated with marked toxicity. Anti-epidermal growth factor receptor therapy may also hold some promise in this disease.⁶⁴

The Southwest Oncology Group reported on the largest prospective clinical trial in patients with penile cancer.⁶⁵ In 40 evaluable patients treated with a combination of methotrexate, bleomycin, and cisplatin, an overall response of 32.5% and a complete

response of 12.5% were observed. The median response duration was 16 weeks, and the median survival was 28 weeks. Toxicity was formidable, with 11% treatment-related mortality, and 17% of the remaining patients experiencing life-threatening toxicity. Another prospective trial from a UK consortium reported on 29 patients treated with three 21-day cycles of TPF (docetaxel 75 mg/m² and cisplatin 60 mg/m² on day 1 and 5-FU 750 mg/m² per day days 1 to 5) in patients with locally advanced or metastatic penile cancer. The objective response rate was 28.5% and 1-year overall survival rate was 55%, demonstrating activity of this regimen in advanced penile cancer. There was significant toxicity, however, with neutropenic fever in 25% and dose delays or reductions in nearly half

of patients.⁶⁶ Multimodality therapy, using a combination of chemotherapy and surgery or chemotherapy and radiation, has been used in isolated reports of advanced penile cancer. Small series in men with fixed, unresectable inguinal nodes had neoadjuvant vincristine, bleomycin, and methotrexate before surgery with some long-term responses.⁶⁷ Another small series of patients who underwent surgical resection after neoadjuvant chemotherapy for unresectable penile squamous cell were treated with several different chemotherapy combinations, including bleomycin, methotrexate, cisplatin; ifosfamide, paclitaxel, cisplatin; or paclitaxel/carboplatin with some responses.⁶⁸ Clearly, more tolerable and active regimens are needed for unresectable or metastatic penile cancer.

70 Cancer of the Testis

Lance C. Pagliaro and Christopher J. Logothetis

INTRODUCTION

Testicular cancers are the most common malignant neoplasm affecting men ages 15 to 35 years. Approximately 90% of testicular cancers are germ cell tumors, which can be broadly classified as seminoma or nonseminomatous germ cell tumors (NSGCT). Male extragonadal germ cell tumors are also discussed in this chapter. Analogous germ cell and sex cord stromal tumors in women are not included here, but in many cases the male and female counterparts share a common biology and therapeutic approach.

INCIDENCE AND EPIDEMIOLOGY

In the United States, 8,820 new cases of testicular cancer per year is estimated for 2014.¹ This figure greatly underestimates the prevalence of testicular cancer survivors. This is because the cancer-specific survival rate for testicular cancer with standard treatment is >95%.² The incidence varies among geographic areas, being highest in Scandinavia, Switzerland, and Germany, and lowest in Africa and Asia.³ Although testicular germ cell tumors are most common among adolescent and young adult men, they can potentially occur in males of any age or genetic background. For reasons that have yet to be discovered, the incidence of testicular germ cell tumors has increased over the preceding 30 years in the United States and United Kingdom.⁴

Risk Factors

Men whose family history includes a first-degree relative with testicular germ cell tumor or who have a personal history of cryptorchidism are at increased risk of developing germ cell tumor.^{5,6} Testicular cancer survivors are also at increased risk of a second primary cancer in the contralateral testicle.⁷ These risk factors suggest a genetic or developmental etiology for testicular germ cell tumors. No postnatal environmental risk factors have yet been identified.⁸

In the United States, testicular cancer is rare among African Americans and most common among Caucasian men.⁹ This racial disparity in testicular cancer diagnosis and its geographic distribution suggest a genetic linkage with the Caucasian phenotype, but no high penetrance allele has yet been identified.⁴ Testicular germ cell tumors are commonly accompanied by intratubular germ cell neoplasia (ITGCN). It is thought that all adult germ cell tumors, with the exception of spermatocytic seminoma, arise from ITGCN.¹⁰ The widely accepted theory is that ITGCN begins in utero.¹¹ The multifocality of ITGCN suggests a field effect within the testicle and provides a mechanistic explanation for cases of bilateral testicular cancer.

Men without a history of testicular cancer are occasionally found to have ITGCN on testicular biopsy or orchiectomy that was performed for other reasons. The incidental finding of testicular microlithiasis on ultrasound may also provide evidence of ITGCN in an otherwise healthy man.^{12,13} The risk of testicular cancer for such individuals has not been determined, but they should be counseled regarding a potential increased risk and to report any new testicular symptoms.¹⁴

INITIAL PRESENTATION AND MANAGEMENT

Symptoms and Signs

Testicular swelling is the most common presenting complaint and in most cases is detected by the patient himself. Patients may also report a pressure-like sensation, heaviness, or mild-to-moderate testicular pain. This will sometimes be confused with orchitis or epididymitis and treated initially with antibiotics. Acute or severe pain is rarely caused by testicular cancer and suggests a different etiology such as testicular torsion. Testicular ultrasound should be obtained as soon as a neoplasm is suspected, and it will appear as one or more hypoechoic lesions within the testicle. Ultrasound distinguishes a solid from cystic mass, and intratesticular from intrascrotal/extratesticular location. A solid intratesticular mass on ultrasound is presumed to be a neoplasm and is an indication for radical inguinal orchiectomy.¹⁵

Approximately half of patients present with a testicular mass and no clinical evidence of metastasis (clinical stage I). Others present with metastatic disease that may also be symptomatic. Primary tumors can be small and asymptomatic, even in the presence of metastatic disease, and occasionally they “burn out” leaving only a fibrotic scar (burned-out primary). Metastases can be the source of clinical symptoms on presentation in such cases, and include back pain, shortness of breath, cough, gynecomastia, hemoptysis, and weight loss.¹⁶ Ultrasound of the testicles is helpful in establishing the diagnosis even if there is no palpable testicular mass.¹⁵ The detection of elevated serum tumor markers can also be helpful when an occult testicular primary or extragonadal germ cell tumor is suspected.¹⁷

Diagnosis

Radical inguinal orchiectomy is the standard diagnostic and therapeutic procedure for a solid intratesticular mass.¹⁸ Transscrotal orchiectomy or biopsy is specifically contraindicated because of the risk of tumor cell seeding of the inguinal and pelvic lymphatic drainage. Biopsy is also of limited value because testicular germ cell tumors are heterogeneous. Removal of the entire organ is necessary to properly identify the histologic type(s) present and to select the appropriate therapy. It is reasonable to perform needle biopsy of a metastatic site in cases of occult testicular primary, burned-out primary, or extragonadal germ cell tumor; although, the results of needle biopsy must always be interpreted with caution due to sampling error. The pattern of serum tumor marker elevation is also informative about the likely cell types present (seminoma or nonseminoma), as discussed in the next section.¹⁷

HISTOLOGY

Male germ cell tumors are broadly classified as seminoma and NSGCT (Table 70.1).^{19,20} Patients with pure seminoma are

TABLE 70.1

World Health Organization Histologic Classification of Testicular Germ Cell Tumors

Germ Cell Tumors

Intratubular germ cell neoplasia, unclassified
Other types

Tumors of One Histologic Type (Pure Forms)

Seminoma
Seminoma with syncytiotrophoblastic cells
Spermatocytic seminoma
Spermatocytic seminoma with sarcoma
Embryonal carcinoma
Yolk sac tumor
Trophoblastic tumors
Choriocarcinoma
Trophoblastic neoplasms other than choriocarcinoma
Teratoma
Dermoid cyst
Monodermal teratoma
Teratoma with somatic type malignancies

Tumors of More Than One Histologic Type (Mixed Forms)

Mixed embryonal carcinoma and teratoma
Mixed teratoma and seminoma
Choriocarcinoma and teratoma/embryonal carcinoma
Others

managed differently than patients with NSGCT or mixed histology tumors, although mixed tumors may have a component of seminoma. In that sense, when we refer to seminoma as a clinical diagnosis it is meant as pure seminoma, whereas seminoma as a histologic pattern may also be present in mixed NSGCT.

Seminoma

The microscopic appearance of seminoma is characterized by sheets of neoplastic cells with abundant cytoplasm, round, hyperchromatic nuclei and prominent nucleoli (Fig. 70.1). A prominent lymphocytic infiltrate is common, such that it is sometimes confused with lymphoma until the surface immunophenotype has been determined. Most seminomas do not produce serum tumor

Figure 70.1 Seminoma, classic type, with neoplastic cells (arrow) and the typical accompanying lymphocytic infiltrate (arrowhead). (Source: Rao B, Pagliaro LC. Testicular germ cell tumors. In: Silverman PM, ed. *Oncologic Imaging: A Multidisciplinary Approach*. Philadelphia: Elsevier; 2012:335–357.)

markers, but the presence of syncytiotrophoblastic giant cells in a minority of cases accounts for modest elevations of serum human chorionic gonadotropin (hCG).²¹ Seminomas never produce alpha-fetoprotein (AFP), and patients whose tumors have the histologic appearance of seminoma and whose serum AFP is elevated should be considered to have a mixed NSGCT, even if a nonseminomatous histologic pattern cannot be identified.²² Exceptions are cases in which there is another explanation for the elevated AFP, such as liver disease or a chronic nonspecific elevation.

Immunohistochemistry is usually positive for placental alkaline phosphatase (PLAP), negative for CD30, AFP, and epithelial membrane antigen, and either negative or weak/focally positive for cytokeratin.²³

Histologic variations of seminoma such as “anaplastic” or “atypical” seminoma are of no known clinical relevance. Spermatocytic seminoma, however, is the one variant of seminoma that has a different natural history and is even of uncertain relation to other germ cell tumors. Spermatocytic seminoma usually occurs in older individuals and has low metastatic potential.²⁴ Orchiectomy is the only treatment required. Unlike all other germ cell tumors, spermatocytic seminoma is not associated with ITGCN.

Nonseminomatous Histologies

Germ cell tumors may be composed of a single histology or multiple histologic patterns.¹⁹ Through poorly understood processes of mutation and differentiation, a single clone beginning as ITGCN can develop into an undifferentiated neoplasm (seminoma), or to a primitive zygotic neoplasm (embryonal carcinoma).²⁵ Further differentiation from embryonal carcinoma results in somatically differentiated tumors (teratoma) or extraembryonal-differentiated tumors (yolk sac and choriocarcinoma).²⁶ Nonseminomatous histologies are found in 55% of germ cell tumors. Male germ cell tumors that contain any histologic cell type other than seminoma or syncytiotrophoblasts are collectively referred to as NSGCT.

Embryonal Carcinoma

Embryonal carcinoma is the most undifferentiated type of germ cell tumor and is thought to be pluripotent. Cells are characterized by indistinct borders and scant cytoplasm, which can be arranged in solid sheets or in glandular or tubular structures (Fig. 70.2). On immunohistochemical staining, embryonal carcinoma can be positive for cytokeratin, CD30, PLAP, AFP, and hCG. Modest elevations of serum AFP and/or hCG can be seen, and frequently it is marker-negative. Lactate dehydrogenase (LDH) concentration in the serum is an important prognostic factor in metastatic embryonal carcinoma that is marker negative.

Figure 70.2 Mixed nonseminomatous germ cell tumor comprised of teratoma (arrow) and embryonal carcinoma (arrowhead). (Source: Rao B, Pagliaro LC. Testicular germ cell tumors. In: Silverman PM, ed. *Oncologic Imaging: A Multidisciplinary Approach*. Philadelphia: Elsevier; 2012:335–357.)

Figure 70.3 Chest radiograph of a man with primary mediastinal choriocarcinoma and pulmonary metastases.

Choriocarcinoma

Choriocarcinoma is composed of both cytotrophoblasts and syncytiotrophoblasts.²⁷ The cells strongly express hCG. The clinical presentation of a choriocarcinoma-predominant or pure choriocarcinoma tumor often includes very high serum hCG levels, widespread hematogenous metastases, and tumor hemorrhage (Fig. 70.3). Syncytiotrophoblasts and syncytiotrophoblastic giant cells can be associated with other germ cell histologies, so the presence of cytotrophoblasts is required for the diagnosis.

Yolk Sac Tumor

Yolk sac tumor (endodermal sinus tumor) is commonly seen as a component of mixed NSGCT. Pure yolk sac tumors represent a significant proportion of mediastinal germ cell tumors, but are rarely seen in adult testicular cancer. Histologic patterns include papillary, solid, glandular, hepatoid, macrocystic, and microcystic types. Perivascular arrangements of epithelial cells can be seen in yolk sac tumor and are known as glomeruloid or Schiller-Duval bodies. Immunostains are diffusely positive for AFP and may also be positive for cytokeratin, SALL4, glipican-3, PLAP, and CD117. Yolk sac tumor is associated with high serum levels of AFP.

Teratoma

Teratoma arises from a pluripotent malignant precursor (embryonal carcinoma or yolk sac tumor) and contains somatic cells from at least two germ cell layers (ectoderm, endoderm, or mesoderm). Teratoma is commonly seen as a component of adult mixed NSGCT (see Fig. 70.2). A small percentage (2% to 3%) of postpubertal male germ cell tumors appear to have teratoma as the only histologic type, but these are always assumed to harbor a minor component of pluripotent NSGCT and are treated the same as a mixed NSGCT.

Immature teratoma shows partial somatic differentiation, whereas mature teratoma has terminally differentiated tissues such as cartilage, skeletal muscle, or nerve tissue, and frequently forms cystic structures. Although these cells can resemble normal tissues, teratoma is a low-grade malignancy and if untreated will grow until it is unresectable. Moreover, teratomas can give rise to secondary somatic malignancy, such as rhabdomyosarcoma, poorly

differentiated carcinoma, or primitive neuroectodermal tumor.²⁸ These typically display the biology of their de novo counterparts and are treated accordingly.^{29,30}

Teratoma does not produce elevated serum AFP or hCG. Patients with elevated serum AFP and/or hCG should be assumed to have a nonteratoma germ cell tumor component, unless the elevation can be otherwise explained.

BIOLOGY

Mechanism of Germ Cell Transformation

ITGCN is thought to derive from malignant transformation of primordial germ cells or gonocytes during fetal development.³¹ Primordial germ cells migrate from the proximal epiblast (yolk sac) through the hindgut and mesentery to the genital ridge, and become gonocytes. The precise molecular events underlying transformation to ITGCN are not well understood. The most consistent genetic finding in germ cell tumors is a gain of material from chromosome 12p. The majority of NSGCT and seminomas contain i(12p), an isochromosome comprised of two fused short arms of chromosome 12. The remaining i(12p)-negative germ cell tumors also have a gain of 12p sequences in the form of tandem duplications that may be transposed elsewhere in the genome.

Gain of 12p sequences has been found in ITGCN, indicating that it is an early event in testicular cancer pathogenesis. The acquisition of i(12p) is not thought to be the initiating event, however, because it is preceded by polyploidization.³² Overexpressed genes on 12p are likely to be important, and there are candidate genes on 12p including several that confer growth advantage (*KRAS2*, *CCND2* [cyclin D2]), and others that establish or maintain the stem cell phenotype (*NANOG*, *DPPA3*, *GDF3*). The exact genes that are critical to this step have not yet been identified.

Seminomas are usually hypertriploid, whereas NSGCT is more commonly hypotriploid.³³ Other chromosome regions were found to have nonrandom gains or losses in germ cell tumors with less frequency than 12p. Single gene mutations are uncommon in germ cell tumors. The most commonly mutated genes are *BRAF*, *KIT*, *KRAS*, *NRAS*, and *TP53*.¹¹ The *KIT*/kit ligand (*KITLG*) pathway

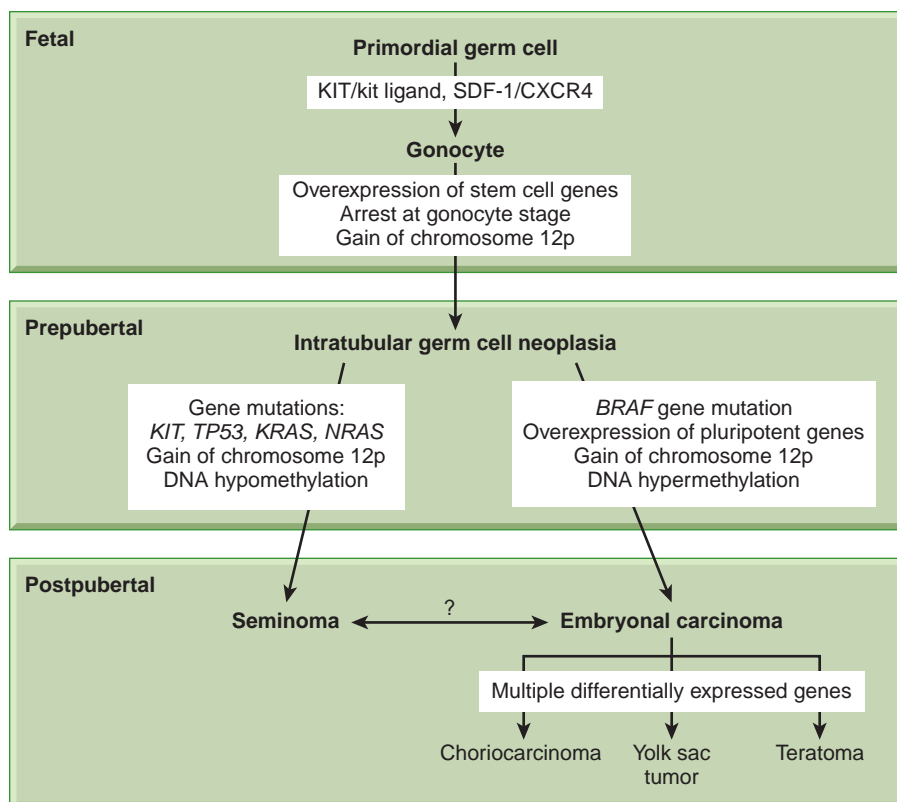

Figure 70.4 Pathogenesis of testicular germ cell tumors. (Adapted from Sheikine Y, Genega E, Melamed J, et al. Molecular genetics of testicular germ cell tumors. *Am J Cancer Res* 2012;2:153–167.)

has special relevance for gonadal development. The biologic function of this pathway is broad and includes development of hematopoietic cells, melanocytes, and germ cells.³⁴ *KITLG* is essential for primordial germ cell survival and motility, as are the chemokine *SDF-1* (*CXCL12*) and its receptor *CXCR4*.¹¹ Immunohistochemical markers found on primordial germ cells and gonocytes (PLAP, CD117 [*KIT*], OCT3/4 [*POU5F1*]) are also found on ITGCN, suggesting a transformation from these cells during fetal development (Fig. 70.4). The biallelic expression of imprinted genes in germ cell tumors has been reported, showing that they likely arose from primordial germ cells where the genomic imprinting is temporarily erased.³¹

Somatic mutations in *KIT* as well as increased copy number have been described in 9% of testicular germ cell tumors and 20% of seminomas.⁴ The somatic alterations in *KIT* found in germ cell tumors are predicted to upregulate pathway activity. *KITLG* plays a role in determining skin pigmentation and has undergone strong selection in European and Asian populations. Difference in the frequency of risk alleles for *KITLG* between European and African populations may provide an explanation for the difference in germ cell tumor incidence between Caucasian and African Americans.

There is evidence that epigenetic regulation of gene expression plays a role in the pathogenesis of germ cell tumors. The DNA methylation patterns are different among histologic types. Global hypomethylation is more common in seminomas than in NSGCT.³¹ In a study of 16 germ cell tumors, the methylation of CpG islands in NSGCT was similar to that observed in other tumor types, whereas it was virtually absent in seminomas.³⁵ Aberrant promoter methylation is generally associated with absent or downregulated expression of the methylated genes. This can result, for example, in the silencing of tumor suppressor genes.³¹ Methylation has also been correlated with germ cell tumor differentiation. The more differentiated tumors (yolk sac tumor, choriocarcinoma, teratoma) were consistently hypermethylated, whereas seminoma and ITGCN were hypomethylated.³⁶ Some of the observed methylation patterns may reflect normal development rather than germ cell tumor pathogenesis.

Pluripotency of Embryonal-Like Differentiation in Germ Cell Tumors

Embryonal carcinoma has a six-gene signature (*DNMT3B*, *DPPA4*, *GAL*, *GPC4*, *POU5F1*, *TERF1*), which was detected in three of five independent studies.¹¹ All six of these genes are involved in establishing and maintaining pluripotency. *SOX2* encodes a transcription factor essential for maintaining self-renewal of embryonic stem cells and is upregulated in embryonal carcinoma. Two additional genes that encode transcription factors associated with stem cell pluripotency, *NANOG* and *POU5F1*, are upregulated in both seminoma and embryonal carcinoma.²⁶ Lineage differentiation takes place in NSGCT, mimicking the development of a normal zygote. Thus, embryonal carcinoma can be thought of as the transformed counterpart of embryonic stem cells, displaying self-renewal, pluripotency, and lineage differentiation.

Familial Predisposition to Germ Cell Tumors

Approximately 1.4% of patients with newly diagnosed germ cell tumor report a family history of germ cell tumor.³⁴ First-degree male relatives of patients with testicular cancer have a 6- to 10-fold increased risk of developing testicular cancer. These observations point to the likely existence of a hereditary germ cell tumor subset. The inheritable effect is mild, and the most common number of affected relatives in a family is two. The age at diagnosis among familial cases is 2 to 3 years younger than sporadic cases, and there is a higher incidence of bilateral tumors.

The *gr/gr* deletion on chromosome Y, common among infertility patients and associated with a two- to threefold increased risk of testicular cancer, was studied as a candidate region for hereditary risk.⁴ The frequency of *gr/gr* variant is low, however, such that it could only account for a small component of hereditary risk. Genome-wide association studies (GWAS) for testicular cancer have been hampered by relatively small sample sizes. Nevertheless, five loci of interest were identified in a GWAS study from the

United Kingdom, on chromosomes 1, 4, 5q31.3, 6, and 12p22, including confirmatory data for the chromosome 6 locus. The single nucleotide polymorphism (SNP) associations on chromosomes 1 and 4 were not convincingly replicated in an independent US study, whereas the associations on chromosomes 5 and 12 were confirmed. The strongest associated SNPs were at 12q22 within the *KITLG* gene, for which there is a >2.5 risk of disease per major allele. For the chromosome 5 and 6 loci, a 1.5-fold increased risk was identified per major allele. The loci on chromosome 5 implicate the gene *SPRY4*, which encodes an inhibitor of the mitogen-activated protein kinase pathway. The locus on chromosome 6 falls within the intron of *BAK1*, which promotes apoptosis. The location of a disease-associated SNP near or within a gene does not definitively implicate that gene, yet all three of the genes identified in GWASs are directly or indirectly associated with the *KIT/KITLG* pathway.¹¹ These genes may be responsible for an estimated 15% of genetic predisposition to germ cell tumors, whereas the genetic basis of the other 85% of familial aggregations remains unexplained.

Cisplatin Sensitivity and Acquired Resistance in Adult Germ Cell Tumors

Exquisite sensitivity to chemotherapy distinguishes germ cell tumors from most other cancers. Levels of p53 protein are elevated in all germ cell tumors except teratoma.³¹ To maintain genomic integrity, embryonic stem cells have a high sensitivity to DNA damage, suggesting that the high levels of wild-type p53 seen in germ cell tumors may be intrinsic to their germ cell nature. *TP53* gene mutations are uncommon in germ cell tumors, however, and the role of acquired *TP53* mutations in the emergence of chemotherapy resistance has not been established.¹¹ Moreover, levels of p53 protein assessed by immunohistochemistry were not associated with outcome. While mutations in *TP53* have been observed in about 7% of seminomas, its significance in germ cell tumors remains unclear.

Mutations of *BRAF* including V600E mutations have been detected in a small percentage of NSGCT. *BRAF* mutations were most prevalent in mediastinal primary tumors, late relapse, and cisplatin-resistant NSGCT, suggesting a role in chemoresistance. Further study is needed to define the prognostic significance of *BRAF* mutation and whether the V600E mutation can be therapeutically targeted. A high ratio of proapoptotic Bax to antiapoptotic Bcl-2 was found in invasive germ cell tumors and may explain the rapid apoptotic response to DNA-damaging drugs; however, the Bax:Bcl-2 ratio was not associated with treatment outcome.³¹ Finally, the emergence of cisplatin resistance may be intimately associated with the expression of genes and pathways responsible for lineage differentiation in NSGCT, in other words, intrinsic to the germ cell biology rather than the result of specific mutations.

IMMUNOHISTOCHEMICAL MARKERS

SALL4 is expressed in almost all germ cell tumors and has been reported to be positive in ITGCN, classic seminoma, spermatocytic seminoma, embryonal carcinoma, yolk sac tumor, choriocarcinoma, and teratoma.^{37,38} *OCT3/4* is variably expressed in ITGCN, classic seminoma, embryonal carcinoma, and yolk sac tumor. Spermatocytic seminoma, choriocarcinoma, and teratoma are usually negative for *OCT3/4*. *CD117* (*KIT*) helps highlight ITGCN and classic seminoma. *CD30*, *SOX2*, and keratin are helpful in the diagnosis of embryonal carcinoma, whereas *SALL4* and *Glypican-3* are often positive in yolk sac tumor.³⁹ In tumors of unknown primary or those presenting as a retroperitoneal or mediastinal mass, *SALL4*, *OCT3/4*, *CD117*, *SOX2*, *CD30*, and low-molecular-weight keratins all may be useful in distinguishing germ cell tumors from non-germ cell tumors.

STAGING

The most widely used system for staging testicular cancer is the tumor, node, metastasis classification endorsed by the American Joint Commission on Cancer and the International Union Against Cancer (Tables 70.2 and 70.3).⁴⁰ An important distinction for germ cell tumors is the inclusion of “S” classification (S0 to S3), signifying serum tumor marker elevation. There are three stage groupings of tumor, node, metastasis/serum tumor marker elevation classifications whereby, in general, stage I disease is confined to the testis, stage II is confined to the retroperitoneal lymph nodes with serum tumor markers in the good-prognosis range (S0 to S1), and stage III includes metastases that extend beyond the retroperitoneum or are extranodal in location. Stage III NSGCT also includes any patient with serum tumor markers in the intermediate- or poor-prognosis range (S2 to S3).

Patterns of Metastasis

Testicular cancers can undergo both lymphatic and hematogenous dissemination. The lymphatics arising from the testicle accompany the gonadal vessels in the spermatic cord. Some follow the gonadal vessels to their origin while others diverge and drain into the retroperitoneum. The landing zone for metastasis from the right testicle is in the interaortocaval lymph nodes just inferior to the renal vessels (Fig. 70.5). The landing zone from the left testicle is in the para-aortic lymph nodes just inferior to the left renal vessels (Fig. 70.6). Large volume disease tends to progress in retrograde fashion to the aortic bifurcation and below, along the iliac vessels.⁴¹

Seminoma

Seminoma can spread extensively through the lymphatic system to include retroperitoneal, retrocrural, mediastinal, supraclavicular, and cervical lymph nodes, often in the absence of hematogenous metastasis.⁴² Metastasis to lungs (stage IIIA) is common; metastasis to nonpulmonary organs (stage IIIB) is less common.⁴³ Serum tumor markers do not affect the stage (except in stage IS) or prognosis in seminoma. Hematogenous metastasis to extrapulmonary organs (e.g., bone) in seminoma carries an intermediate prognosis. There is no stage IIIC or poor-prognosis designation in seminoma.⁴⁴

Nonseminomatous Germ Cell Tumors

Similar to seminoma, lymphatic spread is the most common and usually the earliest type of dissemination in NSGCT. Stage groupings depend on both the anatomic extent of disease and serum tumor markers.⁴⁰ Stage IIIB is distinguished from stage II or IIIA on the basis of tumor markers being in the intermediate-prognosis range (S2). Stage IIIC NSGCT carries a poor prognosis, and more often than seminoma it involves multiple organs such as liver and brain.⁴⁴

Embryonal carcinoma, in some cases, exhibits hematogenous metastasis to lungs or nonpulmonary viscera without clinical involvement of retroperitoneal lymph nodes.⁴⁵ Computed tomography (CT) of the chest is necessary for complete staging workup of tumors that have a high percentage of embryonal carcinoma.

Serum Tumor Markers

Serum tumor markers are an important part of the staging system for germ cell tumors. Three markers, namely AFP, hCG, and total LDH, are considered for establishing the correct prognostic classification (good, intermediate, or poor prognosis).⁴⁴ Markers should be assessed after orchiectomy and before the start of chemotherapy. Markers that are elevated prior to orchiectomy and then normalize appropriately have no prognostic significance. Markers that do not normalize in a patient without any other clinical evidence of metastatic disease are considered stage IS.⁴⁰ In the absence of residual disease, the expected half-life of postoperative serum tumor marker decline is 2 to 3 days for hCG and 5 to 7 days for AFP.

TABLE 70.2

Definition of TNM

TNM Category	Description
Primary Tumor (T)	
pTX	Primary tumor cannot be assessed.
pT0	No evidence of primary tumor (e.g., histologic scar in testis).
pTis	Intratubular germ cell neoplasia (carcinoma in situ)
pT1	Tumor limited to the testis and epididymis without vascular/lymphatic invasion. Tumor may invade into the tunica albuginea but not the tunica vaginalis.
pT2	Tumor limited to the testis and epididymis with vascular/lymphatic invasion or tumor extending through the tunica albuginea with involvement of the tunica vaginalis.
pT3	Tumor invades the spermatic cord with or without vascular/lymphatic invasion.
pT4	Tumor invades the scrotum with or without vascular/lymphatic invasion.
Note: Except for pTis and pT4, extent of primary tumor is classified by radical orchiectomy. TX may be used for other categories in the absence of radical orchiectomy.	
Regional Lymph Nodes (N)	
Clinical	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass 2 cm or less in greatest dimension or multiple lymph nodes; none >2 cm in greatest dimension.
N2	Metastasis with a lymph node mass >2 cm but not >5 cm in greatest dimension, or multiple lymph nodes, any one mass >2 cm but not >5 cm in greatest dimension.
N3	Metastasis with a lymph node mass >5 cm in greatest dimension.
Pathologic (pN)	
pNX	Regional lymph nodes cannot be assessed.
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass 2 cm or less in greatest dimension and ≤5 nodes positive; none >2 cm in greatest dimension.
pN2	Metastasis with a lymph node mass >2 cm but not >5 cm in greatest dimension, or >5 nodes positive, none >5 cm, or evidence of extranodal extension of tumor.
pN3	Metastasis with a lymph node mass >5 cm in greatest dimension.
Distant Metastases (M)	
M0	No distant metastasis.
M1	Distant metastasis
M1a	Nonregional nodal or pulmonary metastases
M1b	Distant metastasis other than to nonregional lymph nodes and lungs
Serum Tumor Markers (S)	
SX	Marker studies not available or not performed
S0	Marker study levels within normal limits
S1	LDH <1.5 × N ^a AND hCG (mIU/mL) <5,000 AND AFP (ng/mL) <1,000
S2	LDH 1.5–10 × N OR hCG (mIU/mL) 5,000–50,000 OR AFP (ng/mL) 1,000–10,000
S3	LDH >10 × N OR hCG (mIU/mL) >50,000 OR AFP (ng/mL) >10,000

TNM, tumor, node, metastasis; LDH, lactate dehydrogenase; hCG, human chorionic gonadotropin; AFP, α-fetoprotein; S, serum tumor markers.

^aN indicates upper limit of normal for the LDH assay.

Germ Cell Tumor Risk Classification

Risk Group	Seminoma	Nonseminoma
Good	Any hCG Any LDH Nonpulmonary visceral metastases absent Any primary site	AFP <1,000 ng/mL hCG <5,000 mIU/mL LDH <1.5 × ULN Nonpulmonary visceral metastases absent Gonadal or retroperitoneal primary site
Intermediate	Nonpulmonary visceral metastases present Any hCG Any LDH Any primary site	AFP 1,000–10,000 ng/mL hCG 5,000–50,000 mIU/mL LDH 1.5–10.0 × ULN Nonpulmonary visceral metastases absent Gonadal or retroperitoneal primary site
Poor	Does not exist	Mediastinal primary site Nonpulmonary visceral metastases present (e.g., bone, liver, brain) AFP >10,000 ng/mL hCG >50,000 mIU/mL LDH >10 × ULN

hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; AFP, α -fetoprotein; ULN, upper limit of normal range.

Source: International Germ Cell Consensus Classification: a prognostic factor-based staging system for metastatic germ cell cancers. International Germ Cell Cancer Collaborative Group. *J Clin Oncol* 1997;15:594–603.

Elevated AFP has special significance in seminoma because it is only produced by NSGCT. Germ cell tumors that histologically appear to be pure seminoma with elevated serum AFP are given the clinical diagnosis of NSGCT, and are treated as such.²² HCG can be elevated in either seminoma or NSGCT, but has prognostic significance only for NSGCT.

Total LDH concentration prior to chemotherapy functions as a prognostic factor in NSGCT and helps to determine stage. In seminoma with bulky metastases, LDH can be markedly elevated but has no prognostic significance.

There are several potential causes of spurious elevation of tumor markers. AFP is not cancer specific; it may be elevated in the presence of liver disease or as a nonspecific chronic elevation. Stability of AFP over time suggests a benign etiology. HCG is cancer specific in men, but it is not specific to germ cell tumors. It can be associated with other neoplasms and with exposure to cannabis products. Patients should be questioned about the use of marijuana. A positive hCG test can also occur as a laboratory artifact in patients with low serum testosterone, owing to the increased secretion of luteinizing hormone and its sequence similarity to hCG.^{46,47}

Clinical Staging

The most commonly used methods for detecting metastatic disease are serum tumor markers and CT scan.¹⁵ Positron emission tomography (PET) scan can be helpful in the staging evaluation of a seminoma patient by distinguishing hypermetabolic lymph node metastases from reactive lymph nodes. PET is not as useful in NSGCT, where CT scan with oral and intravenous contrast is the preferred technique for detecting retroperitoneal adenopathy.

Pathologic Staging

The T classification is determined by pathology of the orchiectomy specimen.⁴⁰ The presence of lymphovascular invasion (LVI) or invasion through the tunica albuginea with involvement of the tunica vaginalis are pT2, invasion of the spermatic cord is pT3, and involvement of the scrotum constitutes pT4 (see Table 70.2).

Prophylactic retroperitoneal lymph node dissection (RPLND) is performed for surgical staging in some patients with clinical

stage I NSGCT. In such cases, if no metastatic germ cell tumor is found, the stage is pathologic stage I; when disease is found, it is designated pathologic stage II.

Factors Affecting Outcome

In clinical stage I NSGCT, the presence of LVI (pT2) is associated with an approximately 50% risk of recurrence with surveillance alone. A high percentage of embryonal carcinoma has also been associated with high risk in some series, but embryonal carcinoma is often seen together with LVI and has not been validated as an independent risk factor.⁴⁵

In clinical stage I seminoma, tumor size ≥ 4 cm is associated with approximately 30% risk of recurrence with surveillance alone. Involvement of rete testis has not been validated as a risk factor, although it is often mentioned.⁴⁹

The classification of patients with metastatic germ cell tumors as good, intermediate, or poor prognosis, based on serum tumor markers and extent of disease, was proposed in 1997 by The International Germ Cell Cancer Collaborative Group (Table 70.4).⁴⁴ In this system, the presence or absence of nonpulmonary, extranodal metastasis was validated as an independent prognostic factor for progression-free survival. For NSGCT, the degree of marker elevation and mediastinal primary (versus testis or retroperitoneal primary) were also validated as prognostic factors. The threshold values for tumor markers (hCG, AFP, and LDH) have been incorporated into the American Joint Commission on Cancer/International Union Against Cancer staging system as the “S” classification. These prognostic groupings are used to make treatment decisions and are discussed in the following sections.

MANAGEMENT OF CLINICAL STAGE I DISEASE

Virtually all patients with clinical stage I germ cell tumors survive (cancer specific survival 98% to 99%).⁴⁸ In general, patients managed with observation have the same life expectancy as those who receive adjuvant intervention. Treatment decisions must therefore be based on considerations of cost, burden of therapy, and patient preference.⁴⁸

Seminoma

Clinical stage I seminoma is grouped into high-risk and average-risk based on tumor size, but similar options exist for all patients with stage I seminoma, regardless of risk.^{48,49} Stage I is a common presentation, accounting for approximately 70% of patients diagnosed with pure seminoma.

Surveillance

The average risk of recurrence with surveillance for stage I seminoma is 15% to 20%. Recurrences are temporally distributed over a 10-year period.⁵⁰ High-risk tumors have a recurrence probability of 30% to 35%, whereas tumors <4 cm without rete testis involvement may have a risk as low as 12%.⁵¹ Observation is heavily dependent on CT scanning because the region at highest risk is in the retroperitoneum, and most seminomas do not secrete tumor markers.

Adjuvant Chemotherapy

Carboplatin is a simple and apparently safe form of adjuvant chemotherapy that is very similar in efficacy to prophylactic radiotherapy. In a randomized trial of carboplatin given as a single infusion (area under curve equals 7) versus radiotherapy to the para-aortic lymph nodes, there was no significant difference in progression-free survival (94.7% and 96%, respectively).^{52,53} There was only one death from seminoma (N = 1,447) reported at a median follow-up of 6.5 years. Recurrences after adjuvant carboplatin were frequently retroperitoneal in location, meaning that follow-up CT scans are mandatory. There has been no reported evidence of second malignant neoplasms (SMN), and there have been fewer contralateral germ cell tumors reported in the patients treated with chemotherapy versus radiotherapy at medium-term follow-up. Two courses of carboplatin have also been shown to be effective in the adjuvant setting, and in its 2014 guidelines the National Comprehensive Cancer Network (NCCN) endorsed one or two courses as a standard of care for clinical stage I seminoma, regardless of the estimated risk of recurrence.⁵⁴ Observation is also standard and is the preferred option.

Prophylactic Radiotherapy

Treatment of para-aortic lymph nodes to a dose of 20 Gy was associated with excellent local control approaching 100%. A randomized trial of 20 Gy versus 30 Gy showed no difference in rate of recurrence.⁵⁵ Omission of ipsilateral iliac lymph nodes from the treatment field resulted in less toxicity (infertility, gastrointestinal effects) and minimal loss of efficacy. The recurrence rate after prophylactic radiotherapy for clinical stage I seminoma is about 4%, and most of those patients survive with additional treatment (combination chemotherapy). Recurrences tend to occur below the radiation field (pelvic lymph nodes) or above it (lungs). Radiotherapy is contraindicated for patients with horseshoe kidney or inflammatory bowel disease.

Radiotherapy was once popularized because it reduced the number of CT scans that were necessary for follow-up, with a net reduction in the cost of treatment.⁵⁶ There is, however, a different type of cost with radiotherapy, and that is the risk of SMN.⁵⁷ Studies of testicular cancer survivors 20 or more years after treatment have revealed an increase in midline cancers such as gastrointestinal and genitourinary malignancies.⁵⁸ This has brought about a reassessment of prophylactic radiotherapy, specifically, whether it is warranted when 80% of seminoma patients will be treated unnecessarily, there is a risk of SMN, and there is no survival benefit. While it continues to be offered, the use of prophylactic radiotherapy for seminoma is declining.⁵⁹

Nonseminomatous Germ Cell Tumor

Clinical stage I NSGCT is broadly categorized as high risk and average risk. Although there are many differences in presentation,

including tumor size, histology, and tumor marker pattern, only LVI has been validated as a risk factor. NSGCT with LVI has a recurrence rate of approximately 50% with observation.⁶⁰ Most recurrences are seen within 2 to 3 years of the orchiectomy.⁵⁰ The average risk is 30%, and most patients with LVI-negative (“good risk”) stage I NSGCT probably have a risk of recurrence <30%. The risk of recurrence for LVI-negative stage I NSGCT with predominantly embryonal carcinoma histology, however, may be higher (30% to 50%).⁶¹

Surveillance

Approximately two-thirds of relapses among patients on surveillance are in retroperitoneal lymph nodes and one-third occur in lungs or by marker elevation alone. Recurrences in nonpulmonary viscera are rare. Most relapses occur within 2 to 3 years of orchiectomy, and patients need to remain on follow-up for at least 5 years. The ability to cure systemic disease with cisplatin-based chemotherapy in those who relapse makes observation an attractive option. It avoids unnecessary therapy for about two-thirds of patients.

Criteria for selecting patients for observation have been suggested in the literature and in the NCCN guidelines.⁵⁴ Selection based on whether the patient is “reliable” (i.e., likely to be compliant with follow-up) was once the prevalent view, but this has been largely replaced by a more objective risk-adapted approach. Observation is the standard of care for patients with stage IA NSGCT. The alternative is nerve-sparing RPLND, which is an unnecessary procedure for the majority of these patients. There is no subgroup of stage IA for whom RPLND is preferred, but patients who choose observation should agree to be compliant with follow-up and to receive chemotherapy in the event of recurrence. Patients with stage IA embryonal carcinoma–predominant tumors are probably the least likely to benefit from RPLND because of the tendency for hematogenous spread and associated risk of recurrence in lungs.^{61,62}

Most patients with LVI-negative, clinical stage I NSGCT are candidates for observation. There is less of a consensus on management of patients with pT2–pT4 tumors (including LVI-positive). A minority of patients with pT2 tumors may choose observation, but they must understand that the risk of recurrence is 50% and they should agree (as in stage IA) to comply with follow-up. The preferred treatment for LVI-positive or advanced T classification NSGCT is adjuvant chemotherapy.

Adjuvant Chemotherapy

Primary chemotherapy for NSGCT consists of bleomycin, etoposide, and cisplatin (BEP) (Table 70.5).^{63,64} There are several published studies using either one or two courses of adjuvant BEP or similar regimens in patients with clinical stage I NSGCT.^{65–68} A phase II study by the Medical Research Council found 98% relapse-free survival after two courses of bleomycin, vincristine, and cisplatin, although chemotherapy-induced neurotoxicity (CIN) remained a problem.⁶⁸ Two courses of BEP are similarly effective in preventing recurrence with less CIN; however, etoposide causes transient myelosuppression and is associated with a low but real risk of treatment-induced leukemia. The toxicity of two courses of BEP makes it unacceptable for stage IA NSGCT, but reasonable for stage IB where the relapse rate on observation is 50%.⁴⁸ One limitation of adjuvant chemotherapy is the continuing risk of growing teratoma syndrome. Only RPLND can remove foci of teratoma from the retroperitoneum, where they may persist and grow following chemotherapy.⁶⁹

One strategy for lowering the toxicity of adjuvant chemotherapy is by shortening treatment to one course of BEP. Two European studies provide data collected prospectively; in one study, patients were randomized to a single course of BEP or RPLND (none were observed), and in a second study, the patients with LVI-negative tumors were offered surveillance or one course of BEP, while

TABLE 70.5

Chemotherapy Regimens for Stage II/III Germ Cell Tumor

Previously Untreated—Good Risk ^a	
Etoposide	100 mg/m ² IV daily × 5 days
Cisplatin	20 mg/m ² IV daily × 5 days; <i>Four cycles administered at 21-day intervals</i>
Etoposide	100 mg/m ² IV daily × 5 days
Cisplatin	20 mg/m ² IV daily × 5 days
Bleomycin	30 units IV weekly (e.g., days 1, 8, 15); <i>Three cycles administered at 21-day intervals</i>
Previously Untreated—Intermediate and Poor Risk	
Etoposide	100 mg/m ² IV daily × 5 days
Cisplatin	20 mg/m ² IV daily × 5 days
Bleomycin	30 units IV weekly (e.g., days 1, 8, 15); <i>four cycles administered at 21-day intervals</i>
Previously Treated—1st-Line Salvage Therapy	
Ifosfamide	1.2 g/m ² IV daily × 5 days
Mesna	400 mg/m ² IV every 8 h × 5 days
Cisplatin	20 mg/m ² IV daily × 5 days
Vinblastine	0.11 mg/kg IV days 1 and 2; <i>Four cycles administered at 21-day intervals</i>
Paclitaxel	250 mg/m ² IV by continuous infusion over 24 h on day 1
Ifosfamide	1.5 g/m ² IV daily on days 2–5
Cisplatin	25 mg/m ² IV daily on days 2–5
Mesna	500 mg/m ² IV every 8 h on days 2–5; <i>Four cycles administered at 21-day intervals</i>

IV, intravenous.

^a Good risk regimens (BEP or EP) can also be used for stage I adjuvant or stage IS.

patients with LVI-positive tumors were offered one or two courses of adjuvant BEP.^{66,67} Both of these studies showed a <5% recurrence rate after one course of BEP and an acceptably low rate of growing teratoma. The 2014 NCCN guideline endorses either one or two courses of adjuvant BEP for stage IB NSGCT.⁵⁴

Retroperitoneal Lymph Node Dissection

RPLND performed in clinical stage I NSGCT is done to accurately stage the patient (as pathologic stage I or stage II) and remove all viable disease. RPLND is curative for teratoma, which has been reported in 21% to 30% of cases with viable disease.⁷⁰ Mortality from RPLND is <1%; minor complications include prolonged ileus, wound infection, and lymphocele. Major complications (hemorrhage, ureteral injury, chylous ascites, pulmonary embolus, wound dehiscence, bowel obstruction) are rare. A notable long-term morbidity is sympathetic nerve damage leading to failure of ejaculation.⁷¹

For optimal outcomes, RPLND should be performed at a referral center with an experienced surgeon. A bilateral infrahilar RPLND includes the precaval, retrocaval, paracaval, interaortocaval, retroaortic, preaortic, paraortic, and common iliac lymph nodes.

There are two types of nerve-sparing RPLND: the modified template RPLND and nerve-dissection bilateral RPLND.^{70,72,73} The template dissection helps the surgeon avoid regions where the risk of metastasis may be less. The nerve-dissection technique identifies and preserves both sympathetic chains, postganglionic sympathetic fibers, and the hypogastric plexus, which are necessary for anterograde ejaculation. The reported incidence of retrograde ejaculation with this technique is <5%. Another innovation is the robot-assisted RPLND, in which robotic instruments are inserted through a series of trocar entry sites and controlled remotely by the surgeon.^{74–76} Patients have less pain, shorter hospitalization time, rapid recovery, and smaller surgical scars.

The relapse rate following RPLND is variable. It may be as low as 4% with a low-risk patient and an experienced surgeon. Most series include patients who also received adjuvant chemotherapy,

typically with two courses of BEP, for pathologic stage II disease. Thus, the success of RPLND comes at the expense of double therapy for some patients. The LVI-positive and other high-risk patients have higher reported failure rates (10% to 14%) with prophylactic RPLND alone.⁶² The greatest advantage of RPLND is the early control of teratoma when it exists. The randomized trial of RPLND versus one course of BEP found a recurrence rate of 8.3% in the RPLND arm and 1.1% in the BEP arm.⁶⁶ With median follow-up of 4.7 years, only one patient had growing teratoma after BEP. Limitations of the study were that unilateral dissections were performed (nonstandard) and that the experience level of surgeons varied, as it was a community-based study. The low incidence (1% to 2%) of growing teratoma seen among patients on observation or adjuvant chemotherapy is lower than one would expect based on results of surgical staging, and this suggests that not all teratoma has the same potential for growth or malignant transformation.

MANAGEMENT OF CLINICAL STAGE II (LOW TUMOR BURDEN)

The anatomic definition of stage II germ cell tumor is metastasis confined to retroperitoneal lymph nodes. For NSGCT, there is the further requirement that tumor markers be in the good-prognosis range (S0 to S1).⁴⁰ For both seminoma and NSGCT, the majority of these patients are cured with standard treatment.

Seminoma

Seminoma is exquisitely sensitive to both chemotherapy and radiation. Radiotherapy to the retroperitoneum with a boost to the involved nodes is standard for disease with a transverse measurement of 3 cm or less.^{77–79} The fields include the landing zone and proximal ipsilateral iliac lymph nodes (dog-leg field). Radiotherapy is curative in 80% to 90% of patients, with recurrence owing largely to occult disease outside the radiation field.⁸⁰ Nevertheless,

prophylactic radiotherapy to the mediastinum or supraclavicular nodes is not recommended because of toxicity concerns.⁸¹ There is an excellent rate of success with combination chemotherapy in the patients who do relapse after radiotherapy.⁸²

For patients with bulky (>3 cm transverse dimension) retroperitoneal disease, primary treatment with cisplatin-based chemotherapy is standard.^{54,82} As in the adjuvant setting, patients with horseshoe kidney or inflammatory bowel disease should not receive radiotherapy; chemotherapy is the primary treatment for such patients regardless of nodal size.

Nonseminomatous Germ Cell Tumor (Low Tumor Burden)

Stage IS

Serum tumor markers that do not normalize after radical orchiectomy are evidence of micrometastases. Treatment is with three courses BEP followed by surveillance.

Pathologic Stage II after Retroperitoneal Lymph Node Dissection

In the case of low-volume metastatic NSGCT, a prophylactic RPLND may be curative without additional therapy.^{69,83} Patients with fewer than six lymph nodes involved, no focus >2 cm, and without extranodal extension (pN1) have an estimated 10% to 20% risk of recurrence and can be managed with surveillance. Adjuvant chemotherapy with BEP or EP (two courses) is an option for selected patients based on their access to follow-up, psychological factors, and tumor histology. Although there is no strong evidence to support adjuvant decision making based on the histology, metastases with predominantly teratoma or yolk sac tumor may have lower post-RPLND risk of recurrence than those that have predominantly embryonal carcinoma or choriocarcinoma. Nevertheless, surveillance and treatment with three or four courses of chemotherapy at recurrence is likely to yield a similar overall survival as adjuvant treatment. Adjuvant chemotherapy should be recommended for patients with pN2-N3 disease.

Clinical Stage IIA

Primary chemotherapy with three courses of BEP is the standard treatment for patients with enlarged retroperitoneal lymph nodes and elevated serum tumor markers (S1).⁶⁵ Patients with enlarged lymph nodes and normal serum tumor markers (N1, S0) may be appropriate for nerve-sparing bilateral RPLND or chemotherapy. A primary RPLND can be considered if the primary tumor contains teratoma and is not embryonal carcinoma–predominant, tumor markers are not elevated, and there is no back pain. Elevated tumor markers, back pain, or nodal size >2 cm suggest multifocal or unresectable disease, and chemotherapy is preferred.⁸⁴

Embryonal carcinoma can be marker negative and also requires chemotherapy. If metastatic embryonal carcinoma is suspected on clinical grounds (enlarged retroperitoneal lymph nodes), chemotherapy is the treatment of choice, whether or not the markers are elevated.

MANAGEMENT OF STAGE II WITH HIGH TUMOR BURDEN AND STAGE III DISEASE

Patients with metastatic germ cell tumor and high tumor burden are curable, but they can be critically ill at presentation. The chance of survival improves with early recognition of the diagnosis by medical providers, often on clinical grounds, and the prompt administration of chemotherapy. Whenever possible, patients with

stage IIIC NSGCT should be treated by an experienced team at a tertiary care center.^{85,86}

Good Prognosis

The International Germ Cell Cancer Collaborative Group risk classification identifies a “good prognosis” subset with overall survival of 90% to 95% with standard therapy.⁴⁴ These patients include most of those with metastatic seminoma, including mediastinal seminoma, excluding only seminoma with nonpulmonary visceral metastasis; and NSGCT stages II and IIIA (metastasis confined to lymph nodes and lungs and tumor markers below the intermediate- [S2] or high-risk [S3] levels).⁸⁷ For good prognosis NSGCT, three courses of BEP results in normalization of tumor markers for the majority of patients.⁶³ Postchemotherapy surgery is necessary for some patients with NSGCT who have a residual mass, as this can harbor teratoma or other viable disease (see Fig. 70.6).⁸⁸

An alternative to three courses of BEP, for the good prognosis patients only, is etoposide and cisplatin (EP) given for four courses.⁸⁹⁻⁹¹ For selected patients, the added risk of CIN and other complications from a fourth course of EP may be balanced by avoidance of the pulmonary toxicity risk of bleomycin. In practice, patients with seminoma are less tolerant of bleomycin because of older age, and four courses of EP is a reasonable standard for the majority of these patients.

Intermediate and Poor Prognosis

The intermediate prognosis subset (stage IIIB) accounts for 25% of patients with metastatic germ cell tumors and has an overall survival of approximately 75% with standard therapy.⁴⁴ The poor prognosis group (stage IIIC) is exclusively NSGCT, accounts for 15% of metastatic germ cell tumors, and has 5-year progression-free survival of 45%. These include any patient with mediastinal primary NSGCT, nonpulmonary visceral metastasis, or tumor markers in the S3 range. Four courses of BEP is the standard primary treatment for stage IIIB and IIIC germ cell tumors.⁹²⁻⁹⁴ Patients with seminoma with intermediate prognosis are unlikely to tolerate bleomycin, and addition of ifosfamide to etoposide and cisplatin (VIP) is a reasonable standard for these patients.⁸² In NSGCT, VIP can also be used instead of BEP if there is an increased risk of bleomycin lung toxicity because of respiratory distress, age 50 years or older, smoking or other chronic respiratory disease, or anticipated major thoracic surgery.

Personalized Strategy Based on Tumor Marker Decline

Serum tumor markers (AFP, hCG) virtually always decline during the initial two to three cycles of chemotherapy. Failure of either marker to normalize is a well-recognized feature of chemotherapy resistance.⁹⁵ The rate of tumor marker decline has also been studied as a predictor of poor outcome. For patients presenting with stage IIIC NSGCT, it is possible to identify a subgroup of about 25% who will do comparatively well, and a larger group of about 75% whose outcome with standard therapy is poor.⁹⁶ This observation led to a phase III clinical trial in which patients with stage IIIC NSGCT received BEP in the first cycle; based on the tumor marker decline in the first cycle, those with favorable decline remained on BEP (four courses total) and the rest were randomized (1:1) to BEP or an intensified regimen. Preliminary results of this study confirmed the superior progression-free and overall survival of the group with favorable decline compared to unfavorable decline (treated with BEP), and demonstrated a statistically significant improvement in progression-free survival for patients randomized to intensified treatment based on unfavorable marker decline.⁹⁷

Central Nervous System Metastases

Patients with brain metastasis are curable.⁹⁸ Imaging of the brain, preferably with magnetic resonance imaging, is appropriate at baseline for stage II or III disease. The initial management for most patients with asymptomatic brain metastases is with systemic chemotherapy. Responses tend to occur swiftly (Fig. 70.7), but there is a risk of intracranial hemorrhage. The risk of bleeding can be minimized by modifying the first cycle of chemotherapy (e.g., EP given for 3 days). Tumors with active bleeding may require craniotomy. Radiotherapy is useful for postchemotherapy consolidation of residual lesions in the brain. Gamma knife is preferable to whole brain radiotherapy in these patients with potentially long survival and risk of cognitive impairment.

The brain is a potential sanctuary site. This can manifest as a solitary recurrence in the brain shortly after the completion of chemotherapy, for which surgical resection may be curative.

Choriocarcinoma Syndrome

Metastatic choriocarcinoma is characterized by rapid hematogenous spread.²⁷ It usually starts as a component of a mixed testicular NSGCT, but can then proliferate and dominate the clinical picture.²⁷ Choriocarcinoma syndrome is recognizable by very high serum hCG levels in the range of 10^5 to 10^6 mIU/mL, and occasionally over 1 million, a testicular mass (or mediastinal mass), diffuse lung metastases, involvement of nonpulmonary viscera (brain, liver), tumor hemorrhage (hemoptysis, hemoperitoneum, intracranial bleed), and hyperthyroidism. The hyperthyroidism occurs at very high levels of hCG because hCG has sequence similarity to thyroid stimulating hormone.^{99,100}

Patients with choriocarcinoma syndrome have a high rate of mortality caused by complications such as hemorrhage or as a result of recurrent/refractory disease. At the time of diagnosis, however, the clinical condition rapidly stabilizes with the administration of chemotherapy. It is not recommended to use bleomycin for the first course in most cases because of high volume pulmonary metastases and the risk of pulmonary hemorrhage. To avoid destabilizing the patient, EP chemotherapy can be shortened to 3 days for

the first course only. For subsequent courses, EP is not sufficient for stage IIIC NSGCT and either BEP or an ifosfamide-containing regimen should be given. Administration of a beta blocker during the first course alleviates symptoms of hyperthyroidism (hypertension, tachycardia).

A male patient with testicular mass or anterior mediastinal mass, serum hCG over 50,000 mIU/mL, and clinical picture of choriocarcinoma syndrome does not require orchiectomy or biopsy prior to the start of treatment. The clinical diagnosis of choriocarcinoma should be recognized and treated as a medical emergency. Immediate chemotherapy offers the best chance for survival. Resection of the involved testis should be performed between cycles when the patient has stabilized, or at the time of RPLND.

Mediastinal Nonseminomatous Germ Cell Tumor

Extragenital germ cell tumors are the result of arrested migration of germ cells along the urogenital ridge during embryogenesis. This aberrant germinal tissue is usually located along the cranio-caudal axis in adult life, and malignant transformation can occur in both women and men. The most common presentation is in the anterior mediastinum of an adult man.¹⁰¹ Patients with Klinefelter syndrome are at increased risk for mediastinal germ cell tumors.^{102,103}

Mediastinal NSGCT is curable but at a lower rate than most testicular germ cell tumors.¹⁰⁴ The 3-year progression-free survival described in recent series was 48% to 54%.¹⁰⁵⁻¹⁰⁸ The first-line chemotherapy is the same as other stage IIIC germ cell tumors, consisting of four courses of BEP for patients with good pulmonary function, and four courses of VIP for those who are unlikely to tolerate bleomycin. Some authors have advocated that VIP is the preferred regimen because most patients will undergo postchemotherapy thoracic surgery.¹⁰⁹ In a prospective multicenter study, however, 66 patients with mediastinal NSGCT were treated with bleomycin-containing regimens and excessive pulmonary complications were not seen.⁹⁷ Mediastinal primary tumors have a high incidence of viable germ cell malignancy, teratoma, and transformation to somatic malignancy in postchemotherapy resections, so surgical consolidation is essential.^{105,110}

Figure 70.7 Brain metastasis in a patient with testicular nonseminomatous germ cell tumor and clinical features of choriocarcinoma syndrome. Magnetic resonance images were acquired (A) at diagnosis and (B) after three cycles of cisplatin-based chemotherapy (9 weeks), using modified regimens to avoid thrombocytopenia.

Management of Residual Mass

Patients with high tumor burden frequently have one or more sites of residual disease after chemotherapy and normalization of tumor markers. The management of a residual mass is critical to the curative management of germ cell tumors. There are different treatment considerations based on the setting of seminoma or NSGCT and the size of the lesion.

Residual Nodal Size <1 cm

For either seminoma or NSGCT, a radiographic complete response does not require consolidative treatment. The size criterion for absence of residual mass in a site of lymph node metastasis is a transverse dimension <1 cm (on CT imaging). There is a potential benefit to some patients with NSGCT from the surgical consolidation of residual masses >0.5 cm and <1.0 cm, based on the possibility of teratoma.⁶⁹ By some estimates, as many as 20% of nodes <0.5 cm and 29% of nodes <1.0 cm harbor teratoma. As noted previously, however, the incidence of growing teratoma syndrome among patients observed without RPLND is lower (1% to 2%) and these can be detected on follow-up with CT imaging. Most are treated successfully, and RPLND for a residual mass <1 cm is the exception rather than the rule.

Residual Mass >1 cm

A persistent mass in a nodal site after chemotherapy is of concern for residual germ cell malignancy in both seminoma and NSGCT, and for teratoma in NSGCT. The same applies for residual masses in extranodal organs.

For NSGCT, the standard management of a residual mass >1 cm in the retroperitoneum is a bilateral RPLND.⁸⁸ Modified template RPLND is not appropriate in this setting, as it may leave behind disease in 7% to 32% of cases. Robot-assisted RPLND is an option for some patients resulting in less short-term morbidity of the procedure compared to an open RPLND.⁷⁵ The principal long-term morbidity is retrograde ejaculation.¹¹¹ After the standard three or four courses of BEP, viable germ cell malignancy is found in only 15% of specimens. A total of 40% contain teratoma, and 45% contain only necrosis and fibrosis. There is no reliable method for determining preoperatively whether teratoma is present. Twenty-five to forty-five percent of patients with no teratoma in the primary tumor can still have teratoma in a residual mass. Biopsy is useless for ruling out the presence of teratoma because of sampling error. Complete excision is the standard of care. For the minority of patients with viable germ cell malignancy (other than teratoma) in a residual mass, the standard treatment is postoperative administration of two additional courses of chemotherapy. Residual teratoma requires no further therapy.

Seminoma

Unlike NSGCT, seminoma does not produce teratoma. A residual mass is common, however, owing to the fibrotic reaction that occurs in the treated lymph nodes. Surgery is technically difficult and in most cases unnecessary. Patients with very high volume seminoma or residual mass >3 cm can suffer relapse from residual seminoma. The optimal consolidation for these patients is an unsettled question. Patients with residual mass <3 cm can remain on observation. For those with a mass >3 cm, radiotherapy is one means to reduce the risk of relapse. An overall survival benefit from postchemotherapy radiation has not been demonstrated. This may be in part due to the overall high survival rate for seminoma and the relatively small proportion of patients at risk for relapse after chemotherapy. The 2014 NCCN guidelines recommend surgery (RPLND), if technically feasible, for residual mass >3 cm with PET positivity.

MANAGEMENT OF RECURRENT DISEASE

Patients in first relapse after BEP chemotherapy can be successfully salvaged in about 50% of cases. The relapse-free survival with high-dose chemotherapy and autologous stem cell transplant (HDC-ASCT) in one retrospective study was 60% (90 of 149 patients with recurrent/refractory NSGCT). Whether this was an improvement in outcome over conventional chemotherapy or a reflection of patient selection is unknown. A randomized trial for patients in first relapse with four courses of paclitaxel, ifosfamide, and cisplatin versus HDC-ASCT will hopefully answer this question.

Conventional Dose Chemotherapy

Standard-dose regimens have resulted in a complete response rate of 35% to 70% in the second line without the use of HDC-ASCT. The most effective regimens for first recurrence after BEP have been combinations with ifosfamide and cisplatin.^{112,113} Examples are vinblastine, ifosfamide, and cisplatin (VeIP), and paclitaxel, ifosfamide, and cisplatin, typically four courses with consolidation surgery (see Table 70.5).^{114,115}

High-Dose Chemotherapy and Stem Cell Transplant

In a retrospective study of patients treated at Indiana University from 1996 to 2004, 135 patients in first recurrence received one to two cycles of standard VeIP followed by two cycles of high-dose carboplatin plus etoposide ("tandem transplant").¹¹⁶ At a median follow-up of 4 years, 94 of 135 (70%) remained continuously disease-free. This study included 61 patients who relapsed from a complete response (favorable), but excluded mediastinal NSGCT, late relapses, and other nongonadal primary sites (unfavorable). In a prospective trial from Memorial Sloan-Kettering Cancer Center, 81 patients received one to two cycles of paclitaxel plus ifosfamide followed by three cycles of high-dose carboplatin plus etoposide as first salvage.¹¹⁷ At a median of 5 years, 56% remained free of disease. This study excluded patients with a testicular primary tumor who either had a prior complete response to first-line chemotherapy or a partial response with negative markers, but included patients with mediastinal NSGCT, late relapse, and other nongonadal primary sites.

Second and Subsequent Relapse

Patients with recurrence after conventional second-line chemotherapy such as VeIP or TIP can be considered for HDC-ASCT.¹¹⁶ Compared to the patients in first relapse, however, these patients have more chemotherapy sequelae such as CIN, renal insufficiency, and decreased performance status, leading to a high complication rate and mortality from HDC-ASCT. Conventional chemotherapy after second-line or HDC-ASCT is usually palliative. Regimens endorsed by NCCN guidelines include gemcitabine and oxaliplatin, gemcitabine and paclitaxel, gemcitabine/oxaliplatin/paclitaxel, and oral etoposide.¹¹⁸⁻¹²¹

Molecular targeted therapies do not yet have an established role in the treatment of germ cell tumors. There are two published studies of sunitinib in relapsed/refractory germ cell tumors.^{122,123} A study from the Canadian Urologic Oncology Group and the German Testicular cancer study group found three confirmed and one unconfirmed partial responses (13%) among 32 patients with refractory germ cell tumors treated with sunitinib. Another study from Memorial Sloan-Kettering Cancer Center found no responses among 10 men with highly refractory germ cell tumors treated with sunitinib, although 4 patients had some decline in serum tumor markers. An inhibitor of cyclin-dependent kinase 4/6 showed activity in patients with unresectable teratoma, leading to

clinical trials.¹²⁴ Patients with chemotherapy-refractory germ cell tumors should be encouraged to participate in clinical trials.

Surgery after Salvage Chemotherapy

Residual lesions that persist after chemotherapy should be resected whenever feasible. There is often viable tumor in the setting of recurrent/refractory disease, even when tumor markers have normalized on chemotherapy.¹²⁵ When tumor markers decline to a plateau but do not normalize, surgery to remove all viable disease is a consideration. Surgical salvage is successful in about 20% of patients.^{126,127} Patients with elevated AFP and normal hCG have better prognosis with surgery than patients with elevated or rising hCG. Adjuvant chemotherapy is not known to improve the outcome when surgery reveals viable germ cell malignancy after salvage chemotherapy.

Late Recurrence Nonseminomatous Germ Cell Tumor

Most NSGCT recurrences after chemotherapy are seen within 2 to 3 years. Only about 2% of patients experience a relapse after 2 years. These late recurrences appear to be less sensitive to subsequent chemotherapy than the earlier recurrences.^{128,129} Surgery can be curative in cases that are slowly growing and anatomically resectable. Treatment must be individualized. Although late recurrences are less chemosensitive as a group, complete responses have been described. Surgery should always be considered and integrated as a component of the overall treatment plan.

TREATMENT SEQUELAE

Both chemotherapy and radiotherapy have long-term adverse effects on survivors of testicular cancer.^{2,57,58,81} With posttreatment life expectancy of 40 years or more, the morbidity attributable to chronic and late effects of treatment can exceed that of the cancer itself.

Cardiovascular Effects

One of the most significant delayed effects of chemotherapy is an increased risk of cardiovascular disease.⁸¹ The risk of suffering a cardiac event is two- to seven-fold higher in survivors of testicular cancer who received cisplatin-based chemotherapy than the general population.^{130,131} Other risk factors such as hyperlipidemia, obesity, and hypertension (metabolic syndrome) are also more common among survivors of testicular cancer. The health and longevity of survivors of testicular cancer can be maximized through early treatment of hypertension and hyperlipidemia, and by interventions such as diet, exercise, and tobacco cessation.

Chemotherapy-Induced Neurotoxicity

Peripheral neurotoxicity is a common adverse effect of cisplatin. Approximately 20% to 40% of patients treated with neurotoxic chemotherapy drugs develop CIN, which can cause painful and permanent sensory disturbance. Drug therapy for CIN is only partially effective in relieving symptoms.¹³² The mechanisms of CIN are not well understood, and they appear to include damage to neuronal cell bodies in dorsal root ganglia.¹³³ Circulating platinum levels remain elevated for many years after chemotherapy, and it is not known whether this also contributes to long-term morbidity.¹³⁴ The severity of CIN is influenced by the cumulative dose of cisplatin, exposure to other neurotoxic drugs (e.g., paclitaxel), and other medical conditions such as diabetes.

Hypogonadism and Infertility

Chemotherapy can damage the germinal epithelium and increase the risk of abnormal sperm morphology, motility, and number. Oligospermia has been associated with prior radiotherapy for seminoma, presumably due to scatter radiation to the contralateral testis. It is also recognized that at the time of diagnosis, the percentage of men with germ cell tumor who are subfertile or infertile is greater than the general male population. Thus, sperm banking should be offered to all patients undergoing chemotherapy or radiotherapy, and to patients undergoing RPLND because they are at risk for retrograde ejaculation.

The risk of infertility from treatment is proportional to the type and duration of treatment. In a study of paternity following treatment, 71% of unselected survivors of testicular cancer were successful at 15 years. For treatment subgroups, successful paternity was 81% with surveillance, 77% after RPLND, 65% after radiotherapy, 62% after chemotherapy, and 38% after high-dose salvage chemotherapy. The risk to patients receiving fewer than four cycles of chemotherapy has not been studied, particularly in the adjuvant setting (one or two cycles), or with carboplatin in the setting of seminoma. While the risk of infertility may be lower in the adjuvant setting, these patients should receive fertility counseling and an opportunity for cryopreservation of semen.

Hypogonadism, or low testosterone, is also a common finding. Testicular dysfunction is more common among survivors of testicular cancer than the general male population. Persistent low testosterone in a patient who has completed therapy is an indication of a functional deficit in the contralateral testis. Testosterone replacement therapy can prevent complications such as weight gain, gynecomastia, erectile dysfunction, loss of libido, fatigue, depression, and osteoporosis.

Ototoxicity

Cisplatin can result in permanent, bilateral sensorineural hearing loss in 19% to 77% of patients, and tinnitus in 19% to 42%.¹³⁵ The incidence and severity of ototoxicity is related to the cumulative dose and dose intensity of cisplatin.¹³⁶ The mechanism is thought to be through overproduction of reactive oxygen species in the cochlea, causing irreversible free radical-related apoptosis of outer hair cells, spiral ganglion cells, and the stria vascularis.¹³⁵ There may be genetic underpinnings to the susceptibility to ototoxicity from chemotherapy. There is no effective method for treating or preventing cisplatin-induced ototoxicity.¹³⁷

Psychosocial Functioning

There are potential short-term and long-term psychological consequences in the posttreatment period.¹³⁸ Anxiety and depression are common in the first 6 months, whereas most patients are well adjusted by 1 year. Certain patients (10% to 30%) continue to suffer moderate to severe nervousness, anxiety, or depression. Patients who have sexual difficulties, are unemployed, or have financial difficulties appear to be at greatest risk. Strain in relationships can be due to a perception of sexual dysfunction; however, some studies suggest that in married couples the patient is more concerned than the spouse, and divorce rates are no higher than the general population.¹³⁹

Second Malignant Neoplasms

Both radiotherapy and chemotherapy increase the risk of SMN later in life. Second malignancies can occur 20 years after treatment or later. An exception is acute leukemia, which occurs 2 to 4 years after chemotherapy. The risk of treatment-related leukemia is proportional to the cumulative dose of etoposide, and is estimated to be <0.5% for two courses (1,000 mg/m²), less than 1% for three or four courses (1,500 to 2,000 mg/m²), and as high as

6% for cumulative etoposide doses $>3,000$ mg/m². Chromosomal translocations involving 11q are characteristic of etoposide-related acute leukemia.¹⁴⁰

Acute leukemia is also seen in a small percentage of patients with mediastinal NSGCT. While chemotherapy may be a contributing factor, the leukemia associated with mediastinal primary tumors has a separate etiology. Megakaryocytic leukemia has been described and may be more common in this setting.¹⁴¹ Studies have identified the clonal marker i(12p) in leukemic cells, indicating that they are clonally descended from the primary germ cell tumor.^{142,143} One hypothesis is that yolk sac tumor (a common histology among mediastinal germ cell tumors) retains the pluripotency of the normal yolk sac, which functions as a hematopoietic organ during embryogenesis.¹⁴⁴ This association has not been described in yolk sac tumor of testicular origin.

Second primary germ cell tumor of the contralateral testicle occurs in approximately 2% of survivors, and occasionally as a synchronous (bilateral) presentation. The risk of second germ cell tumor is present over the lifetime of the individual, making it especially important that the patient is counseled to report any testicular symptoms, and that long-term follow-up includes surveillance of the contralateral testicle. Prophylactic radiation of the contralateral testicle has been promoted in Europe as a means to reduce the risk, and surveillance alone is standard in the United States. Although adjuvant carboplatin for stage I seminoma appeared to reduce the incidence of second primary tumors, longer follow-up is needed to determine whether it is merely a delay in clinical presentation.⁵³

LONG-TERM FOLLOW-UP

The mandatory duration of follow-up for detection and management of recurrence of germ cell tumors is 5 years for NSGCT and 10 years for seminoma. There is wide consensus, however, that survivors of testicular cancer should have lifelong follow-up, whether it is at the primary treatment center or with a general internist who is knowledgeable about survivorship issues. Long-term follow-up is necessary for detection of late recurrences, second testicular primaries, and SMN. Survivors require management of cardiovascular effects and symptoms of neurotoxicity. Special care may be required for maintenance of sexual health, fertility issues, and psychosocial functioning.

MIDLINE TUMORS OF UNCERTAIN HISTOGENESIS

Tumors of unknown primary site in young patients occasionally respond well to cisplatin-based chemotherapy. This can be the presentation of an extragonadal germ cell tumor. The diagnosis should be considered in relatively young patients in whom the tumor has predominantly midline distribution and histologic appearance of poorly differentiated carcinoma. Serum tumor markers may or may not be elevated. Molecular cytogenetic analysis for 12p genetic content can help to confirm the diagnosis, but is often inconclusive. Immunohistochemical markers SALL4, OCT3/4, CD117, SOX2, CD30, and low-molecular-weight keratins can also facilitate the diagnosis.

OTHER TESTICULAR TUMORS

Sex Cord/Gonadal Stromal Tumors

Leydig and Sertoli Cell Tumors

The most common sex cord stromal tumors in men are Leydig cell and Sertoli cell tumors (Table 70.6). These tumors are occasionally

metastatic, but the majority are benign. Treatment is radical orchiectomy. The risk of metastasis has been associated with vascular invasion, cellular atypia, tumor necrosis, infiltrative margins, increased mitotic rate, tumor size >5 cm, older age at presentation, increased proliferation index, and aneuploidy. The pattern of metastasis is initially to the retroperitoneal lymph nodes.^{20,145,146}

Leydig and Sertoli cell tumors are associated with steroid hormone hypersecretion. Sertoli cell tumors may be accompanied by precocious puberty in boys. Patients with Leydig cell tumors may have decreased libido and gynecomastia, or virilization in prepubertal boys.

Chemotherapy and radiotherapy are not known to be effective for metastatic sex cord stromal tumors. There are several reports of treatment with mitotane, which was used because it is known to be effective in adrenocortical carcinoma, another steroid-producing tumor. Reported results with mitotane treatment of metastatic sex cord stromal tumors have been mixed, but it can be considered, especially for functional tumors with symptom of steroid hormone excess.

Granulosa Cell Tumors

Granulosa cell tumors of the testicle are rare.¹⁴⁷ They resemble granulosa cell tumors of the ovary. Tumors secrete estrogen, and patients may present with gynecomastia. Treatment is radical orchiectomy, which is usually curative. Granulosa cell tumor (juvenile type) is the most common testicular neoplasm in neonates.

Gonadoblastoma

Gonadoblastoma contains both germ cell and sex cord stromal elements.²⁰ It is associated with testicular dysgenesis and karyotypic anomalies. It has potential for metastasis of the germ cell component of the primary tumor.

Mesothelioma

Mesothelioma of the tunica vaginalis can invade the testis and spermatic cord.¹⁴⁸ Treatment is radical orchiectomy with complete excision of the spermatic cord and hemiscrotum. RPLND should be considered in patients with LVI or invasion of the testicular parenchyma.

Adenocarcinoma of the Rete Testis

Adenocarcinoma of the rete testis has a poor prognosis.¹⁴⁹ It is not responsive to radiotherapy or chemotherapy. Treatment is radical orchiectomy, and 30% to 50% of patients die within 1 year of metastatic disease. RPLND should be considered for selected patients and may be curative for low-volume metastatic disease.

Epidermoid Cyst

Epidermoid cyst is often asymptomatic.¹⁵⁰ On palpation, it is firm and sharply demarcated, and it appears cystic on ultrasound. It is

of uncertain relation to germ cell tumors and is not associated with ITGCN. Histologically, the cyst is lined with squamous epithelium and the adjacent testicular parenchyma is benign. The clinical course is benign. Treatment with enucleation of the tumor or radical orchiectomy is curative.

Lymphoma

Lymphoma presents as painless enlargement of the testicle and may be bilateral.²⁰ It is the most common secondary malignancy of the testis in men older than 50 years. It typically occurs in the setting of advanced systemic disease, often accompanied by central nervous system or bone marrow involvement.

Metastatic Carcinoma

Metastatic carcinoma is rarely confused with primary testicular cancer. It occurs most commonly in the setting of advanced disseminated disease. Treatment is determined by the type of primary tumor.

71 Molecular Biology of Gynecologic Cancers

Tanja Pejovic, Michael J. Birrer, Matthew L. Anderson, and Kunle Odunsi

INTRODUCTION

Gynecologic cancer research has mirrored all cancer research programs in that it has focused largely on molecular defects in oncogenes, tumor-suppressor genes, and DNA repair mechanisms. Several research groups have also channeled their resources into various carcinogenic phenomena, such as apoptotic pathway defects, growth signaling, angiogenesis, tissue invasion, or metastasis. These efforts have led to a broad understanding of the chromosomal and molecular abnormalities that underlie malignancies of the female genital tract (vulva, vagina, cervix, uterus, ovaries, and fallopian tubes). It is clear that an improvement in outcome of these malignancies can only be achieved if: (1) early diagnosis is achieved, (2) there is accurate prediction of progression and response, and (3) new treatment options reflecting the molecular pathogenesis and progression are developed. This requires detailed disease-specific understanding of the diverse molecular changes in gynecologic malignancies that ultimately lead cells to develop the following hallmarks of cancer: abnormalities in self-sufficiency of growth signals, evasion of apoptosis, insensitivity to antigrowth signals, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastases. Moreover, there is growing evidence for the concept of cancer immunosurveillance and immunoediting based on (1) protection against development of spontaneous and chemically induced tumors in animal systems and (2) the identification of targets for immune recognition of human cancer.¹ This concept is supported by several studies in gynecologic cancers and has opened new avenues for the development of novel biomarkers and therapeutic targets. It is the purpose of this chapter to highlight and summarize some of the recent basic findings in gynecologic malignancies, with an emphasis on clinically applicable developments.

OVARIAN CANCER

Origins of Epithelial Ovarian Cancer

Until recently, epithelial ovarian cancer (EOC) was thought to arise primarily from the ovarian surface epithelium (OSE), with a subset likely originating in the adjacent fimbria.^{2,3} The OSE forms a monolayer surrounding the ovary, but is composed of relatively few cuboidal cells (107 cells per ovary, or 0.05% of the entire organ). Developmentally, it derives from the coelomic epithelium, which also gives rise to the peritoneal mesothelium and oviductal epithelium.⁴ The OSE appears generally stable, uniform, and quiescent, although it can undergo proliferation *in vivo*.⁵ Despite the small number of cells within the OSE and their apparent inactivity, the risk for EOC is nearly 2%, suggesting a high malignant potential. The basis for such a high potential is poorly understood. No physiologic role for the primate OSE has been established,⁶ and the lack of any obvious function could contribute to the asymptomatic nature of early-stage EOC.

In other organs, such as the colon, distinct premalignant lesions have been identified and found to accumulate genetic defects that ultimately result in malignancy. However, the search to identify similar epithelial precursors in the human ovary has proven only partially fruitful, in large part because normal ovaries are only rarely biopsied or examined. Histologic findings consistent with a preinvasive lesion for ovarian cancer have been described by a number of studies where ovaries were removed from women who eventually developed peritoneal carcinomas, ovaries from high-risk women who were undergoing prophylactic oophorectomy, and in areas of ovarian epithelium adjacent to early-stage ovarian cancers that demonstrate a transition from normal to malignant cells.⁷ Surprisingly, occult noninvasive and invasive carcinomas in the fallopian tubes, typically in the fimbria, have been discovered in women undergoing prophylactic salpingo-oophorectomies because of a family history or germ-line mutations of *BRCA1* and *BRCA2*.⁸ This led to the hypothesis that these occult tubal carcinomas might shed malignant cells, which then implant and grow on the ovary, simulating primary ovarian cancer. Moreover, gene expression studies have demonstrated that the expression profiles of ovarian high-grade serous cancers (HGSCs) more closely resembled fallopian tube epithelium (FTE) than the OSE.⁹ Because the tubal carcinomas were associated with serous and not endometrioid, clear cell, or mucinous carcinomas, the noninvasive tubal carcinomas have been designated *serous tubal intraepithelial carcinoma* (STIC).

The new paradigm for the pathogenesis of ovarian serous cancer based on a dualistic model and the recognition that the majority of these tumors originate outside the ovary facilitates the development of novel approaches to prevention, screening, and treatment. The low-grade serous tumors (type I) are generally indolent, present in stage I (tumor confined to the ovary) and develop from well-established precursors, and are characterized by specific mutations, including *KRAS*, *BRAF* and *ERBB2*, but rarely *TP53*. They are relatively genetically stable. In contrast, the HGSCs (type II) are aggressive, present in advanced stage, and develop from STICs. They have a very high frequency of *TP53* mutations, but rarely harbor the mutations detected in the low-grade serous tumors. Although low-grade serous and HGSCs develop along different molecular pathways, both types may develop from FTE and secondarily involve the ovary.¹⁰

Molecular Pathways to Ovarian Cancer

Inherited Syndromes of Ovarian Cancers

A family history of the disease is the most significant known risk factor for EOC. There is a threefold increased risk of developing the disease for an individual with a first-degree relative affected with ovarian cancer.¹¹ Inherited EOC most often occurs as part of families with both ovarian and breast cancer cases or in families with only multiple ovarian cancer cases. Inherited ovarian cancer

is also part of Lynch syndrome or hereditary nonpolyposis colorectal cancer (HNPCC), found in families with multiple cases of colon cancer. It is estimated that 5% to 10% of EOC cases are due to these familial syndromes.¹²

A linkage analysis of familial breast and ovarian cancers provided some of the first insights into the molecular basis of ovarian cancer, ultimately leading to the identification of two genes, *BRCA1* and *BRCA2*, each associated with a significant increased incidence of ovarian cancer. The frequency of *BRCA1* and *BRCA2* mutations in the general population is estimated to be 1 in 800 and 1 in 500, respectively,¹¹ whereas population-based ovarian cancer studies revealed that the frequency of *BRCA1* mutations was 3% to 10% and for *BRCA2*, 0.6% to 6%.¹²

The *BRCA1* gene was cloned in 1994¹³ and was found to have 24 exons spanning 80 kb of genomic DNA, and had a 7.8 kb transcript coding for an 1,863 amino acid protein. The *BRCA2* gene mapped to chromosome 13q12-13, had 27 exons (26 coding), spanning 70 kb of genomic DNA, and had an 11.4-kb transcript and coded a 3,418 amino acid protein.¹⁴ Hundreds of mutations in *BRCA1* have now been identified, most commonly, loss of function nonsense or frameshift mutations. Two specific mutations, 185delAG and 5382insC, are found in 1% and 0.1%, respectively, of Ashkenazi Jewish women. Some missense changes have been found to be pathogenic, but the majority are polymorphisms or unclassified variants (UV), also known as variants of uncertain significance (VUS). A high frequency of large genomic rearrangements (LGR) have been identified in both *BRCA1* and the *BRCA2* gene.¹⁵

The position of mutations within large *BRCA1* and *BRCA2* genes determines the risk of ovarian cancer. The *BRCA1* gene mutation within nucleotides 2402 and 4190 carries the high risk of ovarian cancer (and a lower risk of breast cancer). Both genes show an autosomal-dominant transmission of highly penetrant germ-line mutations and behave as tumor suppressor genes. Both proteins function in the double-strand DNA break repair pathway but may have additional functions; *BRCA1* functions in both checkpoint activation and DNA repair, and *BRCA2* is a mediator of homologous recombination.

Functionally, *BRCA1* regulates *p53*, an oncogene frequently implicated in ovarian cancer. Thus, the loss of *BRCA1* allows DNA damage to accumulate via a loss of its activation of *p53*. However, mutations in *BRCA1* also likely contribute to ovarian cancer by mechanisms other than its interactions with *p53*. Any understanding of the role of *BRCA1* in ovarian cancer is further complicated by reports of women with high-risk mutations in *BRCA1* who fail to develop ovarian cancer. These observations speak clearly to the role of genetic modifiers in determining whether *BRCA1* or *BRCA2* mutations ultimately lead to malignancy. For example, the CAG repeat polymorphism in the androgen receptor has been shown to modify the subsequent risk of ovarian cancer in women with known mutations in *BRCA1*.

High penetrance *BRCA1* and *BRCA2* gene mutation accounts for about 40% of ovarian cancer risk.¹⁶ The remaining risk is due to very rare high risk genes, very few moderate risk genes, and/or multiple low risk genes. The Ovarian Cancer Association Consortium (OCAC) was established in 2005 to investigate the risk of SNP in ovarian cancer. So far, an additional six loci associated with a risk of ovarian cancer have been reported: 2q31, 3q25, 8q24, 9p22.2, 17q21, and 19p13.1.¹¹

Genomic Instability, Fanconi Anemia/BRCA DNA Repair Pathway, and Rare Mutations

BRCA1 indirectly and *BRCA2* directly are associated with maintaining the genome stability (i.e., a cell's ability to tolerate DNA damage). *BRCA2* is a member of BRCA/Fanconi anemia (FA) DNA repair pathway. Studies on the pathogenesis of FA, a rare inherited DNA repair disorder, have helped define the molecular basis of defective DNA damage responses linked to cancer risk. FA is a genetic disorder characterized by skeletal anomalies,

progressive bone marrow failure, cancer susceptibility, and cellular hypersensitivity to DNA cross-linking agents. To date, 15 FA genes have been cloned: *FANCA*, *-B*, *-C*, *-D1*, *-D2*, *-E*, *-F*, *-G*, *-J*, *-L*, *-M*, *-N*, and *-I*, *-O*, and *-P*. Of these, *FANCA*, *FANCB*, *FANCC*, *FANCE*, *FANCF*, *FANCG*, *FANCL*, and *FANCM* form a nuclear core complex. Although the functional scope of this complex has not been fully defined, it is clear that it must be completely intact to facilitate monoubiquitination of the downstream *FANCD2* and *FANCI* proteins, a change that allows *FANCD2* and *FANCI* to colocalize with *BRCA1*, *BRCA2* (and presumably *FANCF* and *FANCN*), and *RAD51* in damage-induced nuclear foci.¹⁷

Four lines of evidence link the FA pathway with ovarian carcinogenesis. First, *BRCA2* has been identified as the FA gene, *FANCD1*. As a result, heterozygotes for *BRCA2* mutations have a high risk of tissue-specific epithelial cancers, whereas homozygotes develop FA. Second, an increased prevalence of ovarian malignancies has been observed in *FANCD2* nullizygous mice. Functionally silencing *FANCF* in ovarian cancer through promoter hypermethylation has also been described. Lastly, low levels of the *FANCD2* protein are found in ovarian surface epithelia from women at risk for ovarian cancer. Taken together, these data suggest that the FA pathway is important in defining a predisposition to ovarian (and breast) cancer, and that aberrations of FA genes may account for some familial ovarian cancer cases not accounted for by *BRCA1* and *BRCA2* mutations.

In sporadic ovarian cancers, the epigenetic silencing of the FA pathway through methylation of the FA gene promoter region is one of the frequent mechanisms of inactivation. One study found that 4 of 19 primary ovarian carcinomas had *FANCF* methylation, although a larger study of 106 ovarian tumors did not identify the loss of *FANCF* expression. Loss of the *BRCA2* mRNA and protein has been reported in 13% of ovarian carcinomas and, in contrast to other FA genes, methylation is not a cause of the protein loss. Epigenetic silencing of *BRCA1* through methylation was found in 23% of advanced ovarian carcinomas.

Interestingly, tumors with inactivated *BRCA2* are responsive to cisplatin. However, due to their low accuracy of DNA repair, these cells accumulate secondary genetic modifications that can lead to a reversal of the *BRCA2* mutation, allowing these cells to acquire resistance to cross-linking agents.¹⁸

Recently, mutations have been identified in four genes: *RAD51C*, *RAD51D*, *BRIP1* and *PALB2* in the FA-BRCA pathway. Mutations in the *RAD51C* and *RAD51D* genes were found in approximately 1% of breast/ovarian cancer families. The relative risk (RR) of ovarian cancer in *RAD51D* carriers was 6.3 (95% confidence interval [CI], 2.9 to 13.9). Mutations in *PALB2* (*FANCN*) were found in 3.4% of breast cancer families, and 55% of these families had family members with ovarian cancer. An Icelandic mutation in *BRIP1* (*FANCF*) with a frequency of 0.41% increased the risk ovarian cancer, OR 8.1 (95% CI, 4.7 to 14.0). A Spanish *BRIP1* mutation had a frequency of 1.3% in ovarian cancer cases and the risk of ovarian cancer was OR 25 (95% CI, 1.8 to 340).¹¹

In 2010, Walsh et al.¹⁹ screened 21 tumor suppressor genes in mutations in 360 unselected ovarian, fallopian tube, or peritoneal cancer cases and found mutations in six additional genes (*BARD1*, *CHEK2*, *MRE11A*, *NBN*, *RAD50*, and *TP53*).¹⁹ These findings suggest that a careful and comprehensive mutational screen of all women may identify that the inherited risk of ovarian cancer is higher than originally thought and that an early identification of the risk may ultimately lead to prevention in 24% of ovarian cancer cases.

Role of Poly (ADP-Ribose)-Polymerase (PARP) and PARP Inhibitors in Gynecologic Cancers

Abnormalities in DNA repair have been identified in many human epithelial cancers. Gynecologic cancers are not an exception, with ovarian cancer being the most extensively studied. Serous ovarian cancer has been characterized as having a major defect

in homologous recombination resulting from mutations within Fanconi pathway, as noted previously. DNA repair is a complex process designed to repair specific abnormalities within the DNA. Single-stranded DNA breaks are repaired by a protein complex containing poly (ADP-ribose)-polymerase (PARP). In contrast, double-stranded breaks that are lethal for the cell require a different complex, which contains the BRCA proteins.

Because PARP proteins are intimately involved in the repair of single-stranded DNA breaks, the inhibition of PARP function impedes single-stranded DNA break repair, leading to the formation of double-stranded breaks. Research performed in multiple laboratories suggested that the inhibition of PARP would be a lethal event in cells that have inactivation of *BRCA1* or *BRCA2*. This concept, called *synthetic lethality* (first proposed for cancer therapeutics in 1997), was tested early in the development of PARP inhibitors.²⁰ Preclinical data strongly supported this concept, with *BRCA*-mutated cell lines showing a 100- to 1,000-fold sensitivity to PARP inhibitors compared with wild-type control cell lines. This laboratory proof of principle led to a rapid transition into the clinic.

The clinical development of PARP inhibitors began in earnest in the mid-2000s where they were tested in early phase trials. The first phase I trial focused on women with germ-line *BRCA* mutation of and yielded encouraging results. The expansion cohort of this study treated woman with ovarian cancer and recorded a 46% response rate in platinum-sensitive patients and a 33% response rate in platinum-resistant patients. Of note, the drug was well tolerated and its oral delivery made it quite convenient. This landmark trial led to a follow-up study that examined doses of 100 mg to 400 mg and involved ovarian cancer mutation carriers. The response rate was dose dependent (13% to 33%) and again demonstrated significant activity in the platinum-resistant disease. PARP inhibitors have also been tested in the maintenance setting after the effective treatment of platinum-sensitive recurrent disease. A dramatic improvement in progression-free survival was demonstrated with a hazard ratio (HR) of 0.15 for mutation carriers.²¹

Despite these results, the development of PARP inhibitors has been slow. Difficulties in formulation, precise dose determination, and the identification of pharmacodynamic endpoints have impeded determining the effective role of these agents. Further, a randomized phase II trial directly comparing a PARP inhibitor to doxorubicin in germ-line mutation patients with recurrent ovarian cancer showed no difference between the arms. Despite these setbacks, continued enthusiasm for these agents has led three companies to recently design phase III trials to establish their role in the treatment of ovarian cancer.

It is important to note that most of these trials have tested the effectiveness of PARP inhibitors in mutation carriers. Recent work from large genomic studies support that a much larger percentage of serous ovarian cancers have homologous recombination deficiencies. Estimates have been as high as 50% of all sporadic ovarian cancers. The precise genomic or protein biomarkers, which predict for responsiveness, is the focus of intense research.

There are important unanswered questions and challenges involving the effective use of PARP inhibitors. The precise optimal dose, duration, and sequence are yet to be determined. Should PARP inhibitors be used up-front with chemotherapy or later in maintenance or relapse disease? At present, there are little long-term safety data on PARP inhibition and, given their mechanisms of action, there is concern about secondary malignancies such as leukemia. This may be dependent on the mode of administration with chronic use versus intermittent being more problematic. Further, the mechanism(s) of PARP inhibitor resistance remains essentially unknown. Recent work has demonstrated an in-frame mutation in the *BRCA* gene that restored the protein function in a small number of resistant tumors. Other mechanisms are surely present and need to be determined. Finally, other potential clinical settings for PARP inhibitors, such as radiation sensitizers in combination with chemotherapy, for cervical or endometrial cancers will need to be evaluated.

Ovarian Cancer Microenvironment, Metastases, and Angiogenesis

The ovarian cancer microenvironment consists of any biologic component that interacts with tumor cells, and it includes stromal components, extracellular matrix (ECM) molecules, and cytokines.²² Together, these components create a microenvironment that interacts with the tumor and influences tumor behavior. Two hallmarks of cancer, angiogenesis and metastatic potential, are dependent on the tumor microenvironment. Targeting the interactions between the tumor and its environment has the potential to revolutionize the treatment for ovarian cancer patients.

Inflammatory Cytokines

Cytokine-mediator molecules have a profound effect on tumors. Tumor necrosis factor alpha (TNF- α) is a cytokine that is expressed on ovarian cancer cells and macrophages and is implicated in inflammation. It works through affecting other cytokines and angiogenesis.²³ Animal studies showed that suppressing TNF- α resulted in lower plasma levels of interleukin (IL)-6, reduced IL-17 levels in the ascites, and reduced tumor burden.²⁴ In a phase I clinical trial with the TNF- α antibody, infliximab, patients with ovarian cancer showed decreased IL-17 ascitic levels.²⁴ In addition to TNF- α , high levels of IL-6, IL-8, and macrophage inflammatory protein are also found in ascites. In a multivariate analysis, IL-6 has shown to be a predictor of poor prognosis. A monoclonal antibody siltuximab, which abrogates the IL-6 signaling pathway, had been tested in a phase II clinical trial in platinum-resistant ovarian cancer with one third of the patients showing a clinically meaningful response.²⁵

Particular attention has recently focused on the role of lysophosphatidic acid (LPA) in promoting the metastasis of ovarian cancers. LPA is constitutively produced by mesothelial cells lining the peritoneal cavity; its levels are increased in the ascites of women with both early- and late-stage ovarian cancers.²⁶ When applied to ovarian cancer cell lines in vitro, LPA promotes both the migration of these cells in a manner dependent on Ras MEK kinase-1 as well as their invasion across artificial barriers analogous to a basement membrane. At a molecular level, exogenous LPA enhances ovarian cancer invasiveness both by activating matrix metalloproteinase-2 via membrane type 1-matrix metalloproteinase (MT1-MMP) and downregulating the expression of specific tissue inhibitors of metalloproteinases (TIMP-2 and -3).²⁷ Its application to cultured ovarian cancer cells has also been shown to promote disassembly of intracellular stress fibers and focal adhesions,²⁸ observations that are consistent with the idea that LPA promotes the dissemination of ovarian cancer by a loss of cell adhesion. However, LPA has also been shown to promote the invasiveness of ovarian cancers by additional mechanisms dependent on IL-8. The G12/13-RhoA and cyclooxygenase pathways have also been implicated in the LPA-induced migration of ovarian cancers. These mechanisms appear to be independent of the ability of LPA to induce changes in MMP2 expression. Lastly, it should be noted that LPA appears to promote ovarian cancer metastasis by stimulating *fas*-ligand expression and the shedding of *fas*-ligand-containing microvesicles, potentially leading to an evasion of tumor immunity.

Stromal Cells

A subset of host cells are typically recruited to tumor site. These include tumor-infiltrating lymphocytes, macrophages, fibroblasts, mesenchymal stem cells (MSC), and adipocytes as a body response to a solid tumor. For example, a distinct population of T cells recruited to the tumor site exhibit a cytotoxic effect, although some tumor cells escape detection by the immune system, possibly through immunosuppression of T cells by stromal cells in the ascites.²⁹ In addition, macrophages are recruited to tumor sites and establish bidirectional interaction with tumor cells via

chemokines and MMPs. Chemokines activate tumor-associated macrophages (TAM) M2 immunosuppressive cells, which is found in ovarian cancer. The M2 phenotype is also induced by colony stimulation factor-1 (CSF-1). CSF-1 is highly expressed in ovarian cancer and associated with poor prognosis.³⁰ In 2004, Turk et al.³¹ have described a method that targets both cancer cells and TAMs and involves the folate receptor that are typically expressed on both TAM and cancer cells. Folate-conjugated liposomes showed greater affinity toward TAMs than to cancer cells, highlighting this method of drug delivery to tumor microenvironment. More recently, trabectedin, a compound that prevents differentiation of monocytes to macrophages, was developed against TAM. In a phase II randomized clinical trial that compared the efficacy of doxorubicin versus trabectedin + doxorubicin combination in patients with platinum-sensitive ovarian cancer. The trabectedin + doxorubicin combination showed improved progression-free survival and response rates.³² Preclinical studies are now assessing if clear cell ovarian carcinoma, a subtype characterized by rich TAM infiltrates, may have a more favorable response to trabectedin.³³

Cancer-Associated Fibroblasts

Fibroblasts are a major component of tissue stroma; cancer-associated fibroblasts (CAF or myofibroblasts) remain activated, forming reactive tumor stroma. They are characterized by an altered phenotype and expression of alpha-smooth muscle actin (alpha-SMA) and fibroblast activation protein (FAP). The interaction between cancer cells and FAPs results in a release of cytokines and signals that promote cancer cells invasiveness via paracrine signaling. Targeting FAP and its paracrine signaling may also be a promising new venue for ovarian therapeutics.

Mesenchymal Stem Cells

MSCs are components of the tumor microenvironment with the ability to differentiate into many different cell types, including CAFs. They have been investigated for their potential use as vehicles for cancer drug delivery by exploiting their ability to migrate to the site of tumor proliferation. For example, such an approach used MSCs transduced with recombinant virus encoding endostatin, an inhibitor of angiogenesis.³⁴

Metastases

Changes in ECM components are associated with cell adhesion and tumor invasion. Malignant cells constantly alter their cells' adhesion molecules in response signals, which favors their ability to disseminate and invade locally. Cell membrane integrins have been shown to be important in the progression of ovarian cancer. Beta 1 integrins and alpha 5B1-integrin mediate the attachment of tumor aggregates to the mesothelium. Targeting alpha 5B1-integrin interactions had been attempted in platinum-resistant ovarian cancer without clinically meaningful results. Khanna et al.³⁵ using a high-throughput, small-molecule inhibitor screen, identified several components that are able to inhibit cell adhesion, thus paving the way to further test these molecules as strategies to minimize cancer invasion/spread.³⁵

Angiogenesis

The growth of both primary ovarian cancers and their metastases requires the formation of new blood vessels to support adequate perfusion. This process, known as *angiogenesis*, mechanistically involves both the branching of new capillaries as well as the remodeling of larger vessels. Other processes, such as vasculogenic mimicry, have also been implicated in tumor angiogenesis.

Angiogenesis is tightly regulated by a balance of pro- and antiangiogenic factors. These include growth factors, such as transforming growth factor (TGF)- β , vascular endothelial growth

factor (VEGF), and platelet-derived growth factor; prostaglandins, such as prostaglandin E₂; cytokines, such as IL-8; and other factors, such as the angiopoietins (Ang-1, Ang-2) and hypoxia-inducible factor-1 α (HIF-1 α). Many of these angiogenic factors have been implicated in ovarian cancer. For example, VEGF is a family of secreted polypeptides with critical roles in both normal development and human disease. Many cancers, including ovarian carcinomas, release VEGF in response to the hypoxic or acidic conditions typical in solid tumors. Near universal, albeit variable, levels of VEGF expression have been reported in ovarian cancers, in which higher levels correlate with advanced disease and poor clinical prognosis.³⁶ Circulating levels of VEGF have also been reported to be higher in the serum of women with ovarian cancers when compared with those with benign tumors. Expression of HIF-1 correlates well with microvessel density in ovarian cancers and has been proposed to upregulate VEGF expression.³⁷ Culturing ovarian cancer cell lines under hypoxic conditions stimulates the expression of both HIF-1 α and VEGF expression, and the addition of prostaglandin E₂ potentiates the ability of hypoxia to induce the expression of both proangiogenic factors.³⁸

Ironically, many of the molecules implicated in regulating angiogenesis in cancer, such as c-met, also regulate other processes critical for cancer metastasis, such as cell migration and invasiveness. The inhibition of PI3K decreases the transcription of VEGF in ovarian cancer cells, an effect that is reversed by the forced expression of AKT. Such observations are consistent with reports that hypoxia not only induces angiogenesis, but also increases the invasiveness of ovarian cancer cells.³⁹ Likewise, an acidic environment induces increased IL-8 expression in ovarian cancer in a manner dependent on transcription factors AP-1 and nuclear factor- κ B (NF- κ B)-like factor, suggesting that the feedback between these pathways may also determine how tumors interact with their external environment. Undoubtedly, better insight into these interactions will help to define the suitability of these molecules as therapeutic targets.

So far, antiangiogenic-targeting treatments have been used in combination with conventional chemotherapy in ovarian cancer. Phase III clinical trials have investigated the potential of the VEGF inhibitor bevacizumab as an addition to carboplatin + paclitaxel for improving progression-free survival in ovarian cancer patients at high risk for progression by approximately 4 months.⁴⁰

Epigenetics

It has become increasingly apparent that epigenetic events can lead to cancer as frequently as a loss of gene function due to mutations or loss of heterozygosity. The overall level of genomic methylation is reduced in cancer (global hypomethylation), but hypermethylation of promoter regions of specific genes is a common event that is often associated with the transcriptional inactivation of specific genes.⁴¹ This is critical because the silenced genes are often tumor suppressor genes, and their loss of function can be evident in early stages of cancer and can also drive neoplastic progression and metastasis. Epigenetic gene silencing is a complex series of events that includes DNA hypermethylation of CpG islands within gene-promoter regions, histone deacetylation, methylation or phosphorylation, or histone demethylation. Global hypermethylation of CpG islands appears to be prevalent but highly variable in ovarian cancer tissue.⁴² Multiple genes are abnormally methylated in ovarian cancer compared with normal ovarian tissue, including p16, retinoic acid receptor beta (RAR- β), H-cadherin, *GSTP1*, *MGMT*, *RASSF1A*, leukotriene B₄ receptor, *MTHFR*, progesterone receptor, *CDH1*, *IGSF4*, *BRCA1*, *TMS1*, estrogen receptor- α , the putative tumor suppressor *km23* (TGF- β component), and others.^{42,43} The degree of DNA methylation, the demethylation activity of chemotherapeutic drugs, the degree of histone acetylation, and the specificity of demethylation of select genes are all critical to ensuring the success of treatment and the prevention of ovarian cancer recurrence.⁴³

Role of Specific Immune Responses

The novel observation by William Coley in the 1890s that severe bacterial infections could induce an antitumor response in patients with partially resected tumors has evolved into an understanding that the immune system can recognize tumor-associated antigens and direct a targeted response. The concept of *cancer immunoediting* suggests that the immune system not only protects the host against the development of primary cancers, but also dynamically sculpts tumor immunogenicity.⁴⁴ In epithelial ovarian cancer, support for the role of immune surveillance of tumors comes from observations that the presence of tumor-infiltrating lymphocytes (TIL) in tumors is associated with improved survival of patients with the disease.^{44,45} A recent meta-analysis of 10 studies with 1,815 ovarian cancer patients confirmed the observation that a lack of intraepithelial lymphocytes (TILs) is significantly associated with a worse survival among ovarian cancer patients (pooled HR, 2.24, 95% CI, 1.71 to 2.91).⁹ This effect was evident regardless of tumor grade, stage, or histologic subtype. In addition, encouraging results from large-scale clinical trials of immune system-provoking therapies^{10–13} have rekindled the promise of harnessing the immune system to attack cancers.

Finally, advanced-stage ovarian cancer patients can have detectable tumor-specific cytotoxic T-cell and antibody immunity. This was illustrated in a study that indicated that immunity to p53 predicted improved overall survival in patients with advanced-stage disease.⁴⁶ All of these observations support clinical trials of immunotherapy for epithelial ovarian cancer in an effort to elicit effective antitumor responses. Major obstacles include the identification of tumor-restricted immunogenic targets, the generation of a sufficient immune response to cause tumor rejection, and approaches to overcome tumor evasion of an immune attack.

Ovarian Cancer-Specific Antigens

Human tumor antigens defined to date can be classified into one or more of the following categories: (1) differentiation antigens, such as tyrosinase, Melan-A/MART-1, and gp100; (2) mutational antigens, such as CDK4, β -catenin, caspase-8, and P53; (3) amplification antigens, such as Her2/neu and p53; (4) splice variant antigens, such as NY-CO-37/PDZ-45 and ING1; (5) viral antigens, such as human papillomavirus (HPV) and Epstein-Barr virus; and (6) cancer-testis antigens, such as MAGE, NY-ESO-1, and LAGE-1. Thus, it is clear that some antigens may play a crucial role in the progression of tumor cells (e.g., Her2/neu) and could be useful as biomarkers of disease progression and targets of therapy. On the other hand, in considering an antigenic target for ovarian cancer immunotherapy, an ideal candidate antigen should not only demonstrate high-frequency expression in the tumor tissues and restricted expression in normal tissues, but should also provide evidence for inherent immunogenicity. In this regard, the cancer-testis antigens are a distinct and unique class of differentiation antigens with high levels of expression in adult male germ cells, but generally not in other normal adult tissues, and aberrant expression in a variable proportion of a wide range of different cancer types. Among cancer-testis antigens, NY-ESO-1, initially defined by a serologic analysis of recombinant cDNA expression (SEREX) libraries in esophageal cancer, is particularly immunogenic, eliciting both cellular and humoral immune responses in a high proportion of patients with advanced NY-ESO-1-expressing ovarian cancer.⁴⁷

The reasons for the aberrant expression of cancer-testis antigens in cancer are currently unknown. Nevertheless, the fact that the expression of these antigens is restricted to cancers, gametes, and trophoblasts suggests a link between cancer and gametogenesis. Although possible mechanisms include global demethylation and histone deacetylation, the induction of a *gametogenic* program in cancer has also been proposed.⁴⁸ Although several lines of evidence have shown that spontaneous or vaccine-induced tumor

antigen-specific T cells can recognize ovarian cancer targets, prolonged survival in patients treated with immunization has only rarely been observed. This is probably a reflection of several *in vivo* immunosuppressive mechanisms in tumor-bearing hosts. A recently described mechanism in ovarian cancer is the expression of inhibitory molecules such as programmed death-1 (PD-1) and lymphocyte activation gene-3 (LAG-3).⁴⁹ Together, these molecules render ovarian tumor-infiltrating CD8+ T cells hyporesponsive, wherein effector function is most impaired in antigen-specific LAG-3+PD-1+CD8+ TILs.

Immunotherapy Clinical Trials in Ovarian Cancer

Several groups have launched clinical trials testing various vaccination strategies of generating antitumor immune responses, either against specific tumor antigens^{50,51} or against autologous tumor lysate.^{52,53} Studies on vaccination combined with immune checkpoint blockade and studies of adoptive T-cell therapy utilizing engineered T cells are ongoing at several institutions.

ENDOMETRIAL CANCER

The current concept of endometrial cancer integrates histopathology with molecular genetic mechanisms of cancer development. Two major pathogenetic variants of endometrial carcinoma, type I (endometrioid) and type II (serous), evolve via divergent pathways and different precursor lesions, different genetic abnormalities, and ultimately, different clinical outcomes parallel their distinct histology.

Type I Cancers

More than 90% of uterine cancers arise in the self-renewing glandular epithelium that lines the uterine cavity. The endometrium epithelium responds to steroid hormones with well-characterized patterns of growth and maturation critical for its role in normal reproduction. Estrogen is a well-recognized growth factor for the endometrium, promoting glandular proliferation. Subsequent exposure to the progestin-rich environment that follows ovulation results in an arrest of endometrial proliferation accompanied by glandular luteinization. Several decades of epidemiologic evidence has convincingly demonstrated that continued, unopposed exposure to estrogen is associated with an increased risk of developing endometrial cancer. These risks are particularly notable among postmenopausal women treated with estrogen-only hormone replacement. Following the introduction of hormone replacement therapy, the incidence of endometrial cancer among women in the United States rose steadily. An association between the growth-promoting effects of estrogen and endometrial carcinomas is thought to underlie the epidemiologic associations found for endometrial cancers, medical conditions such as anovulation, obesity, and other epidemiologically defined risk factors, including early age at menarche and nulliparity.

The estrogen-related endometrioid adenocarcinomas account for 80% of endometrial cancer, demonstrate a large number of genetic changes, and appear to arise via a progression pathway. Common genetic changes in this type of endometrial carcinoma include microsatellite instability (MSI), or specific mutations of *PTEN*, *K-ras*, and β B-catenin genes.

Microsatellite Instability

Microsatellites are short segments of repetitive DNA found predominantly in noncoding DNA and scattered through the genome. The MSI phenotype is expressed in the cells with changes in the number of repeat elements as compared with normal tissue because of DNA repair error during replication. Approximately 20% of type I endometrial cancers demonstrate MSI phenotype, whereas MSI in

type II cancers is very rare and is only present in less than 5% of the cases.⁵⁴ MSI is due to the inactivation of any of the mismatch repair genes and proteins: *MLH1*, *MSH2*, *MSH3*, and *MSH6*. The most common mechanism of MSI in the endometrium is inactivation of *MLH1* by epigenetic silencing of its promoter through hypermethylation of CpG islands, followed by *MSH6* mutation and *MSH3* frameshift mutations. In contrast, the MSI present in colon cancer is predominantly due to mutations in *MSH2*, followed by *MLH1* and *MSH6* mutations. MSI is an early event in type I cancers and it has been described in precancerous lesions. Once established, MSI may specifically target or inactivate genes with susceptible repeat elements, such as TGF- β 1 receptors and IGFIIR, resulting in new subclones with an altered capacity to invade and metastasize.

PTEN

Inactivation of the phosphatase and tensin homolog (*PTEN*) tumor suppressor gene, located at 10q23, is the most common genetic defect in type I endometrial cancers, and it is present in more than 80% of tumors that are preceded by the histologically distinct premalignant phase.⁵⁵ The predominant *PTEN* activity is a lipid phosphatase that converts inositol triphosphates into inositol biphosphate, thus inhibiting survival and proliferative pathways that are activated by inositol triphosphatase. *PTEN* protein functions in maintaining G1 arrest and enabling apoptosis via an AKT-dependent mechanism. *PTEN* inactivation is caused by various mechanisms. The most common *PTEN* defect in endometrial cancer is its complete loss of function through the inactivation of both alleles. Mutations or deletions that result in loss of heterozygosity at the *PTEN* locus are also observed with high frequency. The *PTEN* mutations pattern is different in microsatellite-stable and MSI cancers. MSI tumors have a higher frequency of deletions, involving three or more base pairs, as compared with the microsatellite-stable tumors. In addition, the mutations in MSI tumors only rarely involve the polyadenine repeat of exon 8, which is the expected target.

KRAS mutations have been found in up to 30% of type I endometrial cancers. The frequency of *KRAS* mutations is particularly high in MSI-positive tumors.⁵⁶

β -Catenin

β -Catenin (3p21) is a component of the E-cadherin–catenin complex essential for cell differentiation and maintenance of normal tissue architecture, and it also plays a role in signal transduction. The APC protein downregulates β -catenin levels, inducing the phosphorylation of serine-threonine residues coded in exon 3 of the β -catenin and its degradation via the ubiquitin–proteasome pathway. Gain of function mutations in β -catenin exon 3 are seen in 25% to 38% of type I cancers.⁵⁷ These mutations result in protein stabilization, accumulation, and transcriptional activation. β -Catenin mutations have also been found in premalignant endometrial lesions. β -Catenin changes may characterize pathways of endometrial cancer separate from *PTEN* mutations and are characterized by squamous differentiation. Several genes may be targets of the dysregulated β -catenin pathway. Although in colon cancer, elevated β -catenin levels trigger cyclin D1 expression and uncontrolled progression of tumor cells into the cell cycle, in type I endometrial cancers, β -catenin may regulate the expression of MMP-7, which has a role in the establishment of microenvironment necessary for the maintenance of tumor growth.

Type II Endometrial Cancer

The more aggressive, non-estrogen–related, nonendometrioid cancers (predominantly serous and clear cell carcinomas) are characterized by p53 mutations and Her2/neu amplification and Bcl-2 changes. These high-grade tumors are known to be associated in some cases with an identifiable intraepithelial neoplasia component. The same pattern of genetic changes is seen in the

preneoplastic atrophic endometrium, suggesting that these are early events in type II tumors carcinogenesis.⁵⁸

CERVIX, VAGINAL, AND VULVAR CANCERS

Role of Human Papillomavirus

Persistent infections with specific high-risk HPV genotypes (e.g., HPV-16, HPV-18, HPV-31, HPV-33, and HPV-45) have been identified as an essential, although not sufficient, factor in the pathogenesis of a majority of cancers of the cervix, vagina, and vulva.⁵⁹ The existence of papilloma viruses was first demonstrated by Shope⁶⁰ in the 1930s using an ultrafiltrate of warts from rabbits. Since then, papilloma viruses with an epithelial tropism have been demonstrated in nearly every mammalian species, including humans. The HPVs are encapsulated DNA viruses containing a double-stranded DNA genome of approximately 7,800 base pairs. After infecting a suitable epithelium, viral DNA replication takes place in the basal cells of the epidermis, where the HPV genome is stably retained in multiple copies, guaranteeing its persistence in the epithelium's proliferative cells. This occurs early in preneoplastic lesions, when the viral genome still persists in an episomal state. In most invasive cancers and also in a few high-grade dysplastic lesions, however, integration of high-risk HPV genomes into the host genome is observed. Integration seems to be a direct consequence of chromosomal instability and an important molecular event in the progression of preneoplastic lesions. In a review of more than 190 reported integration loci, HPV integration sites are found to be randomly distributed over the whole genome with a clear predilection for genomic fragile sites. No evidence for targeted disruption or functional alteration of critical cellular genes by the integrated viral sequences could be found.⁶¹

The ability of high-risk HPVs to transform human epithelia relates to the transcription of specific viral gene products. Transcription from the HPV genome occurs in two waves: an early phase with seven to eight gene products, and a late phase with two gene products (L1, L2). Early-phase gene products play a critical role in viral DNA replication (E1, E8) and in the regulation of transcription (E2, E8). In contrast, the L1 and L2 genes code for the capsid's primary and secondary proteins, respectively. The ability of different high-risk HPVs to transform human epithelia has been primarily associated with the expression of two specific viral gene products, E6 and E7. The transformation of human genital tract epithelium likely requires the expression of both E6 and E7; the transfection of human keratinocytes in vitro with either is insufficient to accomplish this phenomenon.

At a molecular level, E6 and E7 interfere with important control mechanisms of the cell cycle, apoptosis, and the maintenance of chromosomal stability by directly interacting with p53 and pRB, respectively. Moreover, recent studies demonstrated that the two viral oncoproteins cooperatively disturb the mechanisms of chromosome duplication and segregation during mitosis and thereby induce severe chromosomal instability associated with centrosome aberrations, anaphase bridges, chromosome lagging, and breaking.⁶² They have also been shown to interact with a number of other cellular proteins, whose role in epithelial transformation remains unclear, including transcriptional coactivators, such as p300, and components of junctional complexes, such as hDlg1. The altered expression of hDlg1 has been observed in high-grade cervical dysplasias, which is consistent with the hypothesis that these gene products play an early role in the HPV-induced progression to cervical cancer. Specific sequence differences have been associated with different levels of risk for ultimately developing cervical cancers. For example, recent evidence demonstrates that the sequence of E6 found in Ashkenazi populations confers a protective advantage against developing cervical cancer, which was previously attributed to the practice of circumcision. Although much

less understood, other early genes, such as E2, have also been implicated in the transformation.

In addition to HPV, somatic mutations in PIK3CA, PTEN, TP53, STK11, and KRAS as well as several copy-number alterations have also been implicated in the pathogenesis of cervical carcinomas. A recent study included a whole-exome sequencing analysis of 115 cervical carcinoma–normal paired samples, transcriptome sequencing of 79 cases, and whole-genome sequencing of 14 tumor-normal pairs.⁶³ Previously unknown somatic mutations in 79 primary squamous cell carcinomas include recurrent E322K substitutions in the MAPK1 gene (8%), inactivating mutations in the HLA-B gene (9%), and mutations in EP300 (16%), FBXW7 (15%), NFE2L2 (4%), TP53 (5%), and ERBB2 (6%) were noted. Moreover, there were somatic ELF3 (13%) and CBF3 (8%) mutations in 24 adenocarcinomas.⁶³ Overall, squamous cell carcinomas have higher frequencies of somatic nucleotide substitutions occurring at cytosines preceded by thymines (Tp^{*}C sites) than adenocarcinomas. HPV integration sites were found within or in close proximity to several fragile sites as well as previously reported genes, including MYC, ERBB2, TP63, FANCC, RAD51B, and CEACAM5.⁶³ HPV integration also occurred closer to amplified regions than expected by chance, with 21 of 51 (41%) integration sites overlapping with amplified regions, supporting the hypothesis that viral integration may trigger genome amplification. Interestingly, recurrent HPV integration into the RAD51B locus was noted in some tumors, involving HPV16, HPV18, and HPV52.⁶³

Immune Evasion by Human Papillomavirus

HPV infection has a transitory pattern, whereby most individuals (70% to 90%) eliminate the virus 12 to 24 months after the initial diagnosis.⁶⁴ HPV has evolved several strategies to evade immune attack. Most obviously, papillomaviruses do not infect and replicate in antigen-presenting cells that are located in the epithelium, nor do they lyse keratinocytes, so there is no opportunity for antigen-presenting cells to engulf virions and present virion-derived antigens to the immune system. Furthermore, there is no blood-borne phase of infection, so the immune system outside of the epithelium has little opportunity to detect the virus. Additionally, HPVs have exploited the redundancy of the genetic code to keep the levels of “late” proteins low.⁶⁵ Papillomavirus capsid protein production in mammalian cells is markedly upregulated if the “viral” codons are replaced by the ones that are used by mammals, thereby limiting opportunities for the host to mount an effective immune attack. Following viral integration and subsequent malignant change, the local tumor environment at the cervical lesion is immunosuppressive. Thus, antigen-loaded dendritic cells (DCs) fail to mature, and immature DCs transmit a tolerogenic, rather

than an immunogenic, signal to T cells, bearing antigen-directed T-cell receptors in draining lymph nodes.

Human Papillomavirus Vaccines

The aim of the prophylactic vaccination is to generate neutralizing antibodies against the HPV L1 and L2 capsid proteins. Prophylactic vaccine development against HPV has focused on the ability of the L1 and L2 virion structural proteins to assemble into viruslike particles (VLP). VLPs mimic the natural structure of the virion and generate a potent immune response. Because the VLPs are devoid of DNA, they are not infectious or harmful. HPV VLPs can be generated by expressing the HPV capsid protein L1 in Baculoviruses or yeast. They consist of five L1 subunits that multimerize into immunogenic pentamers. Seventy-one L1 pentamers, in turn, multimerize into an HPV VLP. Initial studies have shown that VLPs are capable of inducing high titers of neutralizing antibodies to L1 and L2 epitopes.⁶⁶ Furthermore, VLPs have proven effective at generating HPV type-specific protection from viral challenge in animal papillomavirus models.

With the approval of preventive HPV vaccines that encompass HPV-16, -18, -6, and -11, large prevention clinical trials targeting the most prevalent HPV types in different regions of the world are warranted. Questions such as the necessity of repeat vaccinations and the longevity of protection from an HPV infection remain to be determined. It is estimated that if women were vaccinated against all high-risk types of HPV before they become sexually active, there should be a reduction of at least 85% in the risk of cervical cancer and a decline of 44% to 70% in the frequency of abnormal Papanicolaou (Pap) smears attributable to HPV.⁶⁷ Unfortunately, even after vaccination is implemented, a reduction in the incidence of cervical cancer could not be expected to become apparent for at least a decade.⁶⁸ Therefore, therapeutic vaccines are still very much needed to reduce the morbidity and mortality associated with cervical cancer.

The therapeutic approach to patients with preinvasive and invasive cervical cancers is to develop vaccine strategies that induce specific CD8⁺ cytotoxic T-lymphocyte responses aimed at eliminating virus-infected or transformed cells. The majority of cervical cancers express the HPV-16–derived E6 and E7 oncoproteins, which are thus attractive targets for T-cell-mediated immunotherapy. Several HPV vaccine strategies have successfully elicited immune responses against HPV E6 and E7 epitopes and have prevented tumor growth on challenge with HPV-16–positive tumor cells in mice. Early-phase human trials using therapeutic vaccines have shown that they are safe; no serious adverse effects have been reported. Other approaches currently undergoing preclinical development include the use of recombinant alpha viruses such as Venezuelan equine encephalitis virus, Semliki Forest virus, and naked DNA vaccination.

CARCINOMA OF THE VAGINA

Carcinomas of the vagina are rare, accounting for only about 2% of gynecologic malignancies. The American Cancer Society estimated that in the United States in 2014, 3,170 new cases of invasive vaginal cancer will be diagnosed and there will be 880 deaths due to vaginal cancer.¹ According to the International Federation of Gynecology and Obstetrics (FIGO), cases should be classified as vaginal carcinomas only when “the primary site of the growth is in the vagina.”² Any tumor that has extended to the cervical portio and has reached the area of the external os should be classified as a cervical carcinoma, and a tumor that has extended from the vulva to involve the vagina should be classified as a primary vulvar cancer.² In patients with an intact uterus, it is probable that many tumors that originate in the apical vagina are classified as cervical cancers because they have reached the area of the external os by the time of diagnosis. This may explain why a large percentage (30% to 50%) of patients diagnosed with vaginal carcinoma have previously undergone hysterectomy, which prevents classification of tumors as primary cervical cancers.^{3,4}

More commonly, the vagina is a site of metastasis, direct extension, or recurrence of tumors originating in other genital sites, such as the cervix or endometrium, or from extragenital sites, including the rectum and bladder.

Epidemiology

Vaginal intraepithelial neoplasia (VAIN) often accompanies cervical intraepithelial neoplasia (CIN) and is thought to have a similar etiology.⁵ Kalogirou et al.⁶ found 41 cases of VAIN in 993 patients followed with cytologic examination and colposcopy after hysterectomy for CIN. Most VAIN lesions were in the upper vagina, particularly in the vault angles of the suture line.

Investigators have reported a human papillomavirus (HPV) infection rate of 60% to 65% in women with vaginal carcinoma.⁷ Population-based studies indicate that the prevalence of HPV infection is similar in the vaginas of women who have undergone hysterectomy and the cervixes of women who still have their uterus.⁸ The much lower rate of carcinoma in the vagina is thought to reflect the fact that the vagina does not have a transformation zone of immature epithelial cells susceptible to transformation; HPV-induced vaginal lesions are thought to arise in areas of squamous metaplasia that develop during healing of mucosal abrasions caused by coitus, tampon use, chronic pessary use, or other trauma.⁵ Most vaginal cancers arising in patients who used pessaries are located in the posterior wall.⁹ Pelvic irradiation might be a predisposing factor in some cases of vaginal cancer.¹⁰ However, viral and other nontreatment-related factors probably play a role in the etiology of vaginal cancers that arise after treatment of another malignancy.

Primary invasive carcinoma of the vagina is predominantly a disease of elderly women; 70% to 80% of cases are diagnosed in women older than 60 years.¹¹ Except for clear cell carcinomas,

which are associated with maternal diethylstilbestrol (DES) exposure, invasive vaginal carcinomas are extremely rare in women younger than 40 years.^{2,11} African American women have been reported to have significantly poorer survival compared with whites when controlling for age, histology, stage, grade, and treatment modality.

In 1971, Herbst et al.¹² first reported a highly significant association between clear cell carcinoma of the vagina and maternal ingestion of DES during pregnancy. The peak number of DES-associated cases occurred in 1975, when 33 cases were reported to a US registry.¹² The peak risk period for exposed women in the United States was between the ages of 15 and 22 years; few cases were diagnosed after the age of 40 years. Obesity, oral contraceptive use, and pregnancy were suggested as possible risk factors for development of clear cell carcinoma in DES-exposed women, but larger case-matched studies generally failed to confirm these associations.¹³ Infection with HPV may be a cofactor in some cases. Among 14 cases of clear cell carcinoma studied by Waggoner et al.,¹⁴ 3 contained HPV-31 DNA; 10 of the remaining HPV-negative tumors had p53 protein detected by immunohistochemistry, suggesting a TP53 gene mutation.

DES-related clear cell carcinomas appear to have a better prognosis with less likelihood of distant metastasis than other vaginal adenocarcinomas. Because many DES-exposed women with clear cell carcinoma were young at the time of diagnosis, treatment of early lesions has emphasized preservation of vaginal and ovarian function. Senekjian et al.¹⁵ reported successful treatment of early lesions with excision or local radiotherapy only. However, retroperitoneal lymphadenectomy may be indicated when local treatment is considered for stage I lesions, which are reported to have an overall rate of pelvic lymph node metastases of 15% to 20%.¹⁶

There is as yet no evidence that DES-exposed women are at risk for genital tract malignancies other than clear cell carcinoma,¹⁷ although recent studies suggest that they may have an increased risk of developing breast cancer after the age of 40 years.^{18,19}

Natural History and Pattern of Spread

Approximately 50% of vaginal cancers arise in the upper third of the vagina, and there is a fairly even distribution of lesions arising on the anterior, posterior, and lateral walls. Tumors may exhibit an exophytic or ulcerative, infiltrating pattern of growth.

Tumors may invade directly to involve adjacent structures such as the urethra, bladder, and rectum, although <10% of vaginal cancers are found to be stage IVA (spread to adjacent organs and/or direct extension beyond the true pelvis) at presentation.^{4,20,21}

Vaginal cancers may also spread laterally to the paravaginal space and pelvic wall. Although tumors arising in the vagina undoubtedly can spread superiorly to involve the cervix and uterus, such tumors are usually classified as cervical cancers according to FIGO criteria.

The vagina is supplied with a fine anastomosing network of lymphatics in the mucosa and submucosa. Despite the continuity of lymphatic vessels within the vagina, Plentl and Friedman²²

found a regular pattern of regional drainage from specific regions of the vagina. The lymphatics of the vaginal vault communicate with those of the lower cervix, draining laterally to the obturator and hypogastric nodes. The lymphatics of the posterior wall anastomose with those of the anterior rectal wall, draining to the superior and inferior gluteal nodes. The lymphatics of the lower third of the vagina communicate with those of the vulva and drain either to the pelvic nodes or to the inguinofemoral lymph nodes.

Few data are available concerning the incidence of spread of vaginal cancer to the pelvic lymph nodes. However, studies suggest that the incidence of positive pelvic nodes in patients with stage II disease is at least 25% to 30%, emphasizing the importance of regional treatment for these patients.²³

The most frequent site of hematogenous metastasis is the lung. Less frequently, vaginal cancers may metastasize to liver, bone, or other sites.²⁴

Pathology

Eighty to ninety percent of primary vaginal malignancies are squamous cell carcinomas.²⁴ Grossly, these tumors may be nodular, ulcerative, exophytic, or form plaques. Histologically, they are similar to squamous tumors at other sites. Approximately one-third of vaginal squamous cell carcinomas are keratinizing, and more than half are nonkeratinizing, moderately differentiated lesions.

Approximately 5% to 10% of primary vaginal neoplasms are adenocarcinomas.^{24,25} The differential diagnosis of adenocarcinoma occurring in the vagina is often difficult, as it must be distinguished from metastatic tumors originating at other sites. Histologic patterns include clear cell, mucinous, adenosquamous, papillary, and undifferentiated. During the 1970s and 1980s, clear cell carcinomas of the vagina were sometimes seen in young women in association with maternal DES exposure. Today, these are extremely rare, and most adenocarcinomas occur in postmenopausal women. The prognosis of patients with adenocarcinoma appears to be poorer than that of patients with squamous carcinoma of the vagina.²⁶

Primary small cell carcinomas of the vagina are very rare, with <30 cases reported in the literature.²⁶ They are histologically indistinguishable from neuroendocrine small cell carcinomas of the lung or cervix and, like these tumors, may coexist with squamous or adenocarcinoma elements.

Primary vaginal melanomas represent about 3% of primary vaginal cancers and <20% of genital melanomas.²⁴ Primary vaginal melanomas are thought to arise from melanocytes in areas of melanosis or atypical melanocytic hyperplasia. They usually originate in the distal third of the vagina and occur at a mean age of 55 years. Vaginal melanomas tend to be associated with a poorer prognosis than vulvar melanomas; 5-year survival rates are 15% to 20% after treatment with surgery, radiation, or both.²⁷

About 3% of vaginal cancers are sarcomas; about two-thirds of these are leiomyosarcomas, but endometrial stromal sarcomas, malignant mixed Müllerian tumors, and other types have been reported.²⁸ Embryonal rhabdomyosarcoma (sarcoma botryoides) is a highly malignant sarcoma that occurs in girls, usually before 6 years of age. This tumor usually forms soft nodules that fill and protrude from the vagina. The prognosis for children with this tumor has improved with the use of appropriate multimodality therapy.²⁹

Diagnosis, Clinical Evaluation, and Staging

Most patients with VAIN and about 10% to 20% of patients with invasive vaginal carcinoma are asymptomatic at presentation; in these cases, carcinoma is usually diagnosed during investigation of an abnormal Papanicolaou (Pap) smear finding. Colposcopic

evaluation in the case of abnormal cytologic findings should always include a detailed examination of the entire vagina and cervix, even when there is an obvious cervical lesion, because patients can present with multiple areas of abnormality. Women who have persistent positive Pap smear findings after treatment of CIN should be examined carefully for VAIN.

About 50% to 60% of patients with invasive vaginal cancer present with abnormal vaginal bleeding. Patients may also present with complaints of vaginal discharge, a palpable mass, dyspareunia, or pain in the perineum or pelvis.^{4,20,30}

The initial workup of patients with vaginal cancer should include a pelvic examination including thorough visualization of the entire vagina. Examination under anesthesia can be useful to ensure adequate visualization of the full extent of disease and to place marker seeds to delineate the extent of involvement for brachytherapy planning. All patients should have chest radiography, a complete blood cell count, and a biochemical profile. Computed tomography (CT) is useful to evaluate for possible regional spread and to evaluate the kidneys but usually does not provide accurate information about the extent of primary disease. Magnetic resonance imaging (MRI) provides much more detailed information about the extent of paravaginal infiltration but frequently underestimates the extent of superficial vaginal involvement, which is often better appreciated on pelvic examination. 18-Fluorodeoxyglucose (FDG)-positron emission tomography (PET)/CT is useful to evaluate for evidence of nodal involvement. If involvement of adjacent structures is suspected on physical examination or imaging, further evaluation with cystoscopy, ureteroscopy, and/or proctoscopy is recommended.

The FIGO stage categories for vaginal cancers are listed in Table 72.1.² Because this is a clinical staging system, the classification of lesions as stage I or II tends to be somewhat subjective. In general, thin (<0.5 cm), relatively exophytic tumors tend to be classified as stage I, and thicker, infiltrating tumors and those with obvious paravaginal nodularity tend to be classified as stage II.

FIGO recommendations for staging of disease associated with positive lymph nodes are somewhat ambiguous.^{2,31} Although clinical staging is recommended, with rules similar to those used for cervical cancer (e.g., disallowing use of imaging or surgical information about lymph node involvement in assignment of stage), the most recent FIGO manual quoted stage groupings based on nodal involvement. A more specific method of nodal evaluation is elaborated in the American Joint Committee on Cancer staging manual,³¹ which suggests options for pathologic or clinical TNM

TABLE 72.1

International Federation of Gynecology and Obstetrics Clinical Staging of Carcinoma of the Vagina

Stage	Description
0	Carcinoma in situ, intraepithelial carcinoma.
I	The carcinoma is limited to the vaginal wall.
II	The carcinoma has involved the subvaginal tissues but has not extended onto the pelvic wall.
III	The carcinoma has extended onto the pelvic wall.
IV	The carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum. Bullous edema as such does not permit a case to be allotted to stage IV.
IVA	Spread of the growth to adjacent organs and/or direct extension beyond the true pelvis.
IVB	Spread to distant organs.

(tumor, node, metastases) staging. According to the American Joint Committee on Cancer, results of biopsy or fine needle aspiration of lymph nodes may be included in the clinical staging³¹; FIGO states that such results can be used for treatment planning only.² Although the FIGO system could be interpreted to assign patients who have clinically evident inguinal involvement to stage IV, patients with inguinal metastases are sometimes cured with locoregional treatment; Kucera and Vavra³⁰ reported uncorrected 5-year survival rates of 29% for patients with clinically suspicious inguinal nodes and 44% for patients with clinically negative groins.

Prognostic Factors

The rates of local control, distant metastasis, and survival in vaginal carcinoma are all correlated strongly with FIGO stage (Table 72.2).^{4,20,21,30} Tumor size also is an important predictor of outcome.^{4,20,21,32}

Most investigators have been unable to find a correlation between tumor site and outcome.^{20,21,33} However, tumors that involve the entire vagina tend to be associated with a poorer prognosis, probably reflecting the larger size of these lesions. Exophytic tumors may be associated with a better prognosis than infiltrating or necrotic lesions.²¹

Frank et al.²⁵ reported significantly poorer survival and pelvic disease control rates for patients with non-DES-related adenocarcinomas than for patients with squamous cell carcinomas; at 5 years, the overall survival and pelvic disease control rates were 34% and 39%, respectively, for patients with adenocarcinomas versus 58% and 81%, respectively, for patients with squamous carcinomas of the vagina. Although other investigators^{20,34} found no difference in outcome between patients with squamous carcinoma and those with adenocarcinoma, this may reflect inclusion of DES-related clear cell carcinomas, which appear to be associated with a better prognosis than other adenocarcinomas.¹⁵

Treatment

Technical aspects of the treatment of vaginal cancer are highly specialized and vary widely according to the site, size, and distribution of tumor within the vagina and adjacent structures. To achieve the

best results for patients with these rare cancers, treatment should be delivered at a center that has a strong multidisciplinary team, including a radiation oncologist well versed in the specialized brachytherapy and external beam techniques used to treat these cancers.

Vaginal Intraepithelial Neoplasia

Patients with only HPV infection, or VAIN 1, do not require treatment. These lesions often regress spontaneously, are frequently multifocal, and recur quickly after attempts at ablative therapy. VAIN 2 may be treated with observation or topical estrogen. The malignant potential of VAIN 1–2 is uncertain. However, VAIN 3 may progress to an invasive lesion. Thus, when VAIN 3 is found, a careful evaluation should be done to rule out the presence of occult invasive disease.

VAIN 3 lesions that have been adequately sampled to rule out invasion can be treated with laser ablation. Cryosurgery should not be used in the vagina because the depth of injury cannot be controlled and inadvertent injury to the bladder or rectum may occur. Superficial fulguration with electrosurgical ball cautery may be used under careful colposcopic control. Local excision is an excellent method of treatment for small upper vaginal lesions. Intravaginal 5-fluorouracil (5-FU) has been used to treat patients who have persistent disease after resection.

Most authors report that about 5% to 10% of patients who undergo excision of VAIN develop subsequent invasive cancers,^{35,36} and Hoffman et al.⁵ reported finding occult invasive disease in upper vaginectomy specimens from 9 of 32 patients (28%) who had surgery for VAIN 3. These risks are sufficient to warrant close follow-up of patients treated for VAIN.

VAIN can also be treated effectively with intracavitary brachytherapy,^{20,21,34} but this treatment is usually reserved for patients with multifocal, multiply recurrent disease or high operative risk. Although most experiences have been with low-dose-rate (LDR) brachytherapy, MacLeod et al.³⁷ reported a high control rate without major complications using high-dose-rate (HDR) intracavitary brachytherapy; the vaginal surface was treated with a total dose of 34 to 45 Gy in 4 to 10 fractions. In contrast, Ogino et al.³⁸ reported adhesive vaginitis and rectal bleeding in two patients treated to the entire vagina with a less conservative HDR fractionation schedule.

^b Stages III and IVA combined.

Stage I Disease

Radiotherapy is often the treatment of choice for stage I disease because if surgery is used, total vaginectomy or even exenteration may be needed to obtain satisfactory resection margins. However, surgery has a definite role in selected cases.^{23,32} Early tumors that involve the upper posterior vagina can be removed with a radical hysterectomy and partial (proximal) vaginectomy if the uterus is intact or with a radical upper (proximal) vaginectomy if the patient has previously undergone hysterectomy; in both situations, bilateral pelvic lymphadenectomy is also performed. For patients with a prior history of pelvic irradiation, radical surgery (usually pelvic exenteration) is indicated and is often curative.

Disease-specific survival rates for patients with stage I disease treated with definitive irradiation range from 75% to 95%.^{4,21,30,39} Although some authors have suggested that selected patients with small, very superficial tumors may be treated with brachytherapy alone,²¹ others have noted unacceptable rates of paravaginal recurrence after treatment with brachytherapy alone and suggest that external beam irradiation should be used to treat at least the distal pelvis.⁴ Thicker stage I tumors always should be treated with a combination of external beam irradiation and brachytherapy with an aim to deliver 40 to 50 Gy to the pelvic nodes and 70 to 75 Gy to the tumor.

Stage II Disease

Because investigators rarely define their criteria for distinguishing stage I from stage II vaginal carcinoma or for selecting patients for various treatments, different institutional experiences cannot easily be compared. Disease-specific survival rates for patients with stage II disease range from 50% to 80%. To control possible regional disease, patients with stage II disease should receive 40 to 50 Gy to the whole pelvis delivered using conventional fields or intensity-modulated radiotherapy (IMRT). This should be followed by additional irradiation of sites of initial gross disease.⁴ In most cases, brachytherapy is used to supplement the dose to the primary vaginal tumor site. Perez et al.²¹ achieved pelvic tumor control in only 4 of 11 patients (36%) with stage II tumors treated with brachytherapy alone, compared with 54 of 81 patients (67%) treated with a combination of external beam irradiation and brachytherapy.²¹

Brachytherapy should be tailored to the volume and distribution of the tumor and its response to external beam irradiation. For apical tumors that flatten to <5 mm in thickness, the dose to the vagina may be boosted using intracavitary sources in a vaginal cylinder, although interstitial brachytherapy or conformal external beam techniques may still be useful in selected cases. Examination under anesthesia, transvaginal sonography, or MRI may be helpful in evaluation of disease extent for treatment planning. Larger tumors usually require a boost with interstitial brachytherapy or with additional external beam irradiation (taking into account the influence of internal organ motion on external beam radiation doses). Most authors emphasize the importance of brachytherapy in the treatment of vaginal cancer.^{21,39} However, brachytherapy must be designed to treat the entire vaginal tumor. Frank et al.⁴ argue that tumors that cannot be covered adequately with brachytherapy can often be cured with external beam irradiation alone using carefully designed conformal fields.

Selected patients with stage II disease may be cured with radical surgery.³² However, total radical vaginectomy or pelvic exenteration is often required to remove the tumor, and results with radical surgery do not appear to be better than those with radiotherapy alone. Primary radical surgery is usually indicated for patients who have previously had pelvic radiotherapy.

Stage III and IVA Disease

Reported 5-year disease-specific survival rates range from 30% to 60% for patients with stage III disease and from 15% to 40% for

patients with stage IVA disease.^{4,20,21,30} Stage III and IVA tumors are usually bulky, highly infiltrative lesions involving most or all of the vagina as well as the pelvic wall, bladder, or rectum. The extent of these tumors and the proximity of critical normal tissue structures make their management a formidable technical challenge. Pelvic recurrence rates are high in many series; the risk of distant metastasis is also relatively high, although distant relapse is often accompanied by locoregional recurrence.

All patients require treatment with external beam irradiation. Most authors advocate the use of brachytherapy whenever possible. However, Frank et al.⁴ reported a high disease-specific survival rate (58% at 5 years) in a series of patients with stage III and IVA disease in which the majority of patients (31 of 46) were treated with external beam irradiation alone. Brachytherapy is undoubtedly an important part of disease management in some patients. However, in certain cases, interstitial brachytherapy does not provide adequate coverage of tumors that are very large and intimately associated with critical structures. In these cases, it may be appropriate to place greater emphasis on external beam treatment. Conformal radiotherapy techniques such as IMRT may help to increase the dose to tumor while limiting the dose to critical structures.

For selected patients with relatively small, mobile stage IVA cancers who are in otherwise good medical condition, pelvic exenteration with vaginal reconstruction using a gracilis myocutaneous flap or rectus abdominis myocutaneous flap may be the treatment of choice, particularly if a rectovaginal or vesicovaginal fistula is present.⁴⁰ Radical radiotherapy is also curative in some cases; Frank et al.⁴ reported an 86% pelvic control rate in seven patients treated with radiotherapy for stage IVA disease.

Radiotherapy Technique

Pelvic external beam fields must be individualized according to the primary tumor site and potential sites of regional spread. Radiopaque markers placed at the distal edge of the tumor help to define the lower border and facilitate studies of internal organ motion. Treating the patient in an open ("frog-leg") position can often reduce the severity of vulvar cutaneous reactions when coverage of distal lesions necessitates inclusion of the introitus in the radiation field.

When tumors involve the distal third of the vagina, pelvic fields should be designed to include at least the medial inguinal-femoral lymph nodes. When four fields are used to treat the pelvis, care must be taken to cover all the draining lymph nodes. Lateral fields should adequately cover posterior perirectal nodes, particularly when the primary lesion involves the posterior vaginal wall.

Intracavitary brachytherapy is of limited value in the treatment of locally advanced vaginal cancer because the dose falls off very rapidly from the surface of a vaginal cylinder. In general, the dose at a 5-mm depth is only 60% to 70% of the dose at the vaginal surface. Interstitial brachytherapy can provide better coverage of thick vaginal tumors. Vaginal implants can be inserted freehand. Successful use of this technique requires experience, but direct palpation during needle insertion permits excellent control of the position of sources with respect to the vaginal surface and rectal mucosa (Fig. 72.1). Vaginal implants may also be positioned using a perineal template. This technique provides a more homogeneous dose distribution because it facilitates parallel positioning of sources, but the template interferes somewhat with the ability of the brachytherapist to monitor the placement of needles with respect to the rectal and vaginal mucosa. When tumors involve the vaginal apex in patients who have had a hysterectomy, laparoscopic or laparotomy guidance may be needed to ensure accurate needle placement.

Interstitial needles can be placed transperineally while monitoring the position of the needles by direct palpation with fingers in the vagina and rectum. A plastic cylinder in the vagina can be

Figure 72.1 Interstitial implant of a squamous carcinoma involving the right lateral walls of the vagina. Positron emission tomography (A) demonstrated uptake in right lateral wall of vagina. After 50 Gy of external beam radiation with weekly cisplatin, four interstitial needles were placed in the right lateral vaginal wall which could be visualized on magnetic resonance imaging (*blue arrows* shown in B). (C) Brachytherapy treatment plan was optimized to deliver 26 Gy over 72 hours to the residual disease. Isodose contours represent the dose rates (in centigray per hour) delivered to tissues in the axial plane at the approximate center of the implant.

used to displace uninvolved tissues away from the needles, which are loaded with iridium-192 (^{192}Ir) sources. MRI after placement of MRI-compatible applicators allows visualization of residual tumor and can be used to shape the dose distribution.

Efforts to correlate radiation dose with tumor control have yielded inconsistent results and may be misleading because the total dose of radiation prescribed for a vaginal tumor is often influenced by the tumor's size, extent, and initial response to irradiation, all of which determine the feasibility of delivering high-dose brachytherapy.^{4,21,39} When good brachytherapy coverage of the tumor can be accomplished, an effort should be made to treat the tumor to a dose of 75 to 85 Gy. When brachytherapy is not possible, some patients may be cured with external beam irradiation alone using shrinking pelvic fields or IMRT to deliver a tumor dose of 60 to 70 Gy. Treatment can usually be completed in <6 to 7 weeks and should not be protracted unnecessarily. Lee et al.⁴¹ reported a significantly lower pelvic

recurrence rate in patients whose entire treatment course was completed in ≤ 9 weeks.

Complications of Radiotherapy

The close proximity of the bladder and rectum to the vagina makes them vulnerable to damage when invasive vaginal cancers are treated with radiotherapy. In their review of 193 patients treated with definitive irradiation, Frank et al.⁴ reported a 10% actuarial incidence of serious complications at 5 years. The most frequent complications were proctitis, hemorrhagic cystitis, and fistulae. Complication rates were significantly correlated with FIGO stage and with a history of smoking; major complications rates were 4%, 9%, and 21% for patients with stage I, II, or III-IVA disease, respectively. Other authors have reported similar major complication rates.^{20,21,30} There have been no comprehensive studies of

vaginal function in women with vaginal cancer treated with radiotherapy, although some degree of vaginal stenosis or shortening is common.²⁰ The severity of vaginal morbidity is probably related to the damage to vaginal mucosa and submucosa from tumor infiltration, ulceration, and infection; the age and menopausal status of the patient; and the radiation dose and the amount of vaginal tissue treated to high doses.

Role of Chemotherapy

Because primary vaginal carcinomas are rare, few reports have specifically addressed the role of chemotherapy in the treatment of this disease. Chemotherapeutic management is usually based on extrapolations from experience with the treatment of carcinomas of the cervix. For this reason, patients who have metastatic or recurrent vaginal carcinoma that is no longer amenable to local treatment are sometimes treated with cisplatin-based chemotherapy, even though the efficacy of this treatment is not well documented in the literature. Thigpen et al.⁴² noted several responses among 16 patients with vaginal cancers treated with cisplatin (50 mg/m² every 3 weeks).

Because vaginal carcinoma resembles cervical carcinoma in its location, pattern of spread, histologic appearance, relationship to HPV infection, and response to radiotherapy, it may be reasonable to extrapolate from randomized trials demonstrating a benefit from concurrent chemoradiation in patients with locally advanced cervical cancer to justify a similar approach in selected patients with high-risk invasive vaginal cancer.^{43,44} A retrospective analysis of 71 patients treated with or without chemotherapy for vaginal cancer found that chemotherapy delivery concurrent with radiation was independently predictor of survival.⁴⁵

CARCINOMA OF THE VULVA

Epidemiology

Invasive vulvar carcinoma is a rare disease that accounts for about 4% of gynecologic cancers.^{46,47} The American Cancer Society estimated that in the United States in 2014, 4,850 new cases of invasive vulvar cancer will be diagnosed and there will be 1,030 deaths due to vulvar cancer.¹ The median age at diagnosis of patients with invasive vulvar cancer is about 65 to 70 years. In contrast, vulvar intraepithelial neoplasia (VIN) tends to occur in younger women; the median age at diagnosis of women with VIN is 45 to 50 years. The incidence of VIN has more than doubled since the early 1970s.^{46,47} This increase has been particularly marked in

women younger than 55 years. In the past, the incidence of invasive vulvar cancer was thought to be stable; however, recent data suggest that the median age of women presenting with invasive vulvar cancer may be decreasing, probably reflecting an increase in HPV-related vulvar cancers in young women.⁴⁸ This change has also been associated with an increase in the proportion of vulvar cancers involving the periurethral and clitoral region rather than the labia.⁴⁸

Only 30% to 50% of invasive vulvar carcinomas are associated with evidence of HPV infection.^{49,50} However, 80% to 90% of VIN lesions contain HPV-16 or other HPV types. On the basis of these statistics, it has been estimated that HPV vaccination could prevent about half of the vulvar carcinomas in young women and about two-thirds of the VIN lesions.

HPV-positive vulvar cancers are usually basaloid or warty carcinomas with little keratin formation, are often associated with VIN, are frequently multifocal, and tend to occur in younger women (35 to 55 years).^{48,49,51} Patients with HPV-positive tumors are also more likely to have CIN and to have risk factors typically associated with cervical cancer.⁵¹ In contrast, HPV-negative tumors usually occur in older women (55 to 85 years), are often associated with vulvar inflammation or lichen sclerosis (but rarely with VIN), are generally unifocal, and are usually well differentiated with exuberant keratin formation.^{52,53} Although a number of investigators have reported this distinct grouping of patients with vulvar cancer, others have found greater overlap.⁵⁴

Several investigators have reported a high incidence of TP53 mutations in HPV-negative tumors.^{55,56} Lee et al.⁵⁵ found missense mutations of TP53 in 4 of 9 (44%) HPV-negative tumors but in only 1 of 12 (8%) HPV-positive tumors. They postulated that alteration in *p53* activity, either through point mutations or through E6-mediated loss of *p53* function in HPV-infected cells, could be important in the development of vulvar neoplasms.

Natural History and Pattern of Spread

The vulva includes the mons pubis, labia majora, labia minora, clitoris, vestibular bulb, vestibular glands (including Bartholin glands), and vestibule of the vagina. The region between the posterior commissure of the labia and the anus is termed the *gynecologic perineum*. About 70% of vulvar squamous carcinomas involve the labia majora or minora, most frequently the labia majora. Vulvar tumors may extend locally to invade adjacent structures, including the vagina, urethra, and anus; advanced vulvar tumors may invade adjacent pelvic bones.

A rich network of anastomosing lymphatics that frequently cross the midline drains the vulva. Even minimally invasive vulvar tumors may spread to regional lymph nodes (Table 72.3).⁵⁷⁻⁶¹ For most lesions, initial regional metastasis is to the inguinal lymph

Figure 72.2 Inguinal-femoral lymph nodes.

nodes that are superficial to Camper's fascia; tumors may then metastasize secondarily to deeper femoral lymph nodes and to the pelvic lymph nodes (Fig. 72.2). However, some lesions, particularly those involving the clitoris and other medial structures, metastasize directly to medial femoral lymph nodes that lie in the region of the fossa ovalis, a gap in the cribriform fascia.⁶² Theoretically, tumors involving the clitoris can spread directly to the obturator nodes through lymphatics that follow the dorsal vein of the clitoris, although evidence of this route is rarely seen in practice. Despite the extensive anastomosis of lymphatics in the region, metastasis of vulvar carcinoma to contralateral lymph nodes is uncommon in patients with well-lateralized T1 lesions. The lungs are the most common sites of hematogenous metastasis.

Pathology

As classified by the International Society for the Study of Vulvar Disease, nonneoplastic epithelial disorders of the vulva (previously termed *vulvar dystrophies*) include lichen sclerosis, squamous hyperplasia, and other dermatoses.⁶³ About 10% of these lesions have cellular atypia and are termed *vulvar intraepithelial neoplasia*. Histologically, VIN is characterized by disruption of the normal epithelial architecture, varying degrees of cytoplasmic and nuclear maturation, and giant cells with abnormal nuclei.⁴⁹ VIN lesions are assigned a grade from 1 to 3 according to their degree of maturation. The most common VINs contain nuclear atypia throughout the epithelial layers and are frequently associated with HPV.⁴⁹ A second subset of VINs have atypia that is largely confined to the basal layers of the epithelium. These lesions tend to occur in older women and are not usually associated with HPV but are commonly adjacent to areas of lichen sclerosis or hyperplasia. Buscema and Woodruff⁶⁴ estimated that approximately 4% of patients treated for VIN develop a subsequent invasive cancer.

Paget disease of the vulva, a rare intraepithelial lesion located in the epidermis and skin adnexa, accounts for 1% to 5% of vulvar neoplasms. Histologically, vulvar Paget disease is characterized by large, pale, mucopolysaccharide-rich cells that are positive for periodic acid-Schiff. The lesions are usually negative for HPV.⁶⁵ Electron microscopic studies have suggested that Paget cells derive from apocrine cells in the stratum germinativum of the epidermis.⁶⁶ Paget disease usually occurs in postmenopausal women, who

often present with symptoms of vulvar pruritus and discomfort.⁶⁷ Grossly, Paget lesions appear eczematoid or, when extensive, may be raised and velvety with persistent weeping. About 5% to 10% of newly diagnosed Paget lesions are associated with underlying adenocarcinoma arising locally in a vulvar vestibular gland or skin appendage or from a distant site such as the breast or rectum.⁶⁷

The term *microinvasive carcinoma of the vulva* should be used with caution. Stromal invasion by vulvar carcinomas is not measured in a uniform manner, and strict criteria for the diagnosis of microinvasive vulvar cancer have not been defined. VIN is not routinely seen adjacent to invasive vulvar cancer, and the transition from normal tissue to invasive cancer can be abrupt. Elongated rete pegs may extend 6 mm or more from the basement membrane and are sometimes misconstrued as invasive cancer. The International Society of Gynecologic Pathologists recommends that the depth of stromal invasion be measured vertically from the most superficial basement membrane to the deepest extent of tumor. Tumor thickness is defined as the distance between the granular layer of the epidermis and the deepest extent of tumor. Lymph node metastases from tumors <1 mm in depth or thickness are extremely rare (see Table 72.3). For this reason, FIGO now includes in its vulvar carcinoma staging system a stage IA subcategory for tumors that invade no more than 1 mm (Table 72.4).⁶⁸ However, the risk of inguinal lymph node metastasis rises steeply as the depth of invasion exceeds 1 mm.

More than 90% of invasive vulvar cancers are squamous cell carcinomas. Atypical keratinization is the hallmark of invasive vulvar cancer. Most squamous cell carcinomas are well differentiated, but mitoses may be noted. About 5% of vulvar cancers are anaplastic carcinomas, which may consist of large immature cells, spindle sarcomatoid cells, or small cells. Vulvar carcinomas consisting of small cells may resemble small cell anaplastic carcinomas of the lung or Merkel cell tumors, and have demonstrated an aggressive biologic behavior in the few reported cases.⁶⁹

The diagnosis of Bartholin gland carcinoma is based on clinical findings of a tumor arising in the anatomic location of Bartholin glands and on the histologic appearance. Biopsy of a tumor arising from a Bartholin gland usually reveals squamous cell carcinoma, but adenocarcinoma, transitional cell carcinomas (arising from the duct and histologically indistinguishable from transitional cell carcinoma of the bladder), and adenoid cystic carcinomas have also been reported.

TABLE 72.4

International Federation of Gynecology and Obstetrics Staging of Carcinoma of the Vulva (2009)

Stage	Description
I	Tumor confined to the vulva.
IA	Lesions ≤ 2 cm in size, confined to the vulva or perineum and with stromal invasion ≤ 1 mm, ^a no nodal metastasis.
IB	Lesions > 2 cm in size or with stromal invasion > 1 mm, ^a confined to the vulva or perineum, with negative nodes.
II	Tumor of any size with extension to adjacent perineal structures (one-third lower urethra, one-third lower vagina, anus) with negative nodes.
III	Tumor of any size with or without extension to adjacent perineal structures (one-third lower urethra, one-third lower vagina, anus) with positive inguino-femoral lymph nodes.
IIIA	(i) With one lymph node metastasis ≥ 5 mm), or (ii) One or two lymph node metastasis(es) (< 5 mm).
IIIB	(i) With two or more lymph node metastases (≥ 5 mm), or (ii) Three or more lymph node metastases (< 5 mm).
IIIC	With positive nodes with extracapsular spread.
IV	Tumor invades other regional (two-thirds upper urethra, two-thirds upper vagina) or other distant structures.
IVA	Tumor invades any of the following (i) Upper urethral and/or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone, or (ii) Fixed or ulcerated inguino-femoral nodes.
IVB	Any distant metastasis including pelvic lymph nodes.

^aThe depth of invasion is defined as the measurement of the tumor from the epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

Rare cases of primary mammary adenocarcinoma of the vulva have been reported, presumably arising in aberrant mammary tissue occurring along the embryonic milk line.⁷⁰ Other rare carcinomas that may occur in the vulva include basal cell carcinomas,⁷¹ verrucous carcinomas,⁷² and sebaceous carcinomas.⁷³

Malignant melanomas of the vulva account for approximately 2% to 4% of primary vulvar malignancies and 1% to 3% of melanomas arising in women.⁷⁴ Vulvar melanoma occurs most frequently in women older than 60 years of age, but 10% to 20% of vulvar melanomas occur in women younger than 40 years. In a large Swedish series,⁷⁵ 57% of vulvar melanomas were of the mucosal lentiginous type, 22% were nodular, and 16% were superficial spreading or lentiginous. Most investigators have reported a correlation between higher depth of invasion or Breslow thickness and poorer outcome.^{75,76} However, because the vulvar epithelium sometimes lacks a well-developed papillary dermis, which makes it difficult to assign Clark's levels of invasion, a modification of the Clark system is often used to categorize patients with vulvar melanoma.⁷⁷ Other factors that have been associated with a poorer prognosis are ulceration, clinical amelanosis, and older age.⁷⁵

Vulvar sarcomas constitute 1% to 2% of vulvar malignancies and include leiomyosarcomas, rhabdomyosarcomas, angiosarcomas, neurofibrosarcomas, and epithelioid sarcomas. The prognosis appears to depend on three main determinants: lesion size, tumor contour, and mitotic activity. Lesions > 5 cm in diameter with infiltrating margins, extensive necrosis, and more than five mitotic figures per 10 high-power fields are the most likely to recur after surgical resection.^{78,79}

Diagnosis, Clinical Evaluation, and Staging

Patients with VIN may complain of vulvar pruritus, irritation, or a mass, but many are asymptomatic at the time of diagnosis. Patients with invasive vulvar cancer usually complain of a vulvar mass and chronic vulvar pruritus. Advanced lesions may bleed and are often exquisitely tender.

Because VIN can have many manifestations, any new vulvar lesion should be biopsied. Once a diagnosis of high-grade VIN has been established, the entire vulva, cervix, and vagina should be carefully examined because patients often have multifocal or multicentric involvement.⁸⁰ Colposcopic examination may help to define the extent of disease.

Diagnosis of invasive vulvar lesions requires a wedge biopsy of the lesion with surrounding skin and with underlying dermis and connective tissue so that the pathologist can adequately evaluate the depth of stromal invasion. This procedure can usually be performed in the physician's office under local anesthesia. Excisional biopsy is preferred for lesions < 1 cm in diameter.

All patients with invasive disease require a careful physical examination including a detailed pelvic examination, chest radiography, and a biochemical profile. Cystoscopy and proctoscopy should be performed in patients with tumors that are near the urethra or anus, respectively. CT, MRI, and FDG-PET/CT scans can be obtained to evaluate deep inguinal and pelvic lymph nodes and possible local extension of disease to adjacent structures. FDG-PET/CT has relatively poor sensitivity but high specificity in the prediction of lymph node metastases.⁸¹

The correlation between clinical assessment of the inguinal lymph nodes and pathologic findings is poor.⁸² Homesley et al.⁸² reported that 24% of patients with clinically negative nodes had inguinal lymph node metastases and 24% of patients with suspicious but mobile nodes had negative findings at lymphadenectomy. For this reason, in 1988, the FIGO staging system was changed from a clinical staging system to one that incorporates the more accurate information gained from surgical assessment of regional lymph nodes; a subsequent amendment provided a definition of minimally invasive vulvar cancer.⁸³

Studies also suggest that, when corrected for the number of involved lymph nodes, lymph node bilaterality and local factors such as tumor size and early involvement of adjacent structures have little impact on survival.^{84,85} However, extracapsular nodal extension was found to be a powerful prognostic indicator.^{86,87} In 2009, to incorporate these findings and to improve the prognostic accuracy of the FIGO staging system, another major revision was implemented.⁸⁴ In this revision, the role of tumor diameter was diminished; distal urethral, vaginal, and anal involvement were removed as indications for upstaging; and stage III was subdivided to include more detailed information about the number of positive lymph nodes and the presence of extracapsular nodal extension (see Table 72.4).⁶⁸

Prognostic Factors

Our understanding of the importance of various prognostic indicators in vulvar carcinoma has shifted with the increased use of adjuvant radiotherapy and the accumulation of outcome data. In a 1991 retrospective review of 586 patients entered in Gynecologic Oncology Group (GOG) trials between 1977 and 1984, the presence and number of lymph nodes and tumor diameter were the only independent predictors of survival.⁸⁵ Five-year survival rates were 91% for patients with negative inguinal lymph nodes and 75%, 36%, and 24%, respectively, for patients with one or two, three or four, or five or six positive nodes. Using these data, the authors suggested a classification system that categorized patients according to tumor size and number of involved lymph nodes (Table 72.5). Although treatment details were not given, postoperative radiotherapy was not standard in the years of this study, and

TABLE 72.5

Relationship Between International Federation of Gynecology and Obstetrics Risk Groups and Outcome in Patients with Invasive Vulvar Cancer

Risk Group	Surgical Findings	Five-Y Survival Rate (No. of Patients)	
		GOG 36 ⁸⁵	Landrum et al. ⁸⁸
Minimal	Tumor ≤2 cm in diameter and negative lymph nodes	97.9%, n = 154	100%, n = 89
Low	Tumor 2.1–8 cm in diameter and negative lymph nodes or	87.4%, n = 232	97.1%, n = 69
	Tumor ≤2 cm in diameter and one positive lymph node		
Intermediate	Tumor >8 cm in diameter and negative lymph nodes or	74.8%, n = 104	81.8%, n = 11
	Tumor >2 cm in diameter and one positive lymph node or		
	Tumor ≤8 cm in diameter and two unilaterally positive lymph nodes		
High	Tumor >8 cm in diameter and two unilaterally positive lymph nodes	29%, n = 87	100%, n = 6

GOG, International Federation of Gynecology and Obstetrics.

it is likely that most patients did not receive radiotherapy; more recent reviews suggest that modern adjuvant radiotherapy may reduce the influence of tumor size and number of positive nodes on outcome (see Table 72.5).⁶⁸ Nevertheless, the GOG risk classification was a major influence on recent modifications of the FIGO staging system. In addition to the number of lymph nodes, the presence of extracapsular extension has been found to be an important predictor of outcome.^{88,89} However, in a review of patients treated with radiation after lymphadenectomy, Katz et al.⁹⁰ found no correlation between extracapsular extension and inguinal node recurrence if the dose of radiation was ≥56 Gy.

The presence of pelvic lymph node metastases is generally considered to be a predictor of very poor prognosis.⁹¹ However, this impression comes largely from decades-old studies of outcome in patients who had pelvic lymph node dissection without adjuvant radiotherapy. The generalizability of these data to current practice, in which most patients who have nodal involvement receive radiotherapy, is uncertain.

Other factors that have consistently been correlated with lymph node metastasis and outcome include depth of invasion, tumor thickness, and the presence or absence of lymph-vascular space invasion (LVSI).^{82,85,92} More than 75% of patients with LVSI have positive inguinal nodes.⁸² Studies of the relationship between tumor grade and outcome have supported various conclusions, possibly reflecting the inconsistent criteria used to grade vulvar tumors.^{82,89,93} Other factors that have been associated with poorer prognosis include high mitotic rate, aneuploidy, an infiltrative growth pattern, and a basaloid histologic pattern.^{93–95} Several authors have reported that tumors containing HPV DNA have a poorer prognosis than HPV-negative tumors.^{53,96} Some investigators have reported a worse prognosis for patients age 70 years or older, whereas others have found no correlation between prognosis and age.^{82,93}

Studying the relationship between surgical margins and tumor recurrence, Heaps et al.⁹² reported no local failures in 91 patients whose narrowest tumor margin (deep or at the skin surface) was ≥8 mm in the fixed specimen. A total of 10 of 23 patients (43%) with margins of ≤4.8 mm experienced a local recurrence, as did 8 of 13 patients (62%) with margins between 4.8 and 8 mm. The risk of recurrence in patients with narrow margins may be diminished when postoperative radiotherapy is given.⁹⁷

Treatment

During the last 30 years, the treatment of vulvar cancer has evolved away from radical en bloc surgical resection, which was standard before the 1980s, toward a multidisciplinary approach that emphasizes tissue-sparing operations and selective use of radiotherapy

or chemoradiation to optimize local control, survival, and organ function.

High-Grade Vulvar Intraepithelial Neoplasia

After invasive carcinoma has been excluded by a sufficient number of excisional biopsies, the treatment of high-grade VIN (VIN 3) should be as conservative as possible. Focal lesions can be simply excised. Multiple lesions can be excised separately or, if confluent, with a larger single excision. This approach is generally well tolerated and provides material for histologic assessment. When there is more extensive high-grade VIN, the lesions can be vaporized with a CO₂ laser. This method may provide an alternative to more extensive operations but does not yield a specimen for histologic inspection.

Extensive, diffuse VIN 3 may necessitate a wider excision, particularly if the lesion involves the perianal skin. These lesions are sometimes treated with a partial vulvectomy of the superficial skin (“skinning vulvectomy”). Whenever possible, the vulvar skin should be sutured primarily, but a split-thickness skin graft is sometimes needed to close the defect.

VIN 3 often recurs at or near the margins of resection, even when the histopathology analysis demonstrates that the initial lesions were completely resected. Presumably, this phenomenon reflects the multifocal nature of the condition.⁸⁰ VIN 3 can also recur within the donor skin from split-thickness grafts.⁹⁸

Women with HPV-16–positive high-grade VIN showed that vaccination with a mix of long peptides from the HPV-16 viral oncoproteins E6 and E7 induced clinical responses (including sustained complete responses in 47% of patients at 24 months of follow-up) and relief of symptoms.⁹⁹ Complete responses were associated with induction of HPV-16–specific immunity.

Invasive Disease

The optimal treatment of invasive disease requires careful consideration of the potential benefits of various local and regional treatment options to find an overall treatment strategy that will maximize locoregional disease control with as little acute and long-term morbidity as possible.

Treatment of the Vulva. Most small lesions (approximately <4 cm) that do not involve the urethra, anus, or other adjacent structures can be controlled locally with a radical local excision. A wide and deep excision of the lesion is performed, with the incision extended down to the inferior fascia of the urogenital diaphragm. An effort should be made to remove the lesion with a 1-cm margin of normal tissue in all directions unless this would require compromise of the anus or urethra. Small lesions that invade ≤1 mm can

be managed with local resection alone because the risk of regional spread is very small. Patients with more invasive tumors must also have surgical or radiation treatment of the inguinal nodes, as discussed in the next section.

Primary tumors that involve the anus, rectum, rectovaginal septum, or urethra pose a difficult problem because adequate surgical clearance can often be obtained only by sacrificing organ function. Some patients who have tumors that minimally involve the external urethra or anus can undergo initial vulvectomy without sacrifice of major organ function if close margins are accepted near critical structures. Postoperative radiotherapy can then be delivered to prevent local recurrence.¹⁰⁰ Although local recurrences are frequently successfully controlled with additional surgery, Faul et al.¹⁰¹ reported an overall 5-year survival rate of only 40% after the first local recurrence and emphasized the importance of achieving local control. These authors reported a significant reduction in the local failure rate (from 58% to 16%) when tumors that were within 8 mm of the operative margins were treated with radiotherapy after surgery.¹⁰¹ Although some patients with more extensive organ involvement may be cured with ultraradical operations, in some cases with pelvic exenteration, the risks of acute and long-term complications of these procedures are substantial.^{102,103} For this reason, a number of investigators have explored the use of radiotherapy with or without surgery and chemotherapy to spare critical structures in patients with locally advanced disease.

In the 1980s, several investigators^{104–106} reported results of preoperative radiotherapy in small series of patients with locally advanced disease. These reports indicated that modest doses of radiation (45 to 55 Gy) produced dramatic tumor responses in some patients with locally advanced disease, permitting organ-sparing surgery without sacrifice of tumor control. Hacker et al.¹⁰⁶ reported that four of eight patients with T3 or T4 tumors treated preoperatively with 44 to 54 Gy had no residual tumor in the vulvectomy specimen, and that seven of these eight had local control of their disease. More recently, investigators have emphasized the use of concurrent chemoradiation, as discussed later in this section.

Treatment of Regional Disease. Effective treatment of regional disease is the single most important element in the curative management of early vulvar cancer. Although patients with vulvar recurrences may have their disease successfully controlled with additional local treatment, patients who suffer inguinal recurrences are rarely curable.

All patients with primary tumors that invade >1 mm must have their inguinal lymph nodes treated. In the past, this treatment usually included a bilateral radical inguinal-femoral lymphadenectomy, which initially was combined with vulvectomy using a single incision and, more recently, was performed through separate groin incisions. At one time, pelvic lymphadenectomy was also performed in most patients with invasive vulvar cancer. When subsequent studies demonstrated that pelvic node metastases were found only in patients with positive inguinal nodes, use of the procedure was limited to patients found intraoperatively to have inguinal node metastases.

Then, in 1986, Homesley et al.⁹¹ published results of a prospective randomized study that compared pelvic lymphadenectomy with inguinal and pelvic irradiation in patients with inguinal node metastases from carcinoma of the vulva. All patients were initially treated with radical vulvectomy and inguinal-femoral lymphadenectomy. Patient randomization was done intraoperatively after frozen-section evaluation of the inguinal-femoral lymph nodes. This trial was closed prematurely, after 114 eligible patients had been entered, when interim analysis revealed a survival advantage for the radiotherapy arm ($p = 0.03$; Fig. 72.3). The difference was most marked for patients with clinically positive or multiple histologically positive groin nodes. The initial preliminary report was finally updated in 2009,¹⁰⁷ confirming marked reductions in the risks of recurrence and cancer-related death in patients who had radiotherapy. There were 3 inguinal recurrences in the radiation arm versus 13 in the control arm. Although no differences were seen in the number of pelvic recurrences, competing risks and the lack of high-quality tomographic imaging in this early study may have led to underestimates of the risks of pelvic recurrence. In the updated report, the relative risk of disease progression with radiation was 39% (95% confidence interval = 0.17 to 0.88; $p = 0.02$); the relative risk of death was less impressive, with a hazard ratio of 0.61 (95% confidence interval = 0.3 to 1.3; $p = 0.18$), apparently because of a marked difference in the rate of deaths from other causes: 14 in the radiation arm versus 2 in the control arm. With the 1986 publication of this study, most practitioners abandoned routine pelvic lymphadenectomy, and postoperative radiotherapy became standard for most patients with inguinal lymph node metastases.

Although radical inguinal-femoral lymphadenectomy was historically considered the treatment of choice for regional management of invasive vulvar carcinoma, a number of groups have investigated the possibility that regional radiotherapy may be an effective and less morbid way of preventing recurrence in patients with clinically negative groins.^{90,108–110}

Figure 72.3 Survival rates of 114 patients with invasive squamous cell carcinoma of the vulva who were entered on a Gynecologic Oncology Group protocol in which patients with positive groin nodes after radical vulvectomy and bilateral inguinal lymphadenectomies were randomly assigned to undergo pelvic lymph node dissection or postoperative irradiation of the pelvis and inguinal nodes ($p = 0.004$). (From Homesley HD, Bundy BN, Sedlis A, et al. Radiation therapy versus pelvic node resection for carcinoma of the vulva with positive groin nodes. *Obstet Gynecol* 1986;68:733, with permission.)

In 1992, the GOG reported the results of a trial that randomly assigned patients with clinically negative inguinal nodes to receive inguinal lymph node irradiation or inguinal-femoral lymphadenectomy (followed by inguinopelvic irradiation in patients with positive lymph nodes) after resection of the primary tumor.¹¹⁰ The study was closed after entry of only 58 patients, when an interim analysis demonstrated a significantly higher rate of inguinal recurrence and death in the radiotherapy group. The authors concluded that lymphadenectomy was the superior treatment, although the morbidity rate of lymphadenectomy was greater than that of groin irradiation. However, the radiotherapy techniques used in this study have since been criticized. Preirradiation CT scans were not consistently obtained to verify the position and size of inguinal nodes. Patients were treated with anterior appositional fields, the dose was prescribed at a depth of 3 cm, and the use of electrons (usually 12 MeV) was emphasized. This method of treatment can lead to significant underdosage of the inguinal-femoral nodes, which frequently extend to a depth of >5 to 8 cm.¹¹¹

In contrast, retrospective studies have indicated that patients who have negative inguinal nodes (by tomographic imaging) and careful radiotherapy treatment planning rarely experience a regional recurrence after inguinal-pelvic irradiation to 40 to 50 Gy.^{90,108,109} Katz et al.⁹⁰ emphasized the importance of careful technique. They reported three recurrences in 29 patients treated with radiotherapy alone for clinically negative inguinal nodes; two of these recurrences occurred adjacent to radiation fields that had not fully encompassed the lateral inguinal nodes. It appears that, with careful radiotherapy technique, microscopic disease in the inguinal lymph nodes can be readily controlled with radiation alone. Radiation alone appears to be a reasonable treatment to prevent inguinal recurrence, particularly for patients who have clinically and radiographically negative groins but require radiation for locally advanced disease.

Some surgeons have tried to reduce the incidence and severity of surgical complications by reducing the extent of lymph node dissections. In the 1990s, several groups reported the use of a more limited “superficial” inguinal lymphadenectomy for patients with early disease; patients who had positive lymph nodes were referred for radiotherapy. Although many of the complications usually associated with radical lymphadenectomy were avoided, inguinal recurrence rates were higher than expected, ranging from 7% to 16% in patients who had negative dissections.^{90,112} It has been suggested that the procedure used in these studies did not remove medial inguinal-femoral nodes, which may be the primary site of drainage of some vulvar cancers^{113,114}; for this reason, many gynecologic oncologists now recommend removal of at least the superficial and medial inguino-femoral nodes.

During the last decade, a number of investigators have explored the use of intraoperative lymphatic mapping to identify a “sentinel” node that would predict the presence or absence of regional metastases. A number of studies have evaluated the results from sentinel lymph node biopsy followed by regional lymphadenectomy. From the pooled results for 383 patients entered in 10 trials, the authors concluded that the negative predictive value of sentinel node biopsy was 99.3% and the false-negative rate was 2.4%.¹¹⁵ The GROIngen INternational Study on Sentinel nodes in Vulvar cancer (GROINSS)-V¹¹⁶ study assessed the efficacy of sentinel lymph node evaluation alone in patients with invasive vulvar cancers <4 cm in diameter. Of 402 patients registered in this trial, 231 patients with negative sentinel nodes did not undergo lymphadenectomy; at the time of the analysis, groin recurrences had been observed in 9 (3.9%) of these 231 patients, and 7 patients (3.0%) had died. Patients with sentinel lymph node metastasis >2 mm had significantly lower disease-specific survival (69.5% versus 94.4%; $p = 0.001$).¹¹⁷ Robison et al.¹¹⁸ reported long-term follow-up after sentinel lymph node evaluation. With a median follow-up of 58 months, only 3 of 57 patients who were observed after a negative sentinel lymph node developed an inguinal recurrence. A large GOG trial designed to estimate the sensitivity of sentinel lymph node biopsy

in a community-based setting enrolled 452 women who underwent intraoperative lymphatic mapping, sentinel lymph node biopsy, and inguinal femoral lymphadenectomy. Ninety-two percent of patients had at least one sentinel node identified. The sensitivity was 91.7% and the false-negative predictive value (1-negative predictive value) was 3.7%, which was even lower in women whose tumors were <4 cm. These data suggest that sentinel lymph node biopsy is a reasonable alternative to inguinal femoral lymphadenectomy in selected women with squamous cell carcinoma of the vulva.¹¹⁹ On the subsequent observational (GROINSS)-VI study, patients with a positive sentinel nodes received postoperative radiation therapy without undergoing a full lymphadenectomy. The currently enrolling (GROINSS)-VII study uses the same approach for patients with <2 mm of disease in the sentinel node, but patients with >2 mm focus of disease undergo a lymphadenectomy followed by postoperative radiation.

Participants in a 2008 expert panel at an International Sentinel Node Society Meeting concluded that sentinel lymph node biopsy “is a reasonable alternative to complete inguinal lymphadenectomy when [it] is performed by a skilled multidisciplinary team in well-selected patients.”¹¹⁵ They concluded that patients who have tumors that invade >1 mm, no obvious metastatic disease, and a tumor diameter of <4 cm are good candidates for the procedure.

Radiotherapy Technique. Comprehensive regional radiotherapy for vulvar cancer requires adequate coverage of at least the inguino-femoral and distal pelvic lymph nodes. Patients who have extensive inguinal or pelvic disease may require larger fields that encompass the common iliac nodes. If the vulvar cancer has been excised with widely negative margins, some clinicians choose to not treat the primary site. Several techniques have been used to reduce the dose given to the femoral head and neck during treatment of the groin. One approach is to use a combination of photons and electrons; this technique requires careful image-based planning to assure that the treatment is delivering an adequate dose to the superficial and deep inguinal lymph nodes. Alternatively, IMRT can be used to spare soft tissue, bladder, bowel, and other critical structures, but this method is technically challenging and requires a sound understanding of the local and regional anatomy.¹²⁰

Patients who have local risk factors for recurrence but pathologically negative lymph nodes may be treated with local radiation alone using conformal photon fields or, in selected cases, appositional electron beam techniques. Whenever photons are used to treat the vulvar surface, tissue-equivalent materials may need to be applied to ensure that the surface dose is adequate. Thermoluminescent dosimeters can be used to verify that the surface of the vulva is receiving the prescribed dose of radiation.

Chemoradiation in Locoregionally Advanced Disease.

To reduce the need for morbid ultraradical surgery and to improve locoregional control rates, a number of investigators have explored combinations of chemotherapy with radiation and surgery in patients with locally advanced vulvar carcinoma.¹²¹⁻¹²⁸ Most studies have used combinations of cisplatin, 5-FU, and mitomycin-C (Table 72.6), extrapolating from the high response rates observed with such combinations for locally advanced carcinomas of the cervix and head and neck and from studies that have demonstrated the efficacy of these drugs as radiosensitizers in the treatment of carcinomas of the anus. Although studies have usually included small numbers of patients with very advanced local or regional disease, most investigators have observed impressive responses that often appear to be better than would be expected with radiation alone. Randomized trials have not been done and may be difficult to perform because of the small number of patients with locally advanced vulvar cancer. However, results of trials in other types of cancer are encouraging: trials that demonstrated improved local control and survival when concurrent cisplatin-containing chemotherapy was added to radiation treatment of cervical cancers^{129,130} and improved colostomy-free survival when mitomycin-C and

TABLE 72.6

Concurrent Chemoradiotherapy in the Management of Locally Advanced or Recurrent Carcinoma of the Vulva (Series Including 20 or More Patients)

5-FU, 5-fluorouracil; CDDP, cisplatin; Mito, mitomycin-C; NS, not stated.

5-FU were added to radiation treatment of anal cancer¹³¹ suggest that this approach may be also be useful in the treatment of women with vulvar cancer. In a single-arm phase 2 study, the GOG investigated the use of cisplatin with daily radiation therapy to a total dose of 57.6 Gy in locally advanced vulvar cancer.¹³² Overall, 50% of patients achieved a complete pathologic response with this regimen. The current GOG trial will utilize IMRT and deliver gemcitabine in addition to cisplatin.

Several investigators have explored the use of neoadjuvant chemotherapy for locally advanced vulvar cancer.^{133,134} Although partial responses to multiagent chemotherapy have been observed, response rates appear to be lower than for cervical cancers, and survival rates have been discouraging.¹³⁴

Caution is warranted in designing aggressive treatment protocols for patients with vulvar cancers, as these patients typically are elderly and often have concurrent medical problems. Serious pulmonary damage has been observed in a number of patients treated in studies that included bleomycin.¹²⁷ In the largest published series of patients treated with mitomycin-C and 5-FU, hematologic tolerance was acceptable, but the administered dose of mitomycin-C was somewhat lower than that generally used in the treatment of anal cancers.¹²⁸ Although chemotherapy may improve control rates, radiation alone can produce impressive responses and should be considered in patients who are poor surgical candidates and who cannot tolerate chemotherapy.

Complications of Treatment

Most of the serious acute and subacute complications of radical vulvectomy are related to the lymphadenectomy, although these risks have decreased somewhat with the use of separate groin incisions. Acute complications include wound seroma, disruption, or infection in up to 50% to 75% of cases, chronic lymphedema in 20% to 50%, and perioperative death in 2% to 5%.^{109,112,135,136} Other acute complications include urinary tract infection, wound cellulitis, temporary anterior thigh anesthesia from femoral nerve injury, thrombophlebitis, and, rarely, pulmonary embolus.^{91,137} The risk of chronic leg edema decreased from approximately 30% to 15% with the use of separate groin incisions and is rare after sentinel lymph node dissection only.^{116,138} Other chronic complications include genital prolapse, urinary stress incontinence, temporary weakness of the quadriceps muscle, and introital stenosis. These risks are less when radical local excision of the primary lesion is done instead of radical vulvectomy.^{139,140} Patients who undergo vulvectomy without inguinal lymphadenectomy have significantly shorter hospital stays and fewer complications.^{109,112}

The most prominent acute complication of radical radiotherapy for vulvar carcinoma is radiation dermatitis. Moist desquamation is commonly seen in the final weeks of treatment but resolves within 2 to 3 weeks after completion; sitz baths and appropriate use of pain medications are helpful during the acute phase. Skin reactions that occur in the first 2 to 4 weeks of treatment are frequently due to superinfection with *Candida albicans* and should be treated presumptively with antifungal agents. Other acute side effects of radiation include diarrhea, dysuria, and painful defecation. Late complications result from a combination of radiation, surgery, and tissue destruction from locally advanced tumors. Introital or vaginal stenosis, tissue atrophy, and other effects of combined therapy may cause sexual dysfunction. Vulvar edema, tissue atrophy, hyperpigmentation, fibrosis, and telangiectasia may occur and are related to the dose of radiation and the volume of tissue irradiated. Combined effects of treatment may also cause bladder or rectal incontinence, urethral or anal stenosis, ulceration, or fistula.

Treatment of Metastatic Disease

Unfortunately, reports of chemotherapy activity in the treatment of metastatic or recurrent squamous cell carcinoma of the vulva are largely anecdotal. In the absence of reliable data specific to this cancer, clinicians often use single agents and combination regimens that have had some activity in the treatment of cervical cancer. However, there are, as yet, few data to indicate that chemotherapy can provide effective palliation for patients with metastatic or recurrent vulvar carcinomas that are not amenable to locoregional treatments. In terms of molecular-targeted agents, erlotinib has shown promising activity and may represent one of the most active agents for the management of squamous cell carcinoma of the vulva. Specifically, in a phase 2 study, erlotinib exhibited a 67.5% overall clinical benefit rate (i.e., 27.5% partial response and 40.0% stable disease by response evaluation criteria in solid tumors).¹⁴¹

CARCINOMA OF THE CERVIX

Epidemiology

The American Cancer Society estimated that in the United States in 2014, 12,360 new cases of invasive cervical cancer would be diagnosed and there would be 4,020 deaths due to cervical cancer, representing approximately 1.5% of all cancer deaths in women.¹ In the United States and other developed countries, age-adjusted death rates from cervical cancer have declined steadily since the

1930s. However, global cervical cancer incidence increased from 378,000 cases per year in 1980 to 528,000 new cases in 2012; during that period, the annual death rate increased by 7.5% with 266,000 deaths per year in 2012.¹⁴² The decrease in incidence in developed countries is primarily the result of the adoption of routine screening programs; however, the death rates from cervical cancer had begun to decrease before the implementation of Pap screening, suggesting that other, unknown factors may have played some role.¹⁴³

International incidences of cervical cancer tend to reflect differences in cultural attitudes toward sexual practices and differences in the penetration of mass screening programs. The highest incidences tend to occur in populations that have low screening rates combined with a high background prevalence of HPV infection.¹⁴⁴ Rates of invasive cervical cancer are particularly high in Latin America, southern and eastern Africa, India, and Polynesia. In many of these developing countries, cervical cancer is the leading cause of cancer deaths among women. Differences in age-specific incidences between developed and medically underserved countries illustrate the probable impact of mass screening on the development of invasive disease. For example, a comparison between data from Brazil and the United Kingdom showed similar rates of cervical cancer in young women, suggesting similar levels of exposure to HPV, but rapidly diverging rates in older women, probably reflecting differences in the availability of mass screening in the two countries (Fig. 72.4).

Although the overall incidence of cervical cancer is low in the United States, the incidence in black Americans is about 30% higher than the incidence in white Americans, and the incidence in Hispanic women is about twice the incidence in white Americans.¹⁴⁵ Barriers to cervical cancer screening, including lack of insurance, low income, and cultural factors, probably contribute to higher incidences and mortality rates in black and Hispanic women.¹⁴⁶

Molecular and human epidemiologic studies have demonstrated a strong relationship between HPV, CIN, and invasive carcinoma of the cervix. HPV can be identified in >99% of cervical cancers, and infection with HPV is now accepted as a necessary

cause of most cervical cancers.¹⁴⁴ It appears that most of the covariables historically associated with an increased risk of cervical cancer are surrogates for sexually transmitted HPV infection. Women who have coitus at a young age, who have multiple sexual partners, have partners with multiple partners, or who bear children at a young age are at increased risk. A pooled analysis of 26 epidemiologic studies showed a strong inverse association between use of intrauterine devices and cervical cancer, perhaps due to a cellular immune response triggered by the device.¹⁴⁷ Castellsague et al.¹⁴⁸ have reported that circumcised males have a lower incidence of HPV infection than uncircumcised males and a correspondingly lower incidence of cervical cancer in their female partners.

A number of studies suggest that the incidence of cervical adenocarcinoma has been increasing, particularly among women in their 20s and 30s.¹⁴⁹ In a study based on Surveillance, Epidemiology, and End Results program data, Smith et al.¹⁴⁹ found that the age-adjusted incidence of cervical adenocarcinoma in the United States increased by 29.1% during a period (1973–1996) when the overall incidence of cervical cancer decreased by 41.9%. Several investigators have reported a correlation between cervical adenocarcinoma and prolonged oral contraceptive use.¹⁵⁰ However, this relationship may not be causative, given the many potential confounding risk factors and possible changes in diagnostic criteria over time.^{149,151} Another possible explanation for the increase in incidence of cervical adenocarcinoma is that cytologic screening methods may be less effective in detecting preinvasive adenocarcinomas than they are in detecting preinvasive squamous lesions, resulting in a less dramatic reduction in the incidence of invasive adenocarcinomas.

In 1993, the Centers for Disease Control and Prevention added cervical cancer to the list of AIDS-defining neoplasms.¹⁵² However, the relationship between immunosuppression (particularly HIV-related immunosuppression) and the risk of HPV-related disease is complex and incompletely understood.^{153,154} Current data strongly suggest that women infected with HIV have an increased incidence and are more likely to have persistence of cervical HPV infection, even when studies are corrected for confounding risk factors; women infected with HIV also tend to have a faster rate

Figure 72.4 Age-specific incidences of invasive cervical cancer in Brazil and in the United Kingdom (UK). (From Bosch FX, de Sanjose S. Human papillomavirus and cervical cancer—burden and assessment of causality. *J Natl Cancer Inst Monogr* 2003;31:3, with permission.)

of progression to high-grade CIN.^{153,154} Iatrogenic immunosuppression in organ transplant recipients is also associated with an increased prevalence of CIN.¹⁵⁵ Although less definitive, evidence linking HIV infection with invasive cervical cancer has also been increasing.¹⁵⁴ Some investigators¹⁵⁶ have suggested that cervical cancer is a more aggressive disease in immunosuppressed patients, but other studies have failed to reveal an independent linkage.^{153,154} In most cases, antiretroviral therapy does not appear to affect HPV levels, nor does it appear to decrease the risks of high-grade squamous intraepithelial lesions (HSILs) or invasive cancer.¹⁵⁴ Because of the increased risk of HPV infection in women infected with HIV, vigilant surveillance with Pap smears, pelvic examinations, and colposcopy (when indicated) should be part of the routine care of these women.

Human Papillomavirus

HPV is associated with nearly all cases of cervical cancer. Examination of tumor DNA from cervical cancers reveals integration of one the high-risk HPV subtypes, including 16, 18, 31, 33, and 45. The most common subtypes in human cancers are HPV-16 and -18, which are found in 70% of cases. Although cervical cancer is relatively rare in the United States, HPV is highly prevalent in the US population. Vaginal swab testing demonstrated that 26% of US women and 44% of women between 20 and 24 testing positive for HPV.¹⁵⁷ However, in only a small percentage of women does HPV infection lead to the development of premalignant or malignant lesions. This suggests that viral infection is essential, but not sufficient, for the development of high-grade dysplasia or invasive cancers.

In the initial infection, viral DNA remains episomal in the basal cell of the epidermis. Viral DNA integration occurs preferentially into areas of genomic instability, such as fragile sites, and oncogenesis does not appear to require disruption of any critical tumor suppressor genes. Rather, expression of viral genes, E6 and E7, disrupts the function of critical tumor suppressor genes, p53 and pRB, respectively, leading to enhanced cell cycle proliferation, impaired apoptosis, and loss of genome maintenance leading to increased genomic instability.

The strong correlation between high-risk HPV types and cervical carcinoma has led to the development of prophylactic HPV vaccines that have proven highly effective in randomized trials.¹⁵⁸ In response to these studies, the US Food and Drug Administration approved a prophylactic HPV vaccine for women between the ages of 9 and 26 years in 2006. Currently, two vaccines, Gardasil (Merck & Co, White House Station, NJ) and Cervarix (GlaxoSmithKline, Brentford, UK), are available. Both vaccines target HPV subtypes 16 and 18, which account for 70% of cervical cancers. Gardasil also includes antigen from HPV subtypes 6 and 11, which are associated with 90% of cases of benign genital warts. Both of these vaccines deliver viral-like particles composed of the L1 capsid protein that has assembled into the highly immunogenic viral-like particle form. The vaccines are DNA-free and thus carry no risk of infection.

Both vaccines are highly effective at generating a robust and durable immune response, including the production of neutralizing antibodies to the HPV viral capsid protein.¹⁵⁹ The effect appears to be highly durable, lasting at least 5 years and likely significantly longer.¹⁵⁹ The efficacy of these vaccines has been tested in large prospective randomized trials: FUTURE I¹⁶⁰ and FUTURE II^{161,162} for Gardasil, and PATRICIA and the Costa Rica HPV vaccine trial^{160,163} for Cervarix. FUTURE II enrolled 12,167 women between the ages of 15 and 26 years who received three doses of either HPV-6/-11/-16/-18 vaccine or placebo. The study was designed to determine if the vaccine reduced the rate of malignant or premalignancy cervical lesions. In women with no previous infection, the vaccine eliminated 98% of CIN grade 2 or 3, adenocarcinoma in situ, or cervical cancer related to HPV-16 or -18. Among all women, including those with previous infection

with HPV-16 and -18, the vaccine efficacy was significantly lower, just 44%. Other studies have confirmed that the HPV vaccine does not appear to speed clearance of the HPV virus for women who have previous exposure to HPV.¹⁶⁴ As a result, the vaccine is recommended for girls aged 11 to 12 years, with the goal of vaccinating prior to exposure to HPV. Analysis of the Costa Rica HPV vaccine trial has demonstrated that HPV vaccination also prevents oral and anal infection with HPV-16 and -18. Future analysis will determine if this translates to a reduction of HPV-associated oral and anal cancers.

The impact of widespread vaccination programs on HPV infection and HPV-associated disease is now being reported. In Scotland, HPV testing performed prior to and after introduction of the HPV vaccine revealed a reduction in the rate of HPV-16 and -18 positivity on cervical swabs from 29.8% (95% confidence interval = 28.3 to 31.3) to 13.6% (95% confidence interval = 11.7 to 15.8). A reduction in other HPV subtypes, including -31, -33, and -45 was also seen, suggesting cross-protection.

Natural History and Pattern of Spread

Most cervical carcinomas arise at the junction between the primarily columnar epithelium of the endocervix and the squamous epithelium of the ectocervix. This junction is a site of continuous metaplastic change, which is greatest in utero, at puberty, and during first pregnancy, and declines after menopause. Long before the relationship between HPV and cervical cancer was known, Richart and Barron¹⁶⁵ demonstrated that invasive squamous cell cancer of the cervix was the end result of progressive intraepithelial dysplastic changes within metaplastic epithelium of the transformation zone. The greatest risk of neoplastic transformation of virally induced atypical squamous metaplasia coincides with periods of greatest metaplastic activity. The approximately 15-year difference in the mean ages of women with CIN and women with invasive cervical cancer indicates a generally slow progression of CIN to invasive carcinoma.¹⁶⁶

Once tumor has broken through the basement membrane, it may penetrate the cervical stroma directly or through vascular channels. Invasive tumors may develop as exophytic growths protruding from the cervix into the vagina or as endocervical lesions that can cause massive expansion of the cervix despite a relatively normal-appearing ectocervix. From the cervix, tumor may extend superiorly to the lower uterine segment, inferiorly to the vagina, laterally to the broad ligaments (where it may cause ureteral obstruction), or posterolaterally to the uterosacral ligaments. Large tumors may appear fixed on pelvic examination, although true invasion of the pelvic wall musculature is probably uncommon. Although the cervix is separated from the bladder by only a thin layer of fascia and cellular connective tissue, extensive bladder involvement is uncommon, occurring in <5% of cases. Tumor may also extend posteriorly to the rectum, although rectal mucosal involvement is a rare finding at initial presentation.

The cervix has a rich supply of lymphatics that drain the mucosal, muscularis, and serosal layers. The lymphatics of the cervix anastomose extensively with those of the lower uterine segment.¹⁶⁷ The most important lymphatic collecting trunks exit laterally from the uterine isthmus in three groups.¹⁶⁷ The upper branches, which originate in the anterior and lateral cervix, follow the uterine artery, are sometimes interrupted by a node as they cross the ureter, and terminate in the uppermost hypogastric nodes. The middle branches drain to deeper hypogastric (obturator) nodes. The lowest branches follow a posterior course to the inferior and superior gluteal, common iliac, presacral, and subaortic nodes. Additional posterior lymphatic channels arising from the posterior cervical wall may drain to superior rectal nodes or may continue upward in the retrorectal space to the subaortic nodes overlying the sacral promontory. Anterior collecting trunks pass between the cervix and bladder along the superior vesical artery and terminate in the internal iliac nodes.

The incidence of pelvic and para-aortic node involvement is correlated with tumor stage, size, histologic subtype, depth of invasion, and presence of LVSI. Reported rates of regional metastasis, which come primarily from series of patients who underwent lymphadenectomy as part of radical surgical treatment or before radiotherapy, vary widely. For patients with stage I disease treated with radical hysterectomy, most investigators report an incidence of positive pelvic nodes of 15% to 20% and an incidence of positive para-aortic nodes of 1% to 5%. For patients with stage I disease treated with radiation, reported rates of positive para-aortic nodes tend to be higher—usually 10% to 25%—reflecting the fact that stage I tumors selected for treatment with radiation are usually more advanced. Variations in the completeness of lymphadenectomies and histologic processing may lead to underestimates of the true incidence of regional spread from carcinomas of the cervix.¹⁶⁸

Cervical cancer usually follows a relatively orderly pattern of metastatic progression, initially to primary echelon nodes in the pelvis and then to para-aortic nodes and distant sites. Initial presentation with hematogenous metastases is uncommon. FDG-PET scanning is probably the most accurate noninvasive method for the diagnosis of nodal metastasis, with a sensitivity of 82% and specificity of 95% as reported in a 2010 meta-analysis.¹⁶⁹ PET-positive pelvic nodes are frequently identified along the lymphatics that extend from the obturator vessels to the bifurcation of the common iliac vessels. Nodes that lie along the common iliac vessels lie most frequently between the psoas muscle and the common iliac artery and vein.¹⁷⁰ In the para-aortics, the nodes are closely associated with the aorta and are rarely identified to the left of the vena cava. The anatomic distribution of FDG-avid nodal metastasis in the pelvis and para-aortic nodes in a series of patients with cervical cancer demonstrates the areas where lymphatic metastasis are most commonly identified (Fig. 72.5).

The most frequent sites of distant recurrence are lung, left supraclavicular and mediastinal nodes, liver, and bone.

Pathology

Cervical Intraepithelial Neoplasia

Several systems have been developed for classifying premalignant cytologic and histologic cervical findings (Table 72.7). Following

Figure 72.5 Anatomic distribution of positron emission tomography–positive lymph nodes based on a volume probability map. A color gradient corresponding to the visible-light spectrum is used to indicate the frequency of lymph node involvement. *Red*, high frequency; *green*, moderate frequency; *blue*, low frequency. (© 2011 The University of Texas M.D. Anderson Cancer Center.)

a 1988 National Cancer Institute Consensus Conference, the Bethesda system of classification was developed in an effort to further standardize reporting. The Bethesda system divides cytologic specimens into two groups: low-grade squamous intraepithelial lesions (LSIL) and HSILs. LSILs have low-grade dysplasia or changes associated with HPV. They are typically associated with low-risk HPV types and have a low likelihood of progressing to invasive cancers. These are to be distinguished from HSILs, which

TABLE 72.7

Comparison of Cytology Classification Systems for Cervical Neoplasms

Bethesda System	Dysplasia/CIN System		Papanicolaou System
Within normal limits	Normal		Class I
Infection (specify organism)	Inflammatory atypia (organism)		Class II
Reactive and reparative changes	—		—
Squamous cell abnormalities	—		—
Atypical squamous cells of undetermined significance	Squamous atypia		Class IIR
	HPV atypia		
Low-grade squamous intraepithelial lesion			
	Mild dysplasia	CIN 1	
			Class III
—	Moderate dysplasia	CIN 2	
High-grade squamous intraepithelial lesion	Severe dysplasia		
		CIN 3	
	Carcinoma in situ		Class IV
Invasive squamous carcinoma	Invasive squamous carcinoma		Class V

CIN, cervical intraepithelial neoplasia; HPV, human papillomavirus.

have findings of moderate to high-grade dysplasia such as abnormal mitoses, coarse chromatin, and loss of polarity. HSILs are usually associated with high-risk HPV types and have a higher likelihood of progressing to invasive cancer. The Bethesda system was meant to replace the Papanicolaou system and is now widely used in the United States. However, its use is still controversial. Some groups¹⁷¹ argue that the new nomenclature has failed to improve diagnostic accuracy and believe that with dichotomization of the spectrum of atypical lesions, lesions that were formerly classified as CIN 2 (now HSIL) may be overtreated despite their relatively low risk of progression.

The Bethesda system also introduced the term *atypical squamous cells of undetermined significance* (ASC-US). This uncertain diagnosis is now the most common abnormal Pap smear result in United States laboratories,¹⁷² with 1.6% to 9% of Pap smears reported as having ASC-US. Although most cases of ASC-US reflect a benign process, about 5% to 10% are associated with an underlying HSIL and one-third or more of HSILs are heralded by a finding of ASC-US on a Pap smear.¹⁷³ There has been considerable controversy about the evaluation and management of ASC-US, leading the National Cancer Institute to initiate the ASC-US-LSIL Triage Study.¹⁷⁴ This multicenter, randomized trial compared three methods of management—immediate colposcopy, cytological follow-up, and triage by HPV DNA testing—in 5,060 patients who were recruited to the study following a community-based Pap smear report of ASC-US or LSIL. Preliminary analyses of this study¹⁷⁴ demonstrated that in patients with LSIL, the prevalence of high-risk HPV was too high to permit useful triage based on HPV DNA testing, but that in the 3,488 patients with ASC-US, HPV DNA testing had a sensitivity in the detection of HSIL similar to that of immediate colposcopy and reduced the number of referrals for colposcopy by 50%. After exclusion of patients who had a diagnosis of CIN 2 or 3 at initial colposcopy, the cumulative risk of subsequent progression to CIN 2 or 3 was equivalent for women with LSIL (27.6%) or high-risk HPV-positive ASC-US (26.7%).¹⁷⁵

Biopsy specimens that allow evaluation of tissue architecture can be scored as CIN I-III based on the Bethesda system.¹⁷⁶ Although criteria for the diagnosis of CIN and degree of neoplasia vary somewhat between pathologists, the important features of CIN are cellular immaturity, cellular disorganization, nuclear abnormalities, and increased mitotic activity. If mitoses and immature cells are present only in the lower third of the epithelium, the lesion is usually designated CIN 1. Lesions involving only the lower and middle thirds are designated CIN 2, and those involving the upper third are designated CIN 3. The term *cervical intraepithelial neoplasia*, as proposed by Richart,¹⁷⁷ refers only to a lesion that may progress to invasive carcinoma. Although CIN 1 and CIN 2 are sometimes referred to as *mild-to-moderate dysplasia*, the term CIN is now preferred over *dysplasia*.

Adenocarcinoma in Situ

Adenocarcinoma in situ is diagnosed when normal endocervical gland cells are replaced by tall, irregular columnar cells with stratified, hyperchromatic nuclei and increased mitotic activity but the normal branching pattern of the endocervical glands is maintained and there is no obvious stromal invasion. About 20% to 50% of women with cervical adenocarcinoma in situ also have squamous CIN.¹⁷⁸ Because adenocarcinoma in situ is frequently multifocal, cone biopsy margins are unreliable.¹⁷⁹ Although some investigators have described a possible precursor lesion termed *endocervical glandular dysplasia*, the reproducibility and clinical value of this designation are uncertain.¹⁸⁰

Microinvasive Carcinoma

Microinvasive carcinoma is defined by FIGO as “invasive carcinoma which can be diagnosed only by microscopy, with deepest invasion ≤ 5 mm and largest extension ≥ 7 mm” (stage IA in Table 72.8). Thus, this diagnosis can be made only after examination of

TABLE 72.8

International Federation of Gynecology and Obstetrics Staging of Carcinoma of the Cervix (2009)

Stage	Description
I	The carcinoma is strictly confined to the cervix (<i>extension to the corpus should be disregarded</i>).
IA	Invasive carcinoma THAT can be diagnosed only by microscopy, with deepest invasion ≤ 5 mm and largest extension ≥ 7 mm.
IA1	Measured stromal invasion of ≤ 3 mm in depth and extension of ≤ 7 mm.
IA2	Measured stromal invasion >3 mm and not >5 mm in depth with an extension of not >7 mm.
IB	Clinically visible lesions limited to the cervix uteri or preclinical cancers greater than stage IA. ^a
IB1	Clinically visible lesion ≤ 4 cm in greatest dimension.
IB2	Clinically visible lesion >4 cm in greatest dimension.
II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina.
IIA	Without parametrial invasion.
IIA1	Clinically visible lesion ≤ 4 cm in greatest dimension.
IIA2	Clinically visible lesion >4 cm in greatest dimension.
IIB	With obvious parametrial invasion.
III	The tumor extends to the pelvic wall and/or involves the lower third of the vagina and/or causes hydronephrosis or nonfunctioning kidney. ^b
IIIA	Tumor involves lower third of the vagina, with no extension to the pelvic wall.
IIIB	Extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney.
IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy-proven) the mucosa of the bladder or rectum. A bullous edema, as such, does not permit a case to be allotted to stage IV.
IVA	Spread of the growth to adjacent organs.
IVB	Spread to distant organs.

^a All macroscopically visible lesions—even with superficial invasion—are allotted to stage IB carcinomas. Invasion is limited to a measured stromal invasion with a maximal depth of 5 mm and a horizontal extension of not >7 mm. Depth of invasion should not be >5 mm taken from the base of the epithelium of the original tissue—superficial or glandular. The depth of invasion should always be reported in millimeters, even in those cases with “early (minimal) stromal invasion” (~ 1 mm). The involvement of vascular/lymphatic spaces should not change the stage allotment.

^b On rectal examination, there is no cancer-free space between the tumor and the pelvic wall. All cases with hydronephrosis or nonfunctioning kidney are included, unless they are known to be the result of another cause. Data from Pecorelli S, Zigliani L, Odicino F. Revised FIGO staging for carcinoma of the cervix. *Int J Gynaecol Obstet* 2009;105:107.

a specimen that includes the entire neoplastic lesion and cervical transformation zone. This requires a cervical cone biopsy. Following the advent of cytologic screening, the proportion of invasive carcinomas that invade <5 mm increased more than 10-fold to about 20% in the United States.¹⁸¹

The earliest invasion appears as a blurring of the stromoepithelial junction with a protrusion of cells into the stroma. These cells are less well differentiated than the adjacent noninvasive cells and have abundant pink-staining cytoplasm, hyperchromatic nuclei, and prominent nucleoli. They also exhibit a loss of polarity

at the stromoepithelial junction.¹⁸¹ Early microinvasion is usually characterized by a desmoplastic response in adjacent stroma with scalloping or duplication of the neoplastic epithelium or formation of pseudoglands (nests of invasive carcinoma that can mimic crypt involvement). In a study of cone specimens, Reich et al.¹⁸² reported that 12% of microinvasive carcinomas were multifocal. The depth of invasion should be measured with a micrometer from the base of the epithelium to the deepest point of invasion. Lesions that have invaded <3 mm (FIGO stage IA1) are rarely associated with metastases; 5% to 10% of tumors that have invaded 3 to 5 mm (FIGO stage IA2) are associated with positive pelvic lymph nodes.¹⁸³ Until FIGO refined its definition of microinvasive carcinoma (see Table 72.8), most clinicians in the United States used a different definition of microinvasive carcinoma formulated by the Society of Gynecologic Oncologists: cancers that invaded <3 mm with no evidence of LVSI. The importance of LVSI remains somewhat controversial; the risk of metastatic regional disease appears to be exceedingly low for any tumor that invades <3 mm, even in the presence of LVSI.¹⁸¹ Although most clinicians have adopted the FIGO definitions, many think that the risk of regional spread from tumors that have invaded 3 to 5 mm is sufficiently high to warrant evaluation or treatment of the parametria and regional nodes.

For adenocarcinoma, in particular, measuring the depth of invasion can be difficult. Because invasive adenocarcinomas may originate anywhere along the profile of architecturally complex glands that course through the cervical stroma, no reproducible method has been found for measuring the depth of invasion of these tumors. Some authors have measured the extent of invasion from the basement membrane or from the nearest abnormal glandular epithelium; others have defined early adenocarcinoma according to the volume of tumor (in cubic millimeters).¹⁸⁰ Despite these differences in measurement method, it is apparent that a subset of patients with very small adenocarcinomas have a low likelihood of lymph node metastasis or recurrence.¹⁸⁰

Invasive Squamous Cell Carcinoma

Between 80% and 90% of cervical carcinomas are squamous cell carcinomas. Although squamous neoplasms are often subclassified as large cell keratinizing, large cell nonkeratinizing, or small cell carcinomas, these designations do not correlate well with prognosis.¹⁸⁴ Small cell squamous carcinomas have small- to medium-sized nuclei, open chromatin, small or large nucleoli, and abundant cytoplasm, and are believed by most authorities to have a somewhat poorer prognosis than large cell neoplasms with or without keratin. However, small cell squamous carcinomas should not be confused with the much more aggressive anaplastic small cell neuroendocrine carcinomas discussed later. Papillary variants of squamous carcinoma may be well differentiated (occasionally confused with immature condylomata) or very poorly differentiated (resembling high-grade transitional carcinoma).¹⁸¹ Verrucous carcinoma is a very rare warty-appearing variant of squamous carcinoma that may be difficult to differentiate from benign condyloma without multiple biopsies or hysterectomy.¹⁸⁵ Sarcomatoid squamous carcinoma is another very rare variant, demonstrating areas of spindle-cell carcinomatous tumor confluent with poorly differentiated squamous cell carcinoma; immunohistochemistry demonstrates expression of cytokeratin as well as vimentin. The natural history of this uncommon tumor is not well understood.¹⁸⁶

Adenocarcinoma

Invasive adenocarcinoma may be pure or mixed with squamous cell carcinoma (adenosquamous carcinoma). About 80% of cervical adenocarcinomas are endocervical-type adenocarcinomas, which are composed predominantly of cells with eosinophilic cytoplasm, brisk mitotic activity, and frequent apoptotic bodies, although many other patterns and cell types have also been observed. Endocervical-type adenocarcinomas are frequently

referred to as *mucinous*; however, although some have abundant intracytoplasmic mucin, most have little or none.¹⁸⁷

Minimal-deviation adenocarcinoma (adenoma malignum) is a rare, extremely well-differentiated adenocarcinoma that is sometimes associated with Peutz-Jeghers syndrome.¹⁸⁸ Because the branching glandular pattern strongly resembles normal endocervical glands and the mucin-rich cells can be deceptively benign-appearing, minimal-deviation adenocarcinoma may not be recognized as malignant in small biopsy specimens.¹⁸⁷ Earlier studies reported a poor outcome for women with this tumor, but more recently, patients have been reported to have a favorable prognosis if the disease is detected early.¹⁸⁸

Glassy cell carcinoma¹⁸⁷ is a variant of poorly differentiated adenosquamous carcinoma characterized by cells with abundant eosinophilic, granular, ground-glass cytoplasm with large round to oval nuclei and prominent nucleoli. Adenoid basal carcinoma is a well-differentiated tumor that histologically resembles basal cell carcinoma of the skin and tends to have a favorable prognosis.¹⁸⁹ Adenoid cystic carcinoma consists of basaloid cells in a cribriform or cylindromatous pattern; metastases are frequent, although the natural history of these tumors may be long.¹⁸⁹ Rarely, primary carcinomas of the cervix are composed of endometrioid, serous, or clear cells; mixtures of these cell types may be seen, and histologically, some of these tumors are indistinguishable from those arising elsewhere in the endometrium or ovary. In a study of 17 cases, Zhou et al.¹⁹⁰ found that serous carcinomas of the cervix have an aggressive course, similar to that of high-grade serous tumors originating in the other Müllerian sites.

Anaplastic Small Cell/Neuroendocrine Carcinoma

Anaplastic small cell carcinomas resemble oat cell carcinomas of the lung and are made up of small tumor cells that have scanty cytoplasm, small round to oval nuclei, and high mitotic activity; they frequently display neuroendocrine features.¹⁹¹ Anaplastic small cell carcinomas behave more aggressively than poorly differentiated small cell squamous carcinomas; most investigators report survival rates of <50% even for patients with early stage I disease, although recent studies of aggressive multimodality treatments have been somewhat more encouraging.¹⁹²⁻¹⁹⁵ Widespread hematogenous metastases are frequent, but brain metastases are rare unless preceded by pulmonary involvement.¹⁹⁵

Other Rare Neoplasms

A variety of neoplasms may infiltrate the cervix from adjacent sites, and this makes differential diagnosis difficult. In particular, it may be difficult or impossible to determine the origin of adenocarcinomas involving the endocervix and uterine isthmus. Although endometrioid histology suggests endometrial origin and mucinous tumors in young patients are most often of endocervical origin, both histologic types can arise in either site.¹⁹⁶ Metastatic tumors from the colon, breast, or other sites may involve the cervix secondarily. Malignant mixed Müllerian tumors, adenosarcomas, and leiomyosarcomas occasionally arise in the cervix but more often involve it secondarily. Primary lymphomas and melanomas of the cervix are extremely rare. Despite the different prognostic implications of the histologic subtypes of cervical cancer, the treatment approach generally remains the same.

Clinical Manifestations

Preinvasive disease is usually detected during routine cervical cytologic screening. Early invasive disease may not be associated with any symptoms and is also usually detected during screening examinations. The earliest symptom of invasive cervical cancer is usually abnormal vaginal bleeding, often following coitus or vaginal douching. This may be associated with a clear or foul-smelling vaginal discharge. Pelvic pain may result from locoregionally invasive

disease or from coexistent pelvic inflammatory disease. Flank pain may be a symptom of hydronephrosis, which may be complicated by pyelonephritis. Patients with very advanced tumors may have hematuria or incontinence from a vesicovaginal fistula caused by direct extension of tumor to the bladder. External compression of the rectum by a massive primary tumor may cause constipation, but the rectal mucosa is rarely involved at initial diagnosis.

Diagnosis, Clinical Evaluation, and Staging

Diagnosis

The long preinvasive stage of cervical cancer, the relatively high prevalence of the disease in unscreened populations, and the sensitivity of cytologic screening make cervical carcinoma an ideal target for cancer screening. In the United States, screening with cervical cytologic examination and pelvic examination has led to a decrease of >50% in the incidence of cervical cancer since 1975.¹⁹⁷ Only nations with well-developed screening programs have experienced substantial decreases in cervical cancer incidence.

The American Cancer Society, in conjunction with multidisciplinary working groups, recently updated the guidelines for cervical cancer screening.^{198,199} The guidelines are as follows: screening is recommended to begin at age 21 years; screening should be avoided before this age because screening at younger ages may lead to unnecessary and harmful evaluation and treatment in women at very low risk of cancer. Between ages 21 and 29, Pap tests are recommended every 3 years. Between ages 30 and 65, both Pap test and HPV testing is recommended every 5 years. A single negative test for HPV is sufficient to reassure against cervical cancer over 5 years, so women aged 30 years and older who are negative for HPV testing have normal cytology can now safely extend the screening interval.^{200,201} Women with a normal Pap test result who test positive for oncogenic HPV should be rescreened annually. The 5-year screening interval may be also recommended for women infected with HIV who are cytologically normal and are oncogenic HPV-negative based on a recent study showing that the 5-year cumulative incidence of HSIL and CIN-2 is similar in women infected with HIV and women not infected with HIV who are cytologically normal and oncogenic HPV-negative.²⁰² Women who have had a total hysterectomy for benign conditions and who have no history of high-grade CIN may discontinue routine screening. It is also reasonable to discontinue screening for women older than 65 to 70 years who have three or more consecutive negative studies and have had no abnormal test results in the past 10 years. Women previously treated for high-grade CIN or for cancer should continue to have annual screening for at least 20 years and periodic screening indefinitely. Annual gynecologic examination might still be appropriate even if cytologic screening is not performed.¹⁹⁷

Accurate calculation of false-negative rates for the Pap test is difficult; estimates range from <5% to $\geq 20\%$. The sensitivity of individual tests may be improved by ensuring adequate sampling of the squamocolumnar junction and the endocervical canal; smears without endocervical or metaplastic cells are inadequate, and in such cases the test must be repeated. The sensitivity of a screening program is increased by repeated testing; studies of the test frequency required to optimize the sensitivity of screening formed the basis of the American College of Obstetrics and Gynecology recommendations.

Most US gynecologists currently prefer newer liquid-based screening methods to conventional Pap tests. A meta-analysis of available data concluded that "liquid-based cervical cytology is neither more sensitive nor more specific for detection of high-grade CIN compared with the conventional Pap,"²⁰³ but liquid based tests are more widely used based on the ability to perform HPV typing on fluid remaining after cytologic examination. HPV testing of ASC-US smears followed by colposcopy in patients with HPV-positive lesions has been shown to be a highly accurate and cost-effective means of detecting HSIL in cases of equivocal

smears and may also be used to triage postmenopausal women with LSIL.^{203,204}

Patients with abnormal findings on cytologic examination who do not have a gross cervical lesion must be evaluated with colposcopy and directed biopsies. Following application of a 3% acetic-acid solution, the cervix is examined under 10- to 15-fold magnification with a bright, filtered light that enhances the acetowhitening and vascular patterns characteristic of dysplasia or carcinoma. The skilled colposcopist can accurately distinguish between low- and high-grade dysplasia,²⁰⁵ but microinvasive disease cannot consistently be distinguished from intraepithelial lesions on colposcopy.²⁰⁶

In patients with a high-grade Pap smear finding, if no abnormalities are found on colposcopic examination or if the entire squamocolumnar junction cannot be visualized, an additional endocervical sample should be collected. Although some authorities advocate the routine addition of endocervical curettage to colposcopic examination, it is probably reasonable to omit this step in previously untreated women if the entire squamocolumnar junction is visible with a complete ring of unaltered columnar epithelium in the lower canal.²⁰⁷ The rate of detection of endocervical lesions may be higher when specimens are collected using a cytobrush rather than by curettage.²⁰⁸

Cervical cone biopsy is used to diagnose occult endocervical lesions and is an essential step in the diagnosis and management of microinvasive carcinoma of the cervix. Cervical cone biopsy yields an accurate diagnosis and decreases the incidence of inappropriate therapy when (1) the squamocolumnar junction is poorly visualized on colposcopy and a high-grade lesion is suspected, (2) high-grade dysplastic epithelium extends into the endocervical canal, (3) the cytologic findings suggest high-grade dysplasia or carcinoma in situ, (4) a microinvasive carcinoma is found on directed biopsy, (5) the endocervical curettage specimens show high-grade CIN, or (6) the cytologic findings are suggestive of adenocarcinoma in situ.²⁰⁹

Clinical Evaluation of Patients with Invasive Carcinoma

All patients with invasive cervical cancer should be evaluated with a detailed history and physical examination, with particular attention paid to inspection and palpation of the pelvic organs with bimanual and rectovaginal examinations. Standard laboratory studies should include a complete blood cell count and renal function and liver function tests. All patients should have chest radiography to rule out lung metastases. Additional imaging of the abdomen and pelvis should be performed for all patients who have stage IB2 or greater disease and is generally recommended for patients with stage IBI disease. MRI can be used to evaluate the size and extent of the cervical mass as well as suggest invasion into the parametria, bladder, or rectum. Cystoscopy and proctoscopy should be considered in patients with bulky tumors and patients with imaging findings suggestive of organ involvement.

Many clinicians obtain CT or MRI scans to evaluate regional lymph nodes, but these studies have suboptimal accuracy because they fail to detect small metastases and because patients with bulky necrotic tumors often have enlarged reactive lymph nodes that may be free of metastasis.^{210,211} In a large GOG study that compared the results of radiographic studies with subsequent histologic findings, Heller et al.²¹¹ found that the sensitivity of CT in the detection of positive para-aortic nodes was only 34%. PET appears to be a more sensitive, specific, and noninvasive method of evaluating the regional nodes of patients with cervical cancer.^{169,212}

Clinical Staging

The FIGO staging system is the most widely accepted staging system for carcinomas of the cervix.^{213,214} The latest (2009) update of this system is summarized in Table 72.8.²¹³ (Since the earliest versions of the cervical cancer staging system, there have been numerous changes: the designation of preinvasive disease as a

separate category [1950], designation and changes in the definition of microinvasive disease [1962, 1985, and 1994], and subdivisions of the stage I and II categories according to tumor or cervical diameter [1994 and 2009]). Although these changes have gradually improved the discriminatory value of the staging system, the many fluctuations in the definitions of stages IA and IB have complicated efforts to compare the outcomes of patients whose tumors were staged and treated during different periods.²¹⁵

FIGO stage is based primarily on careful clinical examination. The use of diagnostic imaging techniques to assess tumor size and local extent is encouraged but not mandatory in the 2009 staging system. However, FIGO still does not incorporate evidence of lymph node metastasis gained by surgical staging or advanced imaging studies in the 2009 staging system. Some form of imaging must be performed to evaluate the presence or absence of hydronephrosis, but intravenous pyelography is no longer required. Cystoscopy, sigmoidoscopy, and examination under anesthesia are also optional. However, suspected bladder or rectal involvement must be confirmed by biopsy. Stage should be assigned before any definitive therapy is administered. The clinical stage should never be changed on the basis of subsequent findings. When the stage to which a particular case should be allotted is in doubt, the case should be assigned to the earlier stage.

Although surgically treated patients are sometimes classified according to a TNM pathologic staging system, this practice has not been widely accepted because it cannot be applied to patients who are treated with primary radiotherapy.²¹⁶

Surgical Evaluation of Regional Spread

Lymphadenectomy is performed as part of the surgical treatment of most patients with early carcinomas of the cervix. Early studies of diagnostic preradiotherapy lymph node staging were discouraging because of the high complication rates observed when transperitoneal lymph node dissections were combined with large radiation fields. In 1989, Weiser et al.²¹⁷ reported that the proportion of patients with postradiotherapy bowel complications was reduced to <5% if lymphadenectomy was performed using a retroperitoneal approach. Today, laparoscopic methods are often used to reduce the perioperative morbidity and hospitalization times associated with surgical staging.^{218–220} The rate of late complications from radiotherapy following laparoscopic lymphadenectomy is probably less than with transperitoneal surgery but has not yet been fully evaluated. The use of sentinel lymph node evaluation is expanding in cervical cancer, with high rates of detection of positive nodes in most studies reported.^{221,222} In the prospective SENTICOL study, the sensitivity and negative predictive values of sentinel node biopsy in early cervical cancer were 92% and 98.2%, respectively.²²³ In patients where sentinel lymph nodes were identified bilaterally, sensitivity and negative predictive value were 100%.

Pelvic lymphadenectomy is indicated for patients undergoing radical hysterectomy but is controversial in other settings. The detection of microscopic para-aortic or common iliac node involvement may identify patients who will benefit from extended-field irradiation, but lymphadenectomy can also add to the morbidity of treatment. Because patients with radiographically positive pelvic nodes are at greatest risk for occult metastasis to para-aortic nodes, these patients may have the greatest chance of benefiting from surgical staging. An ongoing randomized study, LiLACs, will compare retroperitoneal node dissection with PET staging of para-aortic nodes in patients with IB2-IVA cervical cancer undergoing definitive chemoradiation.²²⁴ Some investigators advocate for resection of large pelvic nodes before radiotherapy to improve the rate of pelvic disease control.^{225,226}

Prognostic Factors

Prognosis is strongly influenced by a number of tumor characteristics that are not included in the staging system. Although FIGO

now subdivides the stage IB and IIA categories according to size greater or less than 4 cm (see Table 72.8), specific information about clinical tumor diameter remains an important prognostic indicator even within these stage categories (Fig. 72.6).²²⁷ Although FIGO stage is correlated with outcome, assessment by clinical examination tends to be inaccurate, and operative findings often do not agree with clinical estimates of parametrial or pelvic wall involvement. Furthermore, some authors have found that the predictive power of stage diminishes or is lost when comparisons are corrected for differences in clinical tumor diameter.²²⁷

Lymph node metastasis is one of the most important predictors of prognosis. Survival rates for patients treated with radical hysterectomy with or without postoperative radiotherapy for stage IB disease were usually reported as 85% to 95% for patients with negative nodes and 45% to 55% for those with lymph node metastases.^{228,229} Survival has also been correlated with the size of the largest lymph node and with the number of involved pelvic lymph nodes.^{229–231} Survival rates for patients with positive para-aortic nodes treated with extended-field radiotherapy range from 10% to 50% depending on the extent of pelvic disease and para-aortic lymph node involvement.

For patients treated with radical hysterectomy, other histologic parameters that have been associated with a poor prognosis are LVSI, deep stromal invasion (≥ 10 mm or $>70\%$ invasion), and parametrial extension.^{231–236} Roman et al.²³⁴ reported a correlation between the percentage of histopathologic sections containing LVSI and the incidence of lymph node metastases. Uterine-body involvement has been associated with an increased rate of distant metastases.²³⁷ A strong inflammatory response in the cervical stroma tends to predict a good outcome.²³⁸

Although some investigators have reported no difference in outcome between patients with squamous carcinomas and those with adenocarcinomas of the cervix, most investigators have concluded that adenocarcinomas confer a poorer prognosis.^{239–249} The evidence for a poorer prognosis is particularly strong for patients whose tumors are stage IB2 or greater. In a multivariate analysis of 1,767 patients treated with radiation for stage IB disease, Eifel et al.²⁴² found that the relative risk of death from cancer for 106 patients with adenocarcinomas ≥ 4 cm in diameter was 1.9 times that for patients with squamous tumors of the same size ($p < 0.01$). Pelvic disease control rates were not correlated with histology, but the incidence of distant metastases was significantly higher in patients with adenocarcinomas. For patients with adenocarcinoma of the cervix, outcome appears to be correlated with the degree of tumor differentiation.^{240,241,244} In a population-based analysis of 24,562 patients from the Surveillance, Epidemiology, and End Results database, women with adenocarcinomas were younger, more often white, more frequently married, and more likely to present with early stage disease than patients with squamous cell tumors. Furthermore, adenocarcinomas were associated with worse survival than squamous cell carcinomas in both early (IB1-IIA) and advanced-stage (IIB-IVA) disease (39% and 21% higher risk of death for early and advanced-stage carcinomas, respectively).²⁵⁰

In patients with squamous carcinomas, the serum concentration of squamous cell carcinoma antigen appears to correlate with stage and tumor size, the presence of lymph node metastases, and the presence of recurrent disease; however, the value of this antigen as an independent predictor of prognosis and the cost-effectiveness of measurement of this antigen as a screening modality have been disputed.^{251,252}

Many studies have demonstrated a relationship between hemoglobin level and prognosis in patients with locally advanced cervical cancer, although the independent influence of hemoglobin on outcome can be difficult to estimate because of numerous confounding prognostic factors.²⁵³ The strongest evidence that anemia plays a causative role in pelvic recurrence comes from a small 1978 randomized study conducted at the Princess Margaret Hospital; in that study, anemic patients who were transfused to a hemoglobin

Figure 72.6 Disease-specific survival (DSS) and pelvic disease control (PDC) rates for 4,490 patients with stage I or II carcinomas of the cervix divided according to clinical tumor diameter and International Federation of Gynecology and Obstetrics (1988) stage. (From Eifel PJ, Jhingran A, Levenback CF, et al. Predictive value of a proposed subclassification of stages I and II cervical cancer based on clinical tumor diameter. *Int J Gynecol Cancer* 2009;19:2, with permission.)

level of at least 12.5 g/dl had a lower rate of locoregional recurrence than those who were maintained at a hemoglobin level of at least 10 g/dl.²⁵⁴ Studies aimed at overcoming the theoretical radiobiologic consequences of intratumoral hypoxia with hypoxic cell sensitizers,^{255,256} hyperbaric oxygen breathing,²⁵⁷ or neutron therapy²⁵⁸ have not been successful. Several investigators have correlated low intratumoral oxygen tension levels with a high rate of regional and distant metastasis and poor survival.^{259,260} A recent GOG study designed to test the value of erythropoietin-induced hemoglobin elevation was closed early because of erythropoietin-related thrombotic events; however, overall survival rates of 74% and 60%, respectively, for patients receiving chemoradiation alone or with erythropoietin were not encouraging.²⁶¹

Other clinical and biologic features have been reported to correlate with outcome but none of these have been incorporated into routine clinical practice.²⁶² Clinical and pathologic factors investigated include patient age,^{229,263} peritoneal cytology,²⁶⁴ and platelet count.²⁶⁵ Molecular markers such as tumor vascularity, cyclooxygenase-2 expression,²⁶⁶ galectin expression²⁶⁷ (and other growth factor receptors) have been reported to correlate with outcome.^{268,269} Several investigators have found the presence of HPV DNA in histologically cancer-free lymph nodes to be correlated with poor outcome.^{270,271} Tumor PIK3CA mutation status has also been identified as a prognostic factor in cervical cancer.²⁷² Specifically, 23% of cervical cancers harbor exon 9 or exon 20 PIK3CA mutations; of these 84% are squamous cell carcinomas. PIK3CA mutation status is strongly associated with poor overall survival in patients with stage IB/II cervical cancer, but not stage III/IVA patients.

Functional imaging approaches, such as FDG-PET, may also be used to refine prognosis. Kidd et al.²⁷³ developed a pretreatment FDG-PET-based prognostic nomogram that identified extent of lymph node metastases, tumor volume, and primary tumor maximum standardized uptake value as three significant independent prognostic variables.²⁷⁴

Treatment

A number of factors may influence the choice of local treatment for cervical cancer, including tumor size, stage, histologic features, evidence of lymph node metastasis, risk factors for complications of surgery or radiotherapy, and patient preference. However, as a rule, HSILs are managed with a loop electroexcision procedure (LEEP); microinvasive cancers invading <3 mm (stage IA1) are managed with conservative surgery (excisional conization or extrafascial hysterectomy); early invasive cancers (stage IA2 and IB1 and some small stage IIA tumors) are managed with radical or modified radical hysterectomy, radical trachelectomy (if fertility preservation is desired), or radiotherapy; and locally advanced cancers (stages IB2 through IVA) are managed with combined chemotherapy and radiotherapy. Selected patients with centrally recurrent disease after maximum radiotherapy may be treated with radical exenterative surgery; isolated pelvic recurrence after hysterectomy is treated with irradiation.

Preinvasive Disease

LEEP is the preferred treatment for HSIL.²⁷⁴ With this technique, a charged electrode is used to excise the entire transformation zone and distal canal. Although control rates are similar to those achieved with cryotherapy or laser ablation, LEEP is more easily learned, is less expensive than laser ablation, and preserves the excised lesion and transformation zone for histologic evaluation.^{274,275} LEEP is an outpatient procedure that preserves fertility. LEEP conization or excisional conization with a scalpel should be performed when microinvasive or invasive cancer is suspected and in patients with adenocarcinoma in situ. Although recurrence rates are low (1% to 5%) and progression to invasion rare (<1% in most series), patients treated with LEEP require careful post-LEEP surveillance.

Treatment with total hysterectomy currently is reserved for women who have other gynecologic conditions that justify the

procedure; invasive cancer still must be excluded before surgery to rule out the need for a more extensive operative procedure.

Microinvasive Carcinoma (Stage IA)

The standard treatment for patients with stage IA1 disease is cervical conization or total (type I) hysterectomy. Because the risk of pelvic lymph node metastases from these minimally invasive tumors is <1%,^{232,276} pelvic lymphadenectomy is not usually recommended.

Patients who have FIGO stage IA1 disease without LVSI and who wish to maintain fertility may be adequately treated with a therapeutic cervical conization if the margins of the cone are negative. Although reports suggest that recurrences are infrequent,^{277,278} patients who have this conservative treatment must be followed very closely with periodic cytologic evaluation, colposcopy, and endocervical curettage.

The likelihood of residual invasive disease after cone biopsy is correlated with the status of the internal cone margin and the results of an endocervical curettage performed after cone biopsy.^{279,280} Roman et al.²⁸¹ reported the surgical findings in 87 patients who underwent a conization that showed microinvasive squamous carcinoma, followed by either a repeat conization or hysterectomy. Residual invasive disease was present in only 4% of patients whose cone margins were free of CIN and who had no disease detected on endocervical curettage. However, residual invasive disease was present in 13% of women who had either CIN in cone margins or positive endocervical curettage findings, and 33% of women who had both of these features ($p < 0.015$), suggesting the need for a second procedure in any patient who has one of these findings. The authors did not find any correlation between the depth of invasion or the number of invasive foci and residual invasive disease.

Therapeutic conization for microinvasive disease is usually performed with a scalpel while the patient is under general or spinal anesthesia. Because an accurate assessment of the maximum depth of invasion is critical, the entire specimen must be sectioned

and carefully handled to maintain its original orientation for microscopic assessment. Complications occur in 2% to 12% of patients, are related to the depth of the cone, and include hemorrhage, sepsis, infertility, stenosis, and cervical incompetence.²⁸¹ The width and depth of the cone should be tailored to produce the least amount of injury while providing clear surgical margins.

For patients whose tumors invade 3 to 5 mm into the stroma (FIGO stage IA2), the risk of nodal metastases is approximately 5%.^{183,233,276} Therefore, in such patients, bilateral pelvic lymphadenectomy should be performed in conjunction with modified radical (type II) hysterectomy. Modified radical hysterectomy is a less extensive procedure than classic radical (type III) hysterectomy (Fig. 72.7). The uterus, cervix, upper vagina, and paracervical tissues are removed after careful dissection of the ureters to the point of their entry to the bladder. The medial halves of the cardinal ligament and the uterosacral ligaments are also removed. With this treatment, significant urinary tract complications are rare, and cure rates exceed 95%.¹³⁹

The potential for fertility-conserving surgery is being investigated for patients with low-risk features and stage IA2-IB1 tumors.²⁸² A radical trachelectomy removes the cervix and parametrial tissues while retaining the uterine corpus. Outcomes appear to be similar for patients treated with radical hysterectomy or radical trachelectomy,²⁸³ and successful pregnancies are reported in a significant percentage of patients after radical trachelectomy. However, it is not clear that removal of the parametria tissue is needed for all patients with low-risk stage IA2-IB1 tumors, as few patients with low-risk early stage cervical cancers have extension to the parametria and many have no residual tumor in the trachelectomy specimen. This has led to the question of whether more conservative surgery, such as simple trachelectomy or cone with or without a nodal assessment, could be performed. An ongoing international study, ConCerv, is currently testing the safety and feasibility of conservative surgery in patients with low-risk features.²⁸² Eligible patients have stage IA2 or IB1 disease, tumor size of ≤ 2 cm, and squamous cell carcinoma (any grade) or adenocarcinoma (grades

Figure 72.7 The pelvic ligaments and spaces. Dotted lines indicate the tissues removed with a modified radical (type II) or radical (type III) hysterectomy. (From Berek JS, Hacker NF. *Practical Gynecologic Oncology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2005, with permission.)

1 or 2) and no evidence of LVSI. Patients who wish to conserve fertility receive cervical cone with lymph node dissection and lymphatic mapping while patients who do not wish to conserve fertility undergo a simple hysterectomy with nodal assessment.

Although surgical treatment is standard for in situ and microinvasive cancer, patients with severe medical problems or other contraindications to surgical treatment can be successfully treated with radiotherapy. Depending on the depth of invasion, these early lesions are treated with brachytherapy alone or brachytherapy combined with external beam irradiation, and cure rates exceed 95%.^{284,285}

Stage IB and IIA Disease

Early stage IB cervical carcinomas can be treated effectively with combined external beam irradiation and brachytherapy or with radical hysterectomy and bilateral pelvic lymphadenectomy. The goal of both treatments is to destroy malignant cells in the cervix, paracervical tissues, and regional lymph nodes. Patients who are treated with radical hysterectomy whose tumors are found to have high-risk disease features may benefit from postoperative radiotherapy or chemoradiation.^{286,287}

Disease-specific survival rates for patients with stage IB cervical cancer treated with surgery or radiation usually range between 80% and 90%, suggesting that the two treatments are equally effective.²⁸⁸⁻²⁹¹ However, biases introduced by patient selection, variations in the definition of stage IA disease, and variable indications for postoperative radiotherapy, concurrent chemotherapy, or adjuvant hysterectomy confound comparisons of efficacy between radiotherapy and surgery. Because young women with small, clinically node-negative tumors tend to be favored candidates for surgery and because tumor diameter and nodal status are inconsistently described in published series, it is difficult to compare the results reported for patients treated with surgery and those treated with radiotherapy.

In 1997, Landoni et al.²⁹² reported results from the only prospective trial comparing radical surgery with radiotherapy alone for cervical cancer. In their study, 343 patients with stage IB or IIA disease were randomly assigned to treatment with radical (type III) hysterectomy or a combination of external beam and LDR intracavitary brachytherapy. In the surgery arm, findings of parametrial involvement, positive margins, deep stromal invasion, or positive nodes led to the use of postoperative pelvic irradiation in 54% of patients with tumors ≤ 4 cm in diameter and in 84% of patients with larger tumors. Patients in the radiotherapy arm received a relatively low median dose to point A of 76 Gy. With a median follow-up of 87 months, the 5-year actuarial disease-free survival rates for patients in the surgery and radiotherapy groups were 80% and 82%, respectively, for patients with tumors that were ≤ 4 cm, and 63% and 57%, respectively, for patients with larger tumors. The authors reported a significantly higher rate of complications in the patients treated with initial surgery, and they attributed this finding to the frequent use of combined-modality treatment in this group.

For patients with stage IB1 squamous carcinomas, the choice of treatment is based primarily on patient preference, anesthetic and surgical risks, physician preference, and an understanding of the nature and incidence of complications with hysterectomy and radiotherapy. For patients with similar tumors, the overall rate of major complications is similar with surgery and radiotherapy, although urinary tract complications tend to be more common after surgical treatment and bowel complications are more common after radiotherapy. Surgical treatment tends to be preferred for young women with small tumors because it permits preservation of ovarian function and may cause less vaginal shortening. Radiotherapy is often selected for older, postmenopausal women to avoid the morbidity of a major surgical procedure.

For patients with stage IB2 tumors, some surgeons have advocated the use of radical hysterectomy as initial treatment.²⁹³⁻²⁹⁵ Patients who have tumors measuring >4 cm in diameter are at high risk for lymph node involvement and parametrial extension.

Because patients with these risk factors have an increased rate of pelvic disease recurrence, surgical treatment is usually followed by postoperative irradiation or chemoradiation, increasing the overall length of treatment and side effects of treatment. Consequently, many gynecologic and radiation oncologists believe that patients with stage IB2 carcinomas are better treated with primary chemoradiation.

Two prospective randomized trials^{43,296} demonstrated that patients who are treated with radiation for bulky stage I cancers benefit from concurrent administration of cisplatin-containing chemotherapy. A third study suggested that patients who require postoperative radiotherapy because of findings of lymph node metastasis or involved surgical margins also benefit from concurrent chemoradiation.²⁸⁶ Patients who have stage IB1 cancers without evidence of regional involvement have excellent pelvic control rates with radiotherapy alone (about 97% at 5 years) and probably do not require chemotherapy when they are treated with primary radiotherapy.^{290,291}

Radical and Modified Radical Hysterectomy

The standard surgical treatment for stage IB and IIA cervical carcinomas is radical (type III) hysterectomy and bilateral pelvic lymphadenectomy. This procedure involves en bloc removal of the uterus, cervix, and paracervical, parametrial, and paravaginal tissues to the pelvic sidewalls bilaterally, with removal of as much of the uterosacral ligaments as possible (see Fig. 72.7). The uterine vessels are ligated at their origin, and the proximal third of the vagina and the paracolpium are resected. Modified radical (type II) hysterectomy may be used for IA2 and selected small (<2 cm in diameter) stage IB lesions; with this procedure, the parametrial and paracervical tissue is removed medial to the ureter, the uterosacral ligaments are partially resected, and only the proximal 1 to 2 cm of the vagina are removed. The decision of whether to remove the ovaries should be individualized and based on the patient's age, menopausal status, and other factors. Ovarian metastases are rare in the absence of metastases to lymph nodes or other sites. If intraoperative findings suggest a need for postoperative pelvic irradiation, the ovaries may be transposed out of the pelvis.

Radical hysterectomy is increasingly being performed using a laparoscopic approach with or without robotic assistance.²⁹⁷⁻²⁹⁹ In experienced hands, these methods may result in reduced blood loss and quicker postoperative recovery times, although operative times may be somewhat longer. Preliminary results suggest that outcomes of laparoscopic radical hysterectomy are similar to those achieved with radical hysterectomy performed using the traditional abdominal approach.

Intraoperative and immediate postoperative complications of radical abdominal hysterectomy include blood loss, ureterovaginal fistula (1% to 2% of patients), vesicovaginal fistula ($<1\%$), pulmonary embolus (1% to 2%), small bowel obstruction (1% to 2%), and postoperative fever secondary to deep vein thrombosis, pulmonary infection, pelvic cellulitis, urinary tract infection, or wound infection (25% to 50%).³⁰⁰ Subacute complications include lymphocyst formation and lower extremity edema, the risk of which is related to the extent of the node dissection.³⁰¹ Lymphocysts may obstruct a ureter, but hydronephrosis usually improves with drainage of the lymphocyst.³⁰² The risk of complications, particularly small bowel obstruction, may be increased in patients who undergo preoperative or postoperative irradiation.²⁹⁴

Most patients have transient decreased bladder sensation after radical hysterectomy. Severe long-term bladder complications are infrequent and are related to the extent of the parametrial and paravaginal dissection but not to the type of surgical approach (abdominal or laparoscopic).^{303,304} Even with careful postoperative bladder drainage, chronic bladder hypotonia or atony occurs in approximately 3% to 5% of patients.^{305,305,306} Radical hysterectomy may be complicated by stress incontinence, but reported incidences vary

widely and may be influenced by the addition of postoperative radiotherapy.^{305,306} Patients may also experience constipation and, rarely, chronic obstipation after radical hysterectomy.

Radical Trachelectomy

In 1994, Dargent et al.³⁰⁷ pioneered the use of radical trachelectomy and laparoscopic pelvic lymphadenectomy as a means of sparing fertility in young women with early cervical cancer. Since then, it has been demonstrated that when these procedures are performed by experienced surgeons, the cure rates are high and many women are able to carry subsequent pregnancies to viability.³⁰⁸ Successful pregnancies have also been reported after radical abdominal trachelectomy.³⁰⁹ In order to keep the residual uterine segment intact, a nonabsorbable cervical cerclage is placed around the uterine isthmus at the time of the trachelectomy. Alexander-Sefre et al.³¹⁰ reported that radical trachelectomy was associated with shorter operative times and hospital stays, less blood loss, and a lower incidence of bladder hypotony than radical hysterectomy. However, patients who had radical trachelectomy had more problems with dysmenorrhea, irregular menstruation, and vaginal discharge; in addition, 14% had cervical suture problems, 10% had isthmic stenosis, and 7% had prolonged amenorrhea.

The use of radical vaginal or abdominal trachelectomy and laparoscopic lymphadenectomy may be indicated in carefully selected women with small IB1 (≤ 2 cm) lesions who are eager to preserve fertility. Patients with extensive endocervical extension are poor candidates for fertility-sparing surgery. Preoperative MRI is a relatively sensitive and specific method to evaluate the possibility of tumor extension beyond the internal os.³¹¹ A recent review of 504 women who underwent radical trachelectomy summarized the outcome of 200 pregnancies.³¹² Although 84 of 200 pregnancies (42%) produced full-term viable infants, 37% of third-trimester deliveries were preterm, indicating that these women are at high risk for complicated pregnancies.

Radiotherapy After Radical Hysterectomy

Retrospective and prospective studies clearly demonstrate that irradiation decreases the risk of pelvic recurrence after radical hysterectomy in patients with high-risk disease features (lymph node metastasis, deep stromal invasion, positive or close operative margins, or parametrial involvement).^{287,313} However, because the patients who received postoperative radiotherapy in most studies were selected because they had high-risk features, it has been difficult to determine the impact of adjuvant irradiation on survival.

GOG-92, a randomized trial first reported in 1999 and updated in 2006,^{287,313} tested the benefit of adjuvant pelvic irradiation in patients with an intermediate risk of recurrence after radical hysterectomy for stage IB carcinoma. Patients were eligible for this study if they had at least two of the following risk factors: greater than one-third stromal invasion, LVSI, or clinical tumor diameter of at least 4 cm. Patients with involvement of the pelvic lymph nodes, parametria, or surgical margins were excluded. Patients who received adjuvant radiotherapy experienced a 46% reduction in the risk of recurrence ($p = 0.007$). Although there was a 30% reduction in the risk of death for patients who received radiotherapy, this difference was not statistically significant ($p = 0.07$). A subset analysis suggested that the benefit of postoperative radiotherapy was particularly striking for patients who had adenocarcinomas or adenosquamous carcinomas.^{287,313}

Although pelvic irradiation reduces the risk of recurrence for patients with pelvic lymph node metastases or parametrial involvement, the risk of pelvic and distant recurrence remains high for these women after radiotherapy. In an attempt to improve the results of combined-modality treatment, the Southwest Oncology Group conducted a prospective trial comparing postoperative pelvic radiotherapy alone versus administration of cisplatin and 5-FU during and after postoperative pelvic radiotherapy for patients with

lymph node metastases, parametrial involvement, or involved surgical margins. Initial results of this trial, published in 2000, demonstrated significantly improved rates of pelvic disease control and survival for patients who received chemotherapy (Table 72.9).²⁸⁶

The use of adjuvant radiotherapy undoubtedly increases the rate of posttreatment small bowel and genitourinary complications in patients who have had radical hysterectomy^{292,313}; however, inconsistencies in the methods of analysis, selection biases, and the relatively small number of patients in most series make studies of this subject difficult to interpret.³¹⁴

Definitive Radiotherapy

Radiotherapy alone also achieves excellent survival and pelvic disease control rates in patients with stage IB cervical cancer.^{227,290,315} Eifel et al.²⁹⁰ reported 5-year disease-specific survival and pelvic control rates of 90% and 98%, respectively, for 701 patients treated with radiation alone for stage IB1 disease. Although outcomes are poorer for patients with larger tumors, even these are frequently curable with a combination of external beam irradiation and brachytherapy. However, patients with stage IB2 and bulky stage IIA cancers are usually treated with concurrent cisplatin-based chemoradiation, which has been demonstrated in randomized trials to yield better outcomes than radiotherapy alone.^{129,296}

As with radical surgery, the goal of radical radiotherapy is to sterilize disease in the cervix, paracervical tissues, and regional lymph nodes in the pelvis. Patients are usually treated with a combination of external beam irradiation to the pelvis and brachytherapy. Even relatively small tumors that involve multiple quadrants of the cervix are usually treated with total doses of 80 to 85 Gy to point A. The dose may be reduced by 5% to 10% for very small superficial tumors. Although patients with small tumors may be treated with somewhat smaller fields than patients with more advanced locoregional disease, care must still be taken to adequately cover the obturator, external iliac, low common iliac, and presacral nodes. Radiation technique, which is similar for patients who have bulky stage I or more advanced cancers, is discussed further in "Stage IIB, III, and IVA Disease."

Irradiation Followed by Hysterectomy

Although early studies from the MD Anderson Cancer Center suggested that local recurrence rates for patients with bulky stage IB cancers were decreased when radiotherapy was followed by adjuvant hysterectomy, subsequent retrospective studies were less convincing and suggested that selection bias may have been responsible for the observed differences.^{316,317} In a study of 1,526 patients with stage IB squamous carcinomas, Eifel et al.²⁹⁰ reported central tumor recurrence rates of $<10\%$ for tumors as large as 7 to 7.9 cm treated with radiation alone, suggesting that the margin for possible improvement with adjuvant hysterectomy is small.

In 2003, the GOG reported results of a prospective randomized trial of irradiation with or without adjuvant extrafascial hysterectomy in patients with stage IB tumors ≥ 4 cm in diameter³¹⁸; the study demonstrated no significant improvement in the survival rate among patients who had adjuvant hysterectomy (relative risk of death = 0.89; 95% confidence interval = 0.65 to 1.21).

These results, combined with those of more recent studies demonstrating low pelvic recurrence rates after concurrent treatment with chemotherapy and radiation,¹²⁹ suggest that there is little role for routine treatment with adjuvant hysterectomy. However, adjuvant hysterectomy may still play a role in selected cases in which uterine fibroids or other anatomic variations limit the dose of radiation deliverable with brachytherapy and in patients who have involvement of the uterine fundus with cancer. In these cases, extrafascial (type I) hysterectomy is usually performed, in which the uterus, cervix, adjacent tissues, and a small cuff of the upper vagina in a plane outside the pubocervical fascia are removed. Radical

hysterectomy is avoided after high-dose irradiation because of an increased risk of fistula and other complications.

Chemotherapy Followed by Radical Surgery

A number of researchers have investigated the use of neoadjuvant chemotherapy followed by radical hysterectomy to treat patients with bulky stage IB or stage II cervical carcinoma. Neoadjuvant regimens have usually included cisplatin and bleomycin plus one or two other drugs.

In an early trial of this approach, Sardi et al.³¹⁹ reported better projected 4-year disease-free survival rates when neoadjuvant chemotherapy was added to radical hysterectomy plus postoperative radiotherapy in patients whose tumors were >4 cm. However, in a subsequent randomized trial,³²⁰ the GOG reported no significant difference in recurrence rates (relative risk = 0.998) or death rates (relative risk = 1.008) for patients who did or did not receive neoadjuvant chemotherapy before radical hysterectomy. In their trial, patients who underwent hysterectomy were treated with postoperative irradiation if they had high-risk disease features; the proportion requiring postoperative irradiation was similar in the two arms (45% for those who did and 52% for those who did not receive neoadjuvant chemotherapy). Several trials have compared radiotherapy alone versus neoadjuvant chemotherapy followed by hysterectomy plus or minus postoperative radiotherapy with conflicting results.^{321,322} However, these trials, conceived before 1999, did not include concurrent chemotherapy in the radiotherapy arms.

Ultimately, the cost and morbidity of triple-modality treatment can only be justified if it proves to be more effective than treatment with the current standard of concurrent chemotherapy and radiotherapy.

Stage IIB, III, and IVA Disease

Radiotherapy is the primary local treatment for most patients with locoregionally advanced cervical carcinoma. The success of radiotherapy depends on a careful balance between external beam radiotherapy and brachytherapy, optimizing the dose to tumor and normal tissues and the overall duration of treatment. For patients treated with radiotherapy alone for stage IIB, IIIB, and IV disease, 5-year survival rates of 65% to 75%, 35% to 50%, and 15% to 20%, respectively, have been reported.^{227,323–325} Results of major clinical trials reported at the end of the 1990s indicate that, barring medical contraindications, patients with locally advanced tumors should also receive concurrent chemotherapy along with radiotherapy. With appropriate chemoradiotherapy, even patients with massive locoregional disease have a significant chance for cure.

External beam irradiation is used to deliver a homogeneous dose to the primary cervical tumor and to potential sites of regional spread and may also improve the efficacy of subsequent intracavitary brachytherapy by shrinking bulky tumor and bringing it within the range of the high-dose portion of the brachytherapy dose distribution. To facilitate brachytherapy, patients with locally advanced disease usually begin with a course of external beam treatment with concurrent chemotherapy. Subsequent brachytherapy exploits the inverse square law to deliver a high dose to the cervix and paracervical tissues while minimizing the dose to adjacent normal tissues.

Breaks during or between external beam and intracavitary treatments should be discouraged, and every effort should be made to complete the entire radiation treatment in <7 to 8 weeks. Several studies have suggested that treatment courses >8 weeks are associated with decreased pelvic disease control and survival rates.^{326–328} A recently analysis of patterns of care for patients with cervical cancer treated across the United States in radiation oncology facilities revealed that a concerning high percentage of patients were not completing treatment within this time frame. Approximately 40% of patients treated in nonacademic facilities failed to complete treatment within 10 weeks.³²⁹ Although treatment protraction also

tended to be a problem in academic centers, the percentage of patients completing treatment in <10 weeks (83%) was significantly greater. These findings highlight the logistical and therapeutic challenges associated with delivery of multimodality cervical cancer treatment and suggest that facilities with experience in treating cervical cancer are more successful at managing these issues to prevent treatment delays.

External Beam Radiotherapy Technique. High-energy photons (15 to 18 MV) are usually preferred for standard three-dimensional conformal pelvic treatment because they spare superficial tissues that are unlikely to be involved with tumor. At these energies, the pelvis can be treated either with four fields (anterior, posterior, and lateral fields) or with anterior and posterior fields alone (Fig. 72.8). When high-energy beams are not available, four fields are usually used because less-penetrating 4- to 6-MV photons often deliver an unacceptably high dose to superficial tissues when only two fields are used.

When lateral fields are used to treat intact cervical cancers, particular care must be taken to adequately encompass the primary tumor and potential sites of regional spread in the radiation fields. Representative axial and sagittal dose distributions obtained with this technique are shown in Figures 72.8C and 72.8D, respectively.

CT simulation is recommended to confirm adequate coverage of the uterus and draining lymphatics. Information gained from radiologic studies such as MRI, CT, and PET can improve estimates of disease extent and assist in localization of regional nodes and paracervical tissues that may contain microscopic disease. The caudad extent of disease can be determined by inserting radiopaque markers in the cervix or at the lowest extent of vaginal disease. It is usually wise to cover the entire presacrococcygeal region when locally advanced cancers are treated to account for internal organ motion.

Tumor response should be evaluated with periodic pelvic examinations. Some practitioners prefer to maximize the brachytherapy component of treatment and begin it as soon as the tumor has responded enough to permit a good placement of the brachytherapy applicators, delivering subsequent pelvic irradiation with a central shield. This technique may reduce the volume of normal tissue treated to a high dose but can also result in overdoses to medial structures such as the ureters or underdosage of posterior uterosacral disease. For these reasons, most clinicians prefer to give an initial dose of 40 to 45 Gy to the whole pelvis, believing that the ability to deliver a homogeneous distribution to the entire region at risk for microscopic disease outweighs other considerations. External beam doses of >40 to 45 Gy to the central pelvis tend to compromise the dose deliverable to paracentral tissues and increase the risk of late complications.

A total dose (external beam and intracavitary) of 45 to 55 Gy appears to be sufficient to sterilize microscopic disease in the pelvic nodes in most patients. It is customary to treat lymph nodes known to contain gross disease and heavily involved parametria to a total dose of 60 to 66 Gy (including the contribution from brachytherapy treatments).

Intensity-Modulated Radiotherapy. The use of IMRT and other forms of highly conformal radiotherapy in patients with gynecologic tumors is increasing.^{330–332} Unlike standard two-field and four-field techniques, IMRT makes it possible to deliver a lower daily dose to the intrapelvic contents than to surrounding pelvic lymph nodes (Fig. 72.9). With standard techniques, the close proximity of bowel has made it difficult to sterilize disease in nodes >2 cm; IMRT allows delivery of doses exceeding 60 Gy to regional nodes with relative sparing of adjacent critical structures.

When the para-aortic region requires treatment, IMRT can reduce the dose of radiation to the small bowel, including the duodenum. IMRT is particularly advantageous when there are grossly involved para-aortic nodes, which can be treated with an integrated

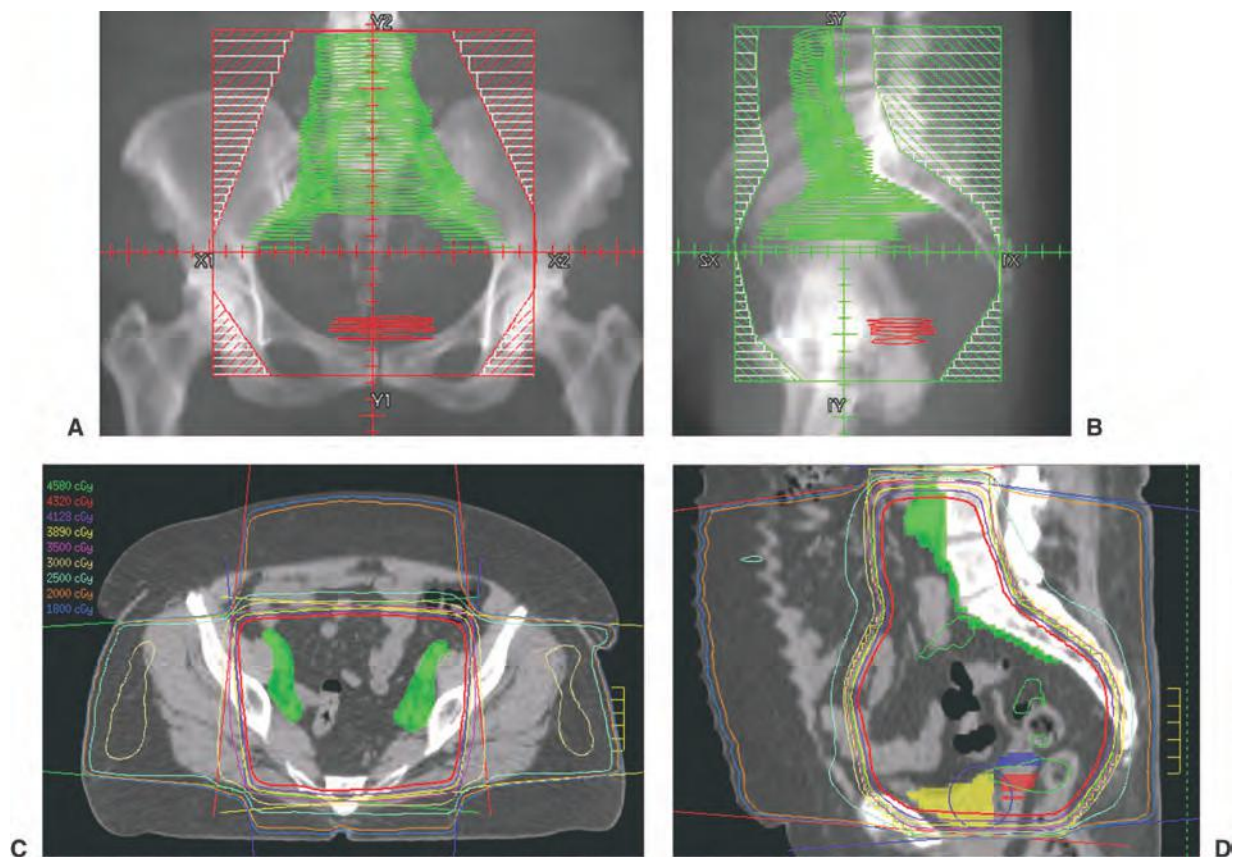

Figure 72.8 Typical anterior (A) and lateral (B) fields used to treat the pelvis with a four-field technique. When lateral fields are used to treat intact cervical cancers, particular care must be taken to adequately encompass the primary tumor and potential sites of regional spread in the radiation fields. Representative axial and sagittal dose distributions obtained with this technique are shown in panels C and D, respectively.

boost. The duodenum should be contoured and avoided in such situations; reducing the volume receiving 55 Gy has been reported to reduce toxicity.³³³ IMRT to the para-aortics can be matched to a four-field or anteroposterior/posteroanterior pelvic field. Alternatively, IMRT can be used to treat the pelvis, but great care should be used to define the volume at risk and to account for the potential for significant uterine motion.

Although IMRT is an extremely useful tool in the treatment of gynecologic cancers, the highly conformal dose distributions

achievable with IMRT also increase the potential for error and require considerable experience and attention to detail on the part of the radiation oncologist. In particular, great attention must be paid to the influence of internal organ motion and intratreatment tumor response on the doses to tumor and critical structures. The uterus and vagina can move 3 to 4 cm with bladder and rectal filling, and even greater excursion is possible with anteverision or retroversion of the uterus, which can occur spontaneously.³³⁴ Daily image guidance with CT or kV imaging should be used with IMRT to

Figure 72.9 Axial and midline sagittal views of an intensity-modulated radiation therapy plan for postoperative pelvic radiotherapy in a patient with adenocarcinoma of the cervix. The target volume was extended to the top of S1 rather than L5 due to an extensive negative node dissection.

ensure that the uterus remains within the target volume. Although some investigators have begun to explore the use of IMRT to treat patients with intact cervical cancers, large inter- and intratreatment variations in the position and size of the target volume raise serious concerns about the risk of missing tumor with these highly conforming treatments; if very ample margins are used to account for variability in the target, the gain relative to simpler treatments may not justify such complex treatment. There is no evidence that IMRT can safely be used as an alternative to brachytherapy for routine treatment of intact cervical cancer. Although IMRT achieves very conformal dose distributions, it cannot accurately reproduce the high-dose gradients produced with intracavitary brachytherapy. More importantly, the large, unpredictable variations that occur in the positions of the bladder, rectum, and target mandate the use of large treatment margins that inevitably encompass adjacent critical structures and reduce the dose deliverable to tumor.

Role of Para-Aortic Irradiation. Two prospective randomized trials conducted during the 1980s addressed the role of prophylactic para-aortic irradiation in patients without known para-aortic node involvement.^{335,336} In a Radiation Therapy Oncology Group study of 367 patients, Rotman et al.³³⁷ demonstrated a significantly better survival rate for patients treated with extended fields than for those treated with standard pelvic radiotherapy (67% versus 55% at 5 years; $p = 0.02$). A second trial, from the European Organization for Research and Treatment of Cancer,³³⁵ involved a similar randomization but included patients with somewhat more advanced disease; in that study, 4-year disease-free survival rates for patients treated with pelvic radiotherapy and those treated with extended fields were not significantly different, although the rate of para-aortic node recurrence was significantly higher in the pelvic-field group. Both studies revealed an increased rate of enteric complications in patients treated with extended fields.

Numerous small series of patients with documented para-aortic node involvement suggest that 25% to 50% have long-term survival after extended-field irradiation. Survival is correlated with the bulk of central disease and the extent and size of involved lymph nodes. Cunningham et al.³³⁸ reported a 48% 5-year survival rate in patients who had para-aortic node involvement discovered at exploration for radical hysterectomy that was then aborted. This experience with patients who had relatively small primary disease demonstrates that extensive regional spread can occur without distant metastases and that patients with para-aortic node metastases can often be cured. The side effects of extended-field radiotherapy, particularly when combined with concurrent chemotherapy,^{339,340} can be substantial, and the management of such patients requires close multidisciplinary collaboration.

Brachytherapy. Brachytherapy was first used to treat cervical cancers in the early 20th century and continues to play a central role in their curative management. The goal of brachytherapy is to deliver a high dose to disease in the cervix and paracervical tissues while preserving function of adjacent critical structures.

The uterine cavity provides an ideal receptacle for radioactive sources, which are positioned using specially designed applicator systems that capitalize on the distinctive anatomy of the distal female genital tract and the physical advantages of the inverse square law. Most applicator systems consist of an angled or curved intrauterine tandem with some form of intravaginal applicator; vaginal applicators used in various clinical settings include several versions of the Fletcher-Suit afterloading colpostats, vaginal rings, French molds, vaginal cylinders, and others.^{341,342} Vaginal packing is used to hold the applicator in place and to maximize the distance between the sources and the bladder and rectum. Radiographs should be obtained at the time of insertion to verify accurate placement, and the system should be repositioned if radiographs indicate that positioning can be improved.

Treatments may be delivered over several days at a continuous LDR or with frequent pulses (pulsed dose rate [PDR]); alternatively,

treatment may be administered in several fractions of radiation delivered at a HDR. For LDR treatments, cesium-137 sources are usually loaded manually after applicator placement has been optimized. In contrast, the remote afterloading units commonly used for HDR or PDR treatments employ a single “stepping” source of ¹⁹²Ir that travels through the applicator tubes, pausing for varying times in a series of “dwell” positions to deliver the desired dose to adjacent tissues. The activity of sources used for HDR is approximately 10 Ci; the activity of sources used for PDR is approximately 0.5 to 1 Ci. However, because a computer controls insertion of the source, exposure to personnel is negligible with these methods. Although the nominal dose of radiation needs to be adjusted for treatment delivered at different dose rates, the applicator systems and rules of optimal brachytherapy placement are similar for LDR, HDR, and PDR treatment. The importance of radiation dose rate and fraction size is discussed in more detail later in this section.

Brachytherapy Dose. The paracentral dose from intracavitary brachytherapy is most frequently expressed at a single reference point, usually designated *point A*. Although point A has been specified in a number of different ways, the most widely accepted definition is a point 2 cm lateral to the cervical collar and 2 cm above the top of the colpostats, measured at their intersection with the tandem midpoint on the lateral radiograph (Fig. 72.10).³⁴³ Point A usually lies approximately at the crossing of the ureter and the uterine artery, but it bears no consistent relationship to the tumor or target volume. Originally developed as part of the Manchester treatment system, point A was meant to be used in the context of a detailed set of rules governing the placement and loading of the intracavitary system and was intended to be used primarily as a means of reporting treatment intensity, not as the sole parameter for treatment prescription. Today, this context is often lost. Other measures have been used to describe the intensity of intracavitary treatment. “Mg-hr” or “mgRaEq-hr” are proportional to the dose of radiation at relatively distant points from the system and therefore give a sense of the dose to the whole pelvis. Total reference air kerma—expressed in micrograys at 1 m—is an alternative measure that allows for the use of various radionuclides.³⁴⁴ Reference points have also been used to estimate the doses to the bladder and rectum. Although normal tissue reference points provide useful information about the dose to a portion of normal tissue, volumetric studies have demonstrated that they consistently underestimate the maximum dose to normal tissue.³⁴⁵ Volumetric MRI-guided dose specification for tumor and normal tissue doses is increasingly being used and is discussed in more detail below.³⁴⁶ The use of volumetric measurements yields much more accurate information about the relationships between dose, treatment volume, and outcome than has been possible with traditional methods.

Whatever system of dose specification is used, emphasis should always be placed on optimizing the relationship between the intracavitary applicators and the cervical tumor and other pelvic tissues. Source strengths and positions should be carefully chosen to provide optimal tumor coverage without exceeding normal tissue tolerance limits. However, optimized source placement can rarely correct for a poorly positioned applicator.

Factors that influence source strength and position are beyond the scope of this chapter and can be found elsewhere.^{344,347} An effort should be made to deliver a dose to point A of at least 85 Gy (with LDR brachytherapy) or its biologic equivalent (with HDR brachytherapy) for patients with bulky central disease. If the intracavitary placement has been optimized, this can usually be accomplished without exceeding a dose of 75 Gy to the bladder reference point or 70 Gy to the rectal reference point, doses that are usually associated with an acceptably low risk of major complications. Suboptimal placements occasionally force compromises in the dose to tumor or normal tissues. To choose a treatment that optimizes the therapeutic ratio in these circumstances requires experience and a detailed understanding of factors that influence tumor control and normal tissue complications.

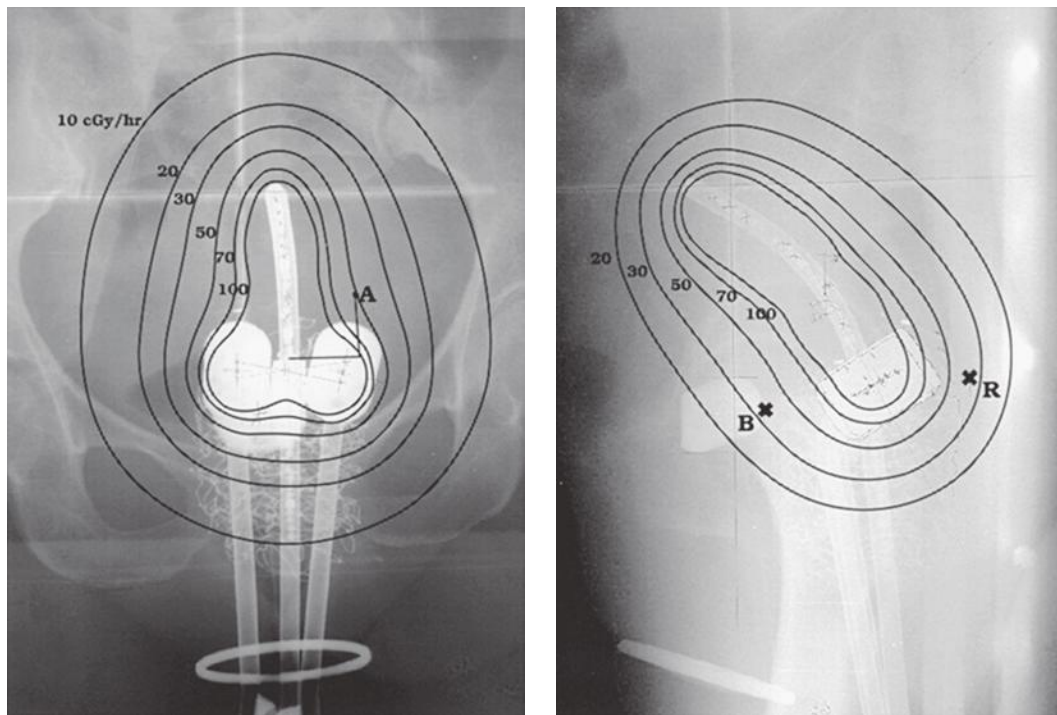

Figure 72.10 Posteroanterior and lateral views of a Fletcher-Suit-Delclos applicator system in a patient with invasive carcinoma of the cervix. Units on the isodose contours are centigray per hour. A, point A; B, bladder reference point; R, rectal reference point.

Image-Based Brachytherapy Treatment Planning. The use of CT and MRI for brachytherapy treatment planning has expanded significantly in the past 10 years. Both modalities can be used to verify appropriate placement of the applicator and evaluate the dose to normal tissues. CT has the advantage of being more widely available than MRI and does not require the use of special MRI-compatible applicators. However, MRI provides much better visualization of soft tissues and more accurate appreciation of the extent of tumor within the cervix and paracervical tissues. Despite this significant advantage, the more limited availability of MRI limited the adoption of MRI-based treatment planning. A survey of radiation oncologists performing brachytherapy in 2007 for cervical cancer reported that 70% of respondents obtained a CT postapplicator placement while only 2% of respondents reviewed images from an MRI with the brachytherapy applicator in place.³⁴⁸ Although most physicians surveyed obtained a CT at the time of brachytherapy planning, most respondents specified a treatment dose to point A rather than contouring and specifying dose to an image-based target volume.

The Groupe Européen de Curiethérapie-European Society of Therapeutic Radiation Oncology (GEC-ESTRO) consortium has developed a series of guidelines on the optimal approach for imaging, delineating target and avoidance volumes and treatment planning using MRI.³⁴⁹⁻³⁵² According to their guidelines, T2 multiplanar images should be obtained after applicator placement to allow delineation of the gross tumor volume that is typically hyperintense on T2 images. The high-risk clinical target volume (CTV) encompasses the entire cervix and gross residual macroscopic disease at the time of brachytherapy. An intermediate-risk CTV includes the initial extent of disease plus 1-cm margin on the high-risk CTV. Using these methods, Georg et al.³⁵³ reported a strong correlation between the dose to the high-risk CTV and local control with a 96% control rate when the equivalent dose at 2 Gy per fractions (EQD2) to 90% of the target volume (D90) was >87 Gy. The GEC-ESTRO recommendation suggests delivering a total dose equivalent of 60 Gy to the intermediate-risk CTV D90. In

addition, organs at risk including the bladder, rectum, and sigmoid should be delineated. Current recommendations suggest limiting the D2cc (minimum dose to the maximally irradiated 2 ml) of the bladder to <90 Gy and the rectum and sigmoid to <70,³⁵⁵ although these dose relationships have only been convincingly demonstrated for the rectum. An example of a MRI-based plan, optimized to cover the high-risk CTV while minimizing dose to normal tissues, is shown in Fig. 72.11.

The advantage of image-guided brachytherapy was evaluated in the prospective multicenter nonrandomized STIC study that

Figure 72.11 Sagittal and axial images of a T2-weighted magnetic resonance imaging obtained in a patient with invasive squamous cell carcinoma of cervix receiving pulsed dose rate brachytherapy with tandem and ovoid implant. Dwell times within the tandem and ovoids were optimized to deliver 22 Gy over 44 hours to the high-risk clinical target volume (peach). Isodose lines represent percentages of the prescribed dose. The dose the D2cc rectum (green), bladder (yellow), and sigmoid (blue) was 6 Gy, 11 Gy, and 12 Gy, respectively.

compared treatment with standard two-dimensional approach to image-guided brachytherapy in 705 patients.³⁵⁴ Patients were assigned to one of three groups: patients receiving brachytherapy alone followed by surgery; patients receiving external beam, brachytherapy, and surgery; or patients with more advanced cervical cancers treated with external beam and brachytherapy. Treatment in the three-dimensional group was performed according to GEC-ESTRO guidelines that were adapted for CT. In all three groups, the local-relapse free survival was higher in the three-dimensional group and the rates of grade 3 or 4 complications were lower. Of note, this benefit was observed despite the low total dose to point A, 70 Gy, in patients receiving definitive radiation.

Brachytherapy Dose Rate and Treatment Schedule. Cervical cancer brachytherapy can be delivered with LDR, PDR, or HDR approach. LDR is typically delivered with a cesium source in two implants over 48 hours, separated by 2 weeks after completion of primary external beam fields. PDR treatment follows a similar treatment schedule as LDR but utilizes a stepping iridium source, which delivers treatment over in hourly pulses. HDR brachytherapy uses a higher activity iridium source to deliver four to seven treatments that are delivered over several minutes and spaced over 2 to 5 weeks. HDR brachytherapy is typically delivered after the completion of primary external beam fields or can be started during external beam for smaller or rapidly responding tumors.

Traditional LDR brachytherapy has been performed with sources that yield a dose rate at point A of approximately 0.45 Gy/h. These low dose rates permit repair of sublethal cellular injury with preferential sparing of normal tissues. In a randomized trial, Haie-Meder et al.³⁵⁵ reported a significant increase in complications when the dose rate was doubled from 0.4 to 0.8 Gy/h, indicating that the total dose must be reduced and the therapeutic ratio of treatment may be compromised with higher dose rates. Differences in the magnitude of the dose-rate effect between tumor and normal tissues may partly reflect differences in the half-times for repair of sublethal radiation damage.³⁵⁶

HDR brachytherapy can be delivered in an outpatient setting, which can make treatment more convenient for patients and physicians. In the past decade, the use of HDR brachytherapy has expanded significantly. The most recent patterns of care study that surveyed practice patterns between 2005 and 2007 found that 68.5% of patients were treated using HDR intracavitary brachytherapy as compared with 15.4% in the 1992 to 1994 survey. HDR brachytherapy may lose the radiobiologic advantage of LDR treatment, potentially narrowing the therapeutic window for complication-free cure, particularly for patients with unfavorable anatomy. Published experiences suggest that survival rates are roughly similar to those achieved with traditional LDR treatment, although these experiences are difficult to compare because of the same potential problems of selection bias that confound other nonrandomized comparisons. Prospective trials suggest that LDR and HDR treatment produce similar results, but these trials have been criticized for methodologic flaws. However, logistical advantages, including increasingly scarce availability of cesium for LDR brachytherapy, have contributed to a steady increase in the proportion of patients treated using HDR techniques. HDR is probably similar to LDR brachytherapy in terms of therapeutic efficacy and side effects when the patient's anatomy permits displacement of the bladder, rectosigmoid, and other critical structures away from intrauterine and intravaginal radiation sources, making it possible to prevent exposure of these tissues to high fractional doses.

As with LDR treatment, successful HDR brachytherapy depends on optimized applicator position, balanced use of external beam therapy and brachytherapy, compact overall treatment duration, and delivery of an adequate dose to tumor with respect for normal tissue tolerance limits. The advent of image-guided treatment planning may contribute to further improvements in the safety of high-dose-per-fraction intracavitary brachytherapy by providing a more realistic understanding of the doses delivered by brachytherapy to critical structures.

Some clinicians advocate the use of interstitial brachytherapy for patients whose anatomy or tumor distribution make it difficult to obtain an ideal intracavitary placement. Template-based interstitial implants are usually placed transperineally, guided by an acrylic glass template that encourages parallel placement of hollow needles that penetrate the cervix and paracervical spaces; needles are usually loaded with ¹⁹²Ir. Advocates of the procedure describe the relatively homogeneous dose distribution achieved with this method, the ease of inserting implants in patients in whom the uterus is difficult to probe, and the ability to place sources directly into the parametrium.^{357,358} In a 1995 review of the combined experiences of Stanford University and the Joint Center for Radiation Therapy,³⁵⁹ the 3-year disease-free survival rates for patients with stage IIB and IIIB disease were only 36% and 18%, respectively; local control rates were 22% and 44%, respectively; and the rate of complications requiring surgical intervention was high. A 1997 report from the University of California, Irvine, described 5-year survival rates of only 21% and 29%, respectively, for patients with stage IIB and IIIB disease, again with a high rate of major complications.

Some treating physicians have explored the use of laparoscopic or image-guided techniques to improve local control and complication rates with interstitial brachytherapy.^{360,361} However, outside of an investigational setting, template-based interstitial treatment of primary cervical cancers should probably be limited to patients who cannot accommodate intrauterine brachytherapy and patients with distal vaginal disease that requires a boost with interstitial brachytherapy. Newer applicators allow the placement of interstitial needles through an ovoid or ring for treatment of bulky cervical tumors. CT or MRI is needed with these applicators to ensure that needles are safely placed.

Complications of Radiotherapy. During pelvic radiotherapy, most patients have mild fatigue and mild-to-moderate diarrhea that usually is controllable with antidiarrheal medications; some patients have mild bladder irritation. When extended fields are treated, patients may have nausea, gastric irritation, and depression of peripheral blood cell counts. Hematologic and gastrointestinal complications are significantly increased in patients receiving concurrent chemotherapy. Unless the ovaries have been transposed, all premenopausal patients who receive pelvic radiotherapy experience ovarian failure by the completion of treatment.

Perioperative complications of intracavitary brachytherapy include uterine perforation, fever, and the usual risks of anesthesia. Thromboembolisms are rare. In a review of 4,043 patients who had 7,662 intracavitary applications for cervical cancer, Jhingran and Eifel³⁶² reported 11 patients (0.3%) with thromboembolisms, 4 of whom—all with pulmonary embolisms—died. All four fatal pulmonary embolisms were in patients with advanced pelvic wall disease.

Estimates of the risk of late complications of radical radiotherapy vary according to the grading system, duration of follow-up, method of calculation, treatment method, and prevalence of risk factors in the study population. However, most reports quote an overall risk of major complications (requiring transfusion, hospitalization, or surgical intervention) of 5% to 15%.^{129,130,355,363,364} In a study of 1,784 patients with stage IB disease, Eifel et al.³⁶³ reported an overall actuarial risk of major complications of 7.7% at 5 years. Although the actuarial risk was greatest during the first 3 years of follow-up, there was a continuing risk to surviving patients of approximately 0.3% per year, resulting in an overall actuarial risk of 14% at 20 years.

During the first 3 years after treatment, rectal complications are most common and include bleeding, stricture, ulceration, and fistula. In the study by Eifel et al.,³⁶³ the risk of major rectosigmoid complications was 2.3% at 5 years. Major gastrointestinal complications were rare 3 years or more after treatment, but a constant low risk of urinary tract complications persisted for many years (Fig. 72.12). The actuarial risk of developing a fistula of any

Figure 72.12 Rates of major rectal and urinary tract complications in 1,784 patients with stage IB carcinomas of the cervix treated with radiotherapy. Complication rates were calculated actuarially, and patients who died without experiencing a major complication were censored at the time of death. (From Eifel PJ, Levenback C, Wharton JT, et al. Time course and incidence of late complications in patients treated with radiation therapy for FIGO stage IB carcinoma of the uterine cervix. *Int J Radiat Oncol Biol Phys* 1995;32:1289, with permission.)

type was 1.7% at 5 years. Complication rates were calculated actuarially, and patients who died without experiencing a major complication were censored at the time of death.

Small bowel obstruction is an infrequent complication of standard radiotherapy for patients without special risk factors. The risk of small bowel obstruction is increased dramatically in patients who have undergone transperitoneal lymph node dissection.^{217,365} However, there appears to be little increase in risk if the operation is performed with a retroperitoneal approach.²¹⁷ Other factors that can increase the risk of small bowel complications in patients treated for cervical cancer include pelvic inflammatory disease, thin body habitus, heavy smoking, and the use of high doses or large volumes for external beam irradiation, particularly with low-energy treatment beams and large daily fraction sizes.³⁶⁵ Most patients treated with high-dose radiotherapy have some agglutination and telangiectasia of the apical vagina. More significant vaginal shortening can occur, particularly in elderly, postmenopausal women and those with extensive tumors treated with a high dose of radiation.^{363,366} Vaginal function can be optimized with appropriate estrogen support and vaginal dilatation.

Concurrent Chemoradiation. At the end of the 1990s, publication of a series of prospective randomized trials provided compelling evidence that the addition of concurrent cisplatin-containing chemotherapy to standard radiotherapy reduces the risk of disease recurrence by as much as 50% (see Table 72.9).^{129,130,227,296,367-369}

Some of the earliest trials of chemoradiation studied the concurrent use of hydroxyurea with radiation; although the validity of these small trials has since been questioned, encouraging results led to the use of hydroxyurea-containing regimens as controls in two subsequent GOG trials.^{130,368,370} In these trials,^{364,368} the GOG randomly assigned patients with stage IIB–IVA disease to receive either hydroxyurea or cisplatin-containing chemotherapy during external beam irradiation. All three of the cisplatin-containing regimens produced local control and survival rates superior to

those for the control arms (hydroxyurea and radiation). In a third study,²⁹⁷ patients with stage IB tumors measuring at least 4 cm in diameter were randomly assigned to receive radiation alone or radiation plus weekly cisplatin before extrafascial hysterectomy. Patients who received cisplatin were more likely to have a complete histologic response and were more likely to be disease-free at the time of preliminary analysis. A fourth study, cosponsored by the Southwest Oncology Group and the GOG,²⁸⁶ included patients who were treated with radical hysterectomy and were found to have pelvic lymph node metastases, positive margins, or parametrial involvement. In this study, patients who were randomly assigned to receive postoperative pelvic irradiation combined with concurrent and postradiation cisplatin and 5-FU had a better disease-free survival rate than those treated with postoperative radiotherapy alone.

During this time, the Radiation Therapy Oncology Group also conducted a trial in which radiotherapy alone (including prophylactic para-aortic irradiation) was compared with pelvic irradiation plus concurrent cisplatin and 5-FU.^{129,369} The results of this trial also demonstrated highly significant differences in the rates of local control, distant metastasis, overall survival, and disease-free survival, favoring the treatment arm that included chemotherapy. Although acute toxic effects of treatment were greater with chemotherapy, the dose of radiation and duration of radiotherapy were similar in the two arms, and there was no significant difference in the incidence of late treatment-related complications. Although the magnitude of benefit appeared greatest for patients with earlier-stage disease, those with stage III and IVA cancers also had improved disease-free survival when treated with concurrent chemotherapy.^{129,365}

Only one large randomized trial, published by Pearcey et al.³⁷¹ in 2002, has failed to demonstrate a significant advantage from concurrent cisplatin-based chemotherapy in patients with cervical cancer. Although the authors suggested that differences in technique could explain the difference between their results and the results of the earlier trials, the survival rate in their control arm indicated that the margin for improvement was similar to that in the earlier trials. This trial also was the smallest of the six, resulting in relatively large confidence intervals, which may have contributed to the lack of significant difference between the treatment arms.

These studies raise interesting questions that will undoubtedly be the subjects of future studies. Of four different cisplatin-containing regimens, only two were compared directly. It is unclear from the results which regimen achieves the most favorable therapeutic ratio and whether the inclusion of 5-FU in several of the studies contributed importantly to the results. Although an early trial suggested that 5-FU delivered by protracted venous infusion with radiation might be of benefit,³⁷² a subsequent GOG trial showed no benefit of 5-FU over a control treatment of weekly cisplatin plus radiation.³⁷³ Although North American studies have emphasized cisplatin-containing regimens, investigators in Southeast Asia have reported improved outcome when radiation was combined with epirubicin³⁷⁴ or mitomycin and 5-FU.³⁷⁵ A recently reported study indicates that the addition of gemcitabine to concurrent and adjuvant cisplatin may have greater benefit in terms of both progression-free survival and overall survival than chemoradiation with weekly cisplatin alone (hazard ratio of 0.68 for both progression-free survival and overall survival).³⁷⁶ However, this regimen had significant acute toxicity even with the limited radiation fields used. In addition, the benefit in the experimental arm may be due to the use of adjuvant chemotherapy in general and may not require use of gemcitabine, which is associated with higher rates of hematologic and gastrointestinal toxicity than the more commonly used carboplatin and taxol regimen. The impact of adjuvant chemotherapy following chemoradiation is being tested in the currently enrolling Australia New Zealand Gynaecological Oncology Group outback trial. Other drugs that are being studied for their radiosensitizing effects in patients with advanced disease are paclitaxel,³⁷⁷ carboplatin,³⁷⁸ and several biologic response modifiers.

Several groups have attempted to develop models that predict distant recurrence in locally advanced cervical cancer after platinum-based chemoradiation. In a Korean gynecology oncology group study, a four-parameter model consisting of pelvic and para-aortic nodal positivity on FDG-PET, nonsquamous cell histology, and pretreatment serum squamous cell carcinoma antigen levels was able to predict 5-year probability of distant recurrence.³⁷⁹

Taken together, the randomized trials provide strong evidence that the addition of concurrent chemotherapy to pelvic radiotherapy benefits selected patients with locoregionally advanced cervical cancer. A meta-analysis of randomized trials confirmed the benefit of concurrent chemoradiation, showing an advantage for both cisplatin- and non-cisplatin-containing regimens.³⁸⁰ However, most trials have explicitly excluded patients with evidence of para-aortic lymph node metastases, poor performance status, or impaired renal function. In the future, clinicians will be challenged to determine whether favorable results can be generalized to patients with cervical cancer who differ from those included in the prospective trials because of serious medical or social problems. A large Canadian population-based study that demonstrated a significant improvement in survival of women with cervical cancer after the 1999 adoption of chemoradiation as a standard did indicate that the benefits of chemoradiation can be generalized beyond the trial setting.³⁸¹

Neoadjuvant Chemotherapy with Radiotherapy. Although investigators were initially encouraged by high response rates of untreated cervical cancer to multiple-agent, cisplatin-containing chemotherapy regimens, these results have not translated to a clear advantage when neoadjuvant chemotherapy is given before radiotherapy. Of seven phase 3 trials of this approach, five^{382–386} demonstrated no benefit from neoadjuvant therapy and two³⁸⁷ demonstrated a significantly better survival rate with radiotherapy alone. Combinations of neoadjuvant followed by concurrent chemoradiotherapy have not yet been tested in large randomized trials. Such combinations should probably be avoided outside an investigational setting because neoadjuvant chemotherapy could compromise patients' tolerance of subsequent chemoradiation.

Stage IVB Disease

Patients who present with disease in distant organs are almost always incurable. The care of these patients must emphasize palliation of symptoms with use of appropriate pain medications and localized radiotherapy. Tumors may respond to chemotherapy, but responses are usually brief.

Single-Agent Chemotherapy. Cisplatin has been studied in a variety of doses and schedules in the management of recurrent or metastatic cervical cancer and is considered the most active agent against this malignancy.^{388,389} Although a number of other agents (e.g., ifosfamide, carboplatin, irinotecan, and paclitaxel) have exhibited a modest level of biologic activity in cervical cancer (producing response rates of 10% to 15%),³⁹⁰ the clinical utility of these drugs in patients who have not responded to cisplatin or who have experienced recurrence or progression after chemoradiation is uncertain. Further, it is well recognized that the objective rate of response to chemotherapy is lower in previously irradiated areas (e.g., pelvis) than in nonirradiated sites (e.g., lung).³⁹¹

Combination Chemotherapy. Most reports of combination chemotherapy for carcinoma of the cervix have described small, uncontrolled phase 2 trials of drug combinations. The results of two phase 3 randomized trials, published in 2004 and 2005, have provided the first solid evidence that combination chemotherapy can improve both progression-free survival (cisplatin plus paclitaxel versus single-agent cisplatin,³⁹² cisplatin plus topotecan versus single-agent cisplatin³⁹³) and overall survival (cisplatin plus topotecan versus single-agent cisplatin³⁹³) when it is administered

for recurrent or metastatic carcinoma of the cervix. However, a recently reported phase 3 trial comparing combinations of cisplatin with either topotecan, paclitaxel, gemcitabine, or vinorelbine revealed no significant differences in outcome between patients treated with the four cisplatin-based regimens.³⁹⁴

Carboplatin is less toxic than cisplatin in terms of nephrotoxicity, neurotoxicity, and emetogenicity, so the combination of carboplatin and paclitaxel has been evaluated in this setting. A multicenter phase 2 study showed that the carboplatin and paclitaxel regimen was feasible and with similar efficacy as other cisplatin-based doublets for the treatment of metastatic or recurrent cervical cancer.³⁹⁵ Furthermore, preliminary data from a randomized phase 3 trial of paclitaxel plus carboplatin versus paclitaxel plus cisplatin in stage IVb, persistent, or recurrent cervical cancer performed by the Japan Clinical Oncology Group (JCOG0505 study) showed that the carboplatin doublet was noninferior to the cisplatin doublet in terms of overall survival.

Molecular Targeted Agents. Several recently reported studies have addressed the role of molecular targeted agents in recurrent or metastatic cervical cancer. Bevacizumab was recently shown to improve overall survival in women with recurrent, persistent, or metastatic cervical cancer.³⁹⁶ Median survival was 3.7 months longer in women who received bevacizumab in addition to chemotherapy with cisplatin and paclitaxel or topotecan with paclitaxel. No difference in outcome was seen between the two chemotherapy regimens. Pazopanib, another antiangiogenic agent that targets vascular endothelial growth factor receptor and platelet-derived growth factor receptor, was shown to be well-tolerated and demonstrated activity in recurrent or metastatic cervical cancer.³⁹⁷ However, agents that target the epidermal growth factor receptor and/or the human epidermal growth factor receptor 2 such as cetuximab or lapatinib have demonstrated limited activity in recurrent or metastatic cervical cancer.^{397,398}

Palliative Radiotherapy. Localized radiotherapy can provide effective relief of pain caused by metastases in bone, brain, lymph nodes, or other sites. A rapid course of pelvic radiotherapy can also provide excellent relief of pain and bleeding for patients who present with incurable disseminated disease.

Special Treatment Problems

Treatment of Locally Recurrent Carcinoma of the Cervix. Patients should be evaluated for possible recurrent disease if a new mass develops; if, in irradiated patients, the cervix remains bulky or nodular or cervical cytologic findings are abnormal ≥ 3 months after irradiation; or if symptoms of leg edema, pain, or bleeding develop after initial treatment. The diagnosis must be confirmed with a tissue biopsy, and the extent of disease should be evaluated with appropriate radiographic studies, cystoscopy, proctoscopy, and serum chemistry studies before treatment is administered.

After Radical Surgery. The treatment of choice for patients who have an isolated pelvic recurrence after initial treatment with radical hysterectomy alone is aggressive radiotherapy. Treatment using external beam radiotherapy with or without brachytherapy is similar to that for patients with a primary carcinoma of the vagina. Pelvic wall recurrences are often treated with external beam irradiation alone, although surgery and intraoperative radiotherapy may contribute to local control in selected patients.³⁹⁹ Patients with vaginal recurrence usually have a better prognosis than those with pelvic wall recurrence. Ijaz et al.⁴⁰⁰ reported a survival rate of 69% 5 years after radical radiotherapy for 16 patients who had isolated vaginal recurrences that did not involve the pelvic wall. Only 18% of patients who had recurrences that were fixed to the pelvic wall or that involved pelvic lymph nodes survived 5 years. Several authors have reported significantly lower rates of successful salvage therapy for patients with locally recurrent adenocarcinoma.^{401,402} Thomas et al.⁴⁰³ reported encouraging results in a group of patients

with recurrent cervical carcinoma treated with radiation and concurrent chemotherapy, but further studies will be needed to determine whether this approach is superior to radiotherapy alone.

After Definitive Irradiation. Some patients who have an isolated central recurrence after radiotherapy can be cured with surgical treatment. Because the extent of disease may be difficult to evaluate and the risk of serious urinary tract complications of pelvic surgery is high after high-dose radiotherapy, surgical salvage treatment usually requires a pelvic exenteration, most often an anterior exenteration. Less extensive operations, such as radical hysterectomy, are reserved for selected patients with small tumors confined to the cervix or lesions that do not encroach on the rectum.^{403,404}

In all cases, preparation for total pelvic exenteration must involve a detailed medical and imaging evaluation as well as careful counseling of the patient and family regarding the extent of surgery and postoperative expectations. Tumor involvement of the pelvic sidewall is a contraindication for exenteration but may be difficult to assess if there is extensive radiation fibrosis. Although advanced age may be a contraindication to pelvic exenteration, studies have suggested that, with careful selection, good outcomes can be achieved with pelvic exenteration even in women aged 65 years or older.⁴⁰⁵

The operation begins with a thorough inspection of the abdomen for evidence of intraperitoneal spread, lymph node metastases, or pelvic sidewall infiltration. Despite careful preoperative evaluation, about 30% of operations are aborted intraoperatively.⁴⁰⁶ Frozen section biopsies are done of suspicious areas. If the biopsy findings are negative, the surgeon proceeds to remove the bladder, rectum, vagina, uterus, ovaries, fallopian tubes, and all other supporting tissues in the true pelvis. A urinary conduit, a transverse or sigmoid colostomy, and a neovagina are created.

Postoperative recuperation may take as long as 3 months. The surgical mortality rate is <10%, with most postoperative complications and deaths related to sepsis, pulmonary thromboembolism, and intestinal complications such as small bowel obstruction and fistula formation.^{407,408} The rate of gastrointestinal complications may be reduced by using unirradiated segments of bowel and by closing pelvic floor defects with omentum, rectosigmoid colon, or myocutaneous flaps.⁴⁰⁷ Advances in low colorectal anastomosis and techniques for creating continent urinary reservoirs have improved the quality of life for selected patients.^{406,409}

Several investigators have studied the quality of patients' lives after surgical salvage treatment for recurrent cervical cancer.^{406,410,411} In the first years after exenteration, patients' quality of life is heavily influenced by worries about the progression of tumor.⁴¹⁰ Most investigators report that the most common problems for survivors relate to their adjustment to urostomy or colostomy. Women with vaginal reconstruction tend to report fewer sexual problems and better quality of life than those without reconstruction.^{407,410} However, vaginal dryness and discharge still may interfere with intercourse.⁴¹¹ In a retrospective study of 75 exenterations, Berek et al.⁴⁰⁶ found that the approach that produced the best outcome included the creation of a neovagina using a pedicled transverse rectus abdominis myocutaneous flap, the creation of a continent urinary conduit using a colonic (Miami) pouch, and the performance of a primary colon reanastomosis or the creation of a rectal J-pouch. All of these findings indicate the importance of adequate counseling following the exenterative surgery. The 5-year survival rate for patients who undergo anterior pelvic exenteration is 33% to 60%; the 5-year survival rate for those who undergo total pelvic exenteration is 20% to 46%.^{406,410,411} For patients who have unresectable recurrent disease after definitive irradiation, treatment options are limited. Several groups are exploring the role of intraoperative irradiation in the treatment of selected patients with recurrent disease that involves the pelvic wall.⁴¹² However, most patients who have unresectable pelvic recurrences after radiotherapy are treated with chemotherapy alone; response rates and prognosis are generally poor.

Treatment After Simple Hysterectomy that Reveals Unsuspected Invasive Cancer. Every patient who undergoes a planned hysterectomy should be carefully screened before the procedure to rule out invasive cervical cancer. When unexpected invasive cancer is detected in a hysterectomy specimen, the patient should be referred for consideration of additional treatment.⁴¹³ Patients with invasion of <3 mm without LVSI usually require no treatment after simple hysterectomy. However, patients with more extensive disease should undergo treatment of the paracolpal tissues and nodes.

Patients who have negative margins usually are treated with pelvic radiotherapy to 45 or 50 Gy. Most clinicians follow this with vaginal intracavitary brachytherapy, delivering an additional vaginal surface dose of 30 to 50 Gy. Patients with positive margins may benefit from a somewhat higher dose of external beam irradiation through reduced fields designed to include the region at highest risk (e.g., parametria and posterior bladder wall).^{413,414} In a report of the results of radiotherapy in 123 patients in whom hysterectomy revealed unsuspected invasive cancer, Roman et al.⁴¹³ reported 5-year survival rates of 79% for patients with negative margins and 59% for those with microscopically positive margins. In contrast, the 5-year survival rate for 30 patients with gross residual disease was only 41% ($p = 0.0001$). Results of studies of treatment for high-risk cervical cancer after radical hysterectomy suggest that concurrent treatment with chemotherapy and radiation should probably be considered for patients who have positive margins or gross residual disease.

Carcinoma of the Cervical Stump. Supracervical hysterectomy was once a popular treatment for benign uterine conditions. Although enthusiasm for the procedure declined after the 1950s, its use has increased somewhat in recent years. The natural history, staging, and workup for cervical stump carcinomas are the same as those for carcinomas of the intact uterus.

Patients with stage IA1 disease may be treated with simple trachelectomy, and selected patients with stage IA2 or small stage IB tumors may be treated with radical trachelectomy and pelvic lymph node dissection. However, most patients are treated with irradiation alone using a combination of external beam therapy and brachytherapy. The altered geometry and short uterine canal in these patients complicate treatment planning. MRI may be an important aid to treatment planning in these patients. However, in most cases, the endocervical canal is 2 cm or longer, and after a course of external beam irradiation, patients can be adequately treated with intracavitary therapy. If the endocervical canal cannot accommodate any sources, a boost dose may be delivered to the tumor with interstitial therapy or transvaginal irradiation. Vaginal ovoids alone rarely deliver an adequate dose to the cervix. If brachytherapy is impossible, some patients can be cured using external beam irradiation with reduced fields. However, brachytherapy should be used whenever possible. Barillot et al.⁴¹⁵ reported a survival rate of 81.5% for patients treated with combined brachytherapy and external beam irradiation versus 38.5% for those treated with external beam irradiation alone. When brachytherapy is used, most investigators have reported survival rates similar to those for patients with carcinomas of the intact cervix.^{415,416}

Carcinoma of the Cervix During Pregnancy. Estimates of the incidence of invasive cervical cancer during pregnancy range from 0.02% to 0.9%.^{417,418} Estimates of the incidence of pregnancy in patients with invasive cervical cancer usually range between 0.5% and 5%. Hacker et al.⁴¹⁷ reported an incidence of cervical carcinoma in situ of 0.013% in pregnant women.

Any suspicious cervical lesion observed during pregnancy should be biopsied. If the Pap smear is positive for malignant cells and the diagnosis of invasive cancer cannot be made with colposcopy and biopsy, a diagnostic conization may be necessary. Because conization subjects the mother and fetus to complications, it should be performed only in the second trimester and only in patients with inadequate colposcopy findings and strong cyto-

logic evidence of invasive cancer. Conization in the first trimester of pregnancy is associated with an abortion rate of up to 33%.⁴¹⁶ Conservative conization under colposcopic guidance may reduce this risk.⁴¹⁹

It appears to be safe to delay definitive treatment of patients with carcinoma in situ or stage IA disease until the fetus has matured.⁴¹⁷⁻⁴¹⁹ Patients whose disease invades <5 mm may be followed to term. The infant may be delivered by a cesarean section, which is followed immediately by modified radical hysterectomy or radical trachelectomy and pelvic lymph node dissection.

Treatment of patients with more advanced cancers depends on the stage of gestation and the wishes of the patient. Modern neonatal care affords a very high survival rates for infants delivered at >28 weeks of gestational age. Fetal pulmonary maturity can be determined by amniocentesis, and, when pulmonary maturity is documented, the infant can be delivered and prompt treatment of the mother can be instituted. It is probably wise to avoid delays in therapy of >4 weeks whenever possible, although this guideline is controversial.^{418,420} For most women with stage IB1 tumors, the recommended approach is classic cesarean section followed by radical hysterectomy with pelvic lymph node dissection. There

should be a thorough discussion of the risks and options with both parents before any treatment is undertaken.

Patients with stage II–IV tumors and some patients with bulky stage IB cervical cancers will require radiotherapy to treat their cancer. If the fetus is viable at the time of diagnosis, it is delivered by classic cesarean section and radiotherapy is begun postoperatively. In the second trimester, a delay of therapy may be entertained to improve the chances of fetal survival. If the patient wishes to delay therapy, it is important to ensure fetal pulmonary maturity before delivery is undertaken.

Compared with other patients with cervical cancer, those with cervical cancer during pregnancy have slightly better overall survival because an increased proportion have stage I disease. Although studies differ in their conclusions about whether pregnancy has an independent influence on the prognosis of patients with cervical cancer, case-matched studies have suggested similar survival rates for pregnant and nonpregnant patients.⁴²¹

Patients who are diagnosed with invasive cervical cancer shortly after a vaginal delivery and who had an episiotomy appear to be at risk for recurrence at the site of their episiotomy. At least 13 cases demonstrating this unusual pattern of failure have been reported.⁴²²

ENDOMETRIAL CARCINOMA

Epidemiology

Endometrial cancer is the most common gynecologic malignancy and the fourth most frequently diagnosed cancer in women in the United States. The American Cancer Society¹ estimates there will be 52,630 new cases and 8,590 deaths in 2014. The median age of diagnosis for endometrial cancer is 61 years, with 20% diagnosed before menopause, including 5% who develop the disease before age 40.

The exact etiology of endometrial cancer remains unknown, but chronic unopposed estrogenic stimulation is considered the main risk factor. The normal endometrium is a hormonally responsive tissue; estrogenic stimulation produces cellular growth and glandular proliferation, which is cyclically balanced by the maturational effects of progesterone.² Because menarche and menopause are commonly associated with absent or irregular ovulation, women who experience *early menarche* or *late menopause* are more likely to have additional estrogenic exposure, thus higher risk of developing endometrial cancer.³ *Nuliparity* is also associated with increased risk of endometrial cancer,⁴ due in part to anovulatory menstrual cycles. Morbidly obese women are at greatest risk of endometrial cancer, presumably because their adipocytes are able to convert androstenedione of adrenal origin to estrone, a weak circulating estrogen. Obesity may also influence endometrial cancer risk via chronic hyperinsulinemia, which appears to be a key factor for the development of ovarian hyperandrogenism, associated with anovulation and progesterone deficiency, especially for premenopausal women.⁵ *Non-insulin-dependent diabetes mellitus* and *hypertension* also increase the risk of endometrial cancer, in large part secondary to obesity, but there are data showing that these risk factors could operate independently.⁶⁻⁸ The use of *estrogen-only hormone-replacement therapy* and *sequential oral contraceptives* significantly increase endometrial cancer risk (relative risk, 10 to 20), while combined preparations (i.e., that contain progesteragen) have a protective effect (relative risk, 0.3 to 0.5).⁹⁻¹¹

The use of *tamoxifen* in patients with breast cancer has been associated with increased risk of endometrial cancer.¹²⁻¹⁴ In premenopausal women, tamoxifen has an antiestrogenic effect, but in postmenopausal women it has a weak estrogenic effect because of the upregulation of estrogen receptors. In a meta-analysis about adjuvant tamoxifen and endometrial cancer, for patients who were <55 years, there was little absolute risk. In contrast, for patients in the 55 to 69 years age group, the 15-year incidence was 3.8% in the tamoxifen group versus 1.1% in the control group (absolute increase, 2.6%), highlighting the influence of age on the risk of endometrial cancer from tamoxifen use.¹⁵ Initial data seem to indicate that the majority of endometrial cancers associated with tamoxifen use were early stage with favorable features.¹⁶ Other data, however, point to a change in the profile of these endometrial cancers with a rise in the rate of serous carcinoma, clear cell carcinoma, carcinosarcoma, and sarcoma.^{17,18} The risk of endometrial cancer from tamoxifen, including the duration of its use,

has to be weighed against its benefit in reducing mortality from breast cancer.¹⁹

About 5% of endometrial cancers are associated with *Lynch syndrome* or hereditary nonpolyposis colorectal cancer. Lynch syndrome is an autosomal dominant inherited cancer susceptibility syndrome caused by a germline mutation in one of the DNA mismatch repair genes (*MSH2*, *MLH1*, *MSH6*, *PMS2*). Women with this syndrome have a 40% to 60% risk of endometrial cancer, which equals or exceeds their risk of colorectal cancer. In a study of 537 families with Lynch syndrome,²⁰ the estimated cumulative risks for endometrial cancer by age 70 years were 54% for *MLH1* mutation carriers, 21% for *MSH2*, and 16% for *MSH6*. The mean age at endometrial cancer diagnosis in women with Lynch syndrome has been reported to be 46 to 54 years, compared with a mean age of 60 years in the general population.^{21,22} There seems to be a high rate of lower uterine segment involvement in patients with Lynch syndrome associated endometrial cancer.²³ In terms of histology, endometrioid is the most common, but other histology, such as uterine serous carcinoma, clear cell carcinoma, and carcinosarcoma, have been reported in patients with Lynch syndrome.²¹

Natural History and Routes of Spread

The most common presentation for endometrial cancer is postmenopausal vaginal bleeding, which is reported by 80% to 90% of patients. The incidence of endometrial cancer in women presenting with postmenopausal bleeding, however, is only 10% to 15%. This incidence could vary from 1% up to 25% depending on patient's age, the number of vaginal bleeding episodes, and presence of other risk factors such as diabetes and high body mass index.²⁴ Other patterns of presentations include vaginal discharge, abnormal Papanicolaou smear, or thickened endometrium on routine transvaginal ultrasound. Presenting with urinary or rectal bleeding, pain, lower extremity lymphedema, ascites, and cough and/or hemoptysis is rare and often indicative of advanced disease.

The uterus has a rich and complex lymphatic network. The main body of the uterus drains via lymphatic trunks that condense in the parametria and end up in pelvic nodes. Channels draining the superior portion of the fundus and fundal uterine serosa parallel the ovarian vessels and empty into the para-aortic lymph nodes in the upper abdomen. A few small lymphatic vessels course through the round ligaments to the superficial inguinal nodes. Invasion into adjacent organs such as bladder and rectum may occur, although not frequent. Tumor cells may gain access to the peritoneal cavity and at times leading to peritoneal implants, similar to ovarian cancers. Sites of distant spread include lungs, liver, and bone.

Diagnosis and Pretherapy Evaluation

Office endometrial biopsy is the preferred approach to establish the diagnosis of endometrial cancer. Its sensitivity in detecting endometrial cancer in postmenopausal women is 99.6%, compared to 91% in premenopausal women, and its specificity is >98% for both groups.²⁵ However, if symptoms persist, the biopsy

sampling is inadequate, or patient is being considered for conservative fertility-sparing approaches, a dilatation and curettage should be performed instead. In order to confirm a diagnosis of endometrial cancer, a tissue diagnosis is required and it must not be substituted by imaging studies. *Transvaginal ultrasonography* may be a useful imaging modality, particularly in patients who are medically compromised in whom obtaining a tissue sample is not feasible. Normal endometrium looks thin and homogeneously hyperechoic, but it becomes thickened and heterogeneous with hyperplasia, polyps, and cancer.²⁶ The consensus statement from the Society of Radiologists in Ultrasound has defined an endometrial thickness of ≥ 5 mm as being abnormal.²⁷ If the thickness of the endometrium is < 5 mm, the risk of endometrial cancer is minimal; the false negative rate is about 4% in general.²⁸ Recent meta-analysis seems to indicate that perhaps a cut-off of 3 mm thickness provides even better diagnostic accuracy.²⁹

The utility of *computed tomography (CT) imaging* in changing the management of patients with endometrial cancer has been evaluated prospectively. When patients have a preoperative diagnosis of endometrial hyperplasia or endometrioid low-grade carcinoma, CT scan imaging changed the planned treatment only 4% of the time. By contrast, in patients with higher grade histology and high-risk histologic subtypes such as papillary serous or clear cell carcinoma, CT scan imaging changed treatment in 11% of the time.³⁰

Magnetic resonance imaging (MRI), especially dynamic contrast-enhanced MRI, is very useful in detecting myometrial invasion,³¹ with an accuracy of 85% to 93%. In patients with suspected cervical involvement, preoperative MRI may also facilitate determining if the uterine tumor involves the lower uterine segment or if there is true extension into the cervix. Documenting gross cervical involvement from endometrial cancer, albeit a rare finding, is important since radical hysterectomy as opposed to simple hysterectomy might be the preferred surgical approach. *Position emission tomography (PET)/CT* is of little benefit in assessing the primary tumor extension. With regard to regional lymph nodes metastasis, the reported sensitivity is 50% to 100%, specificity 87 to 100, and accuracy 78% to 100%. The main limitation of PET/CT is its inability to detect metastasis in lymph nodes ≥ 5 mm in size.³² *Serum CA 125* levels may be a predictor of extrauterine disease.³³ In a study of 214 endometrial cancer patients, serum CA 125 was found to be an independent risk factor for pelvic and para-aortic lymph node metastasis.³⁴ Elevated levels of CA 125 may also assist in predicting treatment response or in posttreatment surveillance.³⁵

Pathology

Endometrial *hyperplasia* is the precursor lesion of the most common endometrial cancer, endometrioid adenocarcinoma. The World Health Organization classifies endometrial hyperplasia into four subtypes: simple hyperplasia, complex hyperplasia, simple atypical hyperplasia, and complex atypical hyperplasia.³⁶ The risk of progressing to endometrial cancer is only 1% for simple hyperplasia, but increases up to 29% for complex hyperplasia associated with atypia.³⁷ The Gynecologic Oncology Group (GOG) conducted a prospective trial in which all patients with atypical hyperplasia of the uterus underwent an immediate hysterectomy. The rate of underlying concurrent carcinoma in the uterus was 42.6% in these patients.³⁸ The standard recommended treatment for atypical hyperplasia of the uterus is hysterectomy. In patients who desire future fertility or have an absolute contraindication to surgery, progestational therapies may be used with caution.³⁹

The most common histologic subtype of endometrial cancer is *endometrioid*. The grading is primarily driven by the architectural grading, which is determined by the amount of solid masses of tumor cells compared to well-defined glands. Grade 1 is an endometrioid cancer in which $< 5\%$ of the tumor growth is in

solid sheets. Grade 2 is an adenocarcinoma in which 6% to 50% of the tumor is composed of solid sheets of cells. Grade 3 occurs when $> 50\%$ of the tumor is made up of solid sheets. There are several subtypes of endometrioid adenocarcinoma, as shown in Table 73.1. *Serous carcinoma*, also known as uterine papillary serous cancer, is seen in about 10% of endometrial cancers. The presence of marked cellular atypia in addition to papilla is what distinguishes serous carcinoma from others. This is an aggressive subtype with a high propensity for early lymphatic and intraperitoneal dissemination, often despite little myometrial penetration.⁴⁰ Other histologies include clear cell carcinoma and undifferentiated carcinomas. The latter can also be associated with an endometrioid carcinoma component, and such tumors have been referred to as “dedifferentiated carcinomas,” which may belong to the spectrum of gynecologic neoplasms seen in the setting of microsatellite instability and possibly Lynch syndrome.⁴¹

Prognostic Factors

Several clinicopathologic factors have been identified in patients with endometrial carcinoma to help predict the prognosis and individualize the treatment plan.^{42,43} At Memorial Sloan Kettering Cancer Center (MSKCC), a nomogram was developed for predicting overall survival of women with endometrial cancer ($n = 1,735$) following primary therapy.⁴⁴ Five prognostic factors (age, grade, histologic type, number of lymph nodes removed, and International Federation of Gynecology and Obstetrics [FIGO] 1988 surgical stage) were used to predict overall survival (OS) with high concordance probability (Fig. 73.1).

The adverse prognostic factors in endometrial cancer that are part of the staging system include depth of myometrial invasion, cervical stromal involvement, adnexal involvement, pelvic/para-aortic node involvement, extension into bladder or rectum, and distant spread.^{42,43} Other prognostic factors include age, grade, histologic type, and lymphovascular invasion (LVI). The adverse impact of *older age* is often explained away by pointing out that older patients tend to present with aggressive histologies and more advanced disease and are generally treated less aggressively. Age of ≥ 60 years, however, has been shown to be predictive of local-regional recurrence (hazard ratio [HR] 3.9; $p = 0.0017$) and death (HR: 2.66; $p = 0.01$) in a randomized trial limited to stage I and where patients with deep myometrial invasion and grade 3 were excluded.⁴⁵ Further, the adverse impact of advanced age persists even when older patients are treated as aggressively as younger patients.⁴⁶ It is unclear if the prognosis differs significantly between grade 1 and 2 patients. What is clear is the adverse impact of *grade 3* on outcome. In the FIGO annual report,⁴⁷ *grade 3* was an independent predictor of poor survival on multivariate analysis within each stage: stage I (HR: 2.45), II (HR: 2.14), III (HR: 2.44), and

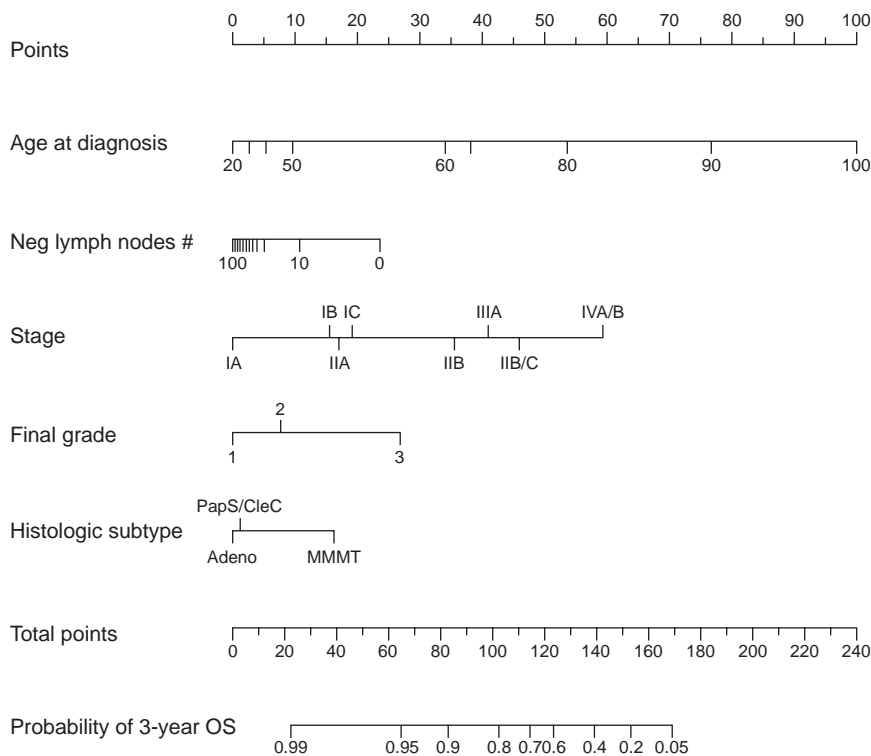

Figure 73.1 Overall survival (OS) nomogram.

stage IV (HR: 2.55). In that report, the 5-year survival rates based on *histology* were 83.2% for endometrioid adenocarcinoma, compared to 52.6% for serous and 62.5% for clear cell in 8,033 surgically staged patients.⁴⁷ LVI is seen in about 15% of patients with clinically stage I (confined to uterus) endometrial cancer.⁴² Its presence causes a four- to six-fold increase in the rate of pelvic and para-aortic nodal metastases.⁴² This translates into more frequent relapses, including vaginal recurrences^{48,49} and a poorer outcome.⁵⁰

On the basis of a prospective study of 366 patients with endometrial carcinoma, Bokhman⁵¹ postulated that there are two different pathogenetic types of endometrial carcinoma. Type I disease arises in women with obesity and signs of hyperestrogenism: anovulatory uterine bleeding, infertility, late onset of the menopause, and hyperplasia of the endometrium. The tumors tend to be well to moderately differentiated, with minimal invasion, and tend to carry good prognosis. Type II arises in women who lack signs of hyperestrogenism and tend to be older. The tumors are often poorly differentiated, with deep myometrial invasion and frequent occurrence of extrauterine spread.⁵¹ What is remarkable is that this clinical observation can now be confirmed at the molecular level. In a review by Dedes et al.,⁵² the most frequently altered molecular pathway in type I endometrial carcinomas is the phosphatidylinositol-3 kinase (PI3K)/phosphatase and tensin homolog (PTEN)/protein kinase B (AKT) pathway, whereas alterations in type II endometrial cancers involve the tumor suppressors p53 and/or p16. More recent genomics data seem to show that there are in fact four distinct types of endometrial cancer with different prognosis based on number of mutations (ultramutated versus hypermutated) and copy numbers (low versus high) observed.⁵³

Staging

In 2009, the FIGO Committee on Gynecologic Oncology (Table 73.2) revised the 1988 staging for endometrial cancer.³⁴ There were several modifications in the new staging system. Patients who used to be staged as IB (i.e., <50% myometrial invasion) are now considered IA. Those with $\geq 50\%$ myometrial

TABLE 73.2

Revised International Federation of Gynecology and Obstetrics Staging for Endometrial Cancer

Stage I ^a	Tumor confined to the corpus uteri
IA ^a	No or less than half myometrial invasion
IB ^a	Invasion equal to or more than half of the myometrium
Stage II ^a	Tumor invades cervical stroma but does not extend beyond the uterus ^b
Stage III ^{a,c}	Local and/or regional spread of the tumor
IIIA ^a	Tumor invades the serosa of the corpus uteri and/or adnexae ^a
IIIB ^a	Vaginal and/or parametrial involvement ^a
IIIC ^a	Metastases to pelvic and/or para-aortic lymph nodes ^a
IIIC1	Positive pelvic nodes
IIIC2	Positive para-aortic lymph nodes with or without positive pelvic nodes
Stage IV ^a	Tumor invades bladder and/or bowel mucosa, and/or distant metastases
IVA ^a	Tumor invasion of bladder and/or bowel mucosa
IVB ^a	Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes

^a Either G1, G2, or G3.

^b Endocervical glandular involvement only should be considered as stage I and no longer as stage II.

^c Positive cytology has to be reported separately without changing the stage. From Pecorelli S. International Federation of Gynecology and Obstetrics: Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynecol Obstet* 2009;105:103–104.

invasion are designated as stage IB. The discriminating power of the new FIGO staging system is being debated. Page et al.⁵⁵ evaluated a total of 10,839 cases from 1998 to 2006 using the Surveillance, Epidemiology, and End Results program. The analysis demonstrated the usefulness of two divisions rather than three for stage I in the new FIGO staging system.⁵⁵ In contrast, a study from MSKCC of 1,307 patients with FIGO 1988 stage I disease showed that the revised system for stage I did not improve its predictive ability over the 1988 system.⁵⁶ Endocervical glandular involvement does not affect staging anymore; only patients with cervical stromal invasion are considered stage II. Having positive peritoneal cytology does not affect staging either. But it is important to continue to obtain peritoneal cytology because of its prognostic impact, especially in patients with other extrauterine features. Milgrom et al.⁵⁷ reported on 196 patients with stage III (2009 FIGO staging system) endometrial cancer, where positive peritoneal cytology was associated with an increased hazard for relapse (HR 2.3; $p = 0.002$) and death (HR 2.9; $p < 0.001$). Parametrial extension is now considered IIIB. Patients with stage IIIC are now subdivided into IIIC1 if pelvic nodes are involved and IIIC2 if para-aortic nodes are involved.

Treatment of Early-Stage (I-II) Disease

Surgery

The main treatment is simple hysterectomy/bilateral salpingo-oophorectomy (BSO), peritoneal cytology, and some form of regional lymph node assessment. Salpingo-oophorectomy is recommended since 5% of patients with clinically stage I (confined to uterus) endometrial cancer may have adnexal involvement.⁴² There is also the concern about synchronous ovarian cancer⁵⁸; among all women with endometrial cancer, 3.1% have a synchronous ovarian cancer, but among women <50 years of age, the rate is as high as 9.4%. Differentiating between metastasis to ovary as opposed to synchronous ovarian cancer is not always easy. The use of genetic profiling may represent a powerful tool for use in clinical practice for distinguishing between metastatic and dual primaries in patients with simultaneous ovarian/endometrial cancer and predicting disease outcome.⁵⁹ The revised staging system requires that cytology be obtained and be reported separately without changing the stage. Positive peritoneal cytology is seen in about 12% of patients with clinically stage I (confined to uterus) endometrial cancer.⁴² The simple hysterectomy could be done with an open approach (i.e., *total abdominal hysterectomy* [TAH/BSO]) or with a minimally invasive approach (i.e., *laproscopic-assisted hysterotomy/BSO* or *robotic assisted hysterectomy/BSO*). The GOG completed a trial where patients with clinical stage I to occult IIA uterine cancer were randomly assigned to laparoscopy ($n = 1,696$) or open laparotomy ($n = 920$), including hysterectomy, salpingo-oophorectomy, pelvic cytology, and pelvic and para-aortic lymphadenectomy. Laparoscopy had fewer moderate to severe postoperative adverse events than laparotomy (14% versus 21%, respectively; $p < 0.0001$). Hospitalization of >2 days was significantly lower in laparoscopy versus laparotomy patients (52% versus 94%, respectively; $p < 0.0001$). The conversion rate to laparotomy was 25.8%. The estimated 5-year OS was 89.8% for laparoscopy and 89.8% for laparotomy.^{60,61} In 2005, the US Food and Drug Administration (FDA) approved the da Vinci robotic system for gynecologic procedures. In a recent systematic review of robotic surgery in gynecology, investigators found that the proficiency plateau seems to be lower for robotic surgery than for conventional laparoscopy. The conclusion from this analysis was that the specific method of minimally invasive surgery, whether conventional laparoscopy or robotic surgery, should be tailored to patient selection, surgeon ability, and equipment availability.⁶²

With regards to regional lymph node assessment, the options range from removing only grossly suspicious nodes to routine lymphadenectomy for all comers. Based on GOG 33 surgical-

pathologic assessment,⁴² the rate of positive pelvic lymph node in patients who are otherwise clinically stage I (confined to the uterus) is 9% and the rate of positive para-aortic node is 6%. Two randomized trials addressed the role of *lymphadenectomy* in early-stage endometrial cancer. In both trials, patients with clinically stage I disease were randomized to pelvic lymphadenectomy versus none. Para-aortic node sampling was optional. In the first trial, 514 patients were randomized and with a median follow-up of 49 months, the 5-year disease-free and OS rates, in an intention-to-treat analysis, were similar between arms (81.0% and 85.9% in the lymphadenectomy arm and 81.7% and 90.0% in the no-lymphadenectomy arm, respectively).^{63,64}

These two trials have been criticized extensively due to multiple flaws in design and to numerous study deviations. Nonetheless, most gynecologic oncologists agree that staging of apparent uterine-confined endometrial cancer is to help guide adjuvant therapy and potentially limit toxic additional therapy but by itself is not therapeutic. A middle ground approach between removing only grossly suspicious node to routine lymphadenectomy is emerging. It is sentinel lymph node (SLN) mapping (Fig. 73.2). In a prospective trial from France, regarding the role of SLN in early-stage endometrial cancer, at least one SLN was detected in 111 of the 125 eligible patients. Of the 111 patients, 19 (17%) had pelvic-lymph-node metastases. Three patients had false-negative results (two had metastatic nodes in the contralateral pelvic area and one in the para-aortic area), giving a negative predictive value of 97% (95% confidence interval = 91 to 99) and sensitivity of 84% (62% to 95%). SLN biopsy upstaged 10% of patients with low-risk and 15% of those with intermediate-risk endometrial cancer.⁶⁵ Currently at MSKCC *sentinel node mapping algorithm* is utilized to further refine the utility of such technique.⁶⁶ SLN mapping is for *normal-appearing nodes*. Any grossly enlarged or suspicious nodes must be evaluated irrespective of mapping. In fact such nodes, while being the sentinel nodes, often do not absorb the injected dye or radiocolloid (i.e. don't map). Similarly, a failed mapping on a hemipelvis cannot be considered a "negative, healthy pelvic sidewall." A failed mapping should be accompanied by a side-specific lymphadenectomy to include the iliac and obturator nodes (Fig. 73.3). In a recent study from MSKCC, 498 patients received a blue dye cervical injection for SLN mapping. At least one lymph node was removed in 95% of cases (474/498); at least one SLN was identified in 81% (401/498). SLN correctly diagnosed 40/47 patients with nodal metastases who had at least one SLN mapped, resulting in a 15% false-negative rate. However, after applying the algorithm mentioned previously, the false-negative rate dropped to 2%. Only one patient, whose lymph node spread would not have been caught by the algorithm, had an isolated positive right para-aortic lymph node with a negative ipsilateral SLN and pelvic lymph node dissection.⁶⁷ In general, isolated para-aortic nodal metastasis in the absence of pelvic nodal metastasis is rare and only seen in 1% to 3% of cases.⁶⁸ Further, there is no definitive, well-documented association between para-aortic nodal assessment and improved OS in endometrial cancer.⁶⁹

In summary, minimally invasive simple hysterectomy/BSO (laproscopic or robotic), peritoneal cytology, and SLN mapping seems to provide the highest prognostic/therapeutic yield while maintaining a low morbidity profile.

Radiation

Indications and types of radiation for early-stage endometrioid adenocarcinoma are shown in Table 73.3. For patients with *stage IA grade 1 and 2* endometrioid adenocarcinoma (no or <50% myometrial invasion), adjuvant radiotherapy (RT) is not routinely recommended. In a trial reported by Sorbe et al.,⁷⁰ 645 such patients were randomized after surgery to observation ($n = 326$) or intravaginal RT ($n = 319$). Surgery consisted of TAH/BSO (laproscopic was allowed), pelvic washing, and removal of enlarged nodes. The

Figure 73.2 Diagrammatic illustration of the location of the sentinel lymph nodes (blue in relationship to vessels between internal and external iliac arteries).

rate of vaginal recurrence was 3.1% in the observation arm compared to 1.2% for the intravaginal RT arm ($p = 0.114$). The rate of pelvic recurrence was 0.9% in the observation arm and 0.3% in the treatment arm ($p = 0.326$). There was no significance difference between the two arms in terms of OS.⁷⁰ Since the data from this trial did not report outcome based on myometrial invasion, it is difficult to determine the true impact of intravaginal RT on patients with <50% invasion as opposed to those without any invasion. Therefore, while observation is still a valid option for patient with grade 1-2 and myometrial invasion that is <50%, age of patient and the presence of LVI should be taken into account. In the randomized trial by Sorbe et al.⁷⁰ mentioned previously, patients with vaginal recurrences were significantly ($p = 0.018$) older (mean age: 68.6 years) compared to patients without vaginal recurrences (mean: 62.6 years). Mariani et al.⁴⁸ reported on 508 patients (152

without any invasion) with stage I endometrial cancer treated with surgery alone. LVI significantly increased the vaginal relapse rate from 3% to 7% ($p = 0.02$). At MSKCC, patients who are ≥ 60 years old or have LVI are recommended to have intravaginal RT.

For patients with *stage IA grade 3* endometrioid adenocarcinoma, those without myometrial invasion could be observed or treated with postoperative intravaginal RT, while patients with <50% invasion are often treated with adjuvant radiation. In PORTEC-1 trial, 715 patients with stage I (excluded were patients with <50% myometrial invasion grade 1 and patients with >50% grade 3) endometrial cancer were randomized after TAH/BSO to observation or pelvic RT.⁷¹ In the subset of patients with <50% myometrial invasion grade 3 endometrioid tumors ($n = 37$), the 5-year vaginal recurrence rate was 14% with surgery alone compared to 0% for those treated with pelvic RT. In contrast, none

TABLE 73.3

Treatment Recommendations for Early-Stage (FIGO 2009) Endometrioid Adenocarcinoma of the Uterus

	Grade 1/2	Grade 3
IA	Observation ^a	Observation versus IVRT
IB	IVRT	IMRT versus IVRT plus CT
II ^b (<50% cervical stromal invasion)	IVRT	IMRT versus IVRT plus CT
II (>50% cervical stromal invasion)	IMRT	IMRT versus IVRT plus CT

^a Consider IVRT for patients with <50% myometrial invasion who are also ≥ 60 years or have lymphovascular invasion.

^b Patients with endocervical gland involvement, although no longer considered stage II, should be treated in a similar fashion to this subgroup of stage II.

IVRT, intravaginal radiation; IMRT, intensity modulated radiation therapy; CT, chemotherapy, generally paclitaxel/carboplatin.

of 37 patients in this subset relapsed in the pelvis irrespective of the treatment.⁷² Horowitz et al.⁷³ ($n = 31$) and Fanning et al.⁷⁴ ($n = 21$) reported no vaginal or pelvic recurrence in their series of patients with <50% myometrial invasion grade 3 treated with postoperative intravaginal RT. Such data indicates that intravaginal RT is the preferred approach in these patients.

For patients with *stage IB grade 1 and 2* endometrioid adenocarcinoma in PORTEC-1 trial, the 5-year vaginal recurrence for patients treated with surgery alone was 10% for those with grade 1 and 13% for grade 2. In contrast, the corresponding 5-year vaginal recurrence rates for patients treated with pelvic RT were 1% and 2%, respectively. The risk of pelvic recurrence at 5 years after surgery alone for these patients (>50% invasion) was 2% for grade 1 and 6% for grade 2 tumors.⁷² One of the important questions in patients with IB grade 1 and 2 is whether pelvic RT could be safely omitted. There are two randomized trials comparing pelvic RT to intravaginal RT. Neither trial required pelvic lymphadenectomy. In PORTEC 2 trial, 427 patients were randomized to pelvic RT ($n = 214$) or intravaginal RT ($n = 213$) after TAH/BSO. Inclusion criteria in this trial differed from that in PORTEC-1. For patients with stage I, they needed to be ≥ 60 years old and have either grade 3 tumors with <50% myometrial invasion or >50% invasion grade 1 and 2 tumors. Patients with endocervical mucosal involvement were also added. The 5-year vaginal recurrence rates were 1.8% in the intravaginal RT arm and 1.6% in the pelvic RT arm ($p = 0.74$). The pelvic recurrence was 3.8% in the intravaginal RT arm compared to only 0.5% in the pelvic RT arm ($p = 0.02$). There was no significant difference in disease-free or OS between the two arms.⁷⁵ The other trial reported by Sorbe et al.,⁷⁶ patients with stage I endometrioid adenocarcinoma with at least one of the following risk factors (grade 3, $\geq 50\%$ myometrial invasion, or DNA aneuploidy) were randomized to adjuvant intravaginal RT ($n = 263$) or pelvic plus intravaginal RT ($n = 264$). The vaginal recurrence rate was 2.7% (7/263) in the intravaginal RT alone arm compared to 1.9% (5/264) in the pelvic RT arm ($p = 0.555$). Pelvic recurrence rate, however, was different: 5.3% in the intravaginal RT alone arm compared to 0.4% in the pelvic RT arm ($p = 0.0006$). There was no significant difference in OS between the two arms (90% versus 89%, respectively).⁷⁶ The data from these trials indicate that the omission of pelvic RT in favor of intravaginal RT did not significantly increase the risk of vaginal recurrence. The reported risk of pelvic recurrence after lymphadenectomy or pelvic RT in patients with >50% invasion grade 1 and 2 tumors is about 1.5% on average.^{73,77-79} But that is not a sufficient reason to recommend routine lymphadenectomy or pelvic RT for two reasons. First, neither pel-

vic RT nor lymphadenectomy have been shown to improve survival in patients with early-stage endometrial cancer. Second, in the PORTEC-2 trial,⁷⁵ most patients with pelvic recurrences had simultaneous distant metastasis. The 5-year rate of isolated pelvic recurrence was only 1.5% in the intravaginal RT arm compared to 0.5% for pelvic RT ($p = 0.3$). At MSKCC, most of these patients (IB, grade 1 and 2) undergo SLN mapping, and if the nodes are pathologically negative, they receive intravaginal RT alone.

Patients with *stage IB grade 3* endometrioid adenocarcinoma were not enrolled in PORTEC 1 or 2 trials, because it was felt that omitting pelvic RT when lymphadenectomy was not performed could not be justified. In the registry study reported by Creutzberg et al.,⁷² 99 patients with $\geq 50\%$ myometrial invasion grade 3 were treated with postoperative pelvic RT. The 5-year rate of vaginal recurrence was 5%, pelvic recurrence 8%, and distant relapse 31%. Very few investigators would recommend surgery alone for these patients. In fact, an argument could be made that pelvic RT might be needed even after a negative lymphadenectomy especially for older patients and those with LVI. In a GOG 99 trial, 190 patients with stage I-II (patients without myometrial invasion were excluded) underwent TAH/BSO, pelvic washing, and pelvic/para-aortic lymph nodes sampling and then were randomized to observation versus pelvic RT.⁸⁰ At 2 years, there was a statistically significant difference in the rates of relapse in favor of the adjuvant pelvic RT arm (3% versus 12%, $p = 0.007$). There was, however, no significant difference in 4-year OS (92% RT versus 86% with surgery alone, $p = 0.557$). The benefit of pelvic RT was predominantly seen in a subset of patients designated “high-intermediate risk (HIR)” based on advancing age, grade 2 or 3 tumors, outer third myometrial invasion, and LVI. Those on the pelvic RT arm demonstrated a somewhat lower overall death rate when compared to those on the observation arm (hazard ratio = 0.73, 90% confidence interval = 0.43 to 1.26) in the HIR subgroup.⁸⁰ At MSKCC, patients with >50% myometrial invasion grade 3 who are HIR per GOG 99 would be offered postoperative pelvic RT even in the setting of negative lymphadenectomy. If they are not HIR, then intravaginal RT could be considered but only with adequate pelvic lymphadenectomy and/or SLN mapping.

Patients with *endocervical mucosal invasion* are no longer considered stage II per the FIGO 2009 staging system. However, there are no data to indicate that observation is safe; in fact such patients were randomized to either pelvic RT or intravaginal RT in PORTEC 2 trial.⁷⁵ At MSKCC, these patients are treated with postoperative intravaginal RT. Having cervical involvement, especially stromal invasion, increases the risk of lymph node involvement. In the GOG 33 surgical-pathologic assessment study, the rate positive pelvic lymph node was 8% when the cervix-isthmus was not involved versus 16% when it was involved.⁴² For patients with *stage II* (cervical stromal invasion) omitting pelvic RT could be justified, in the setting of negative lymphadenectomy, based on an average rate of vaginal recurrence of 1.47% and a similar pelvic recurrence rate of 1.47% reported in the literature for patients who underwent lymphadenectomy and intravaginal RT.^{49,73,81,82} However, patients in these series were highly selected. At MSKCC, intravaginal RT alone as opposed to pelvic RT is considered only for stage II patients who meet the following criteria: grade 1 and 2 endometrioid histology, depth of cervical stromal invasion of <50%, and adequate lymphadenectomy/SLN mapping. Patients with stage II grade 3 or those with cervical stromal invasion >50% are treated with pelvic RT.

It is clear from the data mentioned thus far that if postoperative radiation is needed in early-stage endometrioid adenocarcinoma, the preferred approach is intravaginal RT rather than pelvic RT in most cases. Intravaginal RT targets the most likely site of recurrence in patients with early-stage disease (about 80% of recurrences are vaginal) and its morbidity profile is better than pelvic RT (Fig. 73.4). In the PORTEC 2 trial randomizing patients to pelvic RT versus intravaginal RT, the rate of grade 1 and 2 acute gastrointestinal toxicity was 53% versus 12% ($p < 0.001$) in favor of intravaginal RT.⁷⁵ Furthermore, the increased risk of secondary

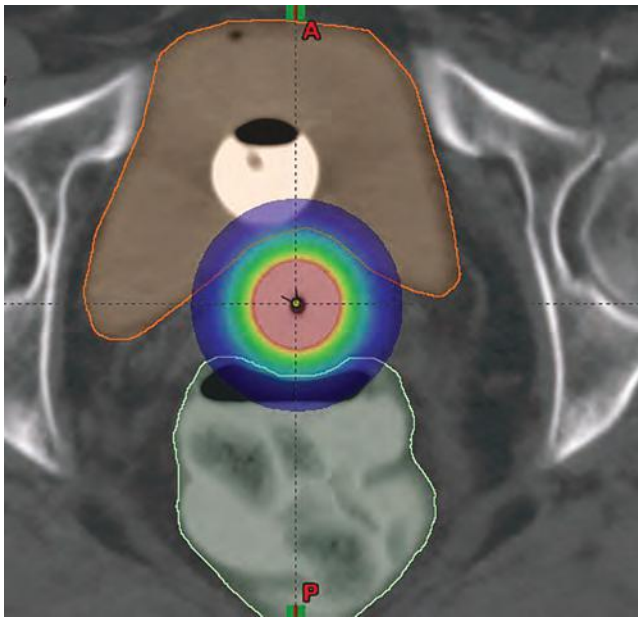

Figure 73.4 Intravaginal radiation therapy conformal dose distribution.

malignancies after pelvic RT for patients who are <60 years old has to be taken into consideration.⁸³

In summary, intravaginal RT provides the best therapeutic ratio for most patients with early-stage endometrial cancer. At MSKCC, intravaginal RT is given as an outpatient treatment using a high dose rate Ir-192. The dose is 18-21 Gy given in three fractions with 1 to 2 weeks between fractions.

Chemotherapy

Adjuvant *chemotherapy* is not routinely recommended for patients with stage I-II endometrioid adenocarcinoma. In the PORTEC-2 trial,⁷⁵ where only the high-risk patients from PORTEC-1 were included, the 5-year rate of distant relapse was 8.3% in the intravaginal RT arm and 5.7% in the pelvic RT arm ($p = 0.46$). In contrast, for patients with deep myometrial invasion grade 3 tumors in the PORTEC registry (all received pelvic RT), the 5-year rate of distant relapse was 31%, indicating the need for effective systemic therapy in this group of patients.⁷² The results of recently completed trial for early-stage high-risk patients with endometrial cancer (GOG249), where patients were randomized to pelvic RT versus intravaginal RT plus three cycles of paclitaxel/carboplatin, are eagerly awaited. At MSKCC, intravaginal RT and chemotherapy are offered as an option for patients with endometrioid adenocarcinoma stage IB grade 3 and stage II grade 3. There are more data in the literature on adjuvant chemotherapy in patients with serous endometrial cancer and to a lesser extent clear cell carcinoma. In a study from MSKCC, 41 patients with stage I-II serous cancer (those with no residual disease in hysterectomy were excluded) were treated with postoperative intravaginal RT and six cycles of paclitaxel/carboplatin. Of the 41 patients, 85% completed treatment as prescribed. With a median follow-up time of 58 months, the 5-year disease-free and OS rates were 85% and 90%, respectively. The 5-year actuarial recurrence rates were 9% in the pelvis, 5% in the para-aortic nodes, and 10% at distant sites. None of the patients developed vaginal recurrence.⁸⁴

Treatment of Stage III Disease

There are three randomized trials comparing adjuvant chemotherapy to adjuvant radiation alone. The Japanese Gynecology

Oncology Group trial randomized 385 patients with stage I (deep invasion)-III endometrial cancer patients to pelvic RT (193 patients) or to chemotherapy (192 patients). Chemotherapy consisted of cyclophosphamide (333 mg/m²), cisplatin (50 mg/m²), and doxorubicin (40 mg/m²) every 4 weeks for three cycles or more. There was no significant difference in progression-free survival (PFS; $p = 0.726$) or OS ($p = 0.462$) between the two groups.⁸⁵ The trial from Italy had similar design and inclusion criteria, where 340 patients were randomized to RT or to chemotherapy. With a median follow-up of 95.5 months, the 5-year disease-free survival was 63% in both arms ($p = 0.44$) and the 5-year overall survival rates were 69% in the radiation arm compared to 66% in the chemotherapy arm ($p = 0.77$). Again, there was no significant difference in outcome despite using five cycles of cyclophosphamide, cisplatin, and doxorubicin.⁸⁶ In GOG 122, 396 patients with stage III-IV disease were randomized to whole abdomen radiation ($n = 202$) versus doxorubicin/cisplatin ($n = 194$) for eight cycles. Progression-free survival was the primary end point of this study. With a median follow-up of 74 months, there was significant improvement in both PFS (50% versus 38%; $p = 0.007$) as well as OS (55% versus 42%; $p = 0.004$), respectively, in favor of chemotherapy.⁸⁷

There are two trials comparing adjuvant RT to chemotherapy plus RT. One trial from Finland,⁸⁸ randomized 156 patients with stage I-IIIa (FIGO 1988) to RT only or RT combined with three cycles of cisplatin (50 mg/m²), epirubicin (60 mg/m²), and cyclophosphamide (500 mg/m²) chemotherapy ($n = 84$). The disease-specific overall 5-year survival was 84.7% in the RT arm versus 82.1% in the chemoradiation arm ($p = 0.148$). The second trial by Hogberg et al.⁸⁹ is a report on two trials. In the MaNGO trial portion, there were 157 patients; 76 were randomized to pelvic RT (45 Gy) and 80 to chemoradiation. The chemotherapy consisted of three cycles of doxorubicin (60 mg/m²) and cisplatin (50 mg/m²). The 5-year PFS was 61% in the RT group compared to 74% for chemoradiation but that difference was not significant ($p = 0.1$). The 5-year OS was also not significant (73% versus 78%, respectively, $p = 0.41$). In the Nordic Society of Gynaecological Oncology/European Organization for Research and Treatment of Cancer (EORTC) trial portion, 383 patients were randomized to RT ($n = 191$) versus chemoradiation ($n = 187$). The type of chemotherapy varied and only a handful of patients were stage III. The 5-year PFS was better for the chemoradiation arm (79% versus 72% for RT, $p = 0.04$) but OS was not significantly better (83% versus 76%, respectively, $p = 0.1$).

Unlike in cervical cancer where the addition of chemotherapy to radiation has been clearly demonstrated in several large-scale randomized trials, the superiority of chemotherapy over radiation alone in endometrial cancer is not conclusive. In fact, even the results from GOG 120 trial are not that definitive. The chemotherapy arm has more patients with stage IIIC disease, therefore PFS and OS were adjusted accordingly. Without that adjustment, there would be no difference between the two arms.⁸⁷ The crude rate of relapse in the radiation arm was 54% compared to 50% in the chemotherapy arm, indicating the need for improvements in both arms of the study. Therefore, the question is no longer chemotherapy versus radiation, but rather what is the optimal way of combining the two modalities? Greven et al.⁹⁰ reported the results of RTOG 9708 phase 2 study on 44 patients with stage I-III endometrial cancer who were treated with pelvic radiation and intravaginal RT given concurrently with cisplatin (50 mg/m²) on day 1 and 28 of radiation followed by four cycles of cisplatin (50 mg/m²) and paclitaxel (175 mg/m²). The 4-year disease-free and OS was 85% and 81%, respectively. In the subset of patients with stage III disease (66% of patients), the corresponding rates were 72% and 77%, respectively.⁹⁰ Currently, the GOG is comparing chemoradiation (similar to RTOG 9708) to six cycles of carboplatin/paclitaxel in patients with stage III disease. The PORTEC 3 randomized trial is comparing chemoradiation to RT alone. Until the results of these trials are available, the decision on whether to give chemoradiation or chemotherapy alone should be based on

risk factors. Patients with stage III endometrial cancer represent a heterogeneous group of patients. In a report from MSKCC on 192 patients with stage III (FIGO 2009) endometrial cancer, three factors emerged as independent predictors of relapse and death from endometrial cancer.⁹¹ These factors were >50% myometrial invasion, positive peritoneal cytology, and aggressive histology defined as grade 3 endometrioid, serous, clear cell, or undifferentiated. The 5-year relapse rate for patients with no risk factors was 13%, one risk factor 27%, and two or more risk factors 62% ($p < 0.001$). The corresponding 5-year rates of death from endometrial cancer were 11%, 20%, and 56% ($p < 0.001$). Therefore, for patients with stage III with two or more risk factors, especially positive peritoneal cytology in the setting of serous endometrial cancer, full systemic chemotherapy (six cycles of paclitaxel/carboplatin) is preferred over chemoradiation. For those with no more than one risk factor (lymph node involvement only, for example), using an approach similar to RTOG 9708 seems feasible. In a report from MSKCC, 40 patients with stage III disease were treated as such. Of the 40 patients, 78% completed chemoradiation followed by four cycles of paclitaxel/carboplatin. With a median follow-up of 49 months, the 5-year rate of freedom from relapse and OS were 79% and 85%, respectively.⁹² When using radiation in stage III endometrial cancer, the preferred approach is intensity modulated (IM)RT because of its favorable morbidity profile. In a report from MSKCC, 46 patients with stage I-III (78% stage III) endometrial cancer were treated with postoperative radiation using IMRT. With a median follow-up of 52 months, the 5-year disease-free survival was 88% and OS was 97%. Chemotherapy was given to 30/46 patients; 5 had grade 3 leukopenia, 8 grade 2 anemia, and 2 grade 2 thrombocytopenia.⁹³

In summary, patients with stage III endometrial cancer are very heterogeneous; the treatment recommendations thus need to be individualized. Concurrent chemoradiation followed by four cycles of paclitaxel/carboplatin seems to provide excellent outcome for most patients. The preferred form of radiation at MSKCC is pelvic/extended-field IMRT to 50.4 Gy in 28 fractions. Patients who are at high risk for peritoneal relapse should be treated with full systemic therapy.

Treatment of Distant Recurrence

Patients with distant recurrence are not generally curable, and treatment choices should take both efficacy and toxicity into account, particularly as many patients with recurrent endometrial cancer are elderly.

Endocrine Therapy

Progestins have been used in the management of recurrent endometrial cancer since the 1961 report by Kelley and Baker⁹⁴ describing a response rate of 29% with various progestational agents, generally parenterally administered hydroxyprogesterone caproate. Subsequent trials generally have used medroxyprogesterone acetate or megestrol acetate (MA), which are available in pill form (Table 73.4).⁹⁵⁻⁹⁹ Results in unselected patient groups show limited activity with short median PFS, and a recent Cochrane analysis found no evidence that hormonal therapy as a single agent or in combination prolonged overall or 5-year disease-free survival.¹⁰⁰ Nonetheless, some patients will have their disease controlled for several years on hormonal therapy with minimal toxicity. In early reports, patients with well-differentiated tumors, a long disease-free interval, and lung metastases were noted to have the best results. Subsequent work suggested that tumors expressing estrogen receptors (ER) and/or progesterone receptors (PR) had the highest chance of response to progestin therapy, and some more recent trials of endocrine therapy have been limited to tumors expressing ERs or PRs.^{95,101}

Sequentially alternating tamoxifen and medroxyprogesterone acetate or MA was tested based on the hypothesis that the antiestrogen therapy could upregulate the progesterone receptor.^{102,103} Response

rates were promising, in the range of 30% in a chemotherapy-naïve population; however, median PFS, as with single agent progestin therapy, was short (approximately 3 months). A small randomized trial of MA alone or with concomitant tamoxifen showed no difference between the two regimens.¹⁰⁴ Phase 2 trials with other agents, including aromatase inhibitors,^{105,160} tamoxifen,¹⁰⁷ and luteinizing hormone-releasing hormone (LHRH) agonists,¹⁰⁸⁻¹¹⁰ have mostly yielded lower response rates than seen with progestins, although results may not be truly comparable, as some of these more recent trials were conducted in patients who had prior chemotherapy or hormonal therapy. It seems likely that results would be inferior in a pretreated population. A recent randomized phase 2 trial comparing the mTOR inhibitor ridaforolimus to control treatment (control treatment consisting of progestin therapy with either medroxyprogesterone [200 mg/day] or megestrol [60 mg/day] in 53 patients and chemotherapy in 13 patients) in women with one or two prior chemotherapy regimens reported a response rate of only 4.3% for control therapy.¹¹¹

Preclinical data have suggested that inhibiting the PI3K/Akt pathway reverses progestin resistance in endometrial cancer,¹¹² and attempts have been made to improve results of endocrine therapy by combining it with an mTOR inhibitor (analogous to the FDA-approved use of everolimus with exemestane in patients with breast cancer). GOG conducted a randomized phase 2 trial testing the mTOR inhibitor temsirolimus with or without a regimen of MA alternating with tamoxifen in patients with no more than one prior chemotherapy regimen. Unfortunately, the combination of temsirolimus with MA/tamoxifen resulted in an unacceptable rate of venous thrombosis (seven events in 22 patients), and the combination arm was closed to accrual after the first stage. Three of twenty-one patients had a response (14%), which is in the range of reported with temsirolimus alone (see the following).¹¹³ A phase 2 open-label single arm study of the combination of everolimus and letrozole enrolled 28 patients who had received one or two prior chemotherapy regimens¹¹⁴ and showed a somewhat more promising objective response rate of 21%.

In summary, hormonal therapy should be considered for women with low grade ER-positive tumors, particularly if they have a long interval from diagnosis to recurrence. Commonly used regimens in the United States are MA 80 mg twice a day and MA 80 mg twice a day for 3 weeks alternating with tamoxifen 20 mg twice a day for 3 weeks.

Cytotoxic Chemotherapy

First-Line Chemotherapy. Most women with recurrent or stage IV endometrial carcinoma should be assessed for treatment with cytotoxic chemotherapy. Current combination chemotherapy regimens can yield response rates of 50% to 60% with median OS about 12 to 15 months.

Historically, doxorubicin showed reproducible activity in multiple phase 2 and phase 3 studies of patients with chemotherapy-naïve disease (Table 73.5),¹¹⁵⁻¹¹⁸ with response rates in the range of 20% to 30%. Single-agent cisplatin¹¹⁹ and carboplatin^{120,121} therapy subsequently produced similar results. As the combination of doxorubicin plus cisplatin (AP) appeared more active than single agent doxorubicin,^{115,122} it became the standard for use in both adjuvant and metastatic disease settings. Taxanes were next found to have meaningful activity and, indeed, remain the class of agents that have produced the highest response rates in the setting of pretreated disease (see Table 73.5).¹²³ In a phase 3 trial of women with recurrent or stage IV endometrial cancer, the triplet of paclitaxel, cisplatin, and doxorubicin (TAP) produced a superior response rate (57% versus 34%), PFS (median, 8.3 versus 5.3 months), and OS (median, 15.3 versus 12.3 months; $p = 0.037$) when compared to AP.¹²⁴ TAP is the only treatment proven to produce a survival benefit in women with recurrent or stage IV endometrial disease. However, a subsequent phase 3 trial comparing TAP to AP as adjuvant therapy after surgery and radiation for stage III and resected stage IV disease

showed no difference between the two regimens, although the subset of women with gross residual disease had a 50% reduction in the risk of recurrence or death with the addition of paclitaxel.¹²⁵

The TAP regimen required growth factor support and produced grade 2 or higher neurotoxicity in 25% to 40% of patients. As phase 2 studies had shown good tolerability and activity with paclitaxel/carboplatin (TC), a 1,300-woman phase 3 noninferiority trial for those with stage III, IV, or recurrent disease was conducted comparing TC to TAP. Preliminary results showed no significant difference in median PFS (14 months in each arm) or median OS (32 months for TC, 38 months for TAP; not statistically significant). Regarding toxicity, study treatment was discontinued due to toxicity in 18% of subjects on TAP and 12% on TC.¹²⁶

One interesting alternative option for front-line therapy might be the combination of liposomal doxorubicin/carboplatin. Considering the well-reproduced activity of free doxorubicin, single-agent liposomal doxorubicin produced a disappointingly low response rate of 11.5% in patients with chemotherapy-naïve endometrial

cancer.¹²⁷ Oddly, almost the same level of activity was reported¹²⁸ in women with pretreated disease (9.5%), raising the question of whether some unknown adverse selection factors were operating in the front-line trial (e.g., since upfront combination chemotherapy was already established at the time, perhaps less fit patients elected to participate in the trial of single-agent liposomal doxorubicin). The Multicentre Italian Trials in Ovarian Cancer and Gynecologic Malignancies Group conducted a single arm phase 2 trial of pegylated liposomal doxorubicin plus carboplatin in the front-line therapy of advanced endometrial cancer and reported a response rate of 59.5% and a median survival of 80.1 weeks.¹²⁹ While the combination of carboplatin/liposomal doxorubicin has performed well compared to TC in a randomized trial for women with ovarian cancer,¹³⁰ it has not been compared to other options in women with endometrial cancer. Nonetheless, the carboplatin/liposomal doxorubicin regimen, which produces minimal alopecia and neuropathy, might be a reasonable choice, particularly for patients with contraindications to taxane therapy.

^a Including patients with stage III disease.

RR, relative risk; PFS, progression-free survival; OS, overall survival; Dox, doxorubicin; CTX, cyclophosphamide; IFX, ifosfamide; n/a, not available; CDDP, cisplatin; PTX, paclitaxel; G-CSF, granulocytic colony-stimulating factor; CPL, carboplatin; AUC, area under the curve.

In summary, TC therapy every 3 weeks is the usual first-line chemotherapy treatment in the United States for women with stage IV endometrial cancer. Issues of duration of therapy, optimal treatment after adjuvant TC (which is increasingly used, particularly for women with serous carcinomas), and of paclitaxel scheduling (weekly versus every three weeks) remain to be addressed.

Second (and Later)-Line Chemotherapy. The efficacy of second-line cytotoxic chemotherapy remains very limited. Women who have a prolonged disease-free interval after prior carboplatin/taxane therapy can be retreated with a similar regimen. Nagao et al.¹³¹ reviewed 262 patients, 49% of whom had a platinum-free interval of ≥ 12 months, and 51% of whom had a platinum-free interval of ≥ 12 months. Over half received their initial chemotherapy regimen in the adjuvant setting. They found response rates to retreatment with a platinum-based regimen for platinum-free intervals of < 6 months, 6 to 11 months, 12 to 23 months, and ≥ 24 months to be 25%, 38%, 61%, and 65%, respectively, suggesting that the general concept of “platinum sensitivity” in selection of second-line therapy can be applied to endometrial cancer as well as ovarian cancer. However, trials of second-line treatments for endometrial cancer have not traditionally been prospectively stratified along these lines (which may contribute to some of the variability seen in response rates of small phase 2 studies in endometrial cancer to agents such as pegylated liposomal doxorubicin).

Results of selected trials with standard available cytotoxic agents in patients who have received prior chemotherapy are shown in Table 73.6.¹³²⁻¹⁴⁹ Taxanes showed good activity in the days before taxane-containing therapy was the standard first-line approach.¹²³ Neither doxorubicin nor platinum agents have generally produced high response rates when used second-line. Other agents such as topotecan and gemcitabine have likewise shown minimal efficacy in previously treated populations.¹⁵⁰

In summary, women with a prolonged disease-free interval from their front-line platinum therapy can be retreated with a platinum-containing combination. However, in general, response rates to second-line cytotoxic therapy (and noncytotoxic agents) are low.

Predictors of Response to Cytotoxic Therapy. As discussed previously, endometrial carcinoma is composed of several biologically different subsets, including endometrioid (high and low grade), serous, and clear cell. The proportions of the subtypes with advanced recurrent/disease different than in early-stage disease, where low-grade tumors are most common. These histologic subtypes have been shown to have very different genetic makeup, but to date, differences in response to standard front-line cytotoxic therapy have not been observed. McMeekin et al.¹⁵¹ published results showing that histologic subtype was not an independent predictor of response to doxorubicin/cisplatin/doxorubicin-based regimens. The overall response rate to treatment was 42% (endometrioid 44%, serous 44%, clear cell 32%). The effect of grade was not considered in this analysis.¹⁵¹ A primary endpoint of the 1,300 patient GOG 209 trial comparing TC to TAP is to determine whether ER status of the tumor has any effect on chemotherapy outcomes, and these data should be available soon.

An integrated genomic analysis of serous and endometrioid endometrial carcinomas by the The Cancer Genome Atlas revealed that 19.6% of histologically classified high-grade endometrioid endometrial carcinomas had genomic profiles that resemble those of serous carcinomas. Four molecular subgroups were described: a POLE ultramutated subgroup, a hypermutated/microsatellite-unstable subgroup, a copy number-low microsatellite-stable group, and a copy number-high subgroup.⁵³ Hopefully, improved classifications will eventually help select those tumors most likely to respond to conventional agents as well as identifying targets for novel therapies.

Therapeutic Agents in Development

Antiangiogenic Agents. Antiangiogenic therapies have shown some activity in the treatment of endometrial cancer (see Table 73.6). Bevacizumab, an antivascular endothelial growth factor monoclonal antibody, produced a response rate of 13.5% in patients with one or two prior cytotoxic regimens, and 40% of subjects were progression-free at 6 months.¹⁵² A front-line randomized phase 2 GOG trial randomly assigning patients to TC with either bevacizumab or temsirolimus or to carboplatin plus ixabepilone with bevacizumab has completed accrual and results should be available soon.

TABLE 73.6

Representative Single Agent Trials in Chemotherapy-Pretreated Endometrial Cancer

Cytotoxic Agents	Dose	RR
Cisplatin ¹³²	50 mg/m ² q 3 wk	4%
Etoposide oral ¹³³	50 mg/m ² /d × 21 q 28 d ^a	0

Gefitinib ¹⁵⁹	500 mg po qd	3%
Erlotinib ¹⁶⁰	150 mg po qd	12.5%

^a 30 mg/m²/d in patients with prior radiotherapy. RR, relative risk.

Other antiangiogenic agents tested have generally not appeared quite as active, although a preliminary report suggested that sunitinib produced a 15% response rate.¹⁵³ Trials of multiple other multitargeted antiangiogenic agents, including cediranib, brivanib, cabozantinib, nintedanib, lenvatinib, and AMG 386 (trebananib), are ongoing or completed but not yet reported.

Phosphatidylinositol-3 Kinase/mTOR Pathway. Endometrial cancers harbor the highest rates of PI3K pathway alterations reported to date. Germline mutations in PTEN, which deactivates

the PI3K-AKT signaling pathway, are the etiology of Cowden syndrome, for which endometrial cancer is a diagnostic criterion. PTEN mutations are extremely common in sporadic type I endometrial cancer. There has therefore been widespread interest in testing PI3K pathway inhibitors in endometrial cancer.

Numerous trials involving the rapamycin analogs have been published, and in general modest activity is seen in patients with chemotherapy-naïve disease, but response rates in patients with prior therapy are low (see Table 73.6). The randomized phase 2 trial comparing ridaforolimus progestins as second-line therapy reported improved PFS with ridaforolimus (3.6 versus 1.9 months), but no objective responses in the ridaforolimus arm.¹¹¹ Nonetheless, sporadic patients treated with mTOR inhibitors have prolonged responses, and these responses are seen across histologic subtypes, including endometrioid, serous, and clear cell cancers. Several studies have explored the association between molecular biomarkers and response. No association between clinical benefit and any marker, including PTEN mutation, PIK3CA mutation, PTEN protein expression or mutation, or stathmin protein expression, has been observed. One analysis noted that K-Ras mutation was associated with decreased PFS and OS.¹⁵⁴

Trials of newer PI3K pathway agents, including pan-PI3K, dual PI3K/mTOR, AKT, and catalytic mTOR inhibitors, are underway or have been completed, and results are expected soon. A preliminary report of a phase 2 trial of the allosteric AKT inhibitor, MK-2206, noted a 5.5% response rate with no clear association between PIK3CA mutation and response.¹⁵⁵

Combinations of mTOR inhibitors with other agents are also being explored. Combinations of mTOR inhibitors with hormonal therapy and chemotherapy are described previously (see “Endocrine Therapy” and “Antiangiogenic Agents”). Two trials have combined temsirolimus with bevacizumab. In previously treated patients, the combination produced a 24.5% response rate, but there was significant toxicity, with two gastrointestinal-vaginal fistulas, one grade 3 epistaxis, two intestinal perforations, and one grade 4 thrombosis/embolism. Three patient deaths were possibly treatment related.¹⁵⁶ When the same combination was tested in patients with no prior chemotherapy for metastatic disease, a 20% response rate was reported with only two grade 4 events that were possibly related, a duodenal perforation, and an anorectal infection.¹⁵⁷

Anti-HER1/2 Agents. Endometrial cancer can overexpress epidermal growth factor receptor (EGFR) (HER1), and EGFR overexpression has been correlated with poor survival.¹⁵⁸ However, phase 2 trials of single agent anti-EGFR agents have not shown meaningful activity in unselected populations with reported response rates of 3% for the anti-EGFR tyrosine kinase inhibitor (TKI) gefitinib,¹⁵⁹ 12.5% for the anti-EGFR TKI erlotinib,¹⁶⁰ 3% for the anti-EGFR monoclonal antibody cetuximab,¹⁶¹ and 3% for the dual HER1/2 inhibitor lapatinib.¹⁶² Association of biomarkers with response has been explored in several of these trials. In the lapatinib trial, exons 18 to 21 of EGFR from tumor specimens were sequenced. Three mutations in EGFR were identified. Two of these were not associated with response or PFS, but a newly identified mutation in exon 18, E690K, was found in the tumor of the patient with a partial response. Only 8% of tumors expressed HER2 in the primary specimen, and the HER2 expression was weak. In the erlotinib trial, there was no association between EGFR gene amplification by fluorescence in situ hybridization, and none of the responders had an EGFR mutation. Responses were seen in subsets both with and without EGFR expression by IHC. There was also no correlation between severity of rash and response. In the gefitinib trial, the single responding tumor did not have an EGFR mutation.

HER2 overexpression and amplification is found in 20% to 30% of serous carcinomas, and a percentage of high-grade endometrioid tumors; it is rare in lower grade endometrioid tumors. This has been confirmed in multiple reports, including The Cancer Genome Atlas analysis.⁵³ While there is at least one case report

suggesting activity of trastuzumab,¹⁶³ a phase 2 trial of single-agent trastuzumab in women with HER2-overexpressing or amplified disease reported no responses.¹⁶⁴ This trial allowed unlimited prior chemotherapy, and this may have simply been too resistant a population to demonstrate benefit. A randomized trial of TC with or without trastuzumab in women with HER2-positive, platinum-sensitive endometrial cancer is ongoing. It is also possible that there are biologic differences between endometrial cancer and breast cancer that would inhibit the effectiveness of single-agent trastuzumab. One major determinant of resistance to trastuzumab in breast cancer is believed to be activation of downstream signaling via the PI3K/AKT pathway.¹⁶⁵ As discussed previously, a large fraction of endometrial carcinomas have upregulated PI3K signaling; if this were the cause of resistance to trastuzumab it might be overcome by combinations of PI3K pathway blockade and anti-HER2 therapy, or by conjugation of a cytotoxic agent to an anti-HER2 antibody. A trial with the cytotoxic-HER2 conjugate ado-trastuzumab emtansine has been approved by the GOG.

Luteinizing Hormone-Releasing Hormone Conjugates.

Over 80% of endometrial cancers are reported to have functional binding sites for LHRH.¹⁶⁶ Unmodified LHRH agonists (see Table 73.4) have produced low response rates in the treatment of advanced endometrial carcinoma. AEZS-108 is a LHRH agonist chemically linked to doxorubicin designed for specific uptake by tumors expressing LHRH receptors. Phase 1 and 2 studies showed some activity against ovarian and endometrial cancers,¹⁶⁷ and there is an ongoing phase 3 trial comparing AEZA-108 to free doxorubicin as second-line therapy for recurrent/metastatic endometrial carcinoma.

Other Targets

Fibroblast growth factor receptor 2 inhibitors. The fibroblast growth factor receptor 2 (FGFR2) tyrosine kinase is somatically mutated in approximately 10% of endometrioid carcinomas, and in preclinical studies endometrial cancer cell lines expressing activating FGFR2 mutations were sensitive to FGFR inhibitors.^{168,169} Dovitinib, a multikinase inhibitor targeting FGFRs as well as vascular endothelial growth factor receptors, is currently being evaluated in a phase 2 study.

MEK inhibitors. Activation of the mitogen-activated protein kinase pathway is a frequent event in endometrial cancer. However, results from a phase 2 trial of the selective MEK-1/2 inhibitor AZD6244 showed only a 6% response rate.¹⁷⁰

Poly (adenosine diphosphate ribose) polymerase inhibitors. Poly (adenosine diphosphate ribose) polymerase (PARP) inhibitors may be a therapeutic option for some endometrial carcinomas. In addition to regulating the PI3K pathway, it has been suggested that PTEN has a role in the repair of DNA damage via homologous recombination; PTEN-deficient endometrial cancer cell lines have been reported to show increased sensitivity to PARP inhibition.¹⁷¹ There is a case report of tumor shrinkage with single-agent olaparib in a patient whose cancer was negative for somatic BRCA1 or 2 mutations but had loss of PTEN.¹⁷²

Metformin. Retrospective studies have suggested that patients with diabetes and endometrial cancer who use metformin have superior OS and relapse-free survival compared to patients with endometrial cancer with or without diabetes who do not use metformin.^{173,174} In preclinical models, metformin inhibited cell proliferation, induced apoptosis, and decreased tumor growth, with one study showing the greatest response in cells harboring activating mutations in K-Ras.¹⁷⁵ In the everolimus/letrozole trial described previously, higher response rates were observed in patients who used metformin. These data have led to a phase 2 trial of combined everolimus, letrozole, and metformin. In addition, the GOG has proposed a randomized trial of carboplatin/paclitaxel/metformin versus carboplatin/paclitaxel/placebo in the front-line setting.

In summary, single-agent bevacizumab has modest activity in pretreated endometrial cancer, and its role in front-line therapy is being explored. Multiple other newer agents are under investigation, but none have yet produced high response rates as single agents in unselected (or selected) populations.

Treatment of Locally Recurrent Disease

Treatment for locally recurrent endometrial cancer should be individualized. Factors to consider include location of recurrence (vaginal versus pelvic), and whether the patient had prior radiation. Creutzberg et al.¹⁷⁶ reported on survival after relapse in patients with endometrial cancer who were randomized to observation versus postoperative pelvic RT (PORTEC-1 trial). The 3-year survival rate was 73% for patients with vaginal recurrence compared to 8% for pelvic recurrence ($p < 0.001$). The 3-year survival rate for patients who relapsed after surgery alone was 51% compared to 19% who relapsed after postoperative pelvic RT ($p = 0.004$).

Surgery

Surgery should be reserved for patients with recurrent disease in an irradiated area (i.e., received external beam radiation). Achieving complete gross resection is important.¹⁷⁷ Awtrey et al.¹⁷⁸ evaluated patients with recurrent endometrial cancer who underwent non-exenterative surgery and found that patients with residual disease ≤ 2 cm had a median disease-specific survival of 43 months compared with 10 months for those with > 2 -cm residual.¹⁷⁸

Pelvic exenteration may be considered in women with isolated central pelvic recurrences who had prior pelvic radiation. Five-year survival rates for such patients range between 17% and 62%. Poor prognostic factors include age > 69 years, recurrence within 3 years of prior treatment, and positive resection margins.^{179,180} A study by Barakat et al.¹⁸¹ showed that the complication rate in 44 patients undergoing pelvic exenteration for recurrent endometrial cancer is 80% and the 5-year survival rate was only 20%.

Radiation

Radiotherapy is commonly used in patients with locally recurrent disease.^{183–188} Survival rates range from 24.1% to 96%, with patients with isolated vaginal recurrences representing a particularly favorable group. Pai et al.¹⁸⁵ evaluated the outcome of 20 patients with isolated vaginal involvement treated with salvage radiotherapy. The 10-year actuarial local control and cause-specific survival were 74% and 71%, respectively. Favorable prognostic factors include long disease-free intervals, low-grade disease, adenocarcinoma histology, and no prior RT. Particularly poor outcomes have been reported in women with high-grade disease even when the recurrence is limited to the vagina.¹⁸⁷

Local control is achieved in 65% to 100% of patients treated with salvage RT, with the majority of series reporting rates between 40% and 70%. A major determinant of local control is tumor size. Wylie et al.¹⁸⁵ reported 5-year local control rates of 80% for tumors < 2 cm as opposed to 54% in tumors > 2 cm ($p = 0.02$).

Select small volume vaginal recurrence can be treated with intravaginal RT alone following excision. But for most vaginal recurrence, the optimal RT approach is a combination of pelvic RT and brachytherapy. The type of brachytherapy to be used in combination with pelvic RT depends on the size of vaginal recurrence. For those with disease > 2 cm, interstitial brachytherapy is the preferred approach, while intravaginal RT could be used instead in those with smaller volume disease and especially in those who responded well to pelvic RT. The dose of radiation is typically 45 Gy with pelvic RT plus additional 20 to 30 Gy with brachytherapy. With such high doses being required, severe complications may occur, primarily related to the gastrointestinal tract and vaginal mucosa. In a study by Jhingran et al.¹⁸⁶ on 91 patients with isolated vaginal recurrence who were treated with definitive radiation (median dose 75 Gy), the rate of grade 4 complications (requiring surgery)

was 9%. Therefore, when considering observation after surgery for early-stage endometrial cancer, the potential for such complications should be considered. Currently, PORTEC is performing a randomized trial comparing postoperative intravaginal RT to observation with radiation reserved for salvage.

Data regarding radiation for *nodal (pelvic/para-aortic) recurrence* are more limited and less encouraging than that for vaginal recurrence. Typically, external beam radiation is used, with very limited role for brachytherapy. In the PORTEC-1 trial,¹⁷⁶ the 3-year survival rate for pelvic recurrence was only 8%. In an attempt to improve outcome, a combined modality approach is warranted. Viswanathan et al.¹⁸⁹ reported on a phase 2 trial on 15 patients with endometrial cancer who were treated with concurrent radiation and bevacizumab. The 3-year PFS and OS rates were 67% and 80%, respectively. Of 15 patients, 7 had some component of pelvic and/or para-aortic disease at time of enrollment. With a median follow-up of 45.4 months, five of seven patients were alive without evidence of disease.¹⁸⁹

UTERINE SARCOMAS

Uterine sarcomas are uncommon representing about 3% to 7% of all uterine cancers.¹⁹⁰ The World Health Organization classification includes endometrial stromal tumors, smooth muscle tumors, and miscellaneous mesenchymal tumors. In the mixed epithelial and mesenchymal tumors category, the World Health Organization classification includes adenocarcinoma and malignant mixed müllerian tumors or carcinosarcoma.³⁶

Carcinosarcoma

Uterine carcinosarcoma (also referred to as mixed müllerian tumor) accounts for approximately 15% of uterine cancer-associated deaths in the United States.¹⁹¹ It is more common in African Americans.¹⁹² Tamoxifen is a risk factor¹⁹³; among women treated with tamoxifen for breast cancer, the relative risk for carcinosarcomas was found to be 4.62. Approximately 5% to 30% of carcinosarcomas arise in women with previous pelvic RT. Carcinosarcomas are rare in women under the age of 40, and the incidence rises sharply after age 50.¹⁹⁴

Uterine carcinosarcomas are currently regarded as metaplastic carcinomas, with the sarcomatous element being derived as a result of dedifferentiation.¹⁹⁵ Most series suggest that the carcinomatous component tends to predominate in metastases.¹⁹⁶ Review of pathology slides may be important for accurate diagnosis; one GOG trial reported that 23% (5 of 22) subjects entered on a trial for advanced or recurrent uterine carcinosarcoma were excluded after central pathology review.¹⁹⁷

Complete surgical staging is recommended as 10% to 15% of patients with apparent early-stage disease with have involvement of pelvic lymph nodes,¹⁹⁸ and the number of positive lymph nodes correlates with risk for recurrence and death.¹⁹⁹ The FIGO 2009 staging for endometrial cancer is used for carcinosarcomas.

Uterine carcinosarcomas are aggressive tumors with a generally poor prognosis; 5-year OS has been reported to be about 30%, and for those with stage I disease it is about 50%.²⁰⁰ Carcinosarcomas have a generally worse prognosis than even high-grade endometrial carcinomas. One review matched cases with carcinosarcoma and controls with grade 3 endometrioid, serous, or clear cell carcinomas. Median survival was 26 months for women with stage I or II carcinosarcoma and 95 months for control patients with stage I or II disease; there was no difference in median survival for patients with stage III/IV disease.²⁰¹

Adjuvant radiotherapy is frequently used for early-stage disease. The EORTC preformed a prospective randomized trial addressing the role of postoperative pelvic RT in stage I-II uterine sarcomas. There were a total of 224 patients in the trial who underwent TAH/BSO and peritoneal washings ($n = 166$ patients). Lymphadenectomy was optional. There were 103 leiomyosarcomas,

91 carcinosarcomas, and 28 endometrial stromal sarcomas. The 5-year cumulative incidence of locoregional recurrence was 18.8% in the pelvic RT arm compared to 35.9% in the surgery alone arm ($p = 0.0013$). The 5-year cumulative incidence of distant relapse was 45.3% for the pelvic RT and 33.6% for surgery alone, but the difference was not statistically significant ($p = 0.2569$). There was no significant difference in PFS ($p = 0.3254$) or OS ($p = 0.923$) between the two arms. For patients with carcinosarcoma, the rate of pelvic recurrence only was 4% in the pelvic RT arm compared to 24% for the surgery alone arm.²⁰²

There are few randomized trials of *adjuvant chemotherapy* in early-stage carcinosarcoma, and results of small single institution series are difficult to interpret, although platinum-based therapy generally appears to be of benefit.²⁰³ A very small early trial including stage I or II carcinosarcomas and leiomyosarcomas found no difference for the administration of single-agent doxorubicin (60 mg/m² every 3 weeks for eight courses) versus observation in either tumor type.²⁰⁴ GOG-150 is a phase 3 randomized study of whole abdominal irradiation (WAI) versus three cycles of cisplatin, ifosfamide, and mesna (CIM). Eligible patients ($n = 206$) included stage I-IV uterine carcinosarcoma, no more than 1 cm postsurgical residuum, and/or no extra-abdominal spread. The estimated crude probability of recurring within 5 years was 58% (WAI) and 52% (CIM). Adjusting for stage and age, the recurrence rate was 21% lower for CIM patients than for WAI patients (relative hazard = 0.789, $p = 0.245$). The estimated death rate was 29% lower among the CIM group (relative hazard = 0.712, $p = 0.085$). The conclusion was that there was not a statistically significant advantage in recurrence rate or survival for adjuvant chemotherapy over WAI. However, the observed differences favor the use of combination chemotherapy in future trials.²⁰⁵ The rate of vaginal recurrence was 3.8% in the WAI compared to 9.9% in the chemotherapy arm. Based on the higher rate of vaginal recurrence in the chemotherapy arm, combining intravaginal RT with chemotherapy seems warranted. In a recent study from MSKCC, 31 patients with stage I-II carcinosarcoma were treated with intravaginal RT and chemotherapy (84% TC). With a median follow-up of 48 months, the 5-year disease-free survival and OS rates were 66% and 79%, respectively.²⁰⁶ National Comprehensive Cancer Network guidelines recommend that adjuvant therapy for carcinosarcomas be similar to that of poorly differentiated adenocarcinomas.²⁰⁷

Systemic therapy for relapsed disease is noncurative. Ifosfamide, cisplatin, and paclitaxel are the only drugs studied with clear cut activity in the therapy of carcinosarcoma. Ifosfamide produces significant toxicity, including granulocytopenia and central nervous system toxicity in the regimens tested. Trials of doxorubicin have produced inconsistent results. Combination therapy generally produces higher response rates, but median survival is not always improved and is generally <1 year (Tables 73.7 and 73.8).^{182-188,208-215} There is no evidence for effectiveness of antiangiogenic agents. The GOG has an ongoing trial, GOG #261, comparing the regimens of TC and ifosfamide/paclitaxel, and accrual is nearing completion.

Uterine Leiomyosarcoma

Leiomyosarcomas are the most common of the uterine sarcomas. They are malignant smooth muscle tumors that are believed to arise de novo; for most cases, evidence does not show transition from benign leiomyoma (uterine fibroids) to leiomyosarcoma.²¹⁶ They usually present as stage I disease with abnormal bleeding or a pelvic mass, and are more common in African Americans than in Caucasians. The median age at diagnosis is in the early 50s. About 0.5% of patients undergoing hysterectomy for presumed benign leiomyoma will be found to have leiomyosarcoma.²¹⁷ Leiomyosarcomas must be distinguished from atypical leiomyomas and smooth-muscle tumors of uncertain malignant potential. Smooth-muscle tumors of uncertain malignant potential rarely metastasize and have an intermediate histology between benign leiomyoma and leiomyosarcoma. Mitotic rate alone does

TABLE 73.7

Salvage Radiotherapy, Locally Recurrent Endometrial Cancer

Study (Ref.)	Year	No. of Patients (n)	Local Control (%)	Five-Year Survival (%)
Nag et al. ¹⁸²	1997	15	66.6	42.3
Pai et al. ¹⁸³	1997	20	74	71 (10 y)
Hart et al. ¹⁸⁴	1998	26	65	53
Wylie et al. ¹⁸⁵	2000	58	65	53
Jhingran, Burke, and Eifel ¹⁸⁶	2003	91	75	43
Lin et al. ¹⁸⁷	2005	50	80	55
Petignat et al. ¹⁸⁸	2006	22	100	96

not distinguish leiomyosarcomas from tumors of low or uncertain malignant potential; cytologic atypia and coagulative necrosis are important criteria for making the diagnosis.¹⁹⁵

Surgery including simple hysterectomy/BSO is the standard primary treatment for stage I disease. Lymph node involvement is rare, and lymph node dissection is not required.²¹⁸ Chest imaging at time of diagnosis is warranted, as 10% of patients will have lung metastases at time of diagnosis. Five-year survival for stage I disease is 50% to 60%; for stage II, it is about 25%.²¹⁹ A nomogram to predict survival has been developed and validated; factors included were age (older age is associated with worse prognosis), tumor size, tumor grade, cervical involvement, locoregional and distant metastases, and mitotic index.²²⁰ The current FIGO (2009) recognizes the importance of tumor size in leiomyosarcoma.

In the EORTC phase 3 randomized trial comparing observation to adjuvant pelvic RT, 103 patients with leiomyosarcoma were included.

RT produced no improvement in survival or local control (20% local recurrence in RT arm compared to 24% for surgery alone).²⁰²

Only very limited data exist on the effect of adjuvant chemotherapy on survival. The GOG performed a small prospective trial of eight cycles of adjuvant doxorubicin versus observation after tumor resection. Stage I or II leiomyosarcomas and carcinosarcomas were included, and radiation was at the discretion of the treating physician. Of the 25 patients with leiomyosarcoma in the doxorubicin group 11 (44%) recurred, compared with 14 out of 23 (61%) in the observation group.²⁰⁴ The French Sarcoma Group conducted a randomized clinical trial of adjuvant chemotherapy with doxorubicin, ifosfamide, and cisplatin followed by RT versus RT alone in patients with localized uterine sarcomas. Eighty-one patients were included of whom, fifty-three had leiomyosarcoma. The 3-year disease-free survival was 55% in patients receiving chemoradiation versus 41% for RT alone ($p = 0.048$). The corresponding 3-year overall survival rates were 81% versus 69%, respectively ($p = 0.41$).²²¹

The recent 3-year follow-up update of SaRC 005, a nonrandomized trial prescribing four cycles of gemcitabine/docetaxel followed by four cycles of doxorubicin to 47 patients with high-risk uterine leiomyosarcoma, showed a PFS rate of 57% at 3 years, which compares favorably with historic controls without adjuvant chemotherapy.²²² There is an ongoing randomized trial adjuvant gemcitabine/docetaxel followed by doxorubicin versus no further treatment after surgery for early-stage uterine leiomyosarcoma, which will hopefully provide a definitive answer regarding the benefits of chemotherapy.

For patients with multifocal metastatic disease, treatment is usually systemic chemotherapy. Active agents include gemcitabine, ifosfamide, doxorubicin, dacarbazine, and temozolomide (Tables 73.9 and 73.10).²²³⁻²³⁸ A frequent front-line regimen is the combination of gemcitabine with docetaxel, which is reasonably well tolerated although it requires the administration of granulocyte colony-stimulating factor and is associated with occasional severe pulmonary toxicity.²³⁹ Trials of antiangiogenic agents have produced limited response rates to date, but there a percentage of patients experience prolonged stable disease. Pazopanib, an orally available mul-

kinase angiogenesis inhibitor, has recently been approved by the FDA for the treatment of soft tissue sarcomas including uterine leiomyosarcoma. A phase 2 trial of pazopanib 800 mg by mouth daily showed a PFS at 12 weeks of 44% in patients with leiomyosarcoma treated with two or fewer prior cytotoxic regimens (all primary sites), although there was only one PR in a leiomyosarcoma patient (of 41 treated).²⁴⁰ A subsequent randomized phase 3 trial (PALETTE) in pretreated patients showed a PFS of 4.6 months (all sarcoma subtypes) versus 1.6 months for placebo.²⁴¹ A randomized trial of gemcitabine/docetaxel with or without bevacizumab in the treatment of advanced or recurrent uterine leiomyosarcoma has been completed by the GOG, and results should be available soon.

Leiomyosarcomas express ER or PR in a significant number of cases, and hormone receptor expression has been reported to be prognostic. One study reported that only 1/10 early-stage PR(+) cases recurred and died while 9/10 PR(–) cases recurred, and 5 died.²⁴² It has been suggested that hormonal therapy may be of benefit in patients with advanced-stage leiomyosarcoma that expresses ER or PR, but this remains hypothetical.²⁴³ One prospective phase 2 trial treated 27 patients with leiomyosarcoma whose tumors expressed ER and/or PR with the aromatase inhibitor letrozole at a dose of 2.5 mg daily. The patients had received a median of two prior treatment regimens. There were no objective responses, but the 12-week PFS rate was 50% (90% confidence interval = 30% to 67%), and three

patients, all of whom had tumors expressing ER and PR in >90% of tumor cells, continued to receive letrozole for >24 weeks.²⁴⁴ However, this may merely reflect the indolent natural biology of certain strongly receptors positive uterine leiomyosarcomas.

See Table 73.11 for more information about trials in the system therapy of uterine leiomyosarcoma.^{245–249}

Endometrial Stromal Sarcoma

Endometrial stromal sarcomas (also known as low-grade endometrial stromal sarcomas) are uncommon low-grade malignancies comprising approximately 0.2% of all uterine malignancies and 6% to 20% of uterine sarcomas.²⁵⁰ They usually occur in women 40 to 55 years of age. The tumor cells are usually positive for CD 10 and ERs or PRs.²⁵¹

Translocation of t(7; 17)(p15; q21), resulting in the juxtaposition of two zinc finger genes *JAZF1-SUZ12*, been described in endometrial stromal sarcomas. The exact role this fusion gene plays in the pathogenesis of endometrial stromal sarcomas is not well understood.²⁵¹

In most patients, the disease is diagnosed at an early stage; 65% to 86% of endometrial stromal sarcomas are confined to the uterus at diagnosis. Estimates of the rate of lymph node metastasis range from 10% to 45%, and positive lymph nodes are associated with shorter survival.²⁵⁰ As in leiomyosarcoma, the FIGO (2009) recognizes the importance of tumor size. Approximately one-third of stage I patients eventually develop recurrent disease.²⁵² Recurrences can occur 10 to 20 years after diagnosis. In one study, 5- and 10-year crude survival rates for women with stage I disease were 84% and 77%, respectively; for women with stage II disease, it was 62% and 40%, respectively.²⁵³ Survival after recurrence may be relatively long; in one series, the estimated median survival after recurrence was 133 months.²⁵²

The primary treatment for early-stage endometrial stromal sarcoma is hysterectomy. Lymph node dissection may offer prognostic

information, but it has not been shown to improve survival. In general, removal of the ovaries is recommended, as estrogen has been noted to be a proliferative stimulus. However, some,²⁵⁰ though not all,²⁵² more recent series have suggested that preservation of ovaries may not be associated with worse survival.

Regarding the role of *adjuvant radiation*, in the EORTC randomized phase 3 trial, only 28 cases of endometrial stromal sarcoma were included: relapse rate was 12.5% among patients treated with radiotherapy versus 21.4% for the observation group.²⁰² Sampath et al.²⁵⁴ performed a retrospective review of patients with uterine sarcoma using the National Oncology Database. The impact of adjuvant radiation was assessed in patients who presented with nonmetastatic disease and underwent definitive surgery ($n = 2,206$). For endometrial stromal sarcoma, the rate was 97% with RT (109) versus 93% for surgery alone ($n = 252$, $p < 0.05$). There are no prospective data for the use of *adjuvant hormonal therapy*, but given its efficacy in advanced or recurrent disease, it is often recommended for women with stage III or higher disease.

Surgical resection of limited metastases (e.g., lung) should be considered. In recurrent disease, progestins and aromatase inhibitors can both produce prolonged responses. The role of chemotherapy is unclear, and studies using chemotherapy have not clearly separated out endometrial stromal sarcomas and undifferentiated endometrial sarcomas (which were previously referred to as high-grade endometrial stromal sarcomas).²⁵¹

Undifferentiated endometrial sarcomas are less common than endometrial stromal sarcoma tumors and usually occur in postmenopausal women.²⁵¹ They lack a signature chromosomal translocation and are aggressive tumors with a poor overall prognosis. Half of patients present with stage IV disease. Progression after resection of early-stage disease may occur within months.¹²⁵ Surgery is the primary therapy for early-stage disease; as with endometrial stromal sarcoma, the role of lymph node dissection is uncertain. Gemcitabine/docetaxel-, doxorubicin-, and ifosfamide-based regimens have been reported to achieve short-lived responses.²⁵⁵

74 Genetic Testing in Uterine Cancer

Molly S. Daniels

INTRODUCTION

Uterine cancer is the most common invasive gynecologic cancer in the United States.¹ The median age at diagnosis of uterine cancer in the general population is 60 years.¹ The average woman's lifetime risk of developing uterine cancer is approximately 2.6%.² The vast majority of uterine cancers are endometrial in origin. Five percent or less of uterine cancers are nonendometrial; examples include endometrial stromal sarcoma and uterine leiomyosarcoma.³

Endometrial cancers can be further subdivided into type I and type II. Type I endometrial cancers are endometrioid in histology and account for more than 75% of endometrial cancers. Type II endometrial cancers include all nonendometrioid histologies, such as uterine papillary serous carcinoma (UPSC), clear cell carcinoma, and carcinosarcoma (also called malignant mixed Müllerian tumor).⁴ Type II endometrial cancers are generally diagnosed at later stages and have a poorer prognosis than type I endometrial cancers.⁵

Type I endometrial cancers, in particular, are associated with personal medical history risk factors, likely due to their impact on the amount of estrogen to which the endometrium is exposed. Other than long-term use of unopposed estrogen (which is no longer prescribed for women with an intact uterus because of the associated endometrial cancer risk) and hereditary cancer predisposition (which will be discussed subsequently), the biggest risk factor for endometrial cancer is obesity. Obese women have up to a six-fold risk of endometrial cancer when compared with women at ideal body weight.⁶ Other risk factors include nulliparity, early age at menarche, late age at menopause, and tamoxifen use.⁶ Use of combination oral contraceptives decreases risk of endometrial cancer in the general population, with a relative risk of 0.6.¹

This review also discusses uterine leiomyomas, commonly referred to as uterine fibroids. Uterine leiomyomas are benign smooth muscle tumors that are common in the general population. A US study found that more than 80% of black women and almost 70% of white women develop uterine leiomyomas, although not all were symptomatic.⁷ Symptoms of uterine leiomyomas can include pelvic pain, infertility, pregnancy complications, and menometrorrhagia.⁷

LYNCH SYNDROME (ALSO KNOWN AS HEREDITARY NONPOLYPOSIS COLORECTAL CANCER SYNDROME)

Since Lynch syndrome has been extensively described elsewhere in this book, this section focuses on Lynch syndrome-associated endometrial cancer. Lynch syndrome is an autosomal dominant hereditary cancer predisposition syndrome characterized by significantly increased risks of colorectal, endometrial, and other cancers. Mutations in the DNA mismatch repair genes *MLH1*, *MSH2*, *MSH6*, *PMS2*, and *EPCAM* (via disruption of *MSH2* expression) have been associated with Lynch syndrome.

Two to three percent of women with endometrial cancer have Lynch syndrome.^{8,9} Average age at diagnosis of endometrial cancer for women with Lynch syndrome is in the 40s to 50s in many⁸⁻¹⁰

but not all¹¹ studies, younger than the general population. The likelihood of Lynch syndrome is increased in women with endometrial cancer, diagnosed at younger than 50 years,^{12,13} who have also had colorectal cancer,¹⁴ with lower body mass index,¹² with lower uterine segment tumors,¹⁵ or with family history of colorectal and/or endometrial cancers.^{16,17} Models to assess risk of Lynch syndrome based on personal and family history are available.^{16,17} The identification of Lynch syndrome in the patient with endometrial cancer allows her to take steps to reduce her colorectal cancer risk and also allows family members to benefit from predictive genetic testing and subsequent targeted cancer risk reduction strategies.

The optimal way to screen patients with endometrial cancer for Lynch syndrome is an area of active discussion. Historically, patients with endometrial cancer with personal and/or family histories suggestive of Lynch syndrome have been referred for cancer genetic risk assessment. More recently, some institutions have undertaken universal screening of all patients with endometrial cancer by immunohistochemistry (IHC) and/or microsatellite instability (MSI) analysis of the endometrial tumor.¹⁸ The advantage to this approach is that it has the potential to detect all Lynch syndrome-associated endometrial cancers, some of which occur in the absence of a known family history and would be missed by any strategy that screens patients by family history.^{8,9} Limitations to the universal screening approach include high cost per mutation identified¹⁹ and lower than expected uptake of genetic counseling and genetic testing among patients with endometrial cancer identified via universal screening.¹⁸

By whatever method patients with endometrial cancer are selected for Lynch syndrome evaluation, the recommended first step in genetic testing is tumor studies: IHC for the mismatch repair proteins and/or MSI analysis.^{20,21} Nearly all Lynch syndrome-associated endometrial cancers will demonstrate high MSI (MSI-H) and/or IHC loss of one or more mismatch repair proteins, and the IHC results often allow genetic testing to be targeted to one Lynch syndrome gene.²⁰ *MLH1* promoter hypermethylation analysis is recommended as a follow-up study when an endometrial tumor is MSI-H, and IHC shows loss of *MLH1* and *PMS2*, because 15% to 20% of sporadic endometrial cancers exhibit *MLH1* promoter hypermethylation.²² Whereas sporadic MSI-H colorectal cancers often have somatic *BRAF* mutations, sporadic MSI-H endometrial cancers usually do not,²³ and therefore, *BRAF* mutation analysis is not recommended for distinguishing sporadic MSI-H endometrial cancers from Lynch syndrome-associated endometrial cancers. Lynch syndrome is confirmed by the finding of a germline mutation in a mismatch repair gene through molecular genetic testing, and family members can subsequently undergo predictive genetic testing. Currently, molecular genetic testing is not always able to identify a pathogenic Lynch syndrome mutation when tumor studies are suggestive of Lynch syndrome; possible explanations in these cases include limited genetic test sensitivity for the known mismatch repair genes, other as yet unidentified Lynch syndrome genes, and as yet unidentified other epigenetic causes for the tumor phenotype. Given that Lynch syndrome has not been ruled out in a patient with suggestive tumor studies and negative genetic test results, consideration should be given to following Lynch syndrome management guidelines in these cases.^{20,21}

The lifetime risk of endometrial cancer for women with Lynch syndrome has been recently reported as 33% to 40%.^{10,24} Endometrial cancer risk may vary by gene, with risks highest for women with *MLH1*, *MSH2*, and *MSH6* mutations. Lower endometrial cancer risks have been reported for women with *PMS2* mutations (15% lifetime risk²⁵) or *EPCAM* mutations (up to 12% lifetime risk^{26,27}). Lynch syndrome-associated endometrial cancers can be both type I (endometrioid) and type II (nonendometrioid); nonendometrioid histologies observed in women with Lynch syndrome include clear cell carcinoma, UPSC, and malignant mixed Müllerian tumor (carcinosarcoma).²⁸

Given the high risk of endometrial cancer for women with Lynch syndrome, both cancer screening and risk reduction options should be considered. Patient education regarding endometrial cancer symptoms (such as abnormal vaginal bleeding) and the importance of reporting them promptly are also important.²¹ In terms of risk reduction, hysterectomy (plus bilateral salpingo-oophorectomy [BSO], because ovarian cancer risk is also elevated) is clearly effective in preventing endometrial cancer²⁹ and can be considered if childbearing is completed and/or after menopause.^{21,30,31} If a woman with Lynch syndrome is undergoing surgery for colon cancer, concomitant hysterectomy/BSO can be considered.^{30,31} Risk-reducing hysterectomy/BSO has not been demonstrated to reduce mortality in women with Lynch syndrome. Oral contraceptives reduce risk of endometrial and ovarian cancer in the general population¹; their efficacy in women with Lynch syndrome has not been determined. There is no proven benefit to endometrial cancer screening in women with Lynch syndrome; screening guidelines are based on expert opinion. Transvaginal ultrasound alone does not appear to be an effective screening test in this population^{32,33}; endometrial biopsy plus transvaginal ultrasound may be more effective.³⁴ The National Comprehensive Cancer Network currently recommends considering annual endometrial biopsy as an option.²¹

PHOSPHATASE AND TENSIN HOMOLOG HAMARTOMA TUMOR SYNDROME (ALSO KNOWN AS COWDEN SYNDROME, BANNAYAN-RUVALCABA-RILEY SYNDROME)

Since phosphatase and tensin homolog (PTEN) hamartoma tumor syndrome (PHTS) has also been extensively described elsewhere in this book, this section focuses on uterine manifestations of PHTS. PHTS is a rare autosomal dominant syndrome defined by the presence of a pathogenic *PTEN* mutation. PHTS can manifest in many organ systems, with phenotypic effects ranging from autism^{35,36} to increased cancer risk^{37,38} to characteristic mucocutaneous lesions.³⁹

Uterine leiomyomas have been described as a common finding in women with PHTS,⁴⁰ and uterine leiomyomas are included as a minor diagnostic criterion of PHTS.³⁹ However, given the high prevalence of uterine leiomyomas in the general population,⁷ it is not clear whether the prevalence is actually elevated in PHTS.^{38,41} Uterine leiomyomas are a nonspecific finding and should not by themselves be considered particularly suggestive of PHTS.^{38,41}

Endometrial cancer has been reported to occur at increased frequency in women with PHTS.^{37,41} Reported ages at endometrial cancer diagnosis have been mostly in the 30s to 50s.^{39,42} Endometrial cancer has been reported in adolescence in PHTS.⁴³ Endometrial cancer has been observed in 12 (17%) of 69⁴¹ and 25 (16%) of 158³⁹ of adult women who were referred for *PTEN* genetic testing and tested positive. Data regarding lifetime risk of endometrial cancer in PHTS are sparse; studies to date have focused on probands and are thus subject to significant ascertainment bias. Therefore, a recent estimate of lifetime endometrial cancer risk in PHTS of 28%³⁷ is likely a significant overestimation. PHTS appears to account for a very small proportion of unselected endometrial cancers; a study by Black et al.⁴⁴ found no germline *PTEN* mutations in a series of 240 patients with endometrial cancer.

In light of the limited data regarding lifetime risk of endometrial cancer for women with PHTS, the National Comprehensive Cancer Network does not currently recommend a specific endometrial cancer screening strategy beyond educating women to respond promptly to symptoms and considering enrollment in a clinical trial to determine effectiveness and necessity of screening.⁴⁵ Others have suggested that women with PHTS undergo annual endometrial biopsy and/or transvaginal ultrasound.^{37,40} To date, there is no proven benefit to these screening strategies in the context of PHTS. Based on the lack of efficacy of transvaginal ultrasound as an endometrial cancer screening test for women with Lynch syndrome discussed previously, if screening is undertaken, ultrasound may not be the ideal modality. The National Comprehensive Cancer Network also notes that risk-reducing hysterectomy can be discussed as an option on a case-by-case basis.⁴⁵

HEREDITARY LEIOMYOMATOSIS AND RENAL CELL CARCINOMA

Hereditary leiomyomatosis and renal cell carcinoma (HLRCC) (OMIM 150800) is characterized by increased risk of type 2 papillary renal cell carcinoma, cutaneous leiomyomas, and uterine leiomyomas. The fumarate hydratase (*FH*) gene is the only gene that has been associated with HLRCC. HLRCC exhibits autosomal dominant inheritance. Both point mutations and large rearrangements of the *FH* gene have been reported in individuals with HLRCC.⁴⁶ If germline mutations in both copies of the *FH* gene are present, this causes the severe autosomal recessive condition fumarate deficiency (OMIM 606812), which is characterized by encephalopathy and psychomotor retardation, and is frequently lethal in infancy or childhood.

The uterine leiomyomas seen in the context of HLRCC tend to occur at younger ages than in the general population, with a mean age at diagnosis around 30 years.^{47,48} Women with HLRCC frequently report complications from uterine leiomyomas, including symptoms of menorrhagia, pelvic pain, and reduced fertility,⁴⁹ and are more likely than women with uterine leiomyomas who do not have HLRCC to have had treatment, including hysterectomy.⁴⁸ In a study of North Americans with HLRCC, 98% of women had uterine leiomyomas, and 89% had undergone hysterectomy, often before the age of 30 years.⁴⁷

Uterine leiomyosarcoma has been reported in Finnish women with HLRCC, but a recent review notes that only one clinically malignant uterine leiomyosarcoma has been confirmed in a patient with an *FH* germline mutation.⁵⁰ Therefore, to what extent the risk of uterine leiomyosarcoma may be elevated over that in the general population is not yet clear. It also appears that germline *FH* mutations are not common in women with isolated uterine leiomyosarcoma; a series of 67 uterine leiomyosarcomas diagnosed in Finland were tested for *FH* mutations, and only one patient was found to have a *FH* missense sequence variant, which was present in both tumor and normal tissue but is of uncertain significance.⁵¹

The presence of multiple cutaneous leiomyomas should prompt consideration of HLRCC; studies of patients with multiple cutaneous leiomyomas have found *FH* mutations in 80% to 89%.^{47,49,52} Cutaneous leiomyomas vary in appearance; biopsy is required for diagnosis.⁴⁹ Pain and paresthesias associated with cutaneous leiomyomas are frequently reported.⁴⁷ Ages at onset were reported to be from 10 to 47 years, with mean age at onset of 25 years.⁴⁷ The absence of cutaneous leiomyomas does not exclude the possibility of HLRCC; some patients with HLRCC showed no evidence of cutaneous leiomyoma after detailed skin examination.^{47,53} Rarely, cutaneous leiomyosarcoma has been reported with HLRCC.^{47,53}

The type 2 papillary renal cell carcinomas associated with HLRCC are usually unilateral and unifocal but nonetheless appear to be aggressive in that they can already be metastatic when the primary tumor is still small (<1 cm).⁵⁰ Penetrance of renal cell carcinoma in HLRCC has been reported as approximately 20%.⁵² Age at diagnosis of renal cell carcinoma has been reported as early

as 11 years⁵⁴ and 16 years,⁴⁹ with average age at diagnosis in the 40s.^{47,52} Other types of kidney cancer have also been reported in patients with HLRCC, including collecting duct carcinoma, oncocytoma, clear cell renal cell carcinoma, and Wilms tumor.⁵⁰

Given the relative rarity of HLRCC (estimated approximately 180 families identified worldwide⁵⁰), guidelines for screening and management are still evolving and are based on expert opinion only. Pediatric kidney cancers have been reported in HLRCC but appear to be rare; thus, there is some debate regarding at what age predictive genetic should be offered as well as at what age screening should begin. Proposed kidney cancer screening recommendations have included magnetic resonance imaging, computed tomography, or positron emission tomography–computed tomography; annual or biannual; and beginning at age 18 to 20 or as early as the age of 5 years (perhaps particularly if pediatric kidney cancer has occurred in a family member).⁵⁰ Ultrasound may not be effective at detecting HLRCC-associated kidney cancers and is not recommended.⁴⁷ The aggressive nature of the type 2 papillary renal cell carcinomas also makes designing an effective screening program challenging, and there is not yet evidence that instituting screening favorably impacts morbidity or mortality for patients with HLRCC.

UTERINE CANCER AND OTHER HEREDITARY CANCER SYNDROMES

UPSC is histologically similar to ovarian serous carcinoma⁵ and has been observed in Ashkenazi Jewish women with *BRCA1/BRCA2* mutations who also had personal and/or family histories of breast and/or ovarian cancer.⁵⁵ However, other studies of consecutive series of Jewish patients with endometrial cancer found a *BRCA*-positive rate that is similar to that of the general Jewish population.^{56,57} It therefore seems unlikely that a personal history of endometrial cancer, UPSC or otherwise, increases the likelihood for a woman to have a germline *BRCA1/BRCA2* mutation.

Patients with hereditary retinoblastoma are at increased risk to develop a variety of second malignancies. A recent study found

that women with hereditary retinoblastoma are at significantly increased risk for uterine leiomyosarcoma in particular.⁵⁸

CONCLUSION

Approximately 2% to 3% of endometrial cancers are attributable to Lynch syndrome. Early age at diagnosis, low body mass index, and personal and/or family history of Lynch syndrome–associated cancers increase the likelihood for a patient with endometrial cancer to have Lynch syndrome, but not all Lynch syndrome–associated endometrial cancers occur in the presence of these risk factors. MSI and IHC analyses are the recommended first step in Lynch syndrome evaluation. The identification of Lynch syndrome in the patient with endometrial cancer allows her to take steps to reduce her colorectal cancer risk and also allows family members to benefit from predictive genetic testing and subsequent targeted cancer risk reduction strategies. Unaffected women with Lynch syndrome are at significantly increased risk to develop endometrial cancer and should be educated regarding signs and symptoms of endometrial cancer and should be offered screening and prevention options.

The proportion of endometrial cancer attributable to PHTS (Cowden syndrome) is not precisely known but appears to be <1%. The risk for endometrial cancer is likely elevated in women with PHTS, but the magnitude of this risk is not well defined at this time. Women with PHTS should be educated regarding signs and symptoms of endometrial cancer. Endometrial cancer screening and surgical risk reduction can be considered for women with PHTS.

Symptomatic uterine leiomyomas are more common in those with HLRCC than in the general population, with a tendency toward earlier age at diagnosis. Multiple cutaneous leiomyomas are a characteristic finding in HLRCC. Uterine leiomyosarcoma has occurred in the context of HLRCC, but whether and to what extent this risk exceeds that in the general population remains to be determined. Individuals with HLRCC are at increased risk to develop an aggressive subtype of kidney cancer, and therefore, should consider periodic kidney cancer screening.

75 Gestational Trophoblastic Diseases

Donald P. Goldstein, Ross S. Berkowitz, and Neil S. Horowitz

INTRODUCTION

Gestational trophoblastic neoplasia (GTN) comprise a group of interrelated conditions that arise from trophoblastic tissue and consist of six distinct clinicopathologic entities: complete hydatidiform mole (CHM), partial hydatidiform mole (PHM), invasive mole (IM), choriocarcinoma (CCA), placental site trophoblastic tumors (PSTT), and epithelioid trophoblastic tumors (ETT). All trophoblastic tumors produce human chorionic gonadotropin (hCG), which can be used as a tumor marker for diagnosis, monitoring the effects of therapy and follow-up to detect relapse.¹ Although these tumors represent <1% of gynecologic malignancies, it is important that medical oncologists understand their natural history and management because of their life-threatening potential in reproductive-age females and their high curability with preservation of reproductive potential if treated early and according to well-established guidelines.

INCIDENCE

GTN arises most commonly after a molar pregnancy, but can also occur after normal or ectopic pregnancies and spontaneous or induced abortions. Molar pregnancy occurs in approximately 1:1000 gestations.¹ GTN after spontaneous miscarriage is estimated to occur in 1:15,000 pregnancies, while the incidence after a term pregnancy is 1:150,000 pregnancies. The overall incidence of GTN following all types of pregnancies is estimated at 1:40,000.²

PATHOLOGY AND NATURAL HISTORY

CHM is characterized by clusters of hydropic villi with trophoblastic hyperplasia and atypia. CHMs are diploid and have a chromosomal pattern of either 46XX or 46XY. All chromosomes are androgenetic, that is, of paternal origin, and arise from fertilization of an empty ovum by a haploid sperm that then undergoes duplication. Occasionally, CHMs arise from fertilization of an empty ovum by two sperm. Maternally transcribed nuclear genome is lost, although one can identify maternal mitochondrial DNA.³

PHM shows a variable amount of abnormal villous swelling and focal trophoblastic hyperplasia in association with identifiable fetal or embryonic tissue. PHM contains both maternal and paternal chromosomes and are triploid, typically 69XXY, which occurs by fertilization of a normal ovum by two sperm.⁴

IM occurs when molar tissue invades the myometrial wall. Deep myometrial invasion can lead to uterine rupture and severe intraperitoneal hemorrhage. IM develops in approximately 15% of patients with CHM and about 1% to 5% of patients with PHM.⁵ Most IM remain localized to the uterus, but metastases to distant sites have been reported.

CCA consists of invasive, highly vascular, and anaplastic trophoblastic tissue made up of cytotrophoblasts and syncytiotrophoblasts without villi. CCA metastasizes hematogenously and can follow any type of pregnancy, but most commonly develops after CHM.

Approximately 50% of cases follow a molar pregnancy, 25% follow an abortion or ectopic pregnancy, and 25% follow a term delivery. The most common metastatic site is the lungs, which are involved in >80% of patients with metastases. Vaginal metastases are noted in 30% of patients with metastases. Distant sites such as the liver, brain, kidney, gastrointestinal tract, and spleen occur in about 10% of patients with metastatic disease, and these women are at the highest risk of death from disease. Metastatic disease is most commonly encountered in postpartum patients in whom diagnosis is frequently delayed.⁶

PSTT is a rare and unique form of GTN accounting for only 0.25% of all cases and is derived from neoplastic transformation of intermediate trophoblastic cells that normally play a critical role in implantation. PSTT can occur after any gestational event, but unlike CCA occurs more commonly after a nonmolar or term pregnancy. Microscopically, these tumors show no chorionic villi and are characterized by a proliferation of cells with oval nuclei and abundant eosinophilic cytoplasm. They are slow-growing and tend to locally infiltrate the myometrium, at which point they can metastasize both via the hematogenous and lymphatic systems. PSTT display a wide clinical spectrum and when metastatic, can be difficult to control even with surgery and chemotherapy. Unlike other forms of GTN, these tumors tend to remain localized in the uterus for long periods before metastasizing to regional lymph nodes or other metastatic sites.⁷ PSTT is characterized by low beta-hCG levels because it is a neoplastic proliferation of intermediate trophoblastic cells.⁸ Therefore, a large tumor burden may be present before the disease is diagnosed. Expression, however, of human placental lactogen is increased on immunochemical histologic sections as well as in the serum. PSTT are also characterized by high levels of free beta-hCG.⁸

ETT is a very rare but distinctive form of GTN also derived from intermediate trophoblastic cells that typically presents as a discrete, hemorrhagic, solid, and cystic lesion that is located either in the fundus, lower uterine segment, or endocervix. Microscopically, the tumor is composed of a relatively uniform population of mononucleate intermediate trophoblastic cells forming nests and solid masses. The cells resemble the trophoblastic cells in the chorion laeve, and are therefore designated as “chorionic-type intermediate trophoblast.” Typically, islands of trophoblastic cells are surrounded by extensive necrosis and associated with a hyaline-like matrix creating a “geographic” pattern that is quite characteristic of this lesion.⁹ Patients with ETT are in the reproductive age group and present with abnormal vaginal bleeding. It is not uncommon for ETT to be diagnosed long after an antecedent pregnancy. Patients may also present with extrauterine ETT without evidence of prior gestational trophoblastic disease in the uterus. Serum beta-hCG levels are generally in a low range, but may be absent.

INDICATIONS FOR TREATMENT

Following a Molar Pregnancy

The early diagnosis of molar pregnancy with ultrasound has led to changes in the histologic characteristics and clinical presentation

of CHM without changing the potential for developing persistent disease.¹⁰ Following molar evacuation, the diagnosis of GTN is based on the following International Federation of Gynecologists and Obstetricians (FIGO) guidelines¹¹:

1. A plateau in beta-hCG of four values $\pm 10\%$ over 3 weeks
2. A $\geq 10\%$ rise in beta-hCG levels for three or more values over at least 2 weeks
3. Persistence of beta-hCG levels for >6 months after molar evacuation
4. Histologic evidence of choriocarcinoma
5. Presence of metastatic disease

Following a Nonmolar Pregnancy

Patients who develop rising hCG titers following a nonmolar pregnancy have GTN (CCA, PSTT, or ETT) until proven otherwise. Serum hCG levels are not routinely obtained after nonmolar pregnancies (except in following ectopic pregnancies), unless the woman has had a previous molar pregnancy when it becomes the standard of care because of the increased risk of developing GTN. *However, any woman in the reproductive age group who presents with abnormal vaginal bleeding or evidence of metastatic disease should undergo hCG screening to rule out GTN.* At this point, a thorough clinical and radiologic evaluation of the patient should be carried out to determine the extent of disease. Rapid growth, widespread dissemination, and a high propensity for hemorrhage make CCA a medical emergency. Metastases are found in the lungs (80%), vagina (30%), pelvis (20%), brain (10%), and liver (10%), as well as other sites ($<5\%$).¹²

MEASUREMENT OF HUMAN CHORIONIC GONADOTROPIN

The serial quantitative measurement of hCG is essential for the diagnosis, monitoring the efficacy of treatment, and follow-up of patients with molar pregnancy and GTN. hCG is a glycoprotein that consists of an alpha subunit common to other glycoproteins, and a beta subunit that is hormone-specific. Therefore, the measurement of hCG in patients with GTN should be performed by assays that measure the beta subunit only.¹³ hCG is synthesized by syncytiotrophoblastic cells of the developing placenta and hydatidiform moles. In contrast, the hyperglycosylated form of hCG (H-hCG) is produced by the cytotrophoblastic cells of the developing placenta during early gestation and by malignant GTN (i.e., invasive moles and CCA).¹⁴ After evacuation of a molar pregnancy, beta-hCG levels usually disappear in 8 to 12 weeks. After normal delivery or nonmolar miscarriage, hCG levels become undetectable within 3 to 6 weeks.¹⁵ Persistence of hCG levels indicates local or metastatic disease, which allows for early detection and timely intervention. During treatment, beta-hCG response is used as a guide to determine whether to continue treatment with an agent or switch to another agent. Beta-hCG monitoring after treatment allows for identification of patients who relapse and require additional treatment.

Hyperglycosylated Human Chorionic Gonadotropin

H-hCG is now believed to be a marker for malignant GTN, and its presence is associated with response to chemotherapy.¹⁴ Some patients treated for molar pregnancy or GTN will have persistent (weeks or months) low levels (<200 mIU/ml) of real hCG, but low or absent concentrations of H-hCG. Characteristically, these women have no radiographic or clinical evidence of active disease, and do not appear to respond to chemotherapy. This condition of persistent low-level non-H-hCG is called *quiescent GTN*.¹⁶ Careful follow-up is necessary because 6% to 10% of these patients will

ultimately relapse with evidence of active disease and rising hCG levels with a high concentration ($>30\%$) of H-hCG, at which point chemotherapy becomes effective.

Phantom Human Chorionic Gonadotropin

False-positive findings on hCG tests can occur with the presence of heterophile antibodies that interfere with the immunoassay. Although a rare occurrence, false-positive hCG tests can be confusing to clinicians when attempting to diagnose disorders of pregnancy such as ectopic and GTN. Misinterpretations of false-positive tests have led to inappropriate treatment, including surgery and chemotherapy, when based only on the persistently elevated serum beta-hCG levels. A false-positive hCG result should be suspected if the clinical picture and the laboratory results are discordant, if there is no identifiable antecedent pregnancy, or if patients under treatment with persistent low levels do not respond appropriately. When a false-positive hCG test is suspected, a urinary assay should be performed because heterophile antibodies do not cross the renal tubules. In rare instances, particularly in women approaching menopause or in women treated with multiagent chemotherapy that may suppress ovarian function, the source of the hCG is the pituitary gland.¹⁷

PRETREATMENT EVALUATION

Once the diagnosis of GTN has been made, the following pretreatment evaluation is recommended to determine the extent and location of disease:

1. A complete history and physical examination including a speculum examination to detect vaginal metastases occurring in approximately 30% of patients with metastatic disease.
2. Biopsy of the vaginal lesion is not recommended given the highly vascular nature of the tumor and the risk of uncontrollable hemorrhage.
3. Baseline measurement of the serum hCG value.
4. Hepatic, thyroid, and renal function tests.
5. Baseline peripheral white blood cell and platelet counts.
6. Stool guaiac to screen for the rare gastrointestinal metastasis.
7. Chest X-ray, essential since the lungs are involved in 80% of patients who develop metastatic disease.
8. Pelvic ultrasound to confirm absence of a new pregnancy and to detect pelvic disease, myometrial invasion and retained issue.¹⁸

If there is evidence of metastatic disease on initial evaluation, the workup should be expanded to include the following studies:

1. Chest computed tomography (CT), if chest X-ray is positive. Although pulmonary metastases can be detected by chest CT in up to 40% of patients with a negative chest X-ray, it is not required initially when a plain film is negative since the presence of micrometastases does not affect outcome and are not considered a risk factor.¹⁹
2. Ultrasound or CT scan of the abdomen and pelvis, with special attention to the liver, kidneys, and spleen.
3. Magnetic resonance imaging or CT scan of the head.²⁰
4. Measurement of cerebrospinal fluid hCG level is recommended to confirm central nervous system metastases if the patient exhibits neurologic signs and the head magnetic resonance imaging or CT scan is negative.^{21,22}
5. Selective angiography of abdominal and pelvic organs, if indicated.
6. Whole-body deoxy-2-[¹⁸F]fluoro-d-glucose positron emission tomography (PET) scan to identify active disease site for occult disease, if indicated.^{23,24}
7. Review of all available pathology. Histologic confirmation of the diagnosis of GTN is not required for treatment. However, biopsy of a metastatic site may be indicated if the diagnosis is in doubt.

TABLE 75.1

International Federation of Gynecologists and Obstetricians Staging of Gestational Trophoblastic Neoplasia and World Health Organization Scoring System Based on Prognostic Factors

Stage I	Disease confined to the uterus			
Stage II	GTN extends outside of the uterus, but is limited to the genital structures			
Stage III	GTN extends to the lungs, with or without genital tract involvement			
Stage IV	All other metastatic sites			
A risk factor score (see below) should be assigned to each patient.				
The stage should be followed by the sum of the risk factor score (e.g., II:4).				
	Score			
Prognostic factors	0	1	2	4
Age in years	<40	≥40	—	—
Antecedent pregnancy	Mole	Abortion	Term	—
Interval (months) ^a	<4	≥4 but <7	≥7 but <13	≥13
Pretreatment serum hCG (mIU/mL)	<1,000	1,000 to <10,000	10,000 to <100,000	≥100,000
Largest tumor, including uterine	—	3 to <5 cm	≥5 cm	—
Site of Metastases	Lung	Spleen, Kidney	GI Tract	Brain, Liver
Number of metastases	—	1–4	5–8	>8
Prior failed chemotherapy	—	—	Single drug	Two or more drugs

GTN, gestational trophoblastic neoplasm; hCG, human chorionic gonadotropin; GI, gastrointestinal.

^aInterval (in months) between end of antecedent pregnancy and start of chemotherapy.

STAGING AND PROGNOSTIC SCORE

Table 75.1 summarizes the staging of GTN adopted by FIGO in 2002.²⁵ In addition to anatomic staging, a prognostic scoring system has also been adopted by FIGO to help determine the appropriate chemotherapy regimen that affords the patient optimal management by reducing the risk of developing resistance to chemotherapy.²⁶ Patients with a score <7 are considered at low risk of developing resistance and generally achieve remission with single-agent therapy. Patients with scores of ≥7 are at high risk of developing resistance to single-agent therapy and should be treated primarily with multiple-agent regimens. All patients with stage IV disease are considered high risk. However, recent data from Charing Cross Hospital indicate that only 30% of patients with low-risk GTN with a risk score of 5 to 6 are cured with monotherapy. Patients who prove resistant to sequential single-agent therapy are more likely to be older, have hCG levels >100,000 mIU/mL, develop GTN following a nonmolar antecedent pregnancy with an histologic diagnosis of choriocarcinoma, have metastatic disease, and are found to have ultrasound evidence of large uterine tumor burden.²⁷ A similar “intermediate-risk group” (scores 5–6, etc.) was seen in the Gynecologic Oncology Group trial evaluating two single-agent regimens. For those women with risk scores of 5 to 6, the response rates to single-agent chemotherapy was about 10% to 40%.²⁸

TREATMENT

Chemotherapy is highly effective in most patients with GTN. Cure rates of 100% in low-risk disease and 80% to 90% in high-risk cases are reported from a number of treatment centers.²⁹ Despite the success of chemotherapy, the role of other modalities such as surgery and radiation therapy should not be overlooked. The best results are achieved when patients are treated under the auspices of a multidisciplinary team.

Low-Risk Disease

Most patients with low-risk GTN (risk score <7) including all cases of nonmetastatic disease and most cases of postmolar metastatic disease have survival rates that approach 100% when treated with monotherapy with either methotrexate (MTX) or actinomycin D (actD).²⁹ A number of different regimens are currently in use (Table 75.2). A recently reported study compared biweekly intrave-

TABLE 75.2

Single-Agent Regimens for Low-Risk Gestational Trophoblastic Neoplasms
MTX

- MTX 0.4–0.5 mg/kg IV or IM daily for 5 days (not to exceed 25 mg/d)
- Pulse MTX 50 mg/m² IM weekly

MTX/FA

- MTX 1 mg/kg IM or IV on days 1, 3, 5, 7
- FA 0.1 mg/kg PO on days 2, 4, 6, 8

High-dose MTX/FA

- MTX 100 mg/m² IV bolus
- MTX 200 mg/m² 12-h infusion
- FA 15 mg q 12 h in four doses IM or PO beginning 24 h after starting MTX

Actinomycin regimens

- actD 10–12 mcg/kg IV push daily for 5 days (not to exceed 1,000 mcg/d)
- actD 1.25 mg/m² IV push q 2 weeks

MTX, methotrexate; IV, intravenous; IM, intramuscular; FA, folinic acid (calcium leucovorin); PO, by mouth; actD, actinomycin-D (Cosmegen, Whitehouse Station, NJ).

nous actD and weekly intramuscular MTX regimens, and showed that the biweekly actD regimen was associated with a statistically significantly higher complete response rate.²⁸ Overall, the weekly intramuscular or intermittent continuous intravenous infusion MTX regimens are thought to be less effective than the daily (for 5 days) MTX or the 8-day alternating MTX/leucovorin regimens.³⁰ Lurain et al.³¹ analyzed their experience using secondary actD in patients with MTX resistance and found a 75% complete response rate. The patients who were resistant to both MTX and actD ultimately achieved complete response with multiagent salvage therapy.³¹ Maesta et al.,³² using multivariate analysis, studied prognostic factors that affect time to remission in low-risk GTN and concluded that complete molar histology, metastases, the use of multiagent therapy, and higher FIGO score were the main factors associated with longer time to remission. Chapman-Davis et al.³³ stressed the importance of dose-intensive treatment in patients with low-risk GTN treated initially with 5-day MTX. Shah et al.³⁴ performed a cost analysis of single-agent chemotherapy in low-risk GTN and concluded that 8-day MTX-folinic acid was consistently less expensive than actD.

MTX with folinic acid is the initial choice at the New England Trophoblastic Disease Center for low-risk GTN because it has the least toxicity and a high rate of response.³⁵ Courses are administered at 2-week intervals until the serum beta-hCG level becomes undetectable. The results of a recent study from the Netherlands and United Kingdom suggest that three rather than two additional courses of consolidation therapy should be administered after patients achieve remission to reduce the likelihood of relapse.³⁶ ActD is used when the patient develops resistance to MTX or if there is evidence of MTX-induced abnormal liver function tests. Patients with low-risk GTN who develop resistance to sequential monotherapy should be switched to a multidrug regimen such as MTX, actD, and cyclophosphamide in lower-

Protocols for Modified Triple Therapy for Methotrexate, Actinomycin D, and Cyclophosphamide

Days 1–5	Actinomycin D (Cosmegen, Whitehouse Station, NJ), 12 mcg/kg, IV push ^a Cyclophosphamide, 3 mg/kg, IV bolus over 45–60 min
Days 1, 3, 5, 7	Methotrexate, 1 mg/kg IM or IV
Days 2, 4, 6, 8	Leucovorin calcium, 0.1 mg/kg PO
Repeat cycles every 2 to 3 wk, toxicity permitting.	

IV, intravenous; IM, intramuscular; PO, by mouth.

^aVesicant: Administer through free-flowing IV.

volume disease (Table 75.3); or etoposide, MTX, actD, cyclophosphamide, and vincristine (EMA/CO) for large-volume disease (Table 75.4).³⁷ Remission is defined as an undetectable hCG level for 3 consecutive weeks. Hysterectomy with ovarian preservation should also be considered as primary therapy for patients with stage I disease who have completed their family. It is advisable to administer adjunctive chemotherapy at the time of surgery because of the risk of occult disease.³⁸

After attaining undetectable hCG levels, patients should be followed with monthly hCG levels for 12 months. During this time, effective contraception is mandatory and also serves the useful purpose of suppressing pituitary hCG which can falsely suggest residual disease.³⁹ Pregnancy may be undertaken after 1 year of normal hCG titers.

TABLE 75.4

Protocols for Etoposide, Methotrexate, Actinomycin D, Cyclophosphamide, and Vincristine, and Etoposide, Methotrexate, Actinomycin D, and Cisplatin Regimens

Day	Drug	Dose
Protocol for EMA/CO Regimen		
1	Etoposide actD MTX	100 mg/m ² by infusion in 200 ml saline over 30 min 0.5 mg IV push 100 mg/m ² IV push 200 mg/m ² by infusion over 12 h
2	Etoposide actD Folinic acid	100 mg/m ² by infusion in 200 ml saline over 30 min 0.5 mg IV push 15 mg q 12 h × four doses IM or PO beginning 24 h after starting MTX
8	Cyclophosphamide Vincristine	600 mg/m ² by infusion in saline over 30 min 1.0 mg/m ² IV push
Protocol for EMA/EP Regimen		
1	Etoposide actD MTX	100 mg/m ² by infusion in 200 ml saline over 30 min 0.5 mg IV push 100 mg/m ² IV push 200 mg/m ² by infusion over 12 h
2	Etoposide actD Folinic acid	100 mg/m ² by infusion in 200 ml saline over 30 min 0.5 mg IV push 15 mg q 12 h × four doses IM or PO beginning 24 h after starting MTX
8	Cisplatin Etoposide	60 mg/m ² with prehydration 100 mg/m ² by infusion in 200 ml saline over 30 min

EMA/CO, etoposide, methotrexate, and dactinomycin alternating with cyclophosphamide and vincristine; actD, actinomycin-D (Cosmegen, Whitehouse Station, NJ); IV, intravenous; MTX, methotrexate; IM, intramuscular; PO, by mouth; EMA/EP, etoposide, methotrexate, actinomycin D, and cisplatin.

High-Risk Disease

Dose-intensive multiple-agent chemotherapy should be used initially in all patients with stage II and III disease whose prognostic scores are >6 and all patients with stage IV disease.⁴⁰ Table 75.4 summarizes the most widely used regimens including EMA/CO and etoposide, MTX, actD, and cisplatin (EMA/EP), which are associated with cure rates ranging from 70% to 90%. Cagayan⁴¹ reported a remission rate of 72% with the primary use of EMA/CO and an overall survival rate of 86%. Despite the success of EMA/CO, roughly 30% to 40% of women with high-risk disease will have an incomplete response to first-line multiagent therapy or will relapse from remission and will need additional multiagent chemotherapy with potentially other multimodality treatment. An alternative regimen containing cisplatin (EMA/EP) should be used as salvage therapy for patients who develop resistance to EMA/CO.⁴² A recent Cochrane Database review of chemotherapy for resistant or recurrent GTN recognizes the efficacy of a number of platinum/etoposide combinations.⁴³ 5-Fluorouracil has also been shown to be an active agent in the management of this disease in both low-risk and high-risk patients.⁴⁴ The Charing Cross group has reported that the use of induction low-dose etoposide 100 mg/m², and cisplatin 20 mg/m² (days 1 and 2 every 7 days) in selected patients with high tumor burden may almost completely eliminate early mortality that may result from respiratory compromise and hemorrhage.⁴⁵ They also report a 94% remission rate with EMA/CO by carefully excluding nongestational tumors in patients with atypical presentation using genetic analysis. Treatment should be dose-intensive every 2 to 3 weeks, toxicity permitting. The use of granulocyte colony-stimulating factor and, when absolutely necessary, platelet transfusions are important to maintain adequate dose-intensity and to prevent unnecessary dose reduction. Treatment should be continued until the hCG level becomes undetectable and remains undetectable for 3 consecutive weeks. The administration of four courses of the remission regimen after the patient achieves remission is recommended to reduce relapse.⁴⁶

Role of Radiation Therapy

Radiation therapy has little application in patients with GTN except in selected patients with cerebral metastases. The use of whole brain or localized radiation therapy in conjunction with chemotherapy can prevent a life-threatening or debilitating hemorrhage and should be initiated promptly.⁴⁷ An alternative to the use of radiation for cerebral metastases is the use of intrathecal MTX in combination with multiagent chemotherapy, particularly in the presence of meningeal involvement.⁴⁸

Role of Surgery

Surgery also plays an important role in the management of high-risk patients.⁴⁹ Hysterectomy in patients with heavy bleeding, large bulky intrauterine disease, or in the presence of significant pelvic sepsis should be performed regardless of the patient's parity.³⁸ Removal of tumor masses in the bowel should also be performed because of the risk of hemorrhage. Unresponsive masses in the liver, kidneys, and spleen should be removed, although embolization has been used with some success in controlling liver metastases.

Although pulmonary disease is usually chemosensitive, resection of persistent lung nodules can be curative and should be considered when the metastasis is solitary, limited to one lung, and the beta-hCG $<1,000$.⁵⁰ Normalization of beta-hCG within 1 to 2 weeks after resection of a pulmonary lesion is a good indication of a positive outcome. Alifrangis et al.⁵¹ confirmed the criteria for thoracotomy but also reported that multiple resections over time or resection of more than one lesion can result in salvage after failure of standard or high-dose chemotherapy. When evaluating patients for thoracotomy, it is important to remember that lung nodules can persist for several months or years after completion of chemotherapy and normalization of beta-hCG. These nodules may represent areas of scar tissue or viable tumor which the use of PET or PET/CT may help to determine.²³

Surgery can also play a role in the management of cerebral metastases. Multimodality therapy including chemotherapy with surgical resection and irradiation (whole brain and/or stereotactic radiation) has improved overall survival from 46% to 64% in the last 14 years, even when metastases developed during chemotherapy.⁵² Craniotomy is indicated for the resection of peripheral, solitary, drug-resistant lesions and can be life-saving in the management of intracranial hemorrhage or increased intracranial pressure.

Patients with high-risk disease who achieve remission should be followed for 24 months before pregnancy is attempted. There is no contraindication to the use of oral contraceptives in these patients.

PLACENTAL SITE OR EPITHELIOID TROPHOBLASTIC TUMORS

Patients with PSTT and ETT confined to the uterus can be cured with hysterectomy.⁵³ If deep myometrial involvement is noted, we believe it is advisable to also perform a pelvic lymphadenectomy. Metastatic PSTT/ETT are recognized as having a high fatality rate⁵⁴; FIGO stage and interval from antecedent pregnancy appear to be two important prognostic factors. Although universally accepted guidelines on how to manage PSTT/ETT are not available, given its aggressive clinical behavior, multimodality therapy with surgery and chemotherapy, preferably with EMA/EP, has been shown to improve survival.⁵⁵

SUBSEQUENT PREGNANCY AFTER TREATMENT FOR GESTATIONAL TROPHOBLASTIC NEOPLASIA

Patients with GTN treated successfully with chemotherapy can expect normal reproductive function.⁵⁶ The New England Trophoblastic Disease Center database has follow-up on 668 subsequent pregnancies in patients treated between July 1, 1965 and May 1, 2013 that resulted in 446 term live births (66.8%), 44 premature deliveries (6.6%), 7 ectopic pregnancies (1.0%), 10 stillbirths (1.5%), and 10 repeat molar pregnancies (1.5%). First- and second-trimester spontaneous abortions occurred in 123 pregnancies (18.4%). There were 28 therapeutic abortions (4.2%). Major and minor congenital anomalies were detected in only 12 of 500 births (2.4%). These values are comparable to the general gestational population. The low incidence of congenital malformations is reassuring in spite of the fact that chemotherapeutic agents are known to have teratogenic and mutagenic potential.

Although we advise patients to practice strict contraception during follow-up, patients occasionally become pregnant, either accidentally or intentionally, before their follow-up has been completed. When this occurs and the pregnancy is desired, we monitor the developing fetus and placenta with sonograms at 6 and 10 weeks of gestation. If the 10-week sonogram appears normal, there is little likelihood of recurrence. We strongly advise these patients to undergo hCG testing at the 6 week postpartum or postabortal check-up to ensure complete remission.

PSYCHOSOCIAL ISSUES

Women who develop GTN can experience significant mood disturbance, marital and sexual problems, and concerns over future fertility.⁵⁷ Because GTN is a consequence of pregnancy, patients and their partners must confront the loss of a pregnancy at the same time they face concerns regarding malignancy. Patients can experience clinically significant levels of anxiety, fatigue, anger, confusion, sexual problems, and concern for future pregnancy that last for protracted periods of time. Patients with metastatic disease, in particular, are at risk of psychological disturbances; these patients need assessments and interventions both during treatment and after remission is attained.

76 Ovarian Cancer, Fallopian Tube Carcinoma, and Peritoneal Carcinoma

Stephen A. Cannistra, David M. Gershenson, and Abram Recht

INTRODUCTION

Ovarian cancer is not a single entity but instead represents tumors of epithelial, germ cell, or sex cord–stromal origin. Epithelial ovarian cancer typically occurs in postmenopausal women, most germ cell tumors present in younger women, and sex cord–stromal tumors may occur at any age. Approximately 90% of ovarian cancer is epithelial in origin and poses significant therapeutic challenges due to the advanced stage of most patients with this disease. In contrast, other types of ovarian cancer such as germ cell and sex cord–stromal tumors are often localized in distribution, more amenable to surgical resection, and have a more favorable prognosis. Although primary peritoneal serous carcinoma and fallopian tube carcinoma do not originate in the ovary, they are discussed in this chapter because their clinical and management considerations are similar to those of epithelial ovarian cancer.

EPITHELIAL OVARIAN CANCER

Epidemiology

Epithelial ovarian cancer is expected to occur in 22,240 women and cause 14,030 deaths in the United States in 2013, which makes this tumor the leading cause of gynecologic cancer mortality.¹ The lifetime risk of developing sporadic epithelial ovarian cancer is approximately 1.7%, although patients with a familial predisposition have a much higher lifetime risk, in the range of 10% to 40%.² The median age at diagnosis for sporadic disease is 60 years, although patients with a genetic predisposition may develop this tumor earlier, often in their fifth decade. The age-specific incidence of sporadic disease increases with age, from 15 to 16 per 100,000 in the 40- to 44-year-old age group to a peak rate of 57 per 100,000 in the 70- to 74-year-old age group.¹ There has been a statistically significant improvement in 5-year survival over the past decades, with a rate of 36% in 1977, 39% in 1986, and 45% in 2002.¹ This improvement in survival is likely the result of more effective chemotherapy options and surgical techniques for tumor debulking. African American women in the United States have a lower incidence of ovarian cancer (10.3 per 100,000 women) compared to white women, but both have a similar stage distribution and overall survival rate.¹ A higher risk for developing epithelial ovarian cancer is observed for nulliparous women and a lower risk for those who have had children, who have breastfed, who have undergone tubal ligation, or who have taken oral contraceptives.³

Pathogenesis and Patterns of Metastases

Some epithelial ovarian neoplasms are thought to arise from the surface epithelium covering the ovary, which is contiguous with peritoneal mesothelium. In some cases, malignant transformation appears to occur within epithelium that becomes trapped within

ovarian inclusion cysts during ovulation, where it can develop into a variety of Müllerian-type histologies.⁴ However, emerging evidence suggests that a subset of epithelial ovarian cancers may instead originate in the fallopian tube fimbria, subsequently spreading to the ovary or peritoneal cavity.⁵ Germ cell tumors most likely originate in cells derived from the primitive streak that ultimately migrated to the gonads. The ovarian stroma consists of granulosa cells, theca cells, and fibroblasts, which give rise to the sex cord–stromal tumors.

Several molecular abnormalities have been identified in patients with epithelial ovarian cancer, although their contribution to early malignant transformation is poorly understood. Cytogenetic analysis may reveal complex abnormalities, including deletions of 3p, 6q, 8p, and 10q, and loss of heterozygosity is commonly observed on 11p, 13q, 16q, 17p, and 17q.⁶ Mutation in the *p53* protooncogene occurs in over 50% of cases, predominantly involving tumors in patients with advanced-stage and high-grade serous histology.⁶ In contrast, mutations in *B-raf*, *K-ras*, *PTEN*, or β -catenin may be seen in endometrioid, mucinous, or low-grade histologies.⁵ Mutations in the *ARID1A* gene occur in 50% of patients with clear cell ovarian cancer.⁷ Amplification of the *HER2/neu* gene is observed in only approximately 8% of patients and confers a poorer prognosis.⁸ Overexpression of proapoptotic genes such as *BAX* is associated with chemoresponsiveness and a more favorable prognosis, although the role of *BAX* in the pathogenesis of this tumor has not been well studied.⁹ Surface adhesion proteins such as CD44H and β -1 integrins have been shown to mediate transperitoneal spread of this tumor by promoting the attachment of cancer cells to the peritoneal mesothelial lining.¹⁰ Expression of angiogenic cytokines such as the vascular endothelial growth factor (VEGF) is frequently observed in epithelial ovarian cancer, with high serum levels conferring a worse prognosis.¹¹

The ability of tumor cells to exfoliate from the ovarian surface and to spread in an asymptomatic fashion impedes the development of successful screening approaches that would allow for early diagnosis. The tumor typically spreads to the omentum and to peritoneal surfaces such as the underside of the diaphragm, paracolic gutters, and bowel serosa (Fig. 76.1). The lymphatic drainage of the ovary follows its blood supply through the infundibulopelvic ligament to nodes in the para-aortic region. Lymphatic drainage through the broad ligament and parametrial channels can also result in involvement of pelvic sidewall lymphatics, including the external iliac, obturator, and hypogastric chains. Spread may rarely occur along the course of the round ligament, resulting in involvement of inguinal lymph nodes. Approximately 10% to 15% of patients with ovarian cancer that appears to be localized to the ovaries have metastases to para-aortic lymph nodes, and retroperitoneal lymph node involvement is found in >50% of patients with advanced disease.²

Although epithelial ovarian cancer typically spreads in a locoregional fashion to involve the peritoneal cavity and retroperitoneal nodes, it can be found outside the abdomen as well. The most common site of extra-abdominal spread is the pleural space (thought to occur via transdiaphragmatic lymphatics), where it causes a malignant pleural effusion in some patients. Hematogenous metastases

Figure 76.1 Intraoperative appearance of advanced epithelial ovarian cancer, with multiple tumor implants involving the peritoneal surface of the upper abdomen. (Courtesy of Dr. Jonathan Niloff, Beth Israel Deaconess Medical Center, Boston, MA.)

to the liver, spleen, or lung can also occur during the course of the disease, but are relatively uncommon at presentation. Bone or central nervous system metastases may rarely be observed in patients who have lived for many years after initial diagnosis, during which unusual patterns of disease spread may occur.

Histologic Classification of Epithelial Tumors

Table 76.1 outlines the classification of common epithelial tumors that has been accepted by the World Health Organization (WHO) and the International Federation of Gynecology and Obstetrics (FIGO).⁴ The nomenclature for these tumors reflects the cell type, location of the tumor, and degree of malignancy, ranging from benign lesions to tumors of low malignant potential (LMP) to invasive carcinomas.

Tumors of LMP (borderline tumors) have an excellent prognosis compared with invasive carcinomas.^{12,13} They are characterized by epithelial papillae with atypical cell clusters, cellular stratification, nuclear atypia, and increased mitotic activity. In contrast to epithelial ovarian carcinoma, borderline tumors lack stromal invasion.¹³

Epithelial carcinomas are characterized by histologic cell type and degree of differentiation (tumor grade). The histologic cell type has limited prognostic significance independent of clinical stage, although patients with clear cell and mucinous types of epithelial ovarian cancer fare less well due to the relative chemoresistance of these histologies.¹⁴ Conversely, low-grade serous carcinoma is associated with a better prognosis despite relative chemoresistance.^{15,16} High tumor grade appears to be an important prognostic factor, especially in patients with early stage epithelial tumors.

Certain pathologic and clinical features are characteristic of distinct histologic subtypes of epithelial carcinoma (Table 76.2). For instance, concentric rings of calcification called psammoma bodies (Fig. 76.2) are often observed in the papillary serous variety of epithelial ovarian cancer, although they are not pathognomonic for this disease and may also be seen, for example, in breast, lung, and papillary thyroid cancers. The endometrioid variant of ovarian cancer is associated with endometriosis in about 20% to 30% of cases, with a separate endometrioid uterine cancer (often stage I and low grade) simultaneously present in 15% of cases.¹⁷ Likewise, clear cell histology may also be associated with endometriosis, as well as humorally mediated hypercalcemia (which can also be observed with the rare small cell variant of ovarian cancer). Clear cell cancers are relatively resistant to chemotherapy compared to

TABLE 76.1

World Health Organization Classification of Malignant Ovarian Tumors

Common Epithelial Tumors

Malignant serous tumor

- Adenocarcinoma, papillary adenocarcinoma, papillary cystadenocarcinoma
- Surface papillary carcinoma
- Malignant adenofibroma, cystadenofibroma

Malignant mucinous tumor

- Adenocarcinoma, cystadenocarcinoma
- Malignant adenofibroma, cystadenofibroma

Malignant endometrioid tumor

- Carcinoma
- Adenocarcinoma
- Adenoacanthoma
- Malignant adenofibroma, cystadenofibroma
- Endometrioid stromal sarcoma
- Mesodermal (mullerian) mixed tumor: homologous and heterologous

Other

- Clear cell (mesonephroid) tumor, malignant
- Carcinoma and adenocarcinoma
- Brenner tumor, malignant
- Mixed epithelial tumor, malignant
- Undifferentiated carcinoma
- Unclassified

Sex Cord–Stromal Tumors

Granulosa–stromal cell tumor

- Granulosa cell tumor
- Tumor in the thecoma-fibroma group
- Fibroma
- Unclassified

Androblastoma: Sertoli-Leydig cell tumor

- Well differentiated
- Tubular androblastoma, Sertoli cell tumor (tubular adenoma of Pick)
- Tubular androblastoma with lipid storage, Sertoli cell tumor with lipid storage
- Sertoli-Leydig cell tumor (tubular adenoma with Leydig cells)
- Leydig cell tumor, hilus cell tumor
- Of intermediate differentiation
- Poorly differentiated (sarcomatoid)
- With heterologous elements
- Gynandroblastoma
- Lipid (lipoid) cell tumors
- Unclassified

Germ Cell Tumor

- Dysgerminoma
- Endodermal sinus tumor
- Embryonal carcinoma
- Polyembryoma
- Choriocarcinoma
- Immature teratoma
- Mature dermoid cyst with malignant transformation
- Monodermal and highly specialized
- Struma ovarii
- Carcinoid
- Struma ovarii and carcinoid
- Others
- Mixed forms

Gonadoblastoma

- Pure
- Mixed with dysgerminoma or other form of germ cell tumor

From Young RH. A brief history of the pathology of the gonads. *Mod Pathol* 2005;18:S3.

TABLE 76.2

Common Histologic Types of Epithelial Ovarian Cancer

Histology	Features
Papillary serous	The most common type of epithelial ovarian cancer. May contain psammoma bodies (see Fig. 76.3) and is often associated with CA 125 elevation. Identical histology is observed for primary peritoneal serous cancer.
Endometrioid	Sometimes associated with endometriosis or an independent uterine cancer of similar histology. May occur with early-stage disease in younger patients, although advanced disease is also possible.
Mucinous	May rarely be associated with pseudomyxoma peritonei. CA 125 levels may not be markedly elevated. Relatively chemoresistant. Differential diagnosis of a mucinous ovarian tumor includes metastatic disease from an appendiceal primary.
Clear cell	The most chemoresistant type of ovarian cancer. Often contains “hobnail” cells with cleared out cytoplasm due to glycogen. Sometimes associated with endometriosis or humorally mediated hypercalcemia.

CA, cancer antigen.

their more common papillary serous counterparts. Finally, primary mucinous ovarian cancers are also relatively chemoresistant, are sometimes associated with pseudomyxoma peritonei, and may not be associated with dramatic elevations of the cancer antigen (CA) 125 serum tumor marker.

Gastric, breast (especially infiltrating lobular carcinoma), mesothelioma, and colorectal cancers may occasionally present with diffuse peritoneal implants, ascites, and ovarian metastases that mimic primary ovarian cancer. It is usually possible to distinguish between these possibilities on routine light microscopic histologic evaluation, although immunohistochemistry can be most helpful when the histologic diagnosis is ambiguous. Staining for cytokeratin CK7 is positive and CK20 is negative in most cases of primary serous ovarian cancer, whereas the reverse staining pattern is typically observed for colorectal cancer. Staining for gross cystic disease fluid protein (GCDFP) may be positive in up to 50% of patients with breast cancer, whereas this marker should be negative in patients with gastric, colorectal, or ovarian cancer. Finally, calretinin is usually expressed in mesothelioma but is typically negative in epithelial ovarian cancer.

Diagnosis

Most patients with epithelial ovarian cancer experience no signs or symptoms of the disease until it spreads to the upper abdomen.

Figure 76.2 Photomicrograph of a hematoxylin and eosin-stained section of papillary serous ovarian cancer, showing psammoma bodies. (Courtesy of Dr. Jonathan Hecht, Beth Israel Deaconess Medical Center, Boston, MA.)

Approximately 70% of patients with this tumor present with advanced disease (stage III or IV, Table 76.3), whereas the majority of patients with borderline, germ cell, and sex cord–stromal tumors present with early stage disease limited to the pelvis.² Occasionally, patients with epithelial ovarian cancer will be diagnosed with early stage disease due to discovery of a mass on routine pelvic examination or because of pelvic pain caused by ovarian torsion. Unlike epithelial cancers, which are generally asymptomatic at an early stage, ovarian germ cell malignancies tend to stretch and twist the infundibulopelvic ligament, causing severe pain while the disease is still confined to the ovary.

Abdominal discomfort, bloating, and early satiety are the most common symptoms experienced by women with epithelial ovarian cancer. Patients presenting with such nonspecific complaints may be found to have ascites and a pelvic mass on physical examination. Occasionally an umbilical lymph node metastasis will be present (Sister Mary Joseph node) or a pleural effusion will be found. The mass on pelvic examination is frequently firm and fixed, with multiple nodularities palpable in the cul-de-sac.

The CA 125 serum level is elevated in >80% of serous epithelial ovarian cancers.¹⁸ However, it is not a reliable diagnostic test, as it can also be elevated in a variety of benign gynecologic conditions (such as endometriosis, pelvic inflammatory disease, or pregnancy) and nongynecologic malignancies (such as breast, lung, and gastrointestinal cancers). Furthermore, the CA 125 level is elevated in only approximately 50% of patients with early stage epithelial ovarian cancer, which also limits its value as a screening test.¹⁵ Other tumor markers, such as CA 19-9, which is elevated in some mucinous ovarian carcinomas, and carcinoembryonic antigen (CEA) are less frequently useful. It is typical for a patient with epithelial ovarian cancer to have a normal CEA level in the setting of a significantly elevated CA 125 level. Postoperatively, the CA 125 level provides a sensitive way to monitor treatment response and development of disease recurrence. Because relapsed epithelial ovarian cancer is usually incurable, however, there is currently no evidence that early detection of recurrence through CA 125 surveillance confers either a quality of life or a survival advantage in this disease.¹⁹

Transvaginal ultrasonography (TVU) is an important diagnostic tool in the evaluation of patients with a pelvic mass. TVU is more sensitive at detecting ovarian tumors compared to other tests such as computed tomography (CT), and it can provide qualitative information about the mass that might suggest malignancy. The classic sonographic finding of malignancy is a “complex” cyst, defined as containing both solid and cystic components, sometimes with septations and internal echogenicity (Fig. 76.3). Finding a complex cyst on sonography, especially in the presence of signs and symptoms consistent with ovarian cancer, often requires surgery for further evaluation. It is best to avoid percutaneous biopsy during the initial evaluation, which can result in cyst rupture and spillage of malignant cells into the peritoneal cavity. Bilateral

TABLE 76.3

International Federation of Gynecology and Obstetrics Staging System for Epithelial Ovarian Cancer

Stage I	<i>Tumor limited to ovary or ovaries^a</i>
IA	One ovary, without malignant ascites, positive peritoneal washings, surface involvement, or rupture
IB	Both ovaries, without malignant ascites, positive peritoneal washings, surface involvement, or rupture
IC	Malignant ascites, positive peritoneal washings, surface involvement, or rupture present IC1: Surgical spill IC2: Capsule rupture before surgery or tumor on ovarian or fallopian tube surface IC3: Malignant cells in ascites or peritoneal washings
Stage II	<i>Ovarian tumor with pelvic extension^a</i>
IIA	Involvement of the uterus or fallopian tubes
IIB	Involvement of other pelvic organs (e.g., bladder, rectum, or pelvic sidewall)
Stage III	<i>Tumor involving the upper abdomen or lymph nodes</i>
IIIA	Positive retroperitoneal nodes only or microscopic peritoneal disease outside of the pelvis. IIIA1: Positive retroperitoneal nodes as the only site of extrapelvic spread IIIA1(i): Metastases up to 10 mm in greatest dimension IIIA1(ii): Metastases >10 mm in greatest dimension IIIA2: Microscopic extrapelvic peritoneal involvement (with or without nodal involvement)
IIIB	Macroscopic peritoneal metastases ≤ 2 cm in diameter (with or without nodal involvement) ^b
IIIC	Macroscopic peritoneal metastases >2 cm in diameter (with or without nodal involvement) ^b
Stage IV	<i>Distant organ involvement, including pleural space^c or hepatic/splenic parenchyma</i>
	IVA: Pleural effusion with positive cytology IVB: Parenchymal metastases (e.g., hematogenous spread to liver) or metastases to extra-abdominal sites such as inguinal lymph nodes

^a Patients with disease that appears to be confined to the ovaries or pelvis require nodal biopsy for complete staging, in order to exclude the possibility of occult nodal involvement.

^b Disease measurements for staging purposes are made before debulking has been attempted.

^c Pleural effusion must be cytologically proven to be malignant if used to define stage IV disease.

ovarian involvement and ascites are sometimes detected by sonography as well. Color Doppler imaging evaluates blood flow to an ovarian mass and can potentially identify a malignant process based on the presence of abnormal neovascularization.²⁰

In contrast to complex cysts, “simple” cysts are defined as being thin-walled, fluid-filled, without a mass component, septations, or internal echogenicity on TVU examination. Simple cysts are most often benign in nature and may be found in 5% to 10% of asymptomatic postmenopausal women during TVU examination, especially in the first decade after menopause. Simple cysts do not always require surgical evaluation if they are associated with normal CA 125 levels, although management must be individualized.²¹ Postmenopausal women with simple cysts in association with elevated serum CA 125 levels, simple cysts that are >5 to 10 cm in diameter, or simple cysts in association with abnormal color Doppler flow studies are often referred for surgery.

In premenopausal women, simple cysts detected on TVU examination may be functional (i.e., a corpus luteum cyst) or represent a benign process such as a serous cystadenoma. Such cysts may generally be followed through several menstrual cycles, during which they often resolve. Functional cysts may also disappear when oral contraceptives are used. However, premenopausal women with simple cysts that are persistent or enlarging, especially in the setting of a rising CA 125 level, are reasonable candidates for surgical evaluation to exclude malignancy.²¹ As previously mentioned, several benign conditions in premenopausal women may also be associated with elevated CA 125 levels, such as pregnancy or endometriosis, and there is no absolute CA 125 cutoff to distinguish benign from malignant pathologies.²²

CT or magnetic resonance imaging may sometimes be helpful in defining the extent of peritoneal disease in patients with suspected ovarian cancer. However, for the patient with a complex

ovarian cyst and clinical signs and symptoms to suggest ovarian cancer, these studies generally do not obviate the need for surgical exploration. Occasionally, CT may sometimes be helpful in distinguishing a gynecologic malignancy from a metastatic pancreatic neoplasm, for instance, for which an exploratory laparotomy may not be warranted. In selected patients, CT may also assist in surgical planning by locating the site of suspected bowel

obstruction. Magnetic resonance imaging has not been shown to have a clear advantage over CT in patients with an ovarian mass, except for pregnant patients when ultrasonography is inconclusive and there is a desire to avoid radiation exposure. Positron emission tomography (PET) is a form of functional imaging that most frequently uses the positron-emitting glucose analogue fluorodeoxyglucose. Tumor masses are imaged based on their relatively increased glucose metabolism compared to normal tissues. However, there is currently no proven role for PET in the diagnosis or subsequent follow-up of patients with ovarian cancer.²³ Chest radiographs may sometimes be performed to evaluate the presence of pleural effusions, which occur in 10% of patients with epithelial ovarian cancer at diagnosis.

Screening and Early Detection

A successful screening test for ovarian cancer should be capable of identifying the majority of patients with precancerous lesions or early disease. Because a positive screening test for ovarian cancer would result in major surgery with associated morbidity, costs, and even mortality, the false-positive rate of such a screening test must be low, and its positive predictive value (PPV) relatively high (at least 10%). At present, there are no screening tests for epithelial ovarian cancer that convincingly meet these criteria.

Ovarian palpation has not been established as a useful screening procedure, and most screening studies have used serum tumor marker levels, ultrasonography, or both. The CA 125 serum level is not a useful screening test when used alone, as elevations are not specific for ovarian cancer and may be observed in cirrhosis, peritonitis, pleuritis, pancreatitis, endometriosis, uterine leiomyomata, benign ovarian cysts, and pelvic inflammatory disease. In addition, CA 125 serum levels may be elevated in other malignancies such as breast, lung, colorectal, pancreatic, and gastric cancers. Finally, although the CA 125 level is elevated in the majority of patients with advanced epithelial ovarian cancer, it is abnormal in only half of patients with early stage disease.¹⁸ Therefore, by itself this test would fail to detect a sizable fraction of patients with curable disease. More recently, a number of candidate markers have been discovered that show promise for enhancing the accuracy of CA 125 levels, such as human epididymis 4, osteopontin, mesothelin, and osteoblast-stimulating factor-2. Algorithms that define the behavior of these markers have also been developed, incorporating biologic characteristics of tumor growth and marker behavior.²⁴ Levels of OVX-1 and macrophage colony-stimulating factor have been found to be elevated in patients with clinically evident ovarian cancer but normal CA 125 levels, which suggests that these markers may be complementary to CA 125.²⁵ Lysophosphatidic acid level has also been reported to discriminate patients with ovarian cancer from controls, including cases with early stage disease.²⁶ None of these tests has been proven to have sufficient sensitivity and specificity for routine screening at the current time.

Measurement of the CA 125 level has been combined with performance of TVU in an attempt to improve screening.^{20,27,28} Early studies of TVU suggested a sensitivity of close to 100% but a specificity of 98%, which is insufficient to achieve a PPV of 10%. More recent reports suggest that use of color Doppler imaging improves the specificity of TVU, but it is uncertain whether this will achieve the desired PPV. Investigators at the University of Kentucky improved the specificity of TVU by using a morphologic index. They screened 6,470 women, including high-risk premenopausal women and average-risk postmenopausal women.²⁸ Of 90 women who underwent surgery, 6 were found to have an ovarian malignancy, for a PPV of 6.7%. One interval cancer was found at prophylactic oophorectomy 11 months after screening, for a sensitivity of 86%. All but one of these cancers were stage I, and no deaths due to ovarian cancer were noted in this group.

Two randomized controlled trials are currently under way to evaluate a multimodal screening approach using both CA 125 and

TVU. In the United States, the Prostate, Lung, Colorectal, Ovarian Cancer Screening Trial uses measurement of CA 125 level (single threshold elevation of >35 U/mL) and TVU together, performed annually, as a first-line screen.²⁹ If either test is positive, the woman is referred for surgical consultation. In this two-arm, randomized controlled trial involving 10 centers, 78,216 of general US women aged 55 to 74 years were randomly assigned to the screening arm or to a standard-care control arm. After a median follow-up of 12.4 years, no mortality reduction was observed for patients randomized to the screening arm.³⁰

The second randomized screening trial is currently being conducted in the United Kingdom and uses CA 125 levels (or rate of rise of CA 125) as a trigger for performing TVU. This trial is based on an earlier study by Jacobs et al.³¹ in which 21,935 average-risk postmenopausal women were assigned to undergo three annual screenings or no screening. The screening protocol used CA 125 level as a first-line screen and referred the patient for TVU if the CA 125 level was >30 U/mL. If the TVU revealed an ovarian mass, the patient was referred for surgical consultation. Findings from this trial support the notion that this stepwise approach can yield high specificity and an acceptable PPV.³¹ Specifically, when the decision rule for surgical referral requires that results of both tests be positive, the PPV is 20%. Furthermore, there were one-half as many deaths in the screened group as there were among controls, and there was a statistically significant improvement in survival. Individuals with index cancers survived an average of 72.9 months in the screening group and 41.8 months in the control group. However, the multimodal screening strategy originally described by Jacobs et al.³¹ is limited by the sensitivity of the CA 125 level, which serves as a trigger for performing ultrasound. Accordingly, these investigators are exploring ways to improve on these results by detecting changes in CA 125 levels over time. Skates et al.³² suggested fitting an exponential model that uses data from several prior CA 125 screens, with an exponential rise triggering a callback for additional ultrasound testing. This screening strategy forms the basis of the three-arm randomized trial currently being conducted in the United Kingdom.

Hereditary Ovarian Carcinoma

Approximately 5% to 10% of patients with epithelial ovarian carcinoma carry a germline mutation that places them at substantially increased risk of developing this disease. The breast-ovarian cancer syndrome accounts for approximately 90% of hereditary ovarian cancer and is often suspected whenever the pedigree reveals multiple affected family members with ovarian cancer, bilateral or early onset breast cancer, both breast and ovarian cancer in the same individual, or a male relative with breast cancer.^{33,34} Fallopian tube cancer and primary peritoneal serous cancer (PPSC) are also recognized to be part of this syndrome.³⁵ The high incidence of breast and ovarian cancers in these families is due to inherited germline mutations in the *BRCA1* or *BRCA2* genes, which may be transferred by either parent, meaning that both maternal and paternal family histories must be obtained to determine risk.³⁶ The *BRCA1* gene, located on chromosome band 17q12-21, and the *BRCA2* gene, located on chromosome band 13q12-13, were identified and linked to hereditary breast and ovarian cancers in the 1990s. Emerging evidence suggests that these genes act as tumor suppressors and play a critical role in the repair of double-stranded DNA breaks.³⁶

Many mutations have been described throughout the *BRCA1* and *BRCA2* genes, with nonsense and frameshift mutations being predominant.³⁶ Nonsense mutations occur when a nucleotide substitution results in a stop codon, and frameshift mutations occur when one or more nucleotides are deleted to produce a downstream stop codon. Certain ethnic groups have higher frequencies of distinctive *BRCA* mutations, thought to be due to a founder effect in which certain mutations are preserved within a genetically

isolated population. Three such founder mutations (185delAG *BRCA1*, 5382insC *BRCA1*, and 6174delT *BRCA2*) are carried by 2% to 2.4% of the Ashkenazic Jewish population.³⁷ Furthermore, up to 40% of patients of Jewish descent with epithelial ovarian cancer may carry one of these mutations (regardless of their family histories).³⁷ This is compared to a carrier frequency of approximately 5% among non-Jewish women with ovarian cancer.

The lifetime risk of ovarian cancer is approximately 20% to 40% for patients with *BRCA1* mutations, and 10% to 20% for *BRCA2* mutation carriers.³⁸ Ovarian cancer associated with germline mutations of *BRCA1* appears to present with distinct clinical and pathologic features compared with sporadic ovarian cancer.³⁹ The majority of *BRCA1*-associated cancers are serous adenocarcinomas, with an average age at diagnosis of 48 years, whereas the mean age for *BRCA2*-associated ovarian cancers is 60 years.⁴⁰ Other histologies may also occur, including endometrioid and clear cell tumors, although mucinous ovarian cancer appears to be underrepresented in these genetic syndromes. Furthermore, *BRCA*-associated cancers may have a more favorable course than sporadic ovarian cancer. In a study by Rubin et al.,³⁹ the median survival of 43 patients with advanced *BRCA1*-associated disease was 77 months, compared with 29 months for matched controls. Cass et al.⁴¹ noted a similar survival advantage for carriers in their matched cohort study and suggested that this was a result of having an improved response to platinum-based chemotherapy compared to women with sporadic disease. This increased chemosensitivity may be partly due to the inability of tumor cells to repair platinum-induced DNA damage in the setting of a *BRCA1* or *BRCA2* mutation.³⁶ The more favorable survival of patients with *BRCA1* or *BRCA2* mutations when compared to their sporadic counterparts is not necessarily related to a higher rate of cure, but may also be related to a longer duration of responsiveness to chemotherapy agents used in the relapsed setting. The Gynecologic Oncology Group (GOG) is conducting a prospective study to better compare the clinical course of sporadic ovarian cancer with that associated with *BRCA1* and *BRCA2* mutations.

The hereditary nonpolyposis colorectal cancer (HNPCC) syndrome accounts for approximately 5% to 10% of all hereditary ovarian cancer cases.¹⁷ It is an autosomal dominant genetic syndrome characterized by nonpolyposis colon cancer, often involving the right colon, as well as an increased risk of developing endometrial, ovarian, hepatobiliary, upper gastrointestinal, and genitourinary cancers.⁴² Colorectal and uterine cancers comprise the majority of tumors developing in affected families. The risk of endometrial cancer among women in HNPCC syndrome families is estimated to be 40% to 60% by age 70, compared to 1.5% in the general population. Limited studies have reported a 3.5-fold increase in the risk of ovarian cancer in members of these families.⁴² A germline mutation in one of five genes involved in DNA mismatch repair is responsible for the HNPCC phenotype: *hMSH2* (chromosome arm 2p), *hMLH1* (chromosome arm 3p), *hPMS1* (chromosome arm 2q), *hPMS2* (chromosome arm 7p), and *hMSH6* (chromosome arm 2p).³⁶ The majority of affected patients are found to have defects in either *hMSH2* or *hMLH1*. Patients with HNPCC due to germline mutation of *hMSH6* may be particularly predisposed to uterine cancer. In addition, HNPCC may account for approximately 7% of cases with synchronous uterine and ovarian cancers, which are often (but not always) low grade and of endometrioid histology.¹⁷ The estimated cumulative risks for ovarian cancer by age 70 years can be as high as 24% for those with germline mutations in *MLH1* and *MSH2*.⁴³

Patients at high risk of having a hereditary cancer typically undergo genetic counseling, so that the ramifications of genetic testing can be discussed. Multidisciplinary services available in such a setting often include pretest and posttest counseling, screening, treatment, and psychosocial counseling.⁴⁴ The most direct approach to determine whether a cancer-associated mutation is present is to test the patient affected with the disease (the proband), because he or she is the most likely to carry a deleterious mutation.

The first family member to be tested will often require comprehensive gene sequencing. Other individuals can then be tested for the identified mutation, which may be unique to this particular family. In the Ashkenazic Jewish population, genetic testing for the three founder mutations is required because the carrier frequency in this population is high, and individuals may occasionally harbor germline mutations in both *BRCA1* and *BRCA2*.

Test results may reveal an identifiable mutation, no identifiable mutation, or a polymorphism of indeterminate clinical significance. If the proband has tested positive for a recognized mutation, then a relative with a negative result has likely not inherited the deleterious mutation, and her cancer risk approximates that of the general population. However, if no identifiable mutation is found in the proband, it is still possible that a cancer-associated mutation exists that is not detectable with current testing methods. This is especially the case for probands with a highly suggestive family history of breast, ovarian, or both cancers. In this regard, it has been shown that approximately 12% of probands who test negative for a germline mutation using standard gene sequencing techniques are found to have a clinically significant mutation in *BRCA1* or *BRCA2* when tested by the technique of multiplex ligation dependent probe amplification.⁴⁵ Finally, a minority of test results represent genetic variants or polymorphisms in *BRCA1* or *BRCA2* that are of indeterminate clinical significance. Further study of these genetic variants and associated cancer risks in large populations will help reduce the number of reports of indeterminate findings.

The management of patients with an inherited genetic predisposition to ovarian cancer is complex due to the variable penetrance of genetic alterations and the lack of effective early detection methods for ovarian cancer. Although annual pelvic examinations, serum CA 125 determinations, and TVU are sometimes considered in affected individuals, there is currently no conclusive evidence that ovarian cancer mortality is reduced as a result of these interventions.²⁷ In contrast, the efficacy of prophylactic, risk reduction bilateral salpingo-oophorectomy (RRSO) for patients with the hereditary breast-ovarian cancer syndrome has been more convincingly demonstrated.^{46,47} One study of 259 patients who underwent RRSO found a 96% decrease in ovarian cancers and an approximately 50% reduction in subsequent breast cancer compared to age-matched controls.⁴⁶ More recent studies also confirm the benefit of RRSO in this patient population.⁴⁸ Even after RRSO, *BRCA* mutation carriers are still at small risk for developing PPSC, which is histologically and clinically similar to epithelial ovarian cancer. Such cancers represent malignant transformation of the peritoneal mesothelium, which is contiguous with ovarian surface epithelium.

RRSO is generally considered for patients at high risk for developing ovarian cancer and who have completed childbearing, especially if they are at least 35 years of age.^{27,49} A laparoscopic approach is frequently possible, but the surgical options must be individualized, as must the decision for concomitant hysterectomy (which is an especially relevant consideration for patients with HNPCC undergoing this procedure). It is important to remove the fallopian tubes as part of prophylactic surgery, as the tubal epithelium may harbor dysplasia or may develop in situ cancers in this setting.⁵⁰ The surgical pathologist must perform a careful examination of the surgical specimens, as occult ovarian and tubal carcinoma have been found in 2% to 10% of RRSO specimens.⁵¹ Some patients with occult disease discovered after careful pathologic evaluation may require a second operation to complete surgical staging in order to determine the need for postoperative treatment, as described later in the chapter. Significant issues regarding RRSO remain unresolved, such as the physiologic adjustments to premature surgical menopause and the safety of hormone replacement therapy in this group, especially in those at high risk for breast cancer.⁵²

It has been suggested that chemoprophylaxis with oral contraceptives for 5 years might decrease ovarian cancer risk by 50% in

both the general population and in high-risk women. For example, a case-controlled study of 207 known *BRCA* mutation carriers and their sister controls found a 60% reduction of ovarian cancer risk with oral contraceptive use.⁵³ Other risk-reducing strategies such as tubal ligation and hysterectomy have also been associated with a reduced incidence of ovarian cancer among high-risk women.³ Nonetheless, RRSO is currently the most effective preventative strategy to reduce ovarian cancer risk in patients with *BRCA* mutations.

Staging

Exploratory laparotomy serves three main purposes in the management of patients with suspected ovarian cancer. First, laparotomy permits histologic confirmation of disease, as a complex cyst may not only represent primary ovarian cancer, but may also be caused by metastatic gastric cancer to the ovary (Krukenberg tumor), metastatic disease to the ovary from a gastrointestinal or breast primary (especially infiltrating lobular breast cancer), or benign conditions such as endometriosis.⁵⁴ Surgery is also necessary to determine the extent of disease (staging), which is critical in determining whether postoperative treatment will be necessary, as well as to assess prognosis. Finally, exploratory laparotomy is necessary to permit debulking of as much tumor as possible, as patients who are optimally cytoreduced (defined as having ≤ 1 -cm diameter residual tumor) have a better prognosis compared to those with greater amounts of residual disease.⁵⁵

The staging system for ovarian cancer was updated in 2014 by FIGO and is based on the findings at exploratory laparotomy (see Table 76.3).^{56,56a} Proper surgical staging via exploratory laparotomy requires a midline incision large enough to permit inspection of the peritoneal cavity, including the upper abdomen, as well as evaluation of the retroperitoneal spaces and lymph nodes.⁵⁷ When the peritoneal cavity is entered, ascitic fluid is aspirated and the peritoneal surfaces are irrigated, with the samples sent for cytologic evaluation. The pelvis and paracolic spaces should be irrigated and the fluid sent for cytologic examination. If intraperitoneal (IP) carcinomatosis is absent, it may be most appropriate to first resect the ovarian tumor and then to proceed with surgical staging to avoid rupturing the mass. The grossly normal, opposite ovary may undergo biopsy, or any visible benign-appearing cysts may be excised. Pelvic and para-aortic retroperitoneal lymph nodes are generally evaluated in patients whose tumors do not grossly extend outside the ovary, as approximately 10% to 15% of patients with otherwise stage I disease will have occult nodal involvement that places them in the stage III category.⁵⁷ Any enlarged pelvic retroperitoneal lymph nodes should be removed if technically feasible in order to achieve optimal cytoreduction.

It is frequently necessary to extend the vertical incision above the umbilicus in order to fully inspect the upper abdomen. If gross disease is not present in the omentum, an infracolic omentectomy is usually sufficient for diagnostic purposes. When the omentum demonstrates diffuse infiltration by tumor (an omental cake), it should be excised from the greater curvature of the stomach as completely as possible. The upper abdominal evaluation continues with a careful inspection of the right hemidiaphragm, liver serosa, and liver parenchyma. The spleen is then carefully inspected, as is the left diaphragm. A splenectomy could be considered if this procedure would lead to an optimal surgical cytoreduction. The paracolic spaces and large bowel are then carefully inspected. The small intestine and mesentery are evaluated, and any tumor implants are removed as much as possible. If luminal narrowing is present, especially in the area of the terminal ileum, a small bowel resection and reanastomosis are performed. Similarly, if tumor appears to invade the large bowel, a resection may be required if the mass is large enough to pose a threat for bowel obstruction. Lymphadenectomy is considered if this procedure is technically feasible and would lead to a maximally cytoreductive result. In

postmenopausal women or in women in whom fertility is no longer desired, a bilateral salpingo-oophorectomy and total abdominal hysterectomy are typically performed.

For women who wish to preserve fertility, which is sometimes possible when the tumor is limited to one ovary, staging may be performed without removal of the contralateral ovary and tube and without hysterectomy.⁵⁸ In that regard, patients with endometrioid ovarian cancer may have a synchronous endometrioid uterine cancer in up to 15% of cases, which may not always be appreciated preoperatively.¹⁷ In such cases, the tumor is often minimally invasive and low grade, and the prognosis is often favorable. Therefore, for patients with early stage, endometrioid ovarian cancer in whom a fertility sparing operation is considered, it is reasonable to perform an endometrial biopsy to exclude the presence of a separate uterine cancer that would alter the surgical approach.

On occasion, the initial surgical staging is incomplete due to lack of lymph node or upper abdominal evaluation in a patient with presumptive stage I disease. In this situation, it is reasonable to consider completing the surgical staging if the findings would alter postoperative management. For instance, if a patient has stage IA, grade 1 or 2 disease (see Table 76.3) after complete surgical staging, no further postoperative treatment would generally be indicated.⁵⁹ However, if a patient is already known to have at least stage IC or stage II disease, or if the tumor is grade 3, then postoperative chemotherapy is generally required, and the impact of additional staging procedures might be less important (except perhaps for the patient who is discovered to have stage III disease on re-exploration, in which case IP chemotherapy might play a role if she is optimally cytoreduced (as noted subsequently)). Laparoscopic or robotic surgical techniques may allow para-aortic lymph node dissections and omentectomies to be performed with less morbidity, which is an important consideration in a patient who might have undergone recent, albeit incomplete, surgical evaluation. If this is not possible or practical, an alternative is to obtain a CT scan in an attempt to identify the presence of any subclinical bulky disease that might be amenable to surgical resection. However, CT is not capable of detecting small volume or microscopic disease that could affect decisions regarding the need for postoperative chemotherapy.

Prognostic Factors for Epithelial Ovarian Cancer

Clinicopathologic findings of prognostic value include FIGO stage, volume of residual disease after cytoreductive surgery, histologic subtype, histologic grade, age, and malignant ascites.¹⁴ Tumor stage remains the most important prognostic factor, although only 30% of patients have early stage disease (defined as having stage I or stage II tumors). Stage IA disease is completely encapsulated, without involvement of the ovarian surface, without rupture, malignant ascites, or positive washings (see Table 76.3). The 5-year survival of patients with stage IA disease and grade 1 or 2 histology is $>90\%$ after surgery alone, and several investigators include patients with stage IB, grade 1 or 2 disease, in this good prognostic group.⁵⁹ However, the relapse rate without postoperative adjuvant treatment is 30% to 40% for patients with stage IC disease (defined by the presence of rupture, surface involvement, malignant ascites, or positive washings), those with stage I, grade 3 disease, or those with stage II tumors. These patients comprise a high-risk group of early stage tumors and experience a 5-year survival rate of approximately 80% after receiving postoperative adjuvant therapy.⁵⁹ It should be noted that the prognostic significance of rupture as the sole criterion for stage IC disease is somewhat controversial, as some investigators report that rupture alone does not appear to confer a worse prognosis if it occurred intraoperatively, as opposed to preoperatively.⁶⁰

The majority of patients with epithelial ovarian cancer present with advanced disease (stage III or IV). After postoperative

treatment, the 5-year survival rate of patients with stage III optimally debulked, gross residual disease (≤ 1 -cm diameter residual tumor) is approximately 20% to 30%, and this decreases to $<10\%$ for patients with suboptimally debulked stage III disease or those with stage IV tumors.^{61,62} Patients who have stage IIIA disease on the basis of microscopic upper abdominal involvement (usually detected on omental biopsy) have survivals in the range of 50% after postoperative adjuvant therapy.⁶³ Patients with advanced-stage disease who have mucinous or clear cell histologic also have a worse prognosis, which appears to be related to the relative chemoresistance of these histologies. In a GOG study, no patient with advanced clear cell or mucinous histology achieved a pathologic complete response after chemotherapy, as defined by performance of second-look laparotomy.¹⁴

Preoperative serum CA 125 levels frequently reflect the volume of disease and do not appear to have an independent effect on survival, after correcting for stage and debulking status. However, postoperative CA 125 levels, both during and after completion of first-line chemotherapy, have prognostic value.^{64,65} Some investigators have demonstrated that normalization of the serum CA 125 levels after three cycles of chemotherapy is associated with more favorable outcome, as well as achievement of a CA 125 nadir of ≤ 10 U/mL upon completion of treatment.^{64,65} Although this information has prognostic significance, it has limited therapeutic value in the absence of effective salvage regimens with curative potential.

Germline mutation in *BRCA1* or *BRCA2* genes is associated with an improved prognosis. A pooled analysis of 26 observational studies on the survival of women with ovarian cancer showed that having a germline mutation in *BRCA1* or *BRCA2* was associated with improved 5-year overall survival (for *BRCA1*: hazard ratio [HR] = 0.73; for *BRCA2*: HR = 0.49).⁶⁶ In addition, several other molecular prognostic factors have been investigated in ovarian cancer. These include markers of proliferation or drug resistance, levels of serum cytokines or growth factor receptors, and expression of genes associated with metastases.⁶⁷ More recently, it has been possible to use microarray analysis, which provides a global snapshot of gene expression, to assess prognosis and response to therapy in this disease. At least two profiles have been defined, referred to as the Ovarian Cancer Prognostic Profile and the Chemo Response Profile, that provide information of independent prognostic and predictive value for patients with advanced disease.^{68,69} However, it remains to be determined how best to incorporate such new techniques into the management of patients with this tumor. In the future, it is hoped that gene expression profiling will be capable of identifying patients who might benefit from novel forms of treatment (such as antiangiogenic therapy) or those with poor prognosis who might be appropriate for clinical trial participation.

Management of Early Stage Disease

Postoperative Chemotherapy

The results of two randomized European trials (International Collaborative Ovarian Neoplasm Trial [ICON] 1 and Adjuvant ChemoTherapy in Ovarian Neoplasm Trial) suggest that adjuvant chemotherapy can improve both progression-free survival (PFS) and overall survival in patients with high-risk, early stage ovarian cancer.⁷⁰ Such patients include those with stage I, grade 3, stage IC, or any stage II disease. These two studies collectively enrolled 925 patients, although they differed in eligibility criteria, requirements for surgical staging, and the specific adjuvant chemotherapy program used. Overall survival was superior for platinum-based adjuvant therapy in the entire patient cohort, although subset analysis revealed that the benefit appeared to be restricted to those patients who did not undergo adequate surgical staging. This observation suggested that the observed survival benefit might be due to unintentional enrollment of a subset of patients who actually had occult stage III disease. Nonetheless, caution must be used

when interpreting the results of an unplanned subset analysis, and most physicians feel that these data support the use of adjuvant chemotherapy for patients with high-risk, early stage disease.⁷¹

A study performed by the GOG compared three cycles of carboplatin and paclitaxel to six cycles of this regimen in patients with high-risk, early stage ovarian cancer in order to determine whether a shorter duration of treatment is equally effective and less toxic.⁷² The relapse rate and PFS were not statistically different between these two treatment arms, which led some investigators to conclude that administering three cycles of adjuvant chemotherapy was as effective as six cycles in this setting. However, a recent subset analysis of this trial involving patients with serous histology showed that the 5-year recurrence-free survival for patients who received six cycles was 83%, compared with 60% for those who received three cycles ($p = 0.007$).⁷³ In addition, this study was not sufficiently powered to determine whether three cycles was equivalent to six cycles in terms of an overall survival benefit. In view of these issues, administration of six cycles of adjuvant carboplatin plus paclitaxel chemotherapy can still be considered a reasonable approach for high-risk, early stage patients, unless more definitive data supporting lesser amounts of chemotherapy become available.⁷⁴ The rationale for choosing carboplatin and paclitaxel is based on the experience gained from management of advanced disease, which will be described in detail later in the chapter.

Postoperative Radiation Therapy

The role of radiation therapy in the treatment of patients with primary ovarian cancer has changed markedly over time. For several decades, it was used as the sole modality of treatment. As experience with chemotherapy grew, randomized trials were conducted to compare different chemotherapy regimens to whole abdominal radiotherapy (WAR) or to IP administration of radioactive phosphorus (³²P). Most are now of only historical interest, as the chemotherapy regimens used did not contain platinum compounds, and they will not be reviewed here. In general, these studies showed that WAR and ³²P had similar efficacy compared to prolonged courses of melphalan or chlorambucil, given with or without pelvic irradiation.

The first trial to compare radiation therapy to a platinum-based regimen was conducted from 1981 to 1987 in Birmingham, England. This trial randomized 40 patients with stages IC to III ovarian cancer with no macroscopic residual disease following surgery to either WAR using a moving-strip technique or to cisplatin (100 mg/m², given every 3 weeks for five cycles). With a median follow-up of 84 months, the 5-year survival rates in the two groups were 58% and 62%, respectively.⁷⁵

A trial conducted in Genoa, Italy, from 1985 to 1989 included 70 patients with high-risk stage I or II ovarian carcinoma.⁷⁶ They received either WAR using an open-field technique (24 fractions delivering 43.2 Gy to the pelvis and 30.2 Gy to the upper abdomen) or cisplatin (50 mg/m²) plus cyclophosphamide (600 mg/m²), given every 4 weeks for six cycles. Eight patients randomized to WAR received chemotherapy because of their own or their physicians' preference. Because protocol compliance was poor and accrual low, the study was prematurely closed. At a median follow-up of 60 months, the 5-year overall survival rates in the radiation and chemotherapy arms were 53% and 71%, respectively ($p = 0.16$); relapse-free survival rates were 50% and 74%, respectively ($p = 0.07$). Of note, late bowel obstruction requiring surgery occurred in only one patient.

From 1982 to 1988, 340 eligible patients with stages I through III ovarian carcinoma without residual disease after surgery seen at the Norwegian Radium Hospital in Oslo were randomized to receive either IP radioactive chromic phosphate (7 to 10 mCi, or 260 to 370 MBq) or six cycles of intravenous (IV) cisplatin (50 mg/m²) given every 3 weeks.⁷⁷ Twenty-eight patients with peritoneal adhesions who were randomized to IP ³²P were treated instead with WAR. The 5-year overall survival rates in the two arms were 83% and 81%, respectively; disease-free survival rates were 81% and

75%, respectively. Patients with stage II or III tumors had superior survival when treated with cisplatin, although the difference was not statistically significant. The long-term risk of bowel obstruction without recurrence in radiation and chemotherapy arms was 11% and 2%, respectively.

Finally, a trial conducted between 1986 and 1994 by the GOG randomly allocated 229 eligible patients with stage IA-B grade 3 or stage II tumors without macroscopic residual disease after surgery to either IP ^{32}P (15 mCi) or three cycles every 3 weeks of cyclophosphamide (1,000 mg/m²) and cisplatin (100 mg/m²).⁷⁸ With a median follow-up of nearly 10 years in survivors, the 10-year relapse rates in the radiation and chemotherapy arms were 35% and 28%, respectively, which was not statistically significant. There was a relative reduction of 17% in the overall death rate in the chemotherapy arm, which was not statistically significant. The incidence of nonhematologic grade 3 or 4 toxicities was similar in both arms.

One question not addressed in these trials is whether patients with certain subtypes of ovarian cancer might have better outcome if treated with WAR instead of chemotherapy. A retrospective study of patients with predominantly early-stage clear cell carcinomas treated in Okinawa from 1996 to 2004 found superior 5-year overall survival (82%) and disease-free survival (82%) compared to patients treated with platinum-based chemotherapy (rates of 33% and 25%, respectively), although interpretation is difficult to small patient numbers and the possibility of selection bias.⁷⁹

In summary, these randomized trials generally found WAR or IP ^{32}P was less effective or more toxic than platinum-containing regimens. Hence, adjuvant radiation therapy has fallen out of use as the primary treatment for patients with high-risk, early stage ovarian cancer.

Management of Advanced-Stage Disease

Debulking Surgery

The theoretical benefits of debulking surgery include removal of large, necrotic tumors with poor blood supply that might lead to impaired chemotherapy delivery. It has also been postulated that tumor debulking may permit residual tumor to proliferate more rapidly and thereby enhance sensitivity to postoperative chemotherapy. Although neither of these mechanisms has been proven, the association between successful surgical cytoreduction and more favorable outcome has been demonstrated in many surgical series.^{14,55,63}

The definition of *optimal cytoreduction* achieved through debulking surgery has varied through the years, but residual disease of ≤ 1 cm in maximum individual tumor diameter is most widely accepted. Recently, however, there has been a trend toward redefining *optimal cytoreduction* to refer more specifically to those patients who have no gross residual disease, reflecting complete cytoreduction to microscopic residual status.⁸⁰

Primary debulking surgery refers to performance of surgery prior to administration of first-line chemotherapy and is the standard approach for managing most patients with suspected epithelial ovarian cancer. Despite the importance of primary debulking surgery, some patients with advanced disease are not ideal surgical candidates due to a poor performance status, or extensive amounts of bulky intra-abdominal disease as assessed by radiographic studies, and therefore may not be appropriate candidates for this procedure. In these cases, initiating neoadjuvant chemotherapy is a reasonable approach, followed by an interval attempt at surgical cytoreduction in responding patients after three cycles of chemotherapy have been administered. In this instance, surgery is referred to as *interval debulking surgery*.^{81,82} Theoretical advantages of neoadjuvant chemotherapy in this setting are a more rapid improvement in quality of life, and, if interval debulking surgery is ultimately performed, a technically more feasible operation with shorter hospitalization and less morbidity. Prospective randomized trials incorporating neoadjuvant chemotherapy in the management of advanced-

stage ovarian cancer are under way to better define the value of this strategy. The first of these to be reported was conducted by the European Organisation for Research and Treatment of Cancer (EORTC)-National Cancer Institute of Canada (NCIC), involving 632 patients who were randomized to receive either primary debulking surgery followed by six cycles of platinum-based chemotherapy, or neoadjuvant chemotherapy for three cycles, followed by interval debulking surgery in responding or stable patients, followed by an additional three cycles of chemotherapy.⁸³ Eligibility for this study included stage IIIC and IV disease, performance status ≤ 2 , and no disease in the upper abdomen measuring < 2 cm in greatest diameter as assessed by CT or laparoscopy. Patients with retroperitoneal lymph node involvement as their only site of stage III disease were not included.⁸⁴ In addition, confirmation of the clinical impression of ovarian cancer was required prior to instituting neoadjuvant therapy, using either core biopsy or fine needle aspiration, with supportive serology including a CA 125:CEA ratio of ≥ 25 . For patients whose CA 125:CEA ratio was < 25 , appropriate studies were performed to exclude the possibility of a breast or gastrointestinal primary. The results of this trial show that the overall survival was equivalent between the two treatment approaches, despite the fact that the rate of optimal cytoreduction was higher in patients undergoing neoadjuvant chemotherapy. There was a trend toward less postoperative morbidity in those who received neoadjuvant therapy, although this did not reach statistical significance. However, for the subset of patients whose disease was < 5 cm in greatest diameter at study entry, their overall survival was improved with primary cytoreduction compared to neoadjuvant therapy.⁸⁴ Based upon the results of this study, the approach of neoadjuvant therapy and interval debulking surgery is a reasonable option for patients with bulky upper abdominal peritoneal disease > 5 cm in diameter, or those with medical comorbidities that preclude safe performance of primary surgical cytoreduction. Preliminary results from a second randomized trial of neoadjuvant chemotherapy and interval debulking surgery being performed in the United Kingdom are supportive of this approach, and we await the results of a third confirmatory trial being performed by the Japanese Clinical Oncology Group.⁸⁵ Despite the value of neoadjuvant chemotherapy and interval debulking surgery in appropriately selected patients, primary cytoreduction should still be the preferred initial option for patients with stage IIIC and IV disease with good performance status who have < 5 cm upper abdominal disease, who have retroperitoneal only disease preoperatively, or who might otherwise be considered ideal candidates for IP therapy if optimally cytoreduced (see the following).

Postoperative Chemotherapy for Epithelial Ovarian Cancer

Advanced-stage epithelial ovarian cancer is a chemoresponsive disease in the majority of cases, although relapse often occurs and resistance eventually develops to most forms of treatment. The platinum compounds remain the single most active drugs in the treatment of this disease. Cisplatin was the most frequently used platinum compound in the late 1970s and early 1980s, although it was soon recognized that the use of carboplatin instead of cisplatin conferred an equivalent survival advantage, but with less neuropathy, nephropathy, and emesis.⁸⁶

Although numerous combination chemotherapy regimens have been studied over the past three decades, the combination of an IV platinum compound and a taxane such as paclitaxel is now accepted as an appropriate first-line, postoperative option for many patients. The response rate of this combination is as high as 70% for patients with suboptimally debulked disease, and over 80% for patients who are optimally cytoreduced.^{61,62} Platinum agents exert their effects by forming intrastrand DNA adducts with guanosine bases, whereas taxanes mediate cytotoxicity by binding to and stabilizing the tubulin polymer, thereby preventing physiologic dissociation of the mitotic spindle at the completion of M phase. Given

these nonoverlapping mechanisms of action, it was not surprising to find that taxanes were active agents in the treatment of some patients with relapsed, platinum-resistant ovarian cancer.⁸⁷ These observations formed the basis for investigating the platinum and taxane combination in the first-line setting.

Two phase 3 randomized trials begun in the early 1990s compared a cisplatin and paclitaxel combination to a cisplatin and cyclophosphamide regimen (Table 76.4). In the GOG study, patients with suboptimally resected stage III or IV ovarian cancer were randomized to receive six cycles of either cisplatin and cyclophosphamide or the experimental arm of cisplatin and paclitaxel.⁶² Women treated with the paclitaxel-containing program experienced a statistically significant improvement in response rate (73% versus 60%; $p < 0.01$), median PFS (18 months versus 13 months; $p < 0.001$), and median overall survival (38 months versus 24 months; $p < 0.001$).

These results were confirmed in a trial conducted in Europe and Canada that used a similar but not identical study design.⁸⁸ In this trial, paclitaxel was delivered as a 3-hour infusion of 175 mg/m², whereas in the GOG study a dose of 135 mg/m² was administered over 24 hours. In addition, a much larger percentage

of patients in the control arm of the European-Canadian study received paclitaxel as second-line therapy after relapse, compared to the control arm of the GOG trial. Despite these differences, this study also revealed a statistically significant improvement in both PFS and overall survival associated with the paclitaxel-containing regimen (see Table 76.4).

Neither the GOG nor the European-Canadian trials was able to address whether the survival benefit observed with the platinum-taxane doublet was related to the use of combination chemotherapy or whether it could also be achieved through the use of sequential monotherapy. In an attempt to address this issue, the GOG conducted a randomized trial in which patients with suboptimally debulked advanced disease received either single-agent cisplatin (100 mg/m²), single-agent paclitaxel (200 mg/m² administered over 24 hours), or the combination of cisplatin (75 mg/m²) and paclitaxel (135 mg/m² administered over 24 hours).⁸⁹ Survival was similar between the three study arms, despite a superior objective response rate to both platinum-containing regimens (67%), compared to single-agent paclitaxel (42%). This result is likely explained by the fact that approximately 50% of patients in the single-agent arms were switched to the alternative agent before

TABLE 76.4

Randomized Trials of Paclitaxel Versus Nonpaclitaxel First-Line Therapy in Advanced Epithelial Ovarian Cancer

^a For ICON-3, patients in the control arms could receive either carboplatin alone, or cisplatin, doxorubicin, and cyclophosphamide.

^b There was no significant difference in OS between any of the three treatment arms of GOG-132 ($p = 0.31$).

documented disease progression. These results support the concept that sequential treatment with a platinum agent, followed by paclitaxel, may be therapeutically equivalent to combination therapy with both agents in advanced ovarian cancer. However, as crossover to the alternative agent was not a formal part of this study's design, this interpretation should be viewed with caution, and combination first-line chemotherapy with a taxane and platinum compound remains the standard of care.

A third European randomized trial (ICON-3) compared a nonpaclitaxel, platinum-based control regimen (either single-agent carboplatin or the combination of cisplatin, doxorubicin, and cyclophosphamide) to an experimental arm of carboplatin and paclitaxel.⁹⁰ Surprisingly, this study failed to reveal a difference in survival between either control arm and the paclitaxel-containing experimental arm. Perhaps the most likely explanation for this observation is that one-third of the patients in the control arms of ICON-3 ultimately received paclitaxel at some point in their disease course.⁹¹ Thus, as in the previously mentioned three-arm GOG study,⁸⁹ this outcome provides circumstantial evidence to suggest that the sequential administration of these two active agents may be therapeutically equivalent to combination drug delivery in this setting.

Three randomized trials have directly compared a carboplatin and paclitaxel combination to cisplatin and paclitaxel (Table 76.5).^{61,92,93} These studies found equivalent PFS and overall survivals for either carboplatin- or cisplatin-containing regimens, but with a more favorable toxicity profile associated with carboplatin-based treatment. Thus, the carboplatin-based combination (carboplatin, area under the curve [AUC] = 5 to 6, and paclitaxel, 175 mg/m², administered over 3 hours) is preferred when systemic

chemotherapy is indicated, due to reduced toxicity and the ability to give paclitaxel over a shorter infusion time. For individuals who may have difficulty tolerating a combination regimen (e.g., those with marginal performance status or significant comorbid medical conditions), it is reasonable to initiate treatment with IV single-agent carboplatin and later add IV paclitaxel to the regimen or deliver the drugs as sequential single agents. For appropriate patients with stage III disease who are optimally cytoreduced, IP chemotherapy is an important new option, which will be described in detail subsequently.

The optimal choice of taxane has also been investigated in the first-line setting. A randomized trial comparing IV carboplatin (AUC = 5) plus paclitaxel (175 mg/m²) to IV carboplatin (AUC = 5) and docetaxel (75 mg/m²) has shown equivalent response rates and PFS and overall survival for the two programs, although their toxicity profiles differed.⁹⁴ More grade 4 neutropenia occurred with the docetaxel-containing regimen, and a greater incidence of grade 2 or 3 neuropathy was observed with the paclitaxel-containing program. These data indicate that a carboplatin and docetaxel combination is an acceptable first-line regimen for patients with advanced ovarian cancer, especially in the setting of preexisting neuropathy (where paclitaxel may be difficult to tolerate).

There appears to be no value in extending platinum-based first-line therapy beyond six cycles.^{95,96} Furthermore, there is no convincing evidence to suggest a benefit to the addition of cytotoxic drugs such as liposomal doxorubicin, epirubicin, topotecan, or gemcitabine to the platinum and taxane doublet.⁹⁷ A recent randomized trial performed by the Japanese GOG demonstrated a PFS and overall survival advantage for the use of weekly paclitaxel (in conjunction with day 1 carboplatin) in newly diagnosed

patients with ovarian cancer, and confirmatory trials are under way.⁹⁸ Given the activity of bevacizumab in relapsed disease, there is interest in investigating the value of this agent in the first line and maintenance setting (see the following).

Intraperitoneal Chemotherapy

Epithelial ovarian cancer is largely confined to the peritoneal space during most of its natural history.² Given this relatively localized distribution, efforts to instill chemotherapy directly into the peritoneal cavity have received a great deal of attention over the past two decades. The rationale for this approach is based on the observation that many active drugs such as cisplatin and paclitaxel have favorable peritoneal-to-plasma concentrations, on the order of 20 to 1 and 1,000 to 1, respectively.⁹⁹ The ability to deliver high local concentrations of active drugs, with generally acceptable systemic side effects, suggested that it may be possible to achieve more effective cytoreduction of disease that is present at the peritoneal surface. Given the rather limited penetration of such drugs into peritoneal tumor, to a depth of only a few millimeters, patients with optimally cytoreduced disease are theoretically most likely to benefit from this approach.

Three randomized trials have addressed the role of IP chemotherapy in the first-line management of patients with optimally debulked stage III disease (Table 76.6). Two of these trials showed a statistically significant improvement in both PFS and overall survival rates for patients treated with IP chemotherapy, and the other demonstrated improvement in PFS only (although a nonsignificant trend for improved overall survival in the IP arm was noted). The first of these was an intergroup trial performed in 546 optimally debulked stage III patients with ≤ 2 -cm residual disease (GOG 104).¹⁰⁰ Note that this definition of “optimally

debulked” was widely accepted at the time, although subsequently a 1-cm cutoff has been adopted. Patients were randomized to receive either IP cisplatin or IV cisplatin, in combination with IV cyclophosphamide, every 3 weeks for six cycles (note that paclitaxel was not an approved drug at the time of this study’s design). The median survival of all eligible patients was 49 months for the IP cisplatin arm compared to 41 months for the IV cisplatin group ($p = 0.02$; HR = 0.76). There was also a trend toward a higher likelihood of pathologic complete remission in the IP arm compared to IV treatment (47% versus 36%, respectively). However, the positive results of this study were overshadowed by the emerging value of the IV paclitaxel and platinum combination in the first-line setting,⁶² and the added benefit of the IP route remained uncertain. Specifically, it was argued that perhaps the use of IV paclitaxel might negate the benefit of IP therapy, and this issue led to a second randomized IP trial that included paclitaxel.

The second study performed by the GOG (GOG 114) involved optimally debulked patients with stage III disease (≤ 1 -cm diameter residual) who were randomized to receive either IV paclitaxel (135 mg/m² over 24 hours) and IV cisplatin (75 mg/m²) for six cycles, or IV carboplatin (AUC = 9) for two cycles followed by IV paclitaxel (135 mg/m² administered over 24 hours) and IP cisplatin (100 mg/m²) for six cycles.¹⁰¹ The median PFSs for the IP and IV arms were 28 months and 22 months, respectively ($p = 0.01$; one-sided t test). However, there was only a borderline significant trend in overall survival in favor of the IP treatment arm (63.2 months versus 52.5 months, respectively; $p = 0.05$, one-sided t test), but with substantial toxicity partly due to the use of high-dose, single-agent carboplatin in the experimental arm. The significant toxicity of this regimen, coupled with only a borderline significant survival difference, did not provide convincing enough evidence to adopt this regimen for widespread use.

TABLE 76.6

Selected Randomized Trials of Intraperitoneal First-Line Therapy in Optimally Debulked Stage III Ovarian Cancer

^a Six cycles of chemotherapy were administered in each trial unless otherwise stated.

^b Optimal cytoreduction in GOG-104/SWOG-8501 was defined as ≤ 2 -cm diameter residual disease, whereas a 1-cm cutoff was used for GOG-114 and GOG-172.

^c P value determined using a one-sided t test.

The third GOG study (GOG 172) eliminated the use of high-dose carboplatin and introduced a second dose of paclitaxel, administered via the IP route, on day 8.¹⁰² Patients with optimally debulked disease (≤ 1 -cm diameter residual) were randomized to receive either a control arm of IV paclitaxel (135 mg/m² administered over 24 hours) and IV cisplatin (75 mg/m²) for six cycles, or IV paclitaxel on day 1 (135 mg/m² administered over 24 hours), IP cisplatin on day 2 (100 mg/m²), and IP paclitaxel on day 8 (60 mg/m²) for six cycles. The median overall survival was 65.6 months for the IP arm and 49.7 months for the IV arm (HR = 0.75; 95% confidence interval, 0.58 to 0.97; $p = 0.03$). This significant prolongation of median overall survival was associated with several toxicities, including a higher incidence of neutropenia, infection, catheter blockage, neuropathy, abdominal pain, renal dysfunction, and electrolyte abnormalities. Due to this toxicity, only 42% of patients were able to complete all six cycles of planned IP chemotherapy, and approximately 40% could only receive two or fewer cycles. Thus, while 83% of patients assigned to the IP arm eventually completed six cycles of a taxane and platinum combination, the majority required a switch from IP to IV drug administration at some point during the planned IP treatment course. Patients who required bowel resection during their initial surgical debulking procedure appeared to have a higher incidence of postoperative complications that prevented subsequent use of IP therapy.¹⁰³ The fact that a survival advantage was observed despite failure of most patients to complete six cycles of IP treatment suggested that the benefits of IP treatment may occur early in the treatment course, although this issue was not formally addressed in this trial.¹⁰⁴ Due to concerns over toxicity with the regimen originally described in GOG 172 (see Table 76.6), many have used a modified version of this regimen, characterized by IV paclitaxel on day 1 (135 mg/m² administered over 3 hours), IP cisplatin on day 2 (75 mg/m²), and IP paclitaxel on day 8 (60 mg/m²) for six cycles. This dose reduced regimen is currently being evaluated in GOG 252, which randomizes patients to receive either dose-dense IV chemotherapy, carboplatin-based IP therapy, or the dose-modified GOG 172 regimen mentioned previously.

In addition to the three randomized trials described earlier, four other trials have addressed the value of IP chemotherapy in the first-line setting, and one additional trial has examined the role of IP cisplatin as consolidation therapy after achievement of a complete remission.¹⁰⁵ A meta-analysis of these eight trials showed that IP chemotherapy was associated with a 21.6% reduction in risk of death (HR = 0.79; 95% confidence interval, 0.7 to 0.89).¹⁰⁵ Although some investigators still feel that IP chemotherapy should remain experimental, others feel that these data offer strong support for the IP approach.^{104,106–108} At present, IP therapy has not been shown to be superior to IV treatment in patients with stage IV disease, suboptimally debulked residual disease, or relapsed disease. It should also be avoided in patients with comorbid conditions such as renal insufficiency, significant baseline neuropathy, or extensive intra-abdominal adhesions.

A number of potential ways to improve the tolerability of IP therapy could be considered, including reduction of the day 2 IP cisplatin dose, administration of day 1 IV paclitaxel over 3 hours instead of 24 hours, or omitting day 8 IP paclitaxel until patient tolerance to the first cycle of IP cisplatin can be assessed. It is unknown whether such modifications will reduce toxicity while still preserving the benefits of the IP approach.¹⁰⁴ There is also interest in the use of IP carboplatin instead of IP cisplatin in an attempt to reduce toxicity.¹⁰⁹ Although the pharmacologic advantage of IP carboplatin appears to be favorable, it is not yet known whether carboplatin is as effective as cisplatin when administered via the IP route.

Technical Aspects of Intraperitoneal Chemotherapy Administration

IP administration of either cisplatin or paclitaxel requires placement of a catheter with a subcutaneous access port in the anterior chest wall region, just below the breast, which then tunnels subcutaneously downward to the midabdomen, where it enters the

peritoneal cavity.¹¹⁰ IP catheter insertion can be performed at the time of primary cytoreductive surgery or afterward by laparoscopy. Makhija et al.¹¹¹ reported a reduction in complication rate from 17.6% to 10% by delaying IP catheter insertion in patients undergoing intestinal resection at the time of primary cytoreduction. Walker et al.¹⁰³ found that rectosigmoid or descending colon resection, but not other types of bowel resections or colostomy, at the time of primary surgery was associated with a higher risk of failing to start IP chemotherapy. Based on the available data, colon resection with fecal contamination or left colon resection would appear to represent relative contraindications to placement of an IP catheter at the time of primary cytoreduction.

In the past, the Tenckhoff catheter was a very popular device for administering IP chemotherapy. However, this catheter was associated with adhesion formation within the peritoneal catheter related to the development of a fibrous sheath surrounding the catheter fenestrations and intestinal obstruction due to the Dacron sheath migrating into the peritoneal cavity. Using a single-lumen silicone catheter with an implantable port designed for IV injection may be preferable, as this device appears to cause fewer such complications (Fig. 76.4A).¹¹² Catheter insertion typically involves the following steps:

1. A separate 5 to 6 cm transverse incision is made two to three fingerbreadths above the left inferior costal margin in the mid-clavicular line and is carried down to the fascia.
2. A subcutaneous pocket is created to house the implantable port (Fig. 76.4B).
3. The port is sutured to the fascia at the four corners using 2-0 polypropylene or nylon suture.
4. A tonsil clamp or similar instrument is tunneled subcutaneously above the fascia for approximately 10 cm from the port. At a point about 6 cm lateral to the umbilicus, a small aperture is made in the peritoneum.
5. The proximal end of the catheter is grasped with the clamp and brought through from the peritoneal cavity, through the subcutaneous tunnel, to the port.
6. The catheter is connected to the port, and it is trimmed to allow approximately 10 cm of catheter within the peritoneal cavity (Fig. 76.4C).
7. The catheter is flushed with heparinized saline to check patency.
8. The transverse skin incision is closed.

IP instillation of an agent such as cisplatin or paclitaxel is typically performed by mixing the drug in a volume of 1 L, prewarmed so as to minimize discomfort during the infusion, and allowed to infuse under gravity drip over 1 to 2 hours.¹¹⁰ If the infusion rate is slow, repositioning the patient may be beneficial in an attempt to move the catheter tip away from bowel loops or a pocket caused by adhesions. However, there is no role for applying pressure to the infusion bag, and failure of the solution to infuse over a reasonable period of time may indicate the presence of adhesions that preclude further administration of the IP agent. Once the first liter of fluid has been infused IP, a second prewarmed liter of fluid, which does not contain drug, is then infused IP to further promote homogeneous drug distribution. If the patient becomes uncomfortable due to abdominal distention while receiving the second liter of IP fluid, the infusion may be discontinued. The strategy of mixing the drug with the first liter of IP fluid, followed by a second liter of IP fluid without drug, increases the chance that the patient will receive the intended dose of chemotherapy. Standard premedications for cisplatin and paclitaxel are administered, as well as aggressive attention to IV hydration before and after IP cisplatin administration to prevent nephropathy. Careful monitoring of serum potassium and magnesium levels is required in view of the potential for electrolyte wasting with IP cisplatin.

Interval Debulking Surgery

Interval debulking surgery is defined as a cytoreductive procedure performed after several cycles of chemotherapy have been administered and is typically considered in two clinical circumstances.

Figure 76.4 Peritoneal catheter for administration of intraperitoneal chemotherapy. **(A)** Catheter port, which is placed subcutaneously in the midclavicular line under the breast. **(B)** Appearance of the subcutaneous pocket containing the catheter port, prior to skin closure. **(C)** Laparoscopic appearance of the catheter within the peritoneal cavity. (Courtesy of Dr. Douglas Levine, Memorial Sloan Kettering Cancer Center, New York, NY, and Dr. Christopher Awtrey, Beth Israel Deaconess Medical Center, Boston, MA.)

The first has already been mentioned, namely a patient who is not appropriate for primary debulking surgery due to poor performance status or bulky intra-abdominal disease that is not likely to achieve an optimal result if primary debulking surgery is attempted. As discussed, a reasonable approach to consider in this situation is to perform a biopsy to confirm the clinical impression of ovarian cancer, followed by administration of three cycles of neoadjuvant chemotherapy as a prelude to performing interval debulking surgery (in responding patients).⁸⁴ The second situation in which interval debulking surgery is considered involves patients who underwent primary debulking surgery, but nevertheless were suboptimally cytoreduced. There are data to support administering three cycles of postoperative chemotherapy in this setting, followed by interval debulking surgery in responding patients, followed by three additional cycles of chemotherapy. The EORTC investigated this strategy in a randomized trial involving 319 patients with suboptimally debulked stage III or IV disease (defined as >1-cm diameter) after primary debulking surgery.⁸¹ All patients subsequently received three cycles of cyclophosphamide and cisplatin, and patients with responsive or stable disease were then randomized to either interval surgery or continued chemotherapy without interval debulking surgery. After interval surgery, patients received an additional three cycles of chemotherapy, so that all patients received a total of six chemotherapy cycles, regardless of treatment arm. A total of 278 patients were eligible for randomization (140 in the interval surgery group and 138 in the control arm). Patients in the interval cytoreduction group experienced a 6-month improvement in median overall survival ($p = 0.01$), suggesting a role for this strategy in patients who achieved a suboptimal result after primary debulking surgery.

In contrast, a similar study performed by the GOG failed to show an advantage for the use of interval debulking surgery in the setting of a suboptimal primary debulking attempt.¹¹⁵ A total of 550 eligible patients with residual disease >1 cm in diameter after

initial surgery (performed by a gynecologic oncologist familiar with debulking techniques) were reassessed after three cycles of paclitaxel and cisplatin. Those with stable or responding disease were randomized to either interval debulking surgery followed by three additional cycles of chemotherapy or to three additional cycles of chemotherapy (without interval surgery). This study found no difference in either median PFS (11 months) or median overall survival (32 months) between the two groups.

It is possible that the negative results of the GOG study are partly due to a more rigorous definition of suboptimally debulked disease compared to the EORTC trial, related to performance of initial surgery by a gynecologic oncologist, rather than a general surgeon or gynecologist. In addition, the use of the more effective paclitaxel and cisplatin regimen in the GOG trial (compared to cyclophosphamide and cisplatin in the EORTC trial) may have negated any added value of interval debulking surgery in this setting. Thus, patients who are deemed to be suboptimally cytoreduced after primary debulking surgery performed by a surgeon skilled in this procedure, who then receive first-line paclitaxel- and platinum-based chemotherapy, may not benefit from interval debulking surgery. For those patients who did not undergo a technically adequate attempt at initial cytoreduction (due to lack of surgical expertise in debulking techniques, for example), the EORTC study suggests that an attempt at interval debulking surgery is reasonable if disease control can be achieved during the first three cycles of chemotherapy.

Radiotherapy After First-Line Chemotherapy

Several randomized trials have examined whether radiation therapy administered after chemotherapy is beneficial. A trial performed in Graz, Austria, from 1985 to 1992 randomized 64 patients (54 of whom had stage III disease) who were clinically disease-free (assessed by examination, CT, and CA 125 level) after six cycles of

carboplatin, epirubicin, and prednimustine to observation or WAR (30 Gy in 1.5-Gy fractions, using 12 to 18 MeV photons), followed by pelvic and para-aortic and partial diaphragm boosts (total doses to these regions, 51.6 Gy and 42.6 Gy, respectively).¹¹⁴ The 5-year relapse-free survival and overall survival rates in the observation arm were 26% and 33%, respectively, compared to rates of 49% and 59%, respectively, in the WAR arm. One patient in the WAR arm developed a small bowel obstruction.

A trial conducted by the GOG and North Central Cancer Treatment Group from 1987 to 1996 enrolled 202 patients with initial stage III disease in complete clinical remission following chemotherapy (almost all had received a platinum-containing agent, and 39% also received paclitaxel) who then had a second-look laparotomy that found no gross residual disease.¹¹⁵ They were either observed or treated with IP chromic phosphate (15 mCi). Of note, 15% of patients assigned to the ³²P arm did not receive it for various reasons. With a median follow-up time of 63 months, the 5-year relapse-free survival rates in the two arms were 36% and 42%, respectively, and the 5-year overall survival rates were 63% and 67%, respectively. These differences were not statistically significant. Results were not analyzed according to whether the patient had microscopic or no pathologic evidence of disease at second-look surgery. A total of 2 of 98 patients in the control arm and 3 of 104 in the ³²P arm developed long-term grade 3 or 4 gastrointestinal complications.

A trial conducted in Sweden and Norway from 1988 to 1993 enrolled patients with initial stage III ovarian carcinoma who had no evidence of disease after initial surgery or who responded to induction chemotherapy (four courses of cisplatin 50 mg/m² with either doxorubicin or epirubicin) who then underwent second-look laparotomy.¹¹⁶ Ninety-eight patients with no gross or microscopic residual disease were randomly allocated to observation, six further cycles of the same chemotherapy, or WAR (20 Gy in 1-Gy fractions using an open field technique) followed by an extended pelvic boost (from the L3-4 interspace to the pelvic floor, 20.4 Gy in 1.7-Gy fractions using opposed anterior-posterior fields). Seventy-four patients with microscopic residual disease were randomized to the same chemotherapy or WAR. The length of follow-up was not stated, but data were collected up to early 2002. The 5-year PFS rates in the patients with no residual microscopic disease were 36%, 36%, and 56% in the observation, chemotherapy, and WAR arms, respectively; the difference was statistically significant. However, the 5-year overall survival rates were 65%, 57%, and 69%, respectively, and these differences were not statistically significant. In patients with microscopic residual disease, the 5-year PFS rates in the chemotherapy and WAR arms were 25% and 16%, respectively, and the 10-year rates were 22% and 5%, respectively. The 5-year overall survival rates were 41% for the chemotherapy arm and 32% for the WAR arm; 10-year rates were 23% and 10%, respectively. None of these differences was statistically significant. A total of 4 of 69 patients receiving WAR (6%) required bowel diversion due to bowel obstruction or adhesions, compared to no such complications occurring in the chemotherapy or observation group.

Finally, an international trial conducted from 1998 to 2003 enrolled 447 patients with a negative second-look laparotomy following initial treatment with surgery and platinum-based chemotherapy. Patients were randomly assigned to receive or not to receive a single IP injection of a radiolabeled monoclonal antibody directed against the MUC1 antigen using yttrium-90 (18 mCi, or 666 MBq/m²).¹¹⁷ Two-thirds of patients had stage III disease; 90% had no microscopic residual disease at second-look. With a median follow-up of 3.5 years, there was no difference in relapse or survival rates between the arms.

Despite these negative results, it is possible that patients with certain subtypes of ovarian cancer might derive benefit from consolidation radiation therapy. For instance, retrospective studies from the British Columbia Cancer Agency in Canada suggested that patients with stage I-II clear cell, mucinous, or endometrioid cancers had reduced failure rates and better overall survival

when patients received WAR in addition to three or six cycles of platinum-containing chemotherapy, compared to chemotherapy alone.¹¹⁸ It is also possible that clear cell histology may predict for benefit of radiotherapy, although data from prospective randomized trials are lacking.¹¹⁹

In conclusion, the value of radiation therapy as consolidation therapy following chemotherapy for patients with ovarian cancer is uncertain. The available randomized studies have conflicting results, especially in the subgroup of patients with no detectable residual disease after platinum-based chemotherapy. However, these studies were relatively small, with heterogeneous patient characteristics and treatments, and hence their statistical power to show clinically meaningful differences was limited. Further, no trials have been conducted for patients treated initially with both platinum compounds and paclitaxel. It seems likely that any benefits of consolidation radiation therapy are quite small in this setting. These must be weighed against their potential toxicity, although modern radiation techniques may reduce the toxicity of WAR compared to past approaches.¹²⁰ Hence, routine use of consolidation radiotherapy after chemotherapy is not generally recommended.

Maintenance Therapy

Several investigators have explored the value of maintenance or consolidation approaches after achievement of a clinical complete remission in patients with advanced epithelial ovarian cancer. In a randomized trial conducted by the Southwest Oncology Group and the GOG, women with advanced disease who experienced a clinically defined complete response were randomly assigned to receive either 3 cycles or 12 cycles of single-agent paclitaxel (175 mg/m² over 3 hours) administered every 28 days.¹²¹ The study was stopped early when an interim analysis revealed a 50% reduction in the risk of recurrence associated with the 12-month maintenance strategy (median PFS for the 12-month and 3-month paclitaxel arms was 28 months and 21 months, respectively; $p = 0.0023$). However, there was no difference in overall survival between the two regimens, which was also true in a subsequent analysis with longer follow-up. Interpretation of long-term data from this study will be confounded by crossover, whereby patients randomized to the three-cycle arm received additional maintenance paclitaxel after study closure. Likewise, a more recent randomized trial conducted in Europe showed no survival benefit to the use of six cycles of maintenance single-agent paclitaxel in this setting.¹²² Based on these data, maintenance single-agent paclitaxel cannot be recommended as a standard approach in patients who achieve a complete clinical remission after a platinum-based first-line chemotherapy.

The GOG has conducted a three-arm, placebo-controlled randomized trial investigating the role of maintenance bevacizumab (anti-VEGF-A neutralizing antibody) for 1 year in newly diagnosed patients with stage III or IV disease (GOG 218). This study showed that median PFS was significantly increased by 3.8 months ($p < 0.0001$) in patients receiving bevacizumab during first-line chemotherapy, followed by single-agent maintenance bevacizumab for approximately 1 year thereafter, compared with chemotherapy alone.¹²³ No improvement in quality of life or overall survival was noted at the time of publication. A similar question was addressed in a two-arm European trial (ICON-7) for newly diagnosed patients with either optimally or suboptimally debulked disease. Analysis of mature PFS data from that study showed a 2.4-month median PFS benefit ($p = 0.04$) associated with bevacizumab, without improvement in quality of life or overall survival at the time of publication.¹²⁴ More recently, a randomized trial investigating maintenance pazopanib (a VEGF-receptor tyrosine kinase inhibitor) showed similar results, with extension of PFS but without an overall survival advantage thus far.¹²⁵ Neither bevacizumab nor pazopanib are currently approved by the US Food and Drug Administration for maintenance use in ovarian cancer due to the lack of either an overall survival advantage or quality-of-life improvement, although additional follow-up of these studies is ongoing.

Surveillance After First-Line Chemotherapy

Over 50% of newly diagnosed patients with advanced-stage epithelial ovarian cancer will achieve a clinical complete remission after platinum and taxane induction chemotherapy.² Clinical complete remission is defined as no evidence of disease on physical examination, a normal CA 125 level, and normal radiographic studies such as CT. Patients with advanced-stage disease who achieve a clinical complete remission have a high chance of relapse and are typically followed with serial physician visits, including pelvic examinations and CA 125 determinations. The value of routine CA 125 surveillance after completion of first-line chemotherapy has recently been challenged by the OV05 randomized trial.¹⁹ Patients who underwent CA 125 surveillance, with early institution of cytotoxic chemotherapy for serologic relapse, did not experience improved quality of life or survival compared with those followed solely on the basis of physical examination and symptoms. Despite these negative results, it is possible that CA 125 surveillance may prove to be valuable once more effective salvage therapies become available or for those settings in which clinical trials might be available for patients with early relapse. In addition, CA 125 surveillance may still play an important role in well-informed patients who may feel empowered by knowing their CA 125 levels. Thus, the use of this test for surveillance purposes should be individualized. Routine performance of CT in the absence of symptoms, findings on physical examination, or an elevated CA 125 level has no proven value in the management of patients with this disease. This is partly due to the lack of sensitivity of CT compared to serologic testing with CA 125, which is currently the most sensitive method for detection of early relapse. Thus, CT is typically reserved for further evaluation of signs, symptoms, or serologic evidence of relapse. Likewise, there is currently no proven benefit for routine surveillance with other radiographic tests such as PET scans in the posttreatment setting.²³ Although performance of a second-look laparotomy after completion of first-line therapy will reveal residual disease in over half of all patients with advanced ovarian cancer who have achieved a complete clinical remission, this procedure does not appear to confer a survival advantage.⁶¹ This is due to the current lack of curative treatment options for patients with disease that persists after platinum-based, first-line therapy. In addition, a negative second-look laparotomy does not guarantee against the development of disease relapse, which occurs in 50% of patients with advanced-stage disease who have a negative second-look procedure.² For these reasons, second-look laparotomy is no longer considered a standard procedure in the assessment of patients after completion of first-line therapy, although it is sometimes used as an investigation tool in the context of clinical trials.

Management of Recurrent Disease

Hormonal Therapy

Most patients with advanced ovarian cancer will recur after first-line chemotherapy.² Recurrence is often manifested by a rising CA 125 in the absence of symptoms or objective evidence of disease as assessed by examination or CT (marker-only relapse). Unfortunately, the majority of patients with recurrent ovarian cancer are destined to die of their tumors, regardless of the second-line treatment modality used. Patients who demonstrate marker-only evidence of relapse, without symptoms or findings on examination or CT, are often initially managed with a drug like tamoxifen or an aromatase inhibitor. These drugs are potentially active in ovarian cancer^{126,127} and are generally well tolerated. The response to hormonal agents is typically slow and may require approximately 2 to 3 months before a reduction in the CA 125 level is evident.

Chemotherapy

Chemotherapy for recurrent disease is usually indicated for the development of tumor-related symptoms, objective evidence of

significant disease on examination or CT, or failure of hormonal therapy. Platinum is the most active agent in the management of patients with epithelial ovarian cancer, and retreatment with this drug may produce valuable responses that translate into improvement in quality of life. However, the likelihood of benefit depends on the interval between the last dose of platinum and the time of relapse (i.e., the platinum-free interval, PFI). Patients with a PFI of <6 months are less likely to respond to second-line platinum and are often managed with an alternative agent, as described subsequently.¹²⁸ Such patients are referred to as platinum resistant, although a small percentage may still derive benefit from platinum rechallenge. Patients with a PFI of between 6 and 24 months have an approximately 30% chance of benefit from second-line platinum used at the time of relapse. In patients with a very prolonged PFI (e.g., >2 years), the response rate with second-line platinum may be as high as 60% to 70%.¹²⁸ Patients with a PFI of >6 months are referred to as potentially platinum sensitive and are often treated with either single-agent platinum or a combination of platinum with another agent such as paclitaxel, gemcitabine, or liposomal doxorubicin.

Three randomized trials have investigated the value of combination chemotherapy in the setting of potentially platinum-sensitive relapse (PFI >6 months). The ICON-4 trial compared combination chemotherapy with paclitaxel and platinum to single-agent platinum in patients with potentially platinum-sensitive disease, with most patients having a PFI of ≥ 12 months.¹²⁹ This study demonstrated a statistically significant improvement in overall survival for the combination regimen, with an absolute difference at 2 years of 7% ($p = 0.023$). However, 58% of patients in the single-agent platinum arm never received a taxane as part of first-line therapy, and 69% of patients in the single-agent platinum arm never received a taxane as part of relapse management (i.e., after progression on single-agent platinum). Thus, 40% of patients in the single-agent platinum arm never received a taxane at any point during the course of their disease. Given the proven survival benefit of taxanes in this disease, the imbalance in the use of taxanes between these two treatment arms makes the results of ICON-4 difficult to interpret.

The second trial performed by the Arbeitsgemeinschaft Gynaekologische Onkologie from Germany randomized patients with potentially platinum-sensitive relapse to either gemcitabine and carboplatin or carboplatin alone.¹³⁰ PFS was 8.6 months for the combination versus 5.8 months for single-agent carboplatin ($p = 0.0038$), although overall survival was not improved in the combination chemotherapy arm. Quality of life appeared to be equivalent between the two arms, despite a higher incidence of thrombocytopenia, neutropenia, and anemia with combination chemotherapy.

The third trial compared paclitaxel and carboplatin with liposomal doxorubicin and carboplatin in patients with platinum-sensitive relapse.¹³¹ There was a statistically significant improvement in median PFS (11.3 months versus 9.4 months; $p = 0.005$), with a lower incidence of severe hypersensitivity reactions (5% versus 18%), in favor of the liposomal doxorubicin-containing arm. No difference in overall survival was noted at the time of this report. More frequent grade 2 or greater alopecia (83.6% versus 7%) and sensory neuropathy (26.9% versus 4.9%) were observed in the paclitaxel-containing arm, while more hand-foot syndrome (grade 2 to 3, 12.0% versus 2.2%), nausea (35.2% versus 24.2%), and mucositis (grade 2-3, 13.9% versus 7%) in the liposomal doxorubicin-containing arm.

Because the primary goal of relapse management is palliation of symptoms, the decision to use combinations in this setting should be based on a number of factors, including patient age, amount of disease, kinetics of relapse, and patient preference after a discussion of the issues.¹³² For older patients who require chemotherapy for asymptomatic, minimal volume, potentially platinum-sensitive relapse, it is still reasonable to use single-agent carboplatin as a first step. As described subsequently, liposomal doxorubicin is a generally well-tolerated alternative if there is a contraindication to

the use of carboplatin, if carboplatin fails to induce a response, or if an allergic reaction develops to carboplatin that precludes further administration. With either single-agent carboplatin or liposomal doxorubicin, patients have minimal problems with alopecia or myelosuppression, and their quality of life is generally well preserved. For younger patients who wish to adopt an aggressive approach to the management of potentially platinum-sensitive relapse, combination chemotherapy with either paclitaxel and carboplatin, gemcitabine and carboplatin, or liposomal doxorubicin and carboplatin is reasonable. This is especially the case for the symptomatic patient with kinetically brisk relapse or the patient who has undergone a successful secondary cytoreduction after a very long PFI.¹³² There are currently no data supporting a role for combination chemotherapy regimens in the management of patients with platinum-resistant relapse.

Patients who are platinum resistant, as defined by a short PFI of <6 months or progression during platinum-based chemotherapy, or those who tolerate second-line platinum poorly, are typically treated with a variety of single agents. Potentially non-cross-resistant drugs with activity in the platinum-resistant setting include liposomal doxorubicin, paclitaxel, docetaxel, topotecan, gemcitabine, pemetrexed, ixabepilone, or oral etoposide.¹³³ Liposomal doxorubicin is often well tolerated in doses of 40 mg/m² given every 4 weeks, although the development of palmer-planar erythrodysesthesia (hand-foot syndrome) or mucositis may require dose reductions and treatment delays.¹³⁴ Topotecan may cause significant myelosuppression and fatigue, although this agent is generally well tolerated through the use of weekly dosing schedules.¹³⁵ Unfortunately, the likelihood of obtaining a response to any of these agents in the platinum-resistant setting is <20%, responses are generally short lived (median PFS in the range of 4 to 6 months), and they tend to become progressively shorter with each subsequent regimen.¹³²

Several investigational agents are being studied in the relapsed setting. Bevacizumab is a humanized antibody that recognizes and neutralizes VEGF, an angiogenic factor that is often secreted by ovarian cancer cells. Randomized data in metastatic colorectal, breast, and lung cancers have shown a survival advantage for the use of this drug in combination with chemotherapy.^{136–138} As a single agent, bevacizumab has been shown by the GOG to induce responses in 18% of patients with relapsed ovarian cancer (either platinum sensitive or platinum resistant, treated with less than or equal to two prior regimens), with 39% of patients progression-free at 6 months.¹³⁹ A recent multi-institutional nationwide study restricted to platinum-resistant patients reported a response rate of 16%, with 27% of patients progression free at 6 months.¹⁴⁰ However, there was an 11% incidence of potentially life-threatening bowel perforation, prompting early closure of this study. Compared to the GOG study, all patients in this trial were platinum resistant and heavily pretreated, with 50% having received three prior regimens. It has been suggested that the risk of bowel perforation with bevacizumab in the recurrent ovarian cancer setting might be related to a higher number of prior treatment regimens, radiographic evidence of bowel wall involvement by tumor, or the presence of bowel obstruction.¹⁴⁰ These and other possible risk factors for this complication will require further evaluation.

In addition to its use as a single agent, bevacizumab has also been combined with cytotoxic chemotherapy in the relapsed setting. In patients with platinum-sensitive relapse, the OCEANS study randomized patients to receive either the combination of carboplatin, gemcitabine, and placebo, or the combination of carboplatin, gemcitabine, and bevacizumab, for up to 10 cycles, followed by with single-agent placebo or bevacizumab until progression.¹⁴¹ A 4-month improvement in median PFS in favor of the bevacizumab combination ($p < 0.0001$) was observed, but without an overall survival advantage. The overall response rate was also improved in the bevacizumab-containing arm compared to placebo (78.5% and 57.4%, respectively, $p < 0.0001$), associated with

prolongation of median response duration by 3 months. In patients with platinum-resistant relapse, the combination of bevacizumab with either liposomal doxorubicin, topotecan, or weekly paclitaxel has been studied in the AURELIA trial.¹⁴² As for the OCEANS study, the combination of bevacizumab with either of these single agents was associated with statistically significant prolongation of median PFS, a higher response rate, but no improvement in overall survival. Although not yet approved by the US Food and Drug Administration for these indications, these studies suggest that there may be a role for combining bevacizumab with these specific chemotherapy regimens in the relapsed setting.

Other investigational agents with reported activity in platinum-sensitive (and, to a lesser degree, platinum-resistant) disease include ET743 (trabectedin), halichondrin B, pertuzumab, epothilones, and AMG386.^{143,144} Receptor tyrosine kinase inhibitors that target the VEGF receptor such as AZD2171 (cediranib) appear to have activity and are being studied in combination with platinum-based chemotherapy.¹⁴⁵ In contrast, epidermal growth factor-receptor inhibitors such as gefitinib appear to have low activity in the recurrent disease setting. An exciting new class of agents that inhibit poly-adenosine diphosphate-ribose polymerase is demonstrating important activity in patients with recurrent disease, especially those who harbor a germline mutation in *BRCA1* or *BRCA2*.^{146,147} Poly-adenosine diphosphate-ribose polymerase inhibitors such as olaparib have also been studied as a maintenance strategy in unselected patients with platinum-sensitive relapse, with an improvement in median PFS but without an overall survival benefit.¹⁴⁸ Whether selection of patients on the basis of germline *BRCA* mutation status will enrich for those most likely to derive benefit with maintenance olaparib, in either the first line or recurrent disease setting, is under investigation. At present, none of these agents is currently approved by the US Food and Drug Administration for treating patients with relapsed ovarian cancer, and their ultimate value needs to be better defined.

The agents mentioned previously have largely been studied in patients who have relapsed with high-grade serous disease. Within the past few years, based on a greater understanding of the heterogeneity of epithelial ovarian cancer, particularly the molecular biology of uncommon subtypes, the GOG has initiated clinical trials for women with recurrent low-grade serous carcinoma and clear cell carcinoma. Low-grade serous cancer is a distinct entity characterized by advanced stage, molecular features such as *K-ras* (30%) or *BRAF* (5%) mutation, as opposed to *p53* mutation more typical of high-grade disease, and it is relatively chemoresistant. In the relapsed setting, the response rate to conventional cytotoxic chemotherapy options is in the range of only 5%, whereas the response to hormonal agents like tamoxifen or aromatase inhibitors is generally higher, in the range of 10% to 15%.^{149,150} A recent retrospective review suggests that there may be value in combining bevacizumab with conventional cytotoxic agents in patients who relapse with low-grade serous ovarian cancer, although this requires additional prospective validation.¹⁵¹ Finally, given the presence of *K-ras* mutation, and to a lesser extent *BRAF* mutation, in low-grade serous cancer, it is reasonable to expect that downstream mediators of the MAP-kinase pathway such as MEK might serve as therapeutic targets. In that regard, the MEK 1/2 inhibitor selumetinib was recently shown to yield a 15% response rate in patients with relapsed low-grade serous ovarian or primary peritoneal cancer, although no predictive biomarkers could be identified.¹⁵² In 2014, the GOG has launched a randomized phase 2/3 study of a similar MEK inhibitor, trametinib, in patients with relapsed low-grade serous cancer, comparing the activity of this agent with that of cytotoxic chemotherapy.

Recurrent clear cell carcinoma of the ovary appears also to be relatively chemoresistant.^{153,154} Potential targets for clear cell carcinoma of the ovary include *VEGF*, the *PI3K/AKT/mTOR* pathway, *c-MET*, and the *IL-6/STAT3/HIF* pathway. Thus, the GOG has initiated a clinical trial with sunitinib for women with recurrent clear cell carcinoma, with two other trials in development.

Surgery

Secondary cytoreductive surgery refers to an attempt at surgical debulking of disease at the time of relapse and is performed in selected patients prior to the administration of second-line chemotherapy. The ability to perform a successful secondary cytoreduction, as generally defined by having no gross residual disease >1 cm in diameter, is associated with a median survival advantage in retrospective studies.¹⁵⁵ However, it is possible that the ability to perform a successful secondary cytoreduction may simply identify those patients with biologically less aggressive disease or those with a lower tumor burden at the time of relapse. The only way to determine whether secondary cytoreduction has intrinsic therapeutic value is to conduct a randomized trial of this procedure, which has not yet been performed.

Patients who relapse within 6 to 12 months after completion of first-line therapy, especially if they have ascites, are generally not candidates for this procedure.¹⁵⁵ Occasional patients with late relapses (i.e., >2 to 3 years after finishing chemotherapy) or those with apparently isolated relapses may experience a prolonged disease-free interval after successful secondary cytoreduction followed by additional chemotherapy. The value of secondary cytoreduction is currently being investigated in two prospective, randomized trials: GOG 213 and the Arbeitsgemeinschaft Gynaekologische Onkologie Desktop III study.

Palliative surgery may be of benefit for patients with recurrent ovarian cancer. Common operations performed in this setting include colostomy for relief of a large bowel obstruction, lysis of adhesions, and management of small bowel obstruction. The decision to perform surgery to relieve small bowel obstruction should take into account the time elapsed from the original diagnosis to the development of obstruction, as well as the likelihood for continued responsiveness to chemotherapy postoperatively. Women who develop small bowel obstruction during first-line chemotherapy have biologically aggressive tumors that are usually not amenable to surgical intervention. A palliative gastrostomy tube may be most appropriate in this situation, and frequently this can be inserted endoscopically or under CT guidance. In contrast, women who have had prolonged periods of freedom from disease, usually lasting >1 year from the original diagnosis, may benefit from small bowel surgery to relieve obstruction. Surgery generally plays no role in management of patients with a pseudo-obstructive pattern due to intra-abdominal carcinomatosis, with infiltration of the myenteric plexus of the small bowel. Metoclopramide, which improves motility of the upper gastrointestinal tract without stimulating gastric, biliary, or pancreatic secretions, may at times be helpful for this condition. Large bowel obstruction (particularly sigmoid colon obstruction) is often relieved by performing a colostomy, which can provide significant prolongation of survival and improved quality of life in appropriate patients.

Radiation Therapy

A minority of patients with localized recurrences may experience prolonged survival after WAR or limited-field irradiation.¹⁵⁶⁻¹⁵⁸ For example, a study from the MD Anderson Cancer Center included 102 patients treated with doses of ≥ 45 Gy to localized nodal or extranodal recurrences.¹⁵⁸ With a median follow-up of 37 months, the 5-year PFS and overall survival rates were 24% and 40%, respectively. Results were better for the eight patients with clear cell carcinoma (5-year PFS and overall survival rates of 75% and 88%, respectively) than for patients with other histologies (20% and 33%, respectively). The 5-year in-field disease control rate was higher for the 16 patients who had complete gross tumor resection (88%) than for the 73 patients with gross residual disease (68%) or the 13 patients with a complete response to chemotherapy who did not undergo surgery (68%). However, the small number of highly selected patients in these series, their heterogeneous presentations, and the highly variable treatments they received before and after

radiation make it difficult to adequately assess whether radiation therapy truly improves long-term outcome in this setting.

Although rarely curative, radiation therapy can play a role in the palliation of some patients with recurrent ovarian cancer. Symptoms from a growing pelvic mass can cause pain, bleeding, and rectal narrowing. Palliative pelvic radiotherapy can provide rapid relief and, in some cases, may prevent or delay the need for diverting colostomy. Doses of 8 to 10 Gy in a single fraction, 20 Gy in 5 fractions, 30 Gy in 10 fractions, or higher total doses given in smaller fractions have produced acceptable short-term results, with serious complications in 5% or fewer patients. Finally, patients with epithelial ovarian cancer may rarely develop isolated cerebral or bone metastases that can often be successfully palliated with radiotherapy.

BORDERLINE TUMORS

Definition and Clinical Features

Ovarian borderline tumors are epithelial neoplasms that are histologically distinguished from ovarian carcinomas by the absence of stromal invasion. These neoplasms are also referred to as tumors of LMP, which reflects their indolent natural history.¹⁵⁹ Although borderline tumors generally do not exhibit stromal invasion within the ovary, cells from the primary tumor mass can be shed into the peritoneal cavity and eventually form serosal implants that involve the bowel, omentum, and upper abdomen. Nonetheless, the majority of patients with borderline tumors present with early stage disease.¹²

The median age of women developing borderline tumors is 40 years, approximately 20 years younger than the median age for women with epithelial ovarian cancer. Women may be diagnosed with an asymptomatic mass on routine pelvic examination or may come to medical attention due to pelvic pain. Nonspecific gastrointestinal symptoms such as abdominal bloating or early satiety may rarely occur.

As with epithelial cancers of the ovary, borderline tumors may exhibit serous or mucinous features. Serous borderline tumors are more common and may be bilateral in 10% to 20% of cases.¹⁵⁹ Mucinous borderline tumors tend to be larger than their serous counterparts, are infrequently bilateral, and are occasionally associated with pseudomyxoma peritonei. Pseudomyxoma peritonei is characterized by a hypocellular, gelatinous material secreted by an intra-abdominal tumor, eventually filling the peritoneal cavity and encasing abdominal contents such as bowel. This condition may be associated with mucinous borderline ovarian tumor, mucinous ovarian carcinoma, or gastrointestinal tumors such as appendiceal mucinous cystadenocarcinoma. The latter diagnosis may occur synchronously with a primary ovarian mucinous neoplasm or may mimic a primary ovarian tumor by metastasizing to the ovary (often right sided, reflecting the proximity of the appendix to the right ovary). The mainstay of treatment for pseudomyxoma peritonei is intermittent surgery to remove the gelatinous material, although this is not curative in the majority of cases, and repeated debulking attempts are associated with increased potential for adhesions and complications such as bowel obstruction.

The distinctive pathologic and biologic behaviors of these tumors were recognized by the WHO in 1973 (see Table 76.1).⁴ Borderline malignant potential tumors are distinguished from benign cystadenomas by the presence of epithelial budding, multilayering of the epithelium, increased mitotic activity, and nuclear atypia. They are distinguished from epithelial carcinomas by the absence of stromal invasion. In the spectrum of aggressiveness between epithelial ovarian carcinoma and benign ovarian tumors such as cystadenoma, borderline tumors are closer to benign ovarian tumors in their clinical behavior. However, they are accorded their own classification based on distinctive histologic features, their potential to occasionally spread beyond the ovary, and their ability to recur and lead to death in a minority of patients.

Because the absence of stromal invasion is a criterion for making this diagnosis, careful examination of the tissue blocks is necessary to exclude a component of invasive carcinoma. In this regard, approximately 20% of ovarian tumors diagnosed as borderline on frozen-section analysis prove to be carcinomas on review of the permanent section. The presence of microinvasion (as opposed to deep stromal invasion) is sometimes observed in a borderline tumor, in association with more typical histologic features. In such cases, the microinvasive component is typically no greater than 3 mm in depth, in which case it most likely does not impact on prognosis.¹⁶⁰ Mucinous borderline tumors are characterized by multiloculated cystic masses, with smooth outer surfaces and areas of papulations and solid thickening on the inner surface. Microscopically, the epithelial lining of cysts within a mucinous borderline tumor consists of tall, columnar, mucin-secreting cells, resembling the epithelium of the endocervix or intestine. Although mucinous borderline tumors lack stromal invasion, they are sometimes difficult to distinguish from their invasive mucinous carcinoma counterparts. Most mucinous borderline tumors have fewer than four layers of stratified mucinous cells and lack invasion, whereas mucinous carcinomas often demonstrate an infiltrative or expansile pattern of stromal involvement.¹⁶¹

Greater than 90% of patients with early stage borderline tumors are alive at 10 years, and >50% of patients with advanced disease experience long-term survival.¹² The fact that survival does not appear to be improved by postoperative adjuvant treatment with either chemotherapy or radiation attests to the slow growth rate of this tumor, which confers indolent behavior but at the same time results in resistance to modalities that target actively dividing cells. Nevertheless, a small fraction of patients with borderline tumors exhibits a more aggressive course, and attempts have been made to identify histologic correlates that might predict for worse outcome. Some investigators have proposed that borderline serous tumors may behave more aggressively if they are associated with micropapillary features or invasive implants elsewhere in the peritoneal cavity.^{13,162,163} Micropapillary serous carcinoma is characterized by thin, elongated micropapillae with minimal or no fibrovascular support. Patients with invasive implants in the setting of a primary borderline tumor typically have a desmoplastic reaction within the implant, associated with an irregular, infiltrative border that invades underlying structures and replaces the fatty tissue of the underlying omentum.¹⁶³ An implant that simply shows desmoplasia, without these other features, should be referred to as a desmoplastic *noninvasive* implant and does not appear to predict a worse outcome, in contrast to its invasive counterpart. Patients with serous borderline tumors without invasive implants have expected 10-year survival rates of >95%, whereas those with serous borderline tumors and invasive implants have survival rates of approximately 60% to 70% at 10 years.¹⁶⁴ Of interest, the majority of patients with invasive implants, or those with recurrences that progressed to invasive carcinoma, have been found to have micropapillary features within the primary ovarian tumor on careful sectioning. Thus, it is possible that micropapillary features portend a poorer prognosis because of their association with invasive implants, although this is still an area of controversy.

Surgical Management

Surgery for patients with borderline tumors who have completed childbearing is identical to that recommended for epithelial ovarian cancer, including a total abdominal hysterectomy, bilateral salpingo-oophorectomy, tumor debulking, and full staging. Although unusual, patients with borderline tumors may sometimes have retroperitoneal nodal involvement that can benefit from debulking. In such cases, the tumor typically involves the sinusoidal nodal spaces, as opposed to nodal parenchyma. An appendectomy is considered in patients with suspected mucinous borderline tumors because of its occasional association with a primary appendiceal carcinoma.

In younger patients with early stage borderline tumor who wish to preserve fertility, conservative surgery with preservation of the uterus, the contralateral ovary and fallopian tube, and in some cases the ipsilateral ovary (i.e., cystectomy) may be appropriate treatment. Several studies have reported excellent outcomes with conservative management of such patients. One of the largest studies found a 12% recurrence rate for patients treated conservatively with either unilateral salpingo-oophorectomy ($n = 110$) or ovarian cystectomy ($n = 74$), compared to 2.5% for patients treated with hysterectomy and bilateral salpingo-oophorectomy.¹⁶⁵ Recurrences or progression to carcinoma (1.5%) were more common among patients with invasive implants or advanced-stage disease.

Borderline ovarian tumors have also been diagnosed during pregnancy. Conservative surgery is usually performed, and pregnancy does not appear to affect the prognosis. Most patients go on to deliver at full term without any complications.

Postoperative Management

There is currently no convincing evidence that postoperative adjuvant chemotherapy or radiation confers a survival advantage for patients with borderline tumors of any stage.¹² In the absence of effective postoperative adjuvant therapy, in a disease where long-term survival is generally excellent, simple observation with serial examinations is reasonable, with radiographic studies as needed to investigate new symptoms or findings on examination. Late relapses may occur and reveal persistent borderline histology, although transformation to low-grade invasive serous cancer is a more common occurrence in this setting.¹⁶⁶ Surgery is the mainstay of treating recurrent disease and can lead to long-term survival. Some patients who recur with borderline histology may respond to a hormonal option such as tamoxifen.¹⁶⁷ However, for patients with borderline tumors who recur with low-grade invasive serous cancer, surgical debulking followed by platinum-based chemotherapy is often recommended.

GERM CELL TUMORS OF THE OVARY

Definition and Clinical Features

Germ cell tumors of the ovary are much less common than epithelial ovarian neoplasms, accounting for 2% to 3% of all ovarian cancers in Western countries and usually occurring in younger women, with a peak incidence in women in their early 20s. An increased incidence of germ cell tumors is found in Asian and black populations, where these tumors may represent as many as 15% of all ovarian cancers. It is often possible to cure these malignancies while preserving fertility, which is an especially important consideration given the young age of most patients.

The WHO classification for germ cell tumors of the ovary is shown in Table 76.1.⁴ These tumors are often divided into dysgerminoma, which is the female counterpart of male seminoma, and nondysgerminoma. Abdominal pain, distention, pelvic fullness, and urinary symptoms are common in patients with germ cell tumors of the ovary. In a minority of patients, abdominal pain can be severe, usually the result of hemorrhage, rupture, or ovarian torsion.

The rapid growth of most ovarian germ cell tumors causes pain due to stretching of the ovarian capsule, often prompting the patient to seek medical attention while the tumor is still confined to the ovary. Patients frequently have a palpable adnexal mass that is typically evaluated by TVU, which may show a complex cyst comprised of solid and cystic regions. Serum levels of α -fetoprotein (AFP) and β -human chorionic gonadotropin (HCG) are often helpful in recognizing the presence of an endodermal sinus tumor (AFP elevation only), embryonal carcinoma (both AFP and HCG elevation), or choriocarcinoma (HCG elevation only). Patients with pure immature teratoma of the ovary typically have normal

levels of AFP and HCG, although the AFP may be elevated in 30% of cases. Patients with mature cystic teratoma (dermoid cyst), which is a benign germ cell tumor, usually have normal levels of AFP and HCG. Measurement of AFP and HCG levels is also useful to gauge the effectiveness of postoperative therapy and in monitoring for disease recurrence.

Occasionally, patients with choriocarcinoma have extreme elevation of the β -HCG that results in hyperthyroidism due to homology between β -HCG and thyroid-stimulating hormone. Patients with mature cystic teratoma may also present with hyperthyroidism related to tumor-derived secretion of thyroxine, produced by mature thyroid tissue present within the tumor itself (struma ovarii). Rare patients with mature cystic teratoma will experience a Coomb's positive hemolytic anemia that resolves after surgical resection of the mass.

In contrast to epithelial tumors, 60% to 70% of germ cell tumors are stage I at diagnosis. Stages II and IV tumors are relatively uncommon, and stage III disease accounts for about 25% to 30% of tumors. Bilateral ovarian involvement in most germ cell histologies is uncommon, although dysgerminoma and mature cystic teratoma may be bilateral in 10% to 15% of cases. More advanced disease may involve retroperitoneal lymph nodes and multiple peritoneal surfaces, although ascites is infrequent. Hematogenous spread to the liver, lung, and brain can be observed, especially with choriocarcinoma.

Surgical Management

The principles for surgical management of germ cell tumors are similar to those described for epithelial tumors, with the important caveat that in most patients with germ cell cancer, fertility can be preserved by sparing the contralateral ovary and fallopian tube and the uterus. Even in dysgerminoma, in which bilaterality is more common, bilateral oophorectomy is not routinely necessary because postoperative chemotherapy is often capable of eradicating disease that could not be entirely removed at the time of initial surgery. In cases in which the contralateral ovary is grossly abnormal, cystectomy or biopsy can be performed, and bilateral salpingo-oophorectomy can be undertaken in the case of a dysgenetic gonad.

Once the peritoneal cavity is opened, peritoneal washings are obtained, and all fluids are sent for histologic examination. If disease is grossly confined to the pelvis, random biopsies are often performed as in the surgical staging of early stage epithelial ovarian carcinomas. Particular attention is paid to para-aortic and pelvic lymph node enlargement, because these sites are frequently involved in patients with advanced ovarian germ cell tumors. Although lymph node sampling is often performed for staging, no evidence suggests that lymphadenectomy is beneficial. Although the conventional approach among gynecologic oncologists consists of comprehensive surgical staging (with the possible exception of lymphadenectomy) for patients with apparent early-stage malignant ovarian germ cell tumors, the standard surgical management for children who undergo primary surgery by pediatric surgeons has been less extensive. Billmire et al.,¹⁶⁸ reporting the outcomes of 131 patients with malignant ovarian germ cell tumors who were enrolled in two intergroup studies, found that less comprehensive surgical staging did not compromise survival. Clearly, further study of the extent of surgical staging is warranted.

Cytoreductive surgery is recommended as for epithelial tumors of the ovary. However, whether such an aggressive approach is necessary in selected patients with extensive disease that is generally much more chemosensitive than epithelial ovarian cancer remains unresolved.

There is no role for routine second-look operations in patients with germ cell tumors who are clinically free of disease after chemotherapy. In particular, if the primary tumor is completely resected and does not contain teratomatous elements, second-look procedures after chemotherapy are of no established benefit. In some

patients whose tumor contains teratomatous elements, however, a second-look procedure may be beneficial. Such patients may have residual mature teratoma, which is chemotherapy insensitive, making it reasonable to consider a second-look procedure in selected cases for resection of such residual disease if technically possible. The rationale for this is derived from the experience with testicular germ cell cancer, in which residual teratoma has been known to enlarge and cause local complications or rarely transform to an undifferentiated sarcoma or carcinoma. However, the extent to which residual teratoma may transform to a more aggressive histology in patients with ovarian germ cell tumors has not been well studied.

Postoperative Management of Dysgerminoma

Dysgerminoma is the most common malignant germ cell tumor of the ovary. In contrast to nondysgerminomatous tumors (which contain embryonal, yolk sac, or choriocarcinoma elements), dysgerminomas are more frequently stage I, may involve both ovaries, more often spread to retroperitoneal lymph nodes, and are markedly sensitive to radiotherapy. Because these tumors are also exquisitely sensitive to cisplatin-based chemotherapy, the role of curative radiation therapy has significantly decreased, especially in view of its propensity to cause sterility.

The majority of patients with dysgerminomas are diagnosed with early stage disease. Because preservation of fertility is an important issue for most patients, those with stage IA disease can be observed without further postoperative treatment. Approximately 15% to 25% of such patients will experience recurrence, although salvage chemotherapy is almost always successful.¹⁶⁹ Dysgerminoma in patients with higher than stage IA disease is typically treated with platinum-based chemotherapy. In the early 1980s, ovarian germ cell tumors were treated with the cisplatin, vinblastine, and bleomycin (PVB) regimen, similar to the regimens used in the treatment of testicular cancer. The MD Anderson Cancer Center group began to use the bleomycin, etoposide, and cisplatin (BEP) combination for patients with metastatic dysgerminoma in 1984 and subsequently reported their findings, with all 14 BEP-treated patients disease free at a median follow-up of 22.4 months.¹⁷⁰ The GOG also reported their experience of 20 patients with incompletely resected dysgerminoma who received either PVB or BEP followed by the combination of vincristine, dactinomycin, and cyclophosphamide.¹⁶⁹ With a median follow-up of 26 months, 19 of the 20 patients were disease free.

In an update of the MD Anderson series, Brewer et al.¹⁷¹ reported 26 patients with ovarian dysgerminoma who received BEP chemotherapy, with all patients being disease free at the time of the report. Of the 14 evaluable patients who underwent fertility-sparing surgery, 93% had normal menstrual function, with five pregnancies reported. In an attempt to identify a less-toxic regimen, the GOG conducted a clinical trial in which 39 eligible patients with completely resected, stages IB through III ovarian dysgerminoma received the combination of etoposide and carboplatin; all 39 patients were in sustained remission (median follow-up 7.8 years), with myelosuppression being the most severe toxicity.¹⁷² Although BEP is still considered the preferred regimen for use in this setting, with the etoposide and carboplatin combination being reserved for those patients with completely resected, stages IC through III dysgerminoma who have a contraindication to BEP (such as significant neuropathy or renal dysfunction), there appears to be renewed interest in development of a regimen less toxic than BEP.

Postoperative Management of Nondysgerminoma

Nondysgerminomas include tumors that contain embryonal, yolk sac, choriocarcinoma, and immature teratoma elements. The vast majority of these histologic subtypes require treatment with

surgery followed by combination chemotherapy, as even patients with early stage nondysgerminomas have a significant risk of relapse that can be reduced by postoperative adjuvant therapy. The current regimen of choice is BEP. The GOG reported that 89 of 93 patients with stages I, II, and III disease whose tumors were completely resected remained disease free after three courses of this regimen.¹⁷³ Toxicities of BEP include the risk of bleomycin-induced pulmonary damage, etoposide-induced leukemia, and platinum-induced neuropathy and nephropathy. Many patients who receive the BEP regimen will regain fertility after completion of treatment. Several series have reported that at least 80% of patients with germ cell tumors of the ovary who were treated with fertility-sparing surgery and postoperative chemotherapy regained normal menstrual function, and there are several documented normal pregnancies.¹⁷⁴ However, patients are known to be at increased risk for development of premature menopause following chemotherapy.¹⁷⁵

Although most patients with nondysgerminomatous germ cell cancer will require postoperative chemotherapy, a subset of patients with pure immature teratoma of the ovary has an excellent prognosis after surgery alone. Specifically, patients with stage IA, grade 1 immature teratoma experience 5-year survivals >90%, and there is no evidence to suggest that chemotherapy improves outcome. Patients with stage IA, grades 2 and 3 immature teratoma have a higher relapse rate, which generally warrants consideration of postoperative chemotherapy.

Several investigators have examined the feasibility of surgery followed by close surveillance in a much broader group of patients. Dark et al.¹⁷⁶ reported 24 patients with stage IA germ cell tumors of the ovary who underwent postoperative surveillance. Fifteen of these had nondysgerminomas, with nine immature teratomas and six yolk sac tumors. Three of these fifteen (20%) patients relapsed. The two patients with yolk sac tumor each relapsed at 4 months, and both were salvaged with combination chemotherapy. The third patient became pregnant; she presented with ascites and hepatic metastases during the third trimester, 13 months after diagnosis, and died of a pulmonary embolus 4 weeks after starting chemotherapy.

Cushing et al.¹⁷⁷ reported 44 patients with completely resected ovarian immature teratoma, grades 1 through 3 (31 pure and 13 with yolk sac tumor elements). Ten of twelve patients had elevated levels of serum AFP. The 4-year event-free and overall survival rates for the two groups were 97.7% and 100%, respectively. One patient with a mixed tumor relapsed 18 weeks after primary surgery with a rising AFP level; she was treated with four cycles of BEP and was disease free 57 months after completing chemotherapy. Two other studies reported a total of 39 patients with stage I disease who were treated with surgery alone.^{178,179} The overall survival for the combined studies was 97.4%; 13 patients relapsed, and 12 were salvaged with chemotherapy.

The Children's Oncology Group is currently studying the approach of surgery followed by surveillance in patients with stage I germ cell tumors of the ovary. Although this strategy appears to be potentially promising, further study, particularly in adult patients, is warranted to ensure its safety and efficacy.

SEX CORD-STROMAL TUMORS

Definition and Clinical Features

Ovarian sex cord-stromal tumors represent approximately 5% of all ovarian cancers.⁵⁶ Patients often present with stage I disease, which has an excellent prognosis. However, the potential for late relapse, sometimes occurring more than 10 years after diagnosis, mandates long-term follow-up. Granulosa cell tumors are the most common type of sex cord-stromal malignancy. Such tumors typically present as a solid mass with occasional cystic features, which

Figure 76.5 Cross-section of a granulosa cell tumor, showing the tan-yellow appearance characteristic of steroid production. (Courtesy of Dr. Marisa Nucci, Brigham and Women's Hospital, Boston, MA.)

is often yellow on cross-section due to the presence of cholesterol (Fig. 76.5). In addition, the cells of granulosa cell tumors are characterized by a longitudinal cleft that resembles a coffee bean (Fig. 76.6), and they may be organized into fluid-filled spherical structures known as Call-Exner bodies. These tumors may produce estrogenic or, less commonly, androgenic steroids. The estradiol in such cases is due to production of androstenedione by normal theca cells within the ovarian stroma, which is then converted to estradiol under the influence of aromatase present in the granulosa cell tumor.⁵⁶ In addition to estradiol, sex cord-stromal tumors such as granulosa cell tumors may secrete other factors such as inhibin and Müllerian inhibitory substance, which can sometimes be useful as tumor markers during the surveillance phase of management.^{56,180}

The hormonal manifestations of sex cord-stromal neoplasms such as granulosa cell tumors vary depending on the age of the patient. Thus, granulosa cell tumors occurring in premenarchal girls may present with precocious puberty, whereas women in the reproductive years may present with amenorrhea or abnormal

Figure 76.6 Photomicrograph of a hematoxylin and eosin-stained section of granulosa cell tumor, showing characteristic nuclear grooves (coffee bean nuclei). (Courtesy of Dr. Jonathan Hecht, Beth Israel Deaconess Medical Center, Boston, MA.)

menses or may occasionally develop intra-abdominal hemorrhage that mimics an ectopic pregnancy. Postmenopausal women with granulosa cell tumor may present with postmenopausal bleeding due to endometrial hyperplasia (or a separate uterine carcinoma), resulting from tumor-derived estrogen. Sertoli-Leydig cell tumors may present with symptoms of virilization, but none of these hormonal effects is a reliable diagnostic criterion, and many patients with sex cord–stromal tumors have no hormonal manifestations of their disease. The tumor may present as a mass discovered on routine pelvic examination or during the evaluation of pelvic pain due to ovarian torsion.

Surgical Management

Surgical staging of sex cord–stromal tumors is the same as that for epithelial ovarian cancer, with the exception of management of the retroperitoneum. In two reported series, no lymph node metastases were observed in patients who underwent pelvic and/or paraaortic lymphadenectomy.^{181,182} Furthermore, recurrence involving lymph nodes is uncommon. Surgical management of sex cord–stromal tumors is based on the stage of the tumor as well as the age of the patient. As the tumor is rarely bilateral, premenarchal women or patients presenting in the reproductive years with stage I disease are often managed with unilateral salpingo-oophorectomy in an attempt to preserve fertility. In women who have completed childbearing, initial surgery for sex cord–stromal tumors typically consists of bilateral salpingo-oophorectomy and total abdominal hysterectomy, along with standard surgical staging.

Postoperative Management

Stage is the most important prognostic factor, with 10-year survivals of over 85% for stage I tumors, decreasing to 50% to 65% for stage II disease, and to 17% to 33% for stages III and IV.⁵⁶ Based on these considerations, patients with stages II to IV sex cord–stromal tumors are reasonable candidates for additional therapy after initial surgery, although the survival benefit of such therapy has not been proven due to the rarity of this tumor and resultant lack of randomized trials. Approximately 30% to 50% of patients will respond to platinum-based chemotherapy, and some patients may be rendered into a clinical and pathologic complete response at the time of second-look laparotomy (usually performed in the context of a clinical trial).^{56,183} The most commonly studied platinum combinations are cyclophosphamide, doxorubicin, and cisplatin; PVB; and BEP. The single-agent activity of drugs such as bleomycin or etoposide has not been well established in this disease, and combinations such as PVB or BEP have been used by analogy with germ cell cancer (which derives from a completely different cell lineage). Although randomized comparisons are lacking, the highest response rates and the best tolerance among these three regimens has been observed with BEP, which is often used for sex cord–stromal tumors that require chemotherapy.¹⁸³ However, the BEP regimen is still associated with the potential for serious toxicity, including bleomycin-induced lung damage, etoposide-induced leukemia, renal dysfunction, hypertension, and Raynaud phenomenon. Furthermore, the added benefit of BEP when compared to etoposide and cisplatin (without bleomycin) or even single-agent platinum has not been formally demonstrated. Thus, there may be circumstances in which the clinician may choose other platinum-based regimens in this disease, as opposed to BEP, especially in the older patient who cannot tolerate bleomycin due to underlying pulmonary disease, or in the young patient who is not willing to accept the small chance of etoposide-induced leukemia. In this regard, it has been shown that combined paclitaxel and carboplatin has significant activity in patients with sex cord–stromal tumors, with generally improved tolerance compared to BEP.¹⁸⁴ Whether paclitaxel and carboplatin will eventually become the preferred regimen for this disease will require additional study, although it is

a consideration in patients who wish to avoid the toxicity of BEP or those who cannot tolerate BEP due to side effects. A randomized trial comparing paclitaxel and carboplatin with BEP in patients with newly diagnosed, advanced-stage sex cord–stromal tumors of the ovary is currently under way (GOG 264).

Selected patients with stage I disease may be at higher risk of relapse due to the presence of features such as large tumor size (>10 to 15 cm in diameter) and high mitotic count (>4 to 10 mitoses per 10 high-power fields).⁵⁶ Based on the retrospective nature and small size of most series, it is difficult to know whether the prognostic value of tumor size and mitotic rate is independent of stage. The prognostic value of rupture, surface involvement, or age is even less certain. Nonetheless, it is reasonable to consider some form of adjuvant, platinum-based therapy for selected patients with stage I disease who have high-risk features, although the data to support a survival benefit to this approach are lacking at the present time. In such cases, the uncertain benefits of treatment must be weighed against the potential for side effects.

Sex cord–stromal tumors may recur several years after the original diagnosis. Relapses may be associated with abdominal or pelvic discomfort, a mass on pelvic examination, or an asymptomatic rise in serum tumor markers such as estradiol or inhibin. Such recurrences are often limited to the abdomen or pelvis, although may occasionally present with hematogenous spread to the liver, lung, or bone. Locoregional recurrences are treated with surgical resection followed by postoperative therapy such as platinum-based treatment or radiotherapy. In cases in which the recurrence is isolated and can be encompassed in a radiation field, older literature suggests that radiation therapy may be of value for granulosa cell histology. Eventually, patients become resistant to platinum-based chemotherapy, in which case single-agent paclitaxel, or the use of progestational agents or leuprolide, may be considered.⁵⁶

PRIMARY PERITONEAL SEROUS CARCINOMA

PPSC is histologically identical to serous carcinoma of ovarian origin, but typically presents with diffuse peritoneal implants in the absence of a dominant ovarian mass. This entity is thought to represent malignant transformation of peritoneal surface epithelium, which, like ovarian surface epithelium, is derived from coelomic mesoderm.² Another possibility is that PPSC represents secondary seeding of the peritoneal cavity from an occult primary lesion residing in the fallopian tube fimbria.⁵ Initial reports of PPSC involved patients who underwent a prophylactic oophorectomy for a family history of ovarian cancer, but who later developed diffuse intra-abdominal carcinomatosis that resembled ovarian cancer.¹⁸⁵ In other patients with intact ovaries, diffuse carcinomatosis developed that histologically resembled papillary serous ovarian cancer, but without a dominant ovarian mass. In such cases, it is not unusual to observe small tumor implants involving the ovarian surface, although these are the result of generalized peritoneal seeding from a primary tumor mass in the omentum or deep within the pelvis. These two types of clinical presentations eventually led to the recognition that PPSC is a distinct clinical entity that resembles ovarian cancer histologically, clinically, and in its response to treatment.

Some investigators using molecular markers of clonality have proposed that PPSC is more likely to develop in a multifocal fashion, as opposed to most cases of ovarian cancer, which are clonal in origin.¹⁸⁶ Cases of PPSC that are multifocal may reflect a field defect within the peritoneal mesothelial lining. PPSC occurs at a higher incidence in patients with germline mutations in *BRCA1* and *BRCA2*.³⁵

The differential diagnosis for PPSC is similar to that of epithelial ovarian carcinoma. On occasion, poorly differentiated PPSC may be difficult to distinguish from other entities such as metastatic breast cancer to the abdominal cavity. In such cases, expression of

GCDFP may be helpful, as this marker is highly specific for breast and salivary gland tumors and is usually negative for Müllerian origin tumors such as PPSC or ovarian primaries. The utility of GCDFP as a marker for breast cancer is limited by rather low sensitivity, being positive in only about 50% of cases. Other entities that may rarely be confused with PPSC include peritoneal mesothelioma, gastric or pancreatic cancers, and hepatobiliary tumors.

Patients with PPSC present in a similar fashion to those with epithelial ovarian cancer, although they may not have an adnexal mass on ultrasound or pelvic examination. The abdominal examination may reveal ascites and an omental mass. The stool does not contain blood, and the hematocrit usually does not suggest an iron deficiency anemia (features that would be more suggestive of a gastrointestinal primary site).

In appropriate surgical candidates, an exploratory laparotomy is usually necessary to establish the histologic diagnosis and to perform tumor cytoreduction. Given the more diffuse nature of this entity, almost all patients with PPSC present with stage III or IV disease. The principles of treatment are the same as those for epithelial ovarian cancer. Primary surgical cytoreduction should be performed, followed by combination chemotherapy with paclitaxel and carboplatin. The prognosis of patients with PPSC is likely to be the same, when corrected for stage and debulking status, as for epithelial ovarian cancer.

As PPSC may sometimes be associated with germline mutations in *BRCA1* and *BRCA2*, a careful family history is important in patients with this entity. In addition, individuals with germline *BRCA1* or *BRCA2* mutations who have undergone prophylactic bilateral salpingo-oophorectomy should be informed that there is a risk for developing PPSC, sometimes many years after the prophylactic procedure has been performed. In a series reported by Piver et al.,¹⁸⁷ 6 of 324 women developed PPSC from 1 to 27 years after prophylactic surgery. There is currently no effective screening procedure that enables early detection of PPSC in this clinical setting.

FALLOPIAN TUBE CANCER

Fallopian tube cancer is a rare disease, with only a few hundred new cases diagnosed annually in the United States.¹ Most tubal carcinomas represent papillary serous adenocarcinoma arising within the lumen of the tube, although other Müllerian histologies such as endometrioid tumors may occur. A minority of fallopian tube carcinomas are bilateral at the time of diagnosis. In contrast to patients with ovarian cancer, the majority of patients with tubal carcinoma are diagnosed with disease confined to the tubes and pelvic structures. However, fallopian tube cancer appears to have

a higher propensity for retroperitoneal lymph node spread compared to epithelial ovarian cancer. Advanced-stage disease may occur with a pattern of IP dissemination similar to that observed for epithelial ovarian cancer.

Postmenopausal vaginal bleeding may bring patients with fallopian tube cancer to medical attention. Hydrops tubae profluens, characterized by colicky lower abdominal pain relieved by profuse serous yellow intermittent vaginal discharge, occurs in a minority of cases, but intermittent abdominal pain and leucorrhea are common presentations. Tubal distention produces more intense pain than is usually reported by patients with ovarian cancer. Occasionally, a Papanicolaou smear revealing abnormal glandular cells with negative cervical or endometrial findings may lead to the diagnosis of fallopian tube carcinoma. As for ovarian cancer and PPSC, fallopian tube cancer occurs at higher frequency in patients with germline mutations of *BRCA1* and *BRCA2*, thus requiring a careful family history in affected individuals.⁵⁰

Differentiation of a primary fallopian tube cancer from metastatic ovarian carcinoma can sometimes be difficult. Apart from a dominant mass arising within the fallopian tube lumen, the main criterion used to establish the diagnosis of a primary fallopian tube carcinoma is histologic evidence of a transition between in situ carcinoma and invasive malignancy within the fallopian tube epithelium. In cases where it is impossible to determine whether the tumor began in the fallopian tube and spread to the ovary, or began in the ovary and spread to the lumen of the fallopian tube, the tumors are referred to as *tubo-ovarian carcinoma*.

Survival is partly dependent on the depth of invasion of the primary lesion.¹⁷⁷ For intramucosal lesions, the 5-year survival is 91%, compared with 53% for tumors that invade the muscular wall, and <25% for tumors that have penetrated the tubal serosa. Histologic differentiation and lymphatic capillary space involvement may also have prognostic significance.¹⁸⁸

The surgical management and staging system of fallopian tube carcinoma is identical to that of patients with epithelial ovarian cancer. Patients rendered into a minimal residual disease state after cytoreductive surgery appear to have an improved prognosis. Postoperatively, it is reasonable to use combination chemotherapy with paclitaxel and carboplatin in patients with fallopian tube carcinoma that has spread beyond the tube. In addition, patients with disease limited to the tubal lumen may also be reasonable candidates for postoperative adjuvant treatment, based on features such as muscle wall invasion, serosal extension, or high-grade histology. However, the survival benefit of platinum-based adjuvant therapy for early stage fallopian tube cancer has not been formally demonstrated in randomized trials due to the rarity of this disease.

77 Genetic Testing in Ovarian Cancer

Scott M. Weissman, Shelly M. Weiss, and Anna C. Newlin

INTRODUCTION

Ovarian cancer is responsible for ~3% of all cancers among women, and in 2014, there will be ~21,980 new cases and 14,270 deaths from this cancer.¹ Given this fact, it is of critical importance to identify women who face an elevated risk for ovarian cancer to allow for early detection or prevention. A number of risk factors (e.g., nulliparity, early menarche, late menopause) for ovarian cancer have been identified and reviewed by others.²⁻⁴ By far, the most important risk factor is family history. Having one first-degree relative with ovarian cancer increases the lifetime risk from 1.4% (average risk) to 5% and at least 7% with two or more first-degree relatives.⁵ However, in families with two or more cases of ovarian cancer, there may be a hereditary cause for the cancer, which in turn would result into higher lifetime ovarian cancer risks. Historically, it was believed that ~10% of ovarian cancers were due to an underlying hereditary syndrome, but more recent data indicate that just two syndromes (hereditary breast and ovarian cancer syndrome and Lynch syndrome) account for at least 20% of ovarian cancers, and overall, at least 25% of newly diagnosed cases are due to a hereditary mutation in a single gene⁶⁻⁸; this suggests that a much larger proportion of ovarian cancer cases is hereditary in nature than originally thought (Fig. 77.1). This chapter reviews ovarian cancer within the context of known hereditary cancer syndromes. In addition, we address some of the newer genes ovarian cancer has been linked to as clinical genetic testing for some of these genes are quickly becoming available to health-care professionals.

HEREDITARY BREAST AND OVARIAN CANCER SYNDROM (THE *BRCA1* AND *BRCA2* GENES)

Hereditary breast and ovarian cancer syndrome due to mutations in the *BRCA1* and *BRCA2* (*BRCA1/2*) genes is the most common cause of hereditary ovarian cancer, including fallopian tube and primary peritoneal cancer. Anywhere from 0.125% to 0.20% of the general population carry mutations in *BRCA1/2* compared with 15% of women with a diagnosis of invasive ovarian cancer.^{6,8-10} The contribution of the *BRCA1/2* genes to ovarian cancer is even greater in certain ethnicities that have higher *BRCA1/2* mutation prevalence rates (e.g., Polish, Ashkenazi Jewish [AJ], French Canadian). For example, the prevalence of *BRCA1/2* mutations in individuals of AJ ancestry and women of AJ ancestry with ovarian cancer is ~2.3% and ~30% to 40%, respectively.¹¹⁻¹³ Because of the strong connection between ovarian cancer and *BRCA1/2*, multiple professional societies and organizations recommend genetic counseling and testing for any woman with ovarian cancer regardless of age at onset or family history (Table 77.1). The current sensitivity of *BRCA1/2* genetic testing at the commercial laboratory is ~90% for identifying mutations in either gene.

The lifetime risk of developing ovarian cancer differs between the two genes. A number of studies over the years have quantified

the lifetime risk²⁰⁻²⁶; however, two large meta-analyses suggest an ~40% and 20% lifetime risk for *BRCA1* and *BRCA2* mutation carriers, respectively.^{27,28} In 1997, Gayther et al.,²⁹ in an effort to determine whether there were any genotype-phenotype correlations associated with *BRCA2* mutations, identified a region in exon 11 of *BRCA2* between nucleotides 3,035 and 6,629 that appeared to confer a further increased risk of ovarian cancer; they coined this region the “ovarian cancer cluster region” (OCCR). A follow-up study of the OCCR in families from the Breast Cancer Linkage Consortium (which included the families from the study by Gayther et al.²⁹) further refined the OCCR to nucleotides 3,059 to 4,075 and 6,503 to 6,629, but found that the phenotype of increased ovarian cancer may actually be due to a reduced breast cancer risk.³⁰ Regardless, the potential difference in ovarian cancer risk was not significant enough to affect management recommendations. In addition to genotype-phenotype associations, researchers have studied other genetic modifiers (e.g., single-nucleotide polymorphisms) that can influence ovarian cancer risk in *BRCA1/2* mutation carriers, but these data need maturation before testing for genetic modifiers can be used clinically.³¹⁻³⁴

The average age at onset of ovarian cancer is between 49 and 53 years for *BRCA1* and 55 and 58 years for *BRCA2* compared with 63 years in the general population.^{6,8,35-37} Unlike breast cancer, women with a diagnosis of very early-onset ovarian cancer (>40 years) are significantly less likely to harbor *BRCA1/2* mutations.^{8,26,35,38,39} This is in part due to the fact that early-onset ovarian cancers are more likely to be associated with borderline tumors, earlier stages, and more favorable histologic characteristics, none of which are typical of *BRCA1/2*-related ovarian cancer.⁴⁰

BRCA1/2-associated ovarian cancers are almost uniformly epithelial in origin and, for the most part, are invasive and nonmucinous; there are case reports of germ cell and stromal tumors in *BRCA1/2* mutation carriers. Mucinous and borderline tumors individually account for ~2% of ovarian tumors identified in *BRCA1/2* mutation carriers; this percentage is the same for both prospective and retrospective analyses, which are nicely summarized by Evans et al.⁴¹ Compared with sporadic ovarian cancers, *BRCA1/2* ovarian cancers are more often of serous histology, higher grade, and solid type, and have intact p53 staining on immunohistochemistry (IHC).^{39,41-44} It is important to note that other histologic findings are seen in mutation carriers (e.g., endometrioid, clear cell, papillary), and one study found more giant cell-type cancers in *BRCA1* mutation carriers compared with controls.⁴² Several smaller studies have found that *BRCA1/2*-related ovarian cancers have a better prognosis compared with ovarian cancers in nonmutation carriers.^{39,45-48} This finding seems to have been confirmed as a recent large pooled analysis of 26 observational studies comparing 3,879 *BRCA1/2* ovarian cancers and 2,666 noncarriers found the 5-year survival for *BRCA2* carriers was 52%, 44% for *BRCA1* carriers, and 36% for noncarriers.⁴⁴ The survival difference remained after adjusting for age at diagnosis, stage, histology, and grade.

One potential reason for the differences in survival may be that *BRCA1/2*-related ovarian cancers respond better to platinum-based agents.^{45,48} *BRCA1/2* repair DNA damage through homologous recombination and platinum agents are particularly active

Figure 77.1 Genes responsible for hereditary ovarian cancer (including fallopian tube and primary peritoneal cancer). Other genes include *BARD1*, *BRIP1*, *CHEK2*, *MRE11*, *MSH6*, *NBN*, *PALB2*, *RAD50*, *RAD51C*, and *TP53*. (Data derived from Walsh T, Casadei S, Lee MK, et al. Mutations in 12 genes for inherited ovarian cancer, fallopian tube, and peritoneal carcinoma identified by massively parallel sequencing. *Proc Natl Acad Sci U S A* 2011;108:18032–18037.)

in cells deficient in homologous recombination.^{48,49} It is through this pathway that another class of drugs called poly(ADP-ribose) polymerase (PARP) inhibitors has been developed to help treat *BRCA1/2*-related cancers. Unlike platinum agents targeting homologous recombination, PARP inhibitors block repair of single-strand DNA breaks through base excision repair, which in turn can lead to double-strand breaks that cannot be repaired by *BRCA1/2*-deficient tumor cells at the same time sparing normal cells.^{50–52} A number of phase 1 and phase 2 trials have been reported, and clinical trials continue to study PARP inhibitors in both ovarian and breast cancers.^{53–56}

Identifying women who have a *BRCA1/2* mutation would ideally lead to women either being diagnosed with ovarian cancer at earlier stages or preventing ovarian cancer altogether. When counseling women who have tested positive for a *BRCA1/2* mutation, it is these central tenets, ovarian cancer screening versus prevention, that guide discussions. Current National Comprehensive Cancer Network® Guidelines for managing ovarian cancer risk include the recommendation for risk-reducing bilateral salpingo-oophorectomy (RRSO) between the ages of 35 and 40 years when

TABLE 77.1

Societies or Organizations with Position Statements Recommending *BRCA1/2* Genetic Counseling and/or Testing Related to Ovarian Cancer

Society Organization	Year	Recommendation
American College of Medical Genetics ¹⁴	2005	One or more cases of OC and at least one relative on the same side of the family with BC (at any age)
American College of Obstetrics and Gynecology ¹⁵	2009	Genetic risk assessment is recommended for patients with $\geq 20\%$ – 25% chance of having a predisposition to OC (FT and PPC included), which include women with a personal history of OC; women with OC and an FDR or SDR with OC, premenopausal BC or both; women with BC ≤ 50 y and an FDR or SDR with OC Genetic risk assessment is helpful for patients with a 5%–10% chance of having a predisposition to OC, which include women at any age with OC, PPC, or FT of high grade, serous histology
American Society of Breast Surgeons ¹⁶	2006	A personal or family history of OC (particularly nonmucinous types) should have access to <i>BRCA</i> testing
National Comprehensive Cancer Network ¹⁷	2012	Genetic risk assessment should be offered to any woman with BC who has an FDR, SDR, or TDR with epithelial OC, FT, or PPC at any age; any woman with OC, FT, or PPC; any unaffected individual with a family history of more than one OC from the same side of the family <i>BRCA1/2</i> genetic testing should be offered to any woman with BC < 50 y with more than one FDR, SDR, or TDR with epithelial OC, FT, or PPC at any age; any woman with BC regardless of age when there are more than two FDR, SDR, or TDR with epithelial OC, FT, or PPC at any age; any woman with epithelial OC, FT, or PPC; any individual with PC at any age with more than two FDR, SDR, or TDR with BC and/or OC and/or PC at any age; an unaffected individual who has an FDR or SDR who meet any of the above criteria or a TDR with BC and/or OC/FT/PPC with more than two FDR, SDR, or TDR with BC (one < 50 y) and/or OC
Society of Gynecologic Oncologists ¹⁸	2007	Genetic risk assessment is recommended for patients with $\geq 20\%$ – 25% chance of having a predisposition to OC (FT and PPC included), which include women with a personal history of OC and BC; women with OC and an FDR, SDR, or TDR with OC or BC ≤ 50 y; women with OC at any age who are AJ; women with BC ≤ 50 y and an FDR, SDR, or TDR with OC Genetic risk assessment is helpful for patients with a 5%–10% chance of having a predisposition to OC, which include women with OC or BC at any age and two or more FDR, SDR, or TDR with BC at any age (particularly if at least one BC is ≤ 50 y); unaffected women with an FDR or SDR who meet the above criteria
US Preventative Services Task Force ¹⁹	2005	Unaffected women whose family history is suggestive of a <i>BRCA1/2</i> mutation should be referred for genetic counseling and evaluation for <i>BRCA1/2</i> testing; this includes: Non-AJ women—a combination of both BC and OC among FDR and SDR; a combination of two or more FDR or SDR with OC regardless of age at onset; an FDR or SDR with both BC and OC at any age AJ women—any FDR (or two SDRs on the same side of the family) with OC

OC, ovarian cancer; BC, breast cancer; FT, fallopian tube cancer; PPC, primary peritoneal cancer; PC, pancreatic cancer; FDR, first-degree relative (parent, child, sibling); SDR, second-degree relative (aunt/uncle, grandparent, grandchild, niece/nephew, half-sibling); TDR, third-degree relative (first cousin, great aunt/uncle, great grandparent, great grandchild); AJ, Ashkenazi Jewish.

childbearing is complete; for women not choosing RRSO, transvaginal ultrasound and CA-125 are recommended every 6 months starting at age 30 years or 5 to 10 years before the earliest age at onset of ovarian cancer in the family.¹⁷ Surgical prevention is recommended over screening for two main reasons. First, many women can receive a dual risk reduction with one surgery. RRSO has been shown to reduce ovarian cancer risk by 80% to 95%,^{57–60} and breast cancer risk by 50% (for premenopausal women) in *BRCA1/2* mutation carriers.^{59–62} Anywhere from 2.5% to 17%^{63–65} of women who undergo RRSO are found to have an occult ovarian, fallopian tube, or primary peritoneal cancer upon pathology review, emphasizing the need for a “high-risk” pathologic examination of the tissues.⁶⁶ However, after surgery, women may still face an ~4% risk of developing primary peritoneal cancer over the course of 20 years.⁵⁷ The second major reason surgery is recommended over screening is that ovarian cancer screening is ineffective at detecting ovarian cancer at early stages⁶⁷; the pros and cons of ovarian cancer screening with transvaginal ultrasound and CA-125 have been reviewed elsewhere.⁴ A second option for reducing ovarian cancer risk is through oral contraceptive (OCP) use. OCPs use can reduce ovarian cancer risk by ~50% with 5 years of use; the benefit has been shown for both *BRCA1* and *BRCA2* carriers.^{68,69} However, it is worth noting that data are conflicting about whether OCP use can increase breast cancer risk, so it is important to take into account a woman’s age, family history, and genetic test results before making recommendations to use OCPs.^{70–73} Recently, researchers at Stanford created an online decision tool to aid female *BRCA1/2* mutation carriers in conjunction with a health-care provider making decisions with respect to cancer screening and surgical prevention⁷⁴; the tool is available at <http://brcatool.stanford.edu>.

LYNCH SYNDROME

Approximately 2% to 4% of ovarian cancer is believed to be associated with Lynch syndrome, also referred to as hereditary non-polyposis colorectal cancer syndrome.⁷⁵ Lynch syndrome is an autosomal dominant cancer predisposition syndrome characterized by a significantly increased lifetime risk of colorectal cancer (~30% to 70%) and extracolonic malignancies of the endometrium (28% to 60%), stomach (6% to 9%), small bowel (3% to 4%), urinary tract (3% to 8%), central nervous system (4%), hepatobiliary tract (1%), and sebaceous skin lesions (1% to 9%).⁷⁶

Lynch syndrome is caused by germline mismatch repair (MMR) gene mutations in *MLH1*, *MSH2*, *MSH6*, and *PMS2*. Alterations in these four genes account for approximately 36%, 38%, 14%, and 15% of Lynch syndrome, respectively.⁷⁷ In addition, germline deletions in *EPCAM* inactivate *MSH2* through epigenetic silencing in a small proportion of individuals with Lynch syndrome.⁷⁸ Variations in cancer risk have been noted among the four MMR genes. An increased risk for endometrial cancer and slightly decreased risk for colorectal cancer are observed in families with germline *MSH6* mutations compared with families with *MLH1* and *MSH2* mutations.⁷⁹ Germline mutations in *PMS2* are associated with the lowest overall risk for Lynch syndrome-associated malignancies.⁸⁰

Lynch syndrome is diagnosed clinically within families meeting either the Amsterdam I or Amsterdam II criteria^{81,82} (Table 77.2). Although fulfillment of the Amsterdam criteria is a significant predictor of identifying a germline MMR gene mutation in a family, it is well known that at least 25% of families affected with Lynch syndrome do not meet the Amsterdam criteria.⁸³

The lifetime risk of ovarian cancer in Lynch syndrome is estimated to be anywhere between 4% and 11%,^{78,84,85} with a mean age of diagnosis at 42.7 years.⁷⁵ In this series, approximately one-third of the individuals were younger than 40 years at the time of diagnosis ($n = 80$). Approximately 94% of ovarian tumors in Lynch syndrome are invasive epithelial in origin, with borderline

TABLE 77.2

Amsterdam Criteria for Clinical Diagnosis of Lynch Syndrome

Amsterdam I Criteria⁸¹

- Three affected family members with histologically verified colorectal cancer, one of whom is a first-degree relative of the other two
- Colorectal cancer in at least two successive generations
- At least one of the affected relatives with colorectal cancer is diagnosed at <50 y
- Familial adenomatous polyposis has been excluded

Amsterdam II Criteria⁸²

- Three affected family members with a Lynch syndrome-associated cancer (colon, endometrial, small bowel, ureter, or renal pelvis), one of whom is a first-degree relative of the other two
- Two cancer diagnoses in at least two successive generations
- At least one of the affected relatives with a Lynch syndrome-associated cancer is diagnosed at <50 y
- Familial adenomatous polyposis has been excluded

and granulosa cell tumors representing ~4% of cases. Lynch-related ovarian tumors are most frequently moderately or well differentiated. Of note, synchronous endometrial cancer was identified in 21.5% of cases. In a meta-analysis of 159 cases of MMR-related ovarian cancers, histologic subtypes included serous (32%), endometrioid (29%), mixed (24%), mucinous (19%), and clear cell (18%).⁸⁷ In a study of individuals with Lynch-related ovarian cancer compared with individuals with sporadic ovarian cancer, no significant difference was observed in survival rate, although the total number of Lynch-related ovarian cancers was small ($n = 277$).⁸⁷

Lynch syndrome is one of a few hereditary cancer syndromes that have more than one method available to make a genetic diagnosis by identifying MMR deficiency including (1) tumor studies, specifically microsatellite instability (MSI) and IHC, and (2) germline genetic testing (typically includes DNA sequencing and a technology to look for large structural rearrangements). In initiating a genetic evaluation for Lynch syndrome, tumor studies are generally the recommended first-line tests.⁷⁸ However, because the majority of available data on performing MSI and IHC pertain to colorectal and endometrial tumors,^{76–78} it is not certain whether tumor studies on ovarian cancers as a first-line approach are valid. Approximately 12% of unselected ovarian cancers will have an MSI-high phenotype.⁷⁵ In an analysis of 52 ovarian carcinomas in a population who received a diagnosis at younger than 50 years, defects in MMR expression were identified in 10% of cases using MSI and IHC.⁸⁸ Domanska et al.⁸⁹ evaluated ovarian carcinomas in a population who received a diagnosis at younger than 40 years and found MMR deficiency with IHC in ~6% of cases. If tumor studies are indicative of Lynch syndrome (results show the tumor to be MSI-high and/or loss of ≥ 1 MMR proteins), germline genetic testing should be offered and will identify a deleterious mutation anywhere from 20% to 70% of the time.⁷⁸ Molecular analysis is widely available for the four MMR genes and *EPCAM*. However, if tumor studies are performed on an ovarian cancer, and the results are not indicative of Lynch syndrome, given the paucity of data, Lynch syndrome cannot conclusively be ruled out, and germline genetic testing may still be warranted, depending on the patient’s age at onset and family history.

If a tumor specimen is not available, germline genetic testing may be initiated at the outset. A recent abstract showed that up to 4% of unselected ovarian cancers may be found to have a germline mutation in *MLH1*, *MSH2*, or *MSH6*.⁷ If a patient with ovarian cancer needs a genetic evaluation for Lynch syndrome, the ideal approach would be for the health-care provider to have a detailed

discussion about the pros and cons of each testing methodology with the patient, so that the patient and provider can jointly come to a decision about the best approach given the rest of the family history of cancer.

Current ovarian cancer management guidelines for women with Lynch syndrome include prophylactic hysterectomy and bilateral salpingo-oophorectomy after completion of childbearing; there is not enough data to support routine ovarian cancer screening with transvaginal ultrasound and CA-125 blood tests for women, although it may be considered at the clinician's discretion.⁹⁰

PEUTZ-JEGHERS SYNDROME

Peutz-Jeghers syndrome (PJS) is a rare autosomal dominant inherited disorder characterized by gastrointestinal hamartomatous polyposis, mucocutaneous melanin pigmentation, and benign and malignant tumors of the gastrointestinal tract, breast, ovary, cervix, and testis. The incidence of PJS is unknown but has been estimated between 1:8,300 and 1:200,000 births.^{91,92}

In contrast to the other hamartomatous syndromes in which polyps occur most commonly in the colon, PJS-related polyps occur most commonly in the small intestine (90%), although they can also occur elsewhere in the gastrointestinal tract including the stomach (25%) and large bowel (33%), and may also develop outside the digestive tract in the uterus, bladder, lungs, and nasal passages.⁹³ Gastrointestinal polyps can result in chronic bleeding and anemia, and cause recurrent obstruction and intussusception requiring repeated laparotomy and bowel resection. Polyposis usually becomes symptomatic in early adolescence, although intestinal obstruction has been reported in infancy.⁹⁴ Polyps may be of mixed histologic types (hyperplastic, adenomatous) but are mostly hamartomatous and may number from one to dozens.

The characteristic mucocutaneous hyperpigmentation presents in childhood as dark blue to dark brown macules around the mouth, eyes, and nostrils; in the perianal area; and on the buccal mucosa. Hyperpigmented macules on the fingers are common and can also occur on the feet and in the axillae. The macules may fade in puberty and adulthood; however, pigmented areas inside the mouth or on the gums tend to persist into adulthood.⁹⁵

In a single individual, a clinical diagnosis of PJS may be made when any one of the following is present⁹⁶:

- Two or more histologically confirmed PJS polyps
- Any number of PJS polyps detected in one individual who has a family history of PJS in close relative(s)
- Characteristic mucocutaneous pigmentation in an individual who has a family history of PJS in close relative(s)
- Any number of PJS polyps in an individual who also has characteristic mucocutaneous pigmentation

Individuals with PJS are at increased risk for a wide variety of epithelial malignancies (colorectal, gastric, pancreatic, breast, and ovarian cancers). The estimated incidence of cancer among patients with PJS was identified as 18-fold higher than that in the general population by Giardello et al.,⁹⁷ although a recent meta-analysis by van Lier et al.⁹⁸ placed the lower end of the range at close to 10-fold.

Females with PJS are at risk for sex cord tumors with annular tubules (SCTAT), a distinctive benign ovarian neoplasm, the predominant component of which has morphologic features intermediate between those of the granulosa cell tumor and those of the Sertoli cell tumor; focal differentiation into either tumor may occur. Up to 36% of women who have SCTATs are found to have PJS.⁹⁹ SCTATs may cause sexual precocity and infertility, and they are generally considered benign, but may become malignant. Of the 74 cases that formed the basis of the investigation of Young et al.,⁹⁹ 27 were associated with PJS; these tumors were all benign and were typically multifocal, bilateral, very small or even microscopic in size, and calcified. Although SCTATs predominate

as the ovarian tumors identified in PJS, other histologic findings have been identified including granulosa cell tumors, cystadenomas, nonneoplastic cysts, Brenner tumors, dysgerminomas, and Sertoli cell tumors.¹⁰⁰ Patients have ranged in age from 4.5 to 60 years at the time their ovarian tumors were diagnosed; more than half were 22 years or younger.

In 1998, investigators discovered that mutations in the serine threonine kinase 11 gene (*STK11*, also known as *LKB1* gene) cause PJS.^{101,102} Genetic testing for clinical practice is now widely available; mutations in the *STK11* gene are detected in 50% to 90% of individuals with PJS.^{103–106} The variability in detection rates is likely due to differences in selection criteria and testing methodologies. The majority of mutations are truncating or missense mutations, which eliminate the kinase function of the protein. However, up to 30% of mutations may be large deletions, which would not be detected by sequencing alone.¹⁰⁷ Therefore, the optimal approach for genetic testing would include both full sequencing and analysis for large deletions and duplications. Although the addition of large deletion analysis to *STK11* testing has greatly increased the mutation detection rate, there is still a very small portion of individuals and families meeting the clinical diagnostic criteria in which a deleterious mutation cannot be identified.^{108,109} There are reports of families with a clinical diagnosis of PJS who do not link to 19p13.3, suggesting that there might be another genetic locus causing PJS in rare families.¹¹⁰

Current management guidelines for individuals with PJS are reflected in the current National Comprehensive Cancer Network Guidelines[®] (NCCN Guidelines[®]) (Table 77.3)⁹⁰ and with respect to ovarian cancer screening include consideration of an annual transvaginal ultrasound starting between the ages of 18 and 20 years. These recommendations reflect expert opinion as no controlled trials have been published on the effectiveness of surveillance in PJS.⁹⁶ With respect to uncontrolled data, German investigators recently reported a surveillance strategy that led to the early detection of 50% of all cancers (5/10) diagnosed in 31 patients with PJS.¹⁰⁴ Malignancies that occur in PJS, including SCTATs, should be treated in a standard manner, and conservative management of gonadal tumors in females is deemed appropriate.

NEWER GENES

RAD51C

RAD51C, a *RAD51* paralog, is an integral part of the DNA double-strand break repair through homologous recombination. Biallelic *RAD51C* mutations have recently been identified in patients with Fanconi anemia, and subsequently, monoallelic mutations have been identified in up to 2.9% of highly penetrant breast and ovarian cancer families who previously screened negative for *BRCA1/2* mutations.^{111–114} *RAD51C* families show major similarities in ovarian cancer occurrence with families carrying *BRCA1/2* mutations. Moreover, as these families show apparently complete segregation of the mutation with the cancer phenotype, the penetrance of *RAD51C* mutations is predicted to be at least comparable to that of *BRCA1/2* mutations.

In comparison to the younger age at onset of *BRCA1/2*-associated ovarian cancers, the reported mean age at onset for ovarian cancer in women with *RAD51C* mutations ranges from 57.7 to 77.0 years (range, 50 to 81 years).^{112,115,116} *RAD51C*-associated ovarian tumors are almost uniformly epithelial in origin and, for the most part, are invasive and nonmucinous.^{112,115,116} Other reported histologic findings include invasive endometrioid adenocarcinoma, malignant cystadenoma, and fallopian tube carcinoma.¹¹⁶

Two recurrent founder mutations in the *RAD51C* gene have been identified in Finnish breast and/or ovarian cancer families, suggesting that founder mutations in this gene may exist in other ethnic groups.¹¹⁶

TABLE 77.3

Adapted National Comprehensive Cancer Network Guidelines for Peutz-Jeghers Cancer Screening

Site	Screening Procedure and Interval	Initiation Age
Breast	Mammogram and breast magnetic resonance imaging (MRI) annually Clinical breast examination every 6 mo	~25 y
Colon	Colonoscopy every 2–3 y	~Late teens
Stomach	Upper endoscopy every 2–3 y	~Late teens
Pancreas	Magnetic resonance cholangiopancreatography or endoscopic ultrasound every 1–2 y CA-19-9 at similar intervals	~30–35 y
Small intestine	Small-bowel visualization (computed tomography or MRI enterography) baseline at 8–10 y with follow-up interval based on findings but at least by age 18 y, then every 2–3 y, although this may be individualized, or with symptoms	~8–10 y
Ovary	Pelvic examination and Papanicolaou smear annually	~18–20 y
Cervix Uterus	Consider transvaginal ultrasound	
Testes	Annual testicular examination and observation for feminizing changes	~10 y
Lung	Provide education about symptoms and smoking cessation No other specific recommendations have been made

RAD51D

Identification of *RAD51C* mutations in families with breast and ovarian cancer prompted investigations into the role of another *RAD51* paralog, *RAD51D*, in cancer susceptibility. Monoallelic mutations have been identified in up to 0.9% of highly penetrant breast and ovarian cancer families who previously screened negative for *BRCA1/2* mutations; it is estimated that ~0.6% of unselected individuals with ovarian cancer will harbor *RAD51D* mutations.¹¹⁷ Loveday et al.¹¹⁷ found that mutations were more prevalent in families with more than one ovarian cancer: Four mutations were identified in 235 families (1.7%) with two or more ovarian cancer cases. Remarkably, three mutations were found in 59 families (5.1%) with three or more ovarian cancer cases.

RAD51D-associated ovarian tumors are almost uniformly epithelial in origin, with one report of a clear-cell ovarian carcinoma.¹¹⁸ The relative risk of ovarian cancer for *RAD51D* mutation carriers is estimated to be 6.3, which equates to ~10% cumulative risk by age 80 years.¹¹⁷

The current studies, although few in number, clearly show that *RAD51D* is an ovarian cancer predisposition gene, but further studies in familial and sporadic ovarian cancer series would be of value to further clarify the risks of ovarian cancer. Cells deficient in *RAD51D* are sensitive to treatment with a PARP inhibitor, suggesting a possible therapeutic approach for cancers arising in *RAD51D* mutation carriers.¹¹⁷

Given the recent identification of their contribution to ovarian cancer susceptibility, *RAD51C*, as well as *RAD51D*, has to be validated in larger mutation positive cohorts to generate reliable estimations of the clinical implications of carrying germline mutations as well as determine appropriate screening and cancer prevention strategies.

CONCLUSION

The puzzle of identifying genes causative of hereditary ovarian cancer continues to be deciphered. Historically, *BRCA1* and *BRCA2* have been the only genes considered when evaluating families suggestive of a hereditary ovarian cancer syndrome, but new studies have linked ovarian cancer to other known hereditary syndromes such as Lynch syndrome as well as new genes such as *RAD51C/D*. As genetic testing advances and newer technologies such as next-generation sequencing and whole-exome sequencing are used, additional genes will continue to be discovered. With these discoveries, new insights into ovarian cancer pathogenesis will be understood and hopefully lead to better and more effective treatments such as PARP inhibitors, but more importantly, more women can be identified as being at risk before developing ovarian cancer, leading to increased ovarian cancer prevention.

78 Molecular Biology of Breast Cancer

Shaveta Vinayak, Hannah L. Gilmore, and Lyndsay N. Harris

INTRODUCTION

It has been said that cancer is a genetic disease and can be best understood by studying the DNA alterations that lead to the development of cancer. However, a deeper understanding of carcinogenesis requires insight into how these genetic changes alter cellular programs that lead to growth, invasion, and metastasis. This chapter is presented following the logical progression of DNA to RNA to protein, and it describes, at each step, the lesions that contribute to breast cancer carcinogenesis. The chapter also introduces concepts in epigenetics, microRNAs, and gene expression analyses that illustrate how new biologic discoveries and novel technologies have profoundly affected our understanding of breast cancer pathogenesis and influenced the treatment of patients.

GENETICS OF BREAST CANCER

Breast cancer is a heterogeneous disease fundamentally caused by the progressive accumulation of genetic aberrations, including point mutations, chromosomal amplifications, deletions, rearrangements, translocations, and duplications.^{1,2} Germ-line mutations account for only about 10% of all breast cancers, whereas the vast majority of breast cancers appear to occur sporadically and are attributed to somatic genetic alterations (Fig. 78.1).³

HEREDITARY BREAST CANCER

One of the most important risk factors for breast cancer is family history. Although familial forms comprise nearly 20% of all breast cancers, most of the genes responsible for familial breast cancer have yet to be identified. Breast cancer susceptibility genes can be categorized into three classes according to their frequency and level of risk they confer: rare high-penetrance genes, rare intermediate-penetrance genes, and common low-penetrance genes and loci (Table 78.1).⁴

High-Penetrance, Low-Frequency Breast Cancer Predisposition Genes

BRCA1 and BRCA2

BRCA1 and *BRCA2* mutations account for approximately half of all dominantly inherited hereditary breast cancers. These mutations confer a relative risk of breast cancer 10 to 30 times that of women in the general population, resulting in a nearly 85% lifetime risk of breast cancer development.⁵ *BRCA1* and *BRCA2* mutation carriers are quite rare among the general population; however, the prevalence is substantially higher in certain founder

populations, most notably in the Ashkenazi Jewish population, where the carrier frequency is 1 in 40.

More than a thousand germ-line mutations have been identified in *BRCA1* and *BRCA2*. Pathogenic mutations most often result in truncated protein products, although mutations that interfere with protein function also exist.^{4,5} Interestingly, the penetrance of pathogenic *BRCA1* and *BRCA2* mutations and age of cancer onset appear to vary both within and among family members. Specific *BRCA* mutations as well as gene–gene and gene–environment interactions as potential modifiers of *BRCA*-related cancer risk are areas of active investigation.^{6,7} Variation in risk may be explained by genetic modifiers that are different for both *BRCA1* and *BRCA2* mutation carriers. These alleles have been primarily identified from studies of the Consortium of Investigators of Modifiers of *BRCA1/2* (CIMBA).⁸ The commonly identified single-nucleotide polymorphisms (SNP) that modify *BRCA1/2* are listed in Table 78.2 with their gene location, associated risks, and frequency. Evidence from published studies shows that these modifying SNPs combine multiplicatively, and therefore, may significantly alter a mutation carrier's risk depending on the number of risk alleles present.^{9,10} In addition to retrospective studies, more recently, common breast cancer susceptibility alleles were evaluated prospectively to assess cancer risk conferred among unaffected *BRCA1/2* mutation carriers.¹¹ A risk score was constructed and divided into tertiles for seven *BRCA2*-associated variants and four *BRCA1*-associated variants. Among *BRCA2* mutation carriers, breast cancer risks were significantly different when stratified by tertiles; women in the highest tertile had a breast cancer risk of 72% by age 70 compared to 20% for those in the lowest tertile. There was no significant difference by risk score for *BRCA1* mutation carriers.

BRCA1-related breast cancers are characterized by features that distinguish them from both *BRCA2*-related and sporadic breast cancers.⁴ *BRCA1*-related tumors typically occur in younger women and have more aggressive features, with high histologic grade, high proliferative rate, aneuploidy, and absence of estrogen and progesterone receptors and human epidermal growth factor receptor 2 (HER2). This *triple-negative* phenotype of *BRCA1*-related breast cancers is further characterized by a *basallike* gene expression profile of cytokeratins 5/6, 14, and 17, epidermal growth factor, and P-cadherin.¹² Although *BRCA1* and *BRCA2* genes encode large proteins with multiple functions, they primarily act as classic tumor suppressor genes that function to maintain genomic stability by facilitating double-strand DNA repair through homologous recombination.^{12,13} When loss of heterozygosity (LOH) occurs via loss, mutation, or silencing of the wild-type *BRCA1* or *BRCA2* allele, the resultant defective DNA repair leads to rapid acquisition of additional mutations, particularly during DNA replication, and ultimately sets the stage for cancer development.

The integral role of *BRCA1* and *BRCA2* in double-strand DNA repair holds potential as a therapeutic target for *BRCA*-related breast cancers. For example, platinum agents cause inter-strand cross-links, thereby blocking DNA replication and leading

Figure 78.1 Genetic susceptibility to breast cancer. Familial breast cancer comprises approximately 20% to 30% of all breast cancers. *BRCA1* and *BRCA2* are the two major high-penetrance genes associated with hereditary breast and ovarian cancer syndrome, which together account for nearly half of inherited breast cancers. Other rare breast cancer susceptibility genes have been identified, such as *CHEK2*, *TP53*, *PTEN*, and *STK11*. Several emerging low-penetrance genes and loci recently discovered by genomewide association studies account for a small proportion of familial breast cancers (<5%). To date, about half of familial breast cancers remain unexplained but are likely attributable to as yet unknown genes and/or polygenic susceptibility. (From Olopade O, Grushko TA, Nanda R, Huo D. Advances in breast cancer: pathways to personalized medicine. *Clin Cancer Res* 2008;14:7988–7999, Fig 1.)

to stalled replication forks. Poly (adenosine diphosphate [ADP]-ribose) polymerase-1 (PARP1) inhibitors additionally show promise as specific therapy for *BRCA*-related tumors. PARP1 is a cellular enzyme that functions in single-strand DNA repair through base excision and represents a major alternative DNA repair pathway in the cell.^{14,15} When PARP inhibition is applied to a background deficient in double-strand DNA repair, as is the case in *BRCA*-related tumor cells, the cells are left without adequate DNA repair mechanisms and ultimately undergo cell cycle arrest, chromosome instability, and cell death.⁴ Given their phenotypic similarities to *BRCA1*-related breast cancers, sporadic basal-like breast tumors may display sensitivity to PARP inhibition as well.¹⁵ Phase II studies are currently under way to explore the use of PARP inhibitors in both *BRCA*- and basal-like, non-*BRCA*-related breast tumors. There is much that remains to be understood about the optimal use of PARP inhibitors. Current challenges include, but are not limited to, identifying robust predictive biomarkers of response that can guide patient selection and understanding variations among PARP inhibitors in clinical development. Differences in potency and the mechanism of action have been well elucidated in recent preclinical studies,^{16–20} and the results of ongoing clinical trials will need to be interpreted in this context. Additionally, recent studies have also identified mechanisms of resistance to PARP inhibitors. One of these important mechanisms includes secondary mutations in the *BRCA1/2* gene that can restore the open reading frame, and therefore, DNA repair functional activity,^{21–23} which renders tumors resistant to PARP inhibitors. Secondly, loss of tumor protein p53 binding protein 1 (TP53BP1) in *BRCA1*-deficient cells can restore DNA repair activity,^{24,25} and this may confer resistance.

Other High-Penetrance Genes

A small number of other high-risk, low-frequency breast cancer susceptibility genes exist, and they include *TP53*, *PTEN*, *STK11/LKB1*, and *CDH1*.^{4–6} These high-penetrance genes confer an eight- to tenfold increase in the risk of breast cancer as compared to noncarriers, but they collectively account for less than 1% of breast cancer cases. Like *BRCA1* and *BRCA2*, these genes are in-

herited in an autosomal-dominant fashion and function as tumor suppressors.²⁶ The hereditary cancer syndromes associated with each gene are usually characterized by multiple cancers in addition to breast cancer, as summarized in Table 78.1.

Moderate-Penetrance, Low-Frequency Breast Cancer Predisposition Genes

Four genes have been identified that confer an elevated but moderate risk of developing breast cancer, namely *CHEK2*, *ATM*, *BRIP1*, and *PALB2* (see Table 78.1). Each of these genes confers approximately a two- to threefold relative risk of breast cancer in mutation carriers, although this risk may be higher in select clinical settings.⁵ Mutation frequencies in the general population are rare, on the order of 0.1% to 1%, although some founder mutations have been identified. Together, these genes account for approximately 2.3% of inherited breast cancer. The moderate relative risk of breast cancer of these genes in conjunction with the low population frequency renders this class of genes very difficult to detect with typical association studies. However, these genes were specifically selected for study as candidate breast cancer genes based on their known roles in signal transduction and DNA repair in close association with *BRCA1* and *BRCA2*.⁶

Low-Penetrance, High-Frequency Breast Cancer Predisposition Genes and Loci

Both candidate gene and genome-wide association studies (GWAS) have identified a low-risk panel of approximately 10 different alleles and loci in 15% to 40% of women with breast cancer (see Table 78.1).⁵ Despite their frequency, the relative risk of breast cancer conferred by any one of these genetic variants alone is minimal, on the order of less than 1.5.⁴ Nevertheless, these alleles and loci may become clinically relevant in their suggestion of interactions with other high-, moderate-, and low-risk genes; these additive or multiplicative relationships could account for a measurable

TABLE 78.1

Breast Cancer Susceptibility Genes and Loci

Gene/Locus	Associated Syndrome and Clinical Features	Breast Cancer Risk	Mutation/Minor Allele Frequency
<i>High-Penetrance Genes</i>			
<i>BRCA1</i> (17q21)	Hereditary breast/ovarian cancer: Bilateral/multifocal breast tumor, prostate, colon, liver, bone cancers	60%–85% (lifetime); 15%–40% risk of ovarian cancer	1/400
<i>BRCA2</i> (13q12.3)	Hereditary breast/ovarian cancer: Male breast cancer, pancreas, gall bladder, pharynx, stomach, melanoma, prostate cancer; also causes D1 Fanconi anemia (biallelic mutations)	60%–85% (lifetime); 15%–40% risk of ovarian cancer	1/400
<i>TP53</i> (17p13.1)	Li-Fraumeni syndrome: Breast cancer, soft tissue sarcoma, central nervous system tumors, adrenocortical cancer, leukemia, prostate cancer	50%–89% (by age 50); 90% in Li-Fraumeni survivors	<1/10,000
<i>PTEN</i> (10q23.3)	Cowden syndrome: Breast cancer, hamartoma, thyroid, oral mucosa, endometrial, brain tumor	25%–50% (lifetime)	<1/10,000
<i>CDH1</i> (16q22.1)	Familial diffuse gastric cancer: Lobular breast cancer, gastric cancer	RR 6.6	<1/10,000
<i>STK11/LKB1</i> (19p13.3)	Peutz-Jeghers syndrome: Breast, ovary, testis, pancreas, cervix, uterine, colon cancers; melanocytic macules of lips/digits; gastrointestinal hamartomatous polyps	30%–50% (by age 70)	<1/10,000
<i>Moderate-Penetrance Genes</i>			
<i>CHEK2</i> (22q12.1)	Li-Fraumeni 2 syndrome: Breast, prostate, colorectal, and brain tumors, sarcomas	OR 2.6 (for 1100delC mutation)	1/100–200 (in certain populations)
<i>BRIP1</i> (17q22)	Breast cancer: Also causes FA-J Fanconi anemia (biallelic mutations)	RR 2.0	<1/1000
<i>ATM</i> (11q22.3)	Ataxia telangiectasia: Breast, ovarian, leukemia, lymphoma, possible stomach/pancreas/bladder cancers; immunodeficiency	RR 2.37	1/33–333
<i>PALB2</i> (16p12)	Breast, pancreatic, prostate cancers: Also causes FA-N Fanconi anemia (biallelic mutations)	RR 2.3	<1/1000
<i>Low-Penetrance Genes and Loci</i>			
<i>FGFR2</i> (10q26)	Breast cancer	OR 1.26	0.38
<i>TOX3</i> (16q12.1)	Breast cancer	OR 1.14	0.46
<i>LSP1</i> (11p15.5)	Breast cancer	OR 1.06	0.3
<i>TGFB1</i> (19q13.1)	Breast cancer	OR 1.07	0.68
<i>MAP3K1</i> (5q11.2)	Breast cancer	OR 1.13	0.28
<i>CASP8</i> (2q33–34)	Breast cancer (protective)	OR 0.89	0.13
6q22.33	Breast cancer	OR 1.41	0.21 (in Ashkenazi Jewish)
2q35	Breast cancer	OR 1.11	0.11–0.52
8q24	Breast cancer	OR 1.06	0.4
5p12	Breast cancer	OR 1.19	0.2–0.31

OR, overall risk; RR, relative risk.

fraction of population risk. For example, association studies of fibroblast growth factor receptor 2 (FGFR2) and mitogen-activated protein kinase kinase kinase 1 (MAP3K1) within *BRCA* families showed that these SNPs conferred an increased risk in the presence of *BRCA2* mutations.

Microsatellite Instability in Breast Cancer

There is emerging data that Lynch syndrome, an autosomal-dominant inherited disorder of cancer susceptibility caused by germ-line mutations in the DNA mismatch repair (MMR) genes

including, *MLH1*, *MSH2*, *MSH5*, and *PMS2*, may increase the risk of breast cancer.²⁷ Mutation carriers are at increased risk of colorectal and other cancers, but its association with breast cancer risk has been controversial. A prospective cohort study using the Colon Cancer Family Registry evaluated cancer risks among unaffected carriers and noncarriers with a pathogenic MMR gene mutation; notably, breast cancer risk was estimated to be fourfold among mutation carriers compared to the general population.²⁷ A systematic review of breast cancer risk studies for Lynch syndrome mutation carriers showed mixed results; 13 studies did not observe an increased risk, whereas 8 studies observed an increased risk of breast cancer ranging from 2- to 18-fold compared to the

SNP, single nucleotide polymorphism.

general population.²⁸ Further studies are needed to determine more precise estimates of breast cancer risk in Lynch syndrome carriers with longer follow-ups. These studies may also guide future breast cancer screening guidelines for this population.

MicroRNA and Cancer Susceptibility

Recent studies suggest that microRNA (miRNA) SNPs may also contribute to breast cancer susceptibility, and miRNAs appear to regulate many tumor suppressor genes and oncogenes via degradation of target miRNAs or repression of their translation. Thus, genetic variations in miRNA genes or miRNA binding sites could affect the expression of tumor suppressor genes or oncogenes and, thereby, affect cancer risk. For example, specific SNPs located within *pre-mir-27a* and *mir-196a-2* genes have been associated with reduced breast cancer risk, which has been confirmed in a recent meta-analysis.^{29,30}

SOMATIC CHANGES IN BREAST CANCER

The vast majority of breast cancers are sporadic in origin, ultimately caused by an accumulation of numerous somatic genetic alterations.¹ Recent data suggest that a typical individual breast cancer harbors anywhere from 50 to 80 different somatic mutations.² Many of these mutations occur as a result of erroneous DNA replication; others may occur through exposure to exogenous and endogenous mutagens. To date, hundreds of candidate somatic breast cancer genes have been identified through GWAS.^{31,32}

Determining the role of each identified mutation in the development of breast cancer remains a substantial challenge. Data suggest that the vast majority of identified somatic DNA mutations in a given tumor are *passenger* mutations, representing harmless, biologically neutral changes that do not contribute to oncogenesis.^{1,2} Conversely, *driver* mutations confer a growth advantage on the cell in which they occur and appear to be implicated in cancer development. By definition, driver mutations are found in candidate cancer genes (CAN).³² A comprehensive catalog of somatic mutations and CAN genes has been accumulated through multiple studies. When specific driver mutations are cataloged among several different breast tumors, a bimodal cancer *genomic landscape* appears, comprising a small number of commonly mutated gene *mountains* among hundreds of infrequently mutated gene *hills*.^{1,2} Gene mountains correspond to the most frequently mutated genes found within breast tumors, such as *TP53*, *CDH1*, phosphatidylinositol 3-kinase (*PI3K*), cyclin D, *PTEN*, and *AKT*.⁶ Each individual gene hill, on the other hand, is typically found in less than 5% of breast tumors.^{1,33} This substantial heterogeneity of DNA mutations among breast tumors may explain the wide variations in phenotypes, both in terms of tumor behavior as well as responsiveness to therapy.

Historically, the focus of genetic research has been on the gene mountains, in part because they were the only mutations that available technology could identify. However, emerging data suggest that it is actually the gene hills that play a much more pivotal role in breast cancer, which is consistent with the idea that having a large number of mutations, each associated with a small survival advantage, drives tumor progression. Recent studies have shown that a substantial number of these infrequent somatic mutations sort out among a much smaller number of biologic groups and cell signaling pathways that are known to be pathogenic in breast cancer, thereby vastly reducing the complexity of the genomic landscape. Examples of such pathways include interferon signaling, cell cycle checkpoint, *BRCA1/2*-related DNA repair, p53, *AKT*, transforming growth factor β (*TGF- β*) signaling, Notch, epidermal growth factor receptor (*EGFR*), *FGF*, *ERBB2*, *RAS*, and *PI3K*. In short, it appears that common pathways, rather than individual gene mutations, govern the course of breast cancer development.³³

Although recurrent point mutations are less common in breast cancer than other solid tumors, emerging data show that particular regions of the genome are commonly amplified, and these regions contain genes that drive cancer progression. The best example of an important amplified region is the 17q12 amplicon that harbors the *HER2* oncogene. This amplicon leads to a more aggressive tumor phenotype, now the target of a highly successful antibody therapy, trastuzumab (Herceptin). It has been observed that RNA-mediated interference (RNAi) knockdown of coamplified genes within the 17q12 amplicon results in decreased cell proliferation and increased apoptosis.³⁴ Thus, the 17q12 amplicon appears to encode a concerted genetic program that contributes to the oncogenesis.

There are several other amplicons, in addition to 17q12 (*HER2*), that seem to drive the cancer phenotype and have prognostic significance in breast cancers, for example, 11q13 (*CCND1*) and 8q24 (*MYC*), 20q13.³⁵ These regions contain gene sets that are important in DNA metabolism and in the maintenance of chromosomal integrity, suggesting that a response to DNA damaging agents used as anticancer therapy might be modulated by the presence of particular amplicons. Indeed, these coamplicons are frequent in *HER2*-amplified tumors and may modify tumor behavior and patient outcome.^{36,37} The contribution of these genomic alterations to functional consequences may lie not in the overexpression of individual genes, but of gene cassettes on the amplicon.

Direct clinical translation of the growing catalog of somatic alterations in breast cancer has yet to evolve. However, with advancing technology and further identification and categorization of genetic mutations, new opportunities for individualized diagnosis and treatment options are likely to emerge.

TRANSCRIPTIONAL PROFILING OF BREAST CANCER

The cellular programs that are encoded by DNA are enacted by transcription into messenger RNA (mRNA) and translated into protein. Not surprisingly, the DNA alterations described previously lead to either under- or overexpression of their associated mRNAs; consequently, abnormal gene expression patterns are a common finding in breast tumors. Gene expression profiling has been introduced into the clinical literature during the past decade because research suggests that assessing the expression of multiple genes in a tumor sample may reflect programs turned on by DNA alterations and predict tumor behavior. So-called molecular signatures hold promise for improving the diagnosis, the prediction of recurrence, and the selection of therapies for individual patients.

Several technologies have been developed to generate molecular signatures, including cDNA and oligonucleotide arrays and multiplex polymerase chain reaction (PCR) technologies. These technologies and newly developed statistical methodologies now allow for evaluations of hundreds and even thousands of mRNAs simultaneously with groupings of samples based on coexpressed genes.

Molecular Classification of Breast Cancer

The seminal work by Perou et al.³⁸ and Sorlie et al.³⁹ suggests a classification of breast cancer subtypes based on gene expression patterns they termed *molecular portraits* of breast cancer. Among the categories they defined were the luminal A and B tumor types (typically estrogen-receptor [ER] or progesterone-receptor [PR] positive), HER2 gene-amplified tumors, and a class termed *basal-like* due to the expression of basal keratins. Recent large scale efforts by The Cancer Genome Atlas Network (TCGA)⁴⁰ and the Molecular Taxonomy of Breast Cancer International Consortium (METABRIC)⁴¹ groups have confirmed these earlier findings in addition to providing more detailed molecular portraits.

Luminal Subtypes

The luminal subtypes comprise the majority of breast cancers and are characterized by the expression of genes that are normally expressed in the luminal epithelial of the breast such as cytokeratins 8 and 18 and the luminal expression signature (*ESR1*, *GATA3*, *FOXA1*, *XPB1*, and *MYB*). Luminal subtypes comprise the majority of clinical ER-positive breast cancers and can be divided into two subgroups: luminal A and luminal B. Luminal A tumors are more common and are characterized by high expression levels of ER-related genes and low expression of the HER2 cluster and proliferation-associated genes. In contrast, luminal B tumors are characterized by lower expression levels of ER-related genes, variable expression of the HER2 cluster, and higher levels of proliferation-associated genes. Luminal A tumors have an overall better prognosis than luminal B tumors.

HER2-Enriched Subtype

The HER2-enriched subtype comprises approximately 10% to 15% of all breast cancers and overexpresses both HER2 and proliferation-associated genes and has lower expression of ER-related genes. Interestingly, more recent work by the TCGA demonstrates that not all cancers that are clinically HER2-positive as defined by an immunohistochemical (IHC) analysis and/or fluorescent in situ hybridization (FISH) fall into the HER2-enriched molecular subtype and vice versa. The majority of clinically HER2-positive breast cancers that are not considered part of the HER2-enriched subgroup by gene expression profiling fall into the luminal intrinsic subtype with overexpression of HER2.

Estrogen Receptor–Negative Subtypes

The ER-negative subtypes comprise a heterogeneous group of tumors that clinically are termed triple negative breast cancer (TNBC)

because they typically lack ER, PR, and *HER2*, and are often referred to as *triple negative*, although not all basallike tumors are triple negative and visa versa. The basallike category of the ER-negative subsets were first identified with first-generation microarray technology and show a high expression of proliferation genes and basal cytokeratins^{5,31,34} and a loss of genes associated with cell cycle control, which confer an overall poor prognosis. Though basallike tumors are the most common of the ER-negative subtypes (50% to 75% of all ER-negative tumors) and comprise 15% to 20% of all types of breast cancer, other ER-negative subtypes also exist, which include the recently described claudin-low group, as well as interferon-rich, androgen receptor, normal-like groups. Though the claudin-low subgroup has some similarities to basallike breast cancer, it is distinct because these tumors have low expression of the claudin genes that are involved in epithelial cell tight-tight junctions. The claudin-low tumors have been of particular interest because they possess stem cell–like features of epithelial–mesenchymal transition (EMT).⁴² To further characterize the heterogeneity of TNBC, a recent study did a clustering analysis of gene expression profiling of primary tumors and identified six distinct subtypes.⁴³ Major clusters included two basallike, an immunomodulatory, a mesenchymal, a mesenchymal stem–like, and a luminal androgen receptor subtype. Of further significance, this group provided preclinical evidence that these molecular subtypes were sensitive to different therapies.⁴³ This has direct translational relevance and should be validated further.

Although the exact definition of molecular subtypes is an area of active debate, it is clear that these subtypes are reproducible in multiple, unrelated data sets, and their prognostic impact has been validated in these settings.^{38,40,44,45} As a result, clinical trials are now being designed to subdivide patients by ER/PR and *HER2* status to validate claims that therapeutic approaches should address these groups rather than the population of breast cancer patients as a whole. In 2011, the St. Gallen International Breast Cancer Conference recognized that breast cancer should not be treated as a single disease and recommended defining disease by molecular subtype using genetic array testing or approximated by ER/PR/*HER2* status in conjunction with markers of proliferation, such as Ki-67. The panel reaffirmed this position again in 2013.⁴⁶

Genetic Changes in Breast Cancer by Molecular Subtype

Mutational profiling of all types of breast cancer has demonstrated the marked heterogeneity that exists across the entire spectrum of tumors. Data from the TCGA highlights the fact that somatic mutations in just three genes (*TP53*, *PIK3A*, and *GATA3*) occurred at an incidence of greater than 10%.⁴⁰ However, when the mutation profile of breast cancers is analyzed by intrinsic subgroup, certain patterns continue to emerge. Although the rate of significantly mutated genes is the lowest in the luminal subgroup, it is also the most heterogeneous group in terms of mutational spectrum. The most frequent mutation in luminal A tumors was in *PIK3CA* (45%) followed by *MAP3K1*, *GATA3*, *TP53*, *CDH1*, and *MAP2K4*. Like luminal A cancers, luminal B cancers also showed a wide range, with the most frequently mutation genes being *TP53* and *PIK3CA* (both 29%). However, the *TP53* pathway appears to be differentially inactivated with lower *TP53* mutations in luminal A (12%) and higher mutations in luminal B (29%). Although the HER2-enriched subgroup also shows a high frequency of mutations in *TP53* (72%) and *PIK3CA* (39%), unlike the luminal subtypes, HER2-enriched tumors appear to have a much lower frequency of other significantly mutated genes. Basallike tumors commonly harbor mutations in *TP53* (80%), and there seems to be little overlap with the mutations seen in the luminal subtypes. In addition, the *TP53* mutations present in the basallike group were mostly nonsense and frameshift-type mutations as opposed to more missense mutations seen in the luminal group. In fact, the mutations seen in the basallike group showed significant similarities to serous cancers of the ovary.⁴²

Prognostic and Predictive Genomic Signatures

Prognostic Signatures

Gene expression molecular signatures are currently in clinical use for both defining prognosis and for determining the benefit of systemic therapies, including chemotherapy and endocrine treatment, for breast cancer. Van't Veer et al.⁴⁵ and van de Vijver et al.⁴⁷ were the first to apply gene expression analysis to define a subgroup of breast cancer patients with an increased likelihood of metastasis. The estimated hazard ratio for distant metastases in the group with a poor prognosis signature, as compared to the group with the good prognosis signature, was 5.1 (95% confidence interval [CI], 2.9 to 9.0; $p < 0.001$). The European Organisation for Research and Treatment of Cancer (EORTC) and the Breast International Group (BIG) are currently conducting a prospective clinical trial to validate the utility of this assay for sparing patients from systemic chemotherapy (the MINDACT study).⁴⁸ In a preliminary analysis, the 70-gene profile signature was strongly prognostic, outperforming classic prognostic criteria such as those used by the St. Gallen consensus panel⁴⁹; however, the magnitude of effect was much less than previously reported, with hazard ratios for time to distant metastases of 1.85 (1.14 to 3.0) and for overall survival of 2.5 (1.4 to 4.5). The 70-gene signature is now commercialized as the MammaPrint and has received clearance by the U.S. Food and Drug Administration (FDA) as a class 2, 510(k) product.

Other groups have developed prognostic gene expression signatures, including the 76-gene Rotterdam signature, which identifies a high-risk group of node-negative patients, and the Genomic Grade Index (GGI), which distinguishes poor and good prognosis groups in breast tumors of intermediate histologic grade.⁵⁰ The potential value of these signatures has yet to be clearly defined, but it emphasizes the role of gene expression profiling at distinguishing prognostic groups not otherwise recognizable by standard histologic or clinical parameters.

Predictive Signatures

Endocrine Therapy. Several groups have applied a gene expression profiling analysis to better define the likelihood of benefit from therapy. Such predictive signatures may have particular value as they help oncologists counsel patients about appropriate choices for treatment. Genomics Health Inc. (Redwood City, California) developed the Oncotype DX assay as a predictor of benefit from antiestrogen therapy using multiple real-time reverse transcriptase polymerase chain reaction (RT-PCR) assays in formalin-fixed paraffin-embedded tissue. The assay was developed from 250 candidate genes selected from published literature, genomic databases, and in-house experiments performed on frozen tissue. From these data, a panel of 16 cancer-related genes and 5 reference genes were used to develop an algorithm to compute a recurrence score, ranging from 0 to 100, that can be used to estimate the odds of recurrence over 10 years from the diagnosis.⁵¹ Paik et al.⁵¹ reported an analysis of two randomized controlled trials: the National Surgical Adjuvant Breast and Bowel Project NSABP-B14, in which node-negative patients with ER-positive tumors were randomly assigned to tamoxifen or nil; and NSABP-B20, in which node-negative patients with ER-positive tumors were randomly assigned to tamoxifen alone or with cyclophosphamide, methotrexate, and fluorouracil (CMF) chemotherapy. Using the tissue samples from NSABP-B20, patients were categorized into three recurrence score groups: low risk (recurrence score less than 18), intermediate risk (recurrence score 18 to 30), and high risk (recurrence score 31 to 100). Samples from NSABP-B14 were then analyzed and found to be 6.8% (4.0% to 9.6%), 14.3% (8.3% to 20.3%), and 30.5% (23.6% to 37.4%). Paik et al.⁵¹ further analyzed the performance of the Oncotype DX assay to include patients in the other arms of NSABP-B14 and NSABP-B20 and found that the

Oncotype DX assay was a strong predictor of benefit from CMF in NSABP-B20, with little or no benefit from chemotherapy for patients with low or intermediate recurrence scores but substantial benefit for those with high recurrence scores. Conversely, in NSABP-B14, the benefit from tamoxifen versus observation was confined to the low and intermediate risk categories (p value for interaction of 0.001). These data suggest that in patients who have an apparent favorable prognosis based on clinical features (negative nodes, positive ER), the Oncotype DX assay helps determine those most likely to benefit from tamoxifen only (low recurrence scores) versus those most likely not to benefit from tamoxifen but likely to benefit from chemotherapy (high recurrence scores). The benefits of chemotherapy in the 25% of patients who have intermediate recurrence scores remains uncertain and are the basis of an ongoing prospective randomized trial (Tailor Rx) where those with high recurrence scores will receive endocrine therapy and chemotherapy, those with low recurrence scores will receive endocrine therapy alone, and those with intermediate recurrence scores are randomly assigned to endocrine therapy versus endocrine and chemotherapy. A study by Albain et al.⁵² suggested that a low recurrence score predicts a lack of benefit of fluorouracil (5-FU), adriamycin (doxorubicin), and cyclophosphamide (FAC) chemotherapy in node-positive breast cancer patients treated on Southwest Oncology Group SWOG-8814. Although these provocative data suggest a similar utility for Oncotype DX in node-positive patients, they require additional validation with modern-day regimens. The value of the Oncotype DX assay in predicting a benefit from hormonal therapy in patients treated with aromatase inhibitor therapy has recently been published, demonstrating that the assay performs equally with both tamoxifen and anastrozole but does not distinguish a benefit of one over the other.⁵³ Given the independent prognostic utility of both the Oncotype DX recurrence score and the clinicopathologic factors, such as tumor size and grade, a recent study formally integrated each of these measures to determine whether prognostic and predictive value is improved over using a single measure.⁵⁴ The use of an integrated score, recurrence score-pathology-clinical (RSPC), among ER-positive, node-negative patients provided a more significant prognostic value for distant recurrence when compared to the recurrence score alone. This score also resulted in better risk stratification and reduced the number of patients classified as intermediate risk. However, the addition of clinicopathologic factors to the recurrence score did not improve its predictive value for chemotherapy benefit.⁵⁴

Several other additional predictors for ER-positive breast cancer include the Breast Cancer Index (AvariaDx Inc., Carlsbad, California), a quantitative RT-PCR-based assay that measures the ratio of the *HOXB6* and *IL17BR* genes, and includes a proliferation score. It was shown to be a marker of recurrence risk in untreated ER-positive/node-negative patients^{55,56} in two studies of lymph node-negative, ER-positive, tamoxifen-treated patients with breast cancer and was more recently found to predict late recurrence after adjuvant endocrine therapy.⁵⁷ The breast cancer index (BCI) was compared with Oncotype DX recurrence score, and IHC4, a score based on four protein markers detected by immunohistochemistry. In ER-positive, node-positive breast cancer patients given either tamoxifen or anastrozole in the Arimidex, Tamoxifen, or Alone or in Combination (ATAC) trial, the BCI index was the only prognostic index that identified populations at risk of both early and late recurrences.⁵⁷ This may be of clinical value in postmenopausal patients, who have undergone 5 years of endocrine therapy because the test was defined in this population.

Chemotherapy. Defining predictors of response to chemotherapy and targeted therapies has been more challenging. Ayers et al.⁵⁸ from the M.D. Anderson Cancer Center were the first to report that a multigene analysis of fine needle aspiration specimens predicts a response to neoadjuvant Taxol, 5-fluorouracil, Adriamycin, and cyclophosphamide (TFAC) chemotherapy.⁵⁹ Validation of gene signatures is of utmost importance in the future to determine

the value of these expression profiles at predicting treatment response and clinical outcome in breast cancer patients. National organizations such as the American Society of Clinical Oncology, the National Comprehensive Cancer Network, and the College of American Pathologists have ongoing efforts to interpret the data from the burgeoning field of multigene biomarker tests to help the practicing clinician interpret their clinical utility.⁶⁰

EPIGENETICS OF BREAST CANCER

Cells maintain their stable identity and phenotype over many generations without external stimuli or signaling events. This cellular memory is encoded in the epigenome, a collection of heritable information that exists alongside the genomic sequence. DNA methylation and chromatin modification are major epigenetic mechanisms in higher eukaryotes and are tightly coupled to basic genetic processes, such as DNA replication, transcription, and repair. It is well documented that cancers, including breast cancer, have altered patterns of DNA methylation and histone acetylation, leading to alterations in transcription that appear to be oncogenic.^{61,62} Recent work from TCGA demonstrates different patterns of methylation by breast cancer subtypes as defined by gene expression profiling. Among these subtypes, luminal B subtype had a hypermethylated phenotype, whereas basallike subtype had a hypomethylated phenotype.⁴⁰ Ongoing initiatives, including the Epigenome Project, and further analyses of the TCGA data will likely enhance our understanding of epigenetics in breast cancer.

Major epigenetic cancer drugs include DNA methyltransferase (DNMT) and histone deacetylase (HDAC) inhibitors. Preclinical studies show promise that HDAC inhibitors may have activity in breast cancer cells, and many clinical phase I and II studies are in progress.^{63–65}

MicroRNAs

miRNAs are small noncoding RNAs that belong to a novel class of regulatory molecules that control the expression of hundreds of target mRNA transcripts⁶⁶ in two ways. First, miRNAs that bind to protein-coding mRNA sequences that are exactly complementary to the miRNA induce the RNAi pathway. Messenger RNA targets are then cleaved by ribonucleases in the RNA-induced silencing complex (RISC). Second, miRNAs bind to imperfect complementary sites within the 3' untranslated regions (3'UTR) of their target protein-coding mRNAs and repress the expression of these genes at the level of translation.⁶⁷

miRNAs are known to be associated with breast cancer in both cell lines and clinical samples. For example, *miR-21*, *miR-155*, *miR-7*, and *miR-210* are overexpressed in aggressive human breast cancers,^{68,69} whereas *let-7* and *miR-125a* have been shown to be downregulated in breast cancers.⁷⁰ It has also been shown that *miR-125a* may function as a tumor suppressor by inhibiting ERBB2 and ERBB3. More recently, the TCGA identified seven subtypes by microRNA expression profiling. Among all of these microRNA clusters, only two of them had a positive correlation with TP53 mutation and overlap with the basallike subtype. No additional correlation with mutation status or mRNA-defined breast cancer subtypes was identified.⁴⁰

MicroRNAs and Response to Cancer Treatment

miRNA misexpression patterns were found to be associated with cancer outcome and response to treatment, including radiation and chemotherapy. Certain miRNAs associated with hypoxia, such as *miR-210*, have been shown to be biomarkers of poor outcome in breast cancer.⁶⁸ Furthermore, in vitro data show that certain miRNAs are associated with resistance to doxorubicin⁷¹ or tamoxifen.⁷² In patient samples, an association of miRNA's tumor subtypes have specific miRNA patterns and this is associated with a poor outcome. Defining the role of miRNAs as biomarkers for

prognosis and prediction, as well as their potential as targeted therapies, is an active area of research in breast cancer.

PROTEIN/PATHWAY ALTERATIONS

The molecular mechanisms that lead to cancer have been characterized as the hallmarks of cancer, as proposed by Hanahan and Weinberg and revised in 2011.⁷³ They include sustained proliferative signaling, evading growth suppressors, resisting cell death, replicative immortality through telomerase inhibition, angiogenesis, invasion and metastasis, genomic instability, deregulated metabolism, and avoiding immune destruction. The effectors of genetic and epigenetic abnormalities are, in most cases, reflected in the abnormal levels, functions, and interactions of proteins and signaling pathways. Recent studies of the genome have generated new insights into the proteome associated with specific breast cancer subtypes and suggest important targets for therapy, in addition to those canonical drivers ER and HER2.⁴⁰ Undoubtedly, numerous alterations coordinate to result in the malignant phenotype; however, a number of key proteins and their pathways have emerged as critical drivers of breast cancer development and growth as well as potential therapeutic targets.

ESTROGEN RECEPTOR PATHWAY

Therapeutic Targets in Breast Cancer

Estrogen Signaling

Most breast cancers are intimately linked with exposure to estrogen and alterations in the estrogen receptor signaling pathway. Estrogen is a steroid hormone that exerts its actions by binding to the nuclear ER. Upon activation by its ligand, ER binds in a coordinated fashion with a number of coregulatory proteins to estrogen response elements in the promoter region of estrogen-responsive genes. This in turn directs the transcription of numerous growth-promoting genes, including PR. The level of ER expression is not only of biologic interest, but it is also a highly effective predictor for response to antiestrogens, which is a recommended treatment for all ER-expressing tumors.

Although ER is overexpressed in as many as 70% of invasive breast cancers, the precise mechanism by which this occurs is unclear. Amplification of the gene appears to be one mechanism (approximately 50% of cases with ER overexpression in one study), suggesting that transcriptional deregulation and posttranscriptional modifications (such as alteration of mRNA levels by miRNAs) may also play a role. In addition, recent studies suggest ER mutations can lead to constitutive activation of the pathway and may be a mechanism of resistance to antiestrogen treatment.⁷⁴

Estrogen exerts its actions through both genomic (described previously) and nongenomic mechanisms. In contrast to the genomic actions of ER, nongenomic actions of ER are extremely rapid (within seconds to minutes of estrogen exposure) and are believed to result from the hormone-dependent activation of membrane-bound or cytosolic ERs. These nonnuclear ER actions result in rapid phosphorylation and activation of important growth regulatory kinases, including EGFRs, insulinlike growth factor 1R (IGF-1R), c-Src, Shc, and the p85 α regulatory subunit of PI3K.⁵ This *cross-talk* between ER and growth factor receptors is bidirectional; for example, constitutive HER2 can increase ER signaling to the point where it is unresponsive to antiestrogen treatments. These findings suggest a role for HER2/IGF-1R/EGFR activation in both acquired and de novo resistance to treatment with antiestrogens.⁷⁵

The ER pathway has proven to be an invaluable target for therapeutic treatments in breast cancer. A number of agents have been developed over the prior decades that can inhibit this pathway by either binding to the receptor itself (e.g., selective ER modulators such as tamoxifen, raloxifene, fulvestrant) or by decreasing the production of endogenous estrogen (e.g., aromatase inhibitors, ovarian ablation).

Recent data suggest that a longer duration of tamoxifen (10 years) is superior to 5 years, and 5 years of Aromatase Inhibitor (AI) are standard of care after any duration of tamoxifen in postmenopausal women.⁷⁶ Although these agents are highly effective and have made a significant impact on breast cancer morbidity and mortality, *de novo* and acquired resistance are also quite common. Recent studies suggest that the inhibition of growth factor pathways in conjunction with antiestrogen therapy can overcome resistance to these agents; for example, the mammalian target of rapamycin (mTOR) inhibitor temsirolimus with a steroidal inhibitor (exemestane) is a new standard of care after progression on a nonsteroidal aromatase inhibitor in the metastatic setting.⁷⁷ The challenge for the oncology community is to define optimal biomarkers to predict patients most likely to benefit from longer tamoxifen or AI + mTOR therapy. As described previously, the Oncotype DX assay, IHC4, and Breast Cancer Index

provide insight into the behavior of ER-positive tumors and help in treatment decision making.⁵⁵⁻⁵⁷

Growth Factor Receptor Pathways

Growth factor receptor pathways—in particular, tyrosine-kinase receptors—play an essential role in initiating both proliferative and cell survival pathways in tissues and are tightly regulated. In breast cancer biology, the ErbB family has been studied most extensively, but an expanding number of other growth factors, such as insulin-like growth factor receptors, have also been the subject of intense scrutiny in hopes of identifying effective therapeutic targets.⁷⁸ These growth factor receptor pathways can be constitutively activated by a number of mechanisms, including excessive ligand levels, gain-of-function mutations, overexpression with or without gene amplification, and

Figure 78.2 (A) The ras/raf/MEK/MAPK pathway is activated by multiple growth factor receptors (here exemplified by ErbB1 and ErbB2) as well as several intracellular tyrosine kinases such as SRC and ABL. Activated RAS stimulates a sequence of phosphorylation events mediated by RAF, MEK, and ERK (MAP) kinases. Activated MAP kinase (MAPK) translocates to the nucleus and activates proteins such as MYC, JUN, and FOS, which promote the transcription of numerous genes involved in tumor growth. (B) The phosphatidylinositol 3-kinase (PI3K) pathway is activated by RAS and by a number of growth factor receptors (here exemplified by IGF1R and the ErbB1/ErbB2 heterodimer). Activated PI3K generates phosphatidylinositol-3,4,5-triphosphate (PIP3), which activates phosphoinositide-dependent kinase-1 (PDK). In turn, PDK phosphorylates AKT. PTEN is an endogenous inhibitor of AKT activation. Phosphorylated AKT transduces multiple downstream signals, including the mTOR and the inhibition of the FOXO family of transcription factors. mTOR activation promotes the synthesis of proteins required for cell growth and cell cycle progression. (Redrawn from Golan DE, Tashjian AH, Armstrong EJ. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. 2nd ed. Baltimore: Lippincott Williams & Wilkins; 2008.)

gene rearrangements and resultant fusion proteins with oncogenic potential. This can ultimately lead to inappropriate kinase activity and growth promoting second messenger activation (Fig. 78.2).

Human Epidermal Growth Factor Receptor 2

HER2 (EGFR2 or ErbB2) is a member of a family of receptor tyrosine kinases that also includes EGFR (HER1, ErbB1), ErbB3, and ErbB4. Ligand binding to the extracellular domains of the ErbB1, ErbB3, or ErbB4 receptors induces homo- and heterodimerization and kinase activation. The HER2 protein exists in a closed conformation and has no ligand, but it is the preferred partner for dimerization with HER1, -3, and -4. At a molecular level, *HER2* amplification is associated with deregulation of G1/S phase cell cycle control via the upregulation of cyclins D1, E, and cdk6, as well as p27 degradation. HER2 also interacts with important second messengers, including SH2-domain-containing proteins (e.g., Src kinases).

Importantly, HER2 amplification or protein overexpression (found in 20% of invasive breast cancers) is clearly associated with accelerated cell growth and proliferation, poor clinical outcome, and response to the monoclonal anti-HER2 antibody, trastuzumab. Numerous randomized trials have shown that the addition of trastuzumab to chemotherapy improves survival in both metastatic and early stage disease, leading to its inclusion in the standard of care for all patients with HER2-positive breast cancer.⁷⁹ In addition, several other HER2-targeted agents have been approved for metastatic HER2-positive breast cancer and are being evaluated in the early stage setting. One of these, the monoclonal antibody pertuzumab, which targets the HER2-3 heterodimerization site, has recently been approved for use in the preoperative setting for stage II and III HER2-positive breast cancer.⁸⁰ These rapid advances in the setting of targeted therapy for HER2-positive disease illustrate the profound effect that targeting an important molecular *driver* can have on clinical practice.

The precise mechanism of action of the FDA-approved HER2-targeted therapies trastuzumab, pertuzumab, lapatinib, and trastuzumab emtansine (TDM-1) are not well understood.^{79,81} In preclinical studies, the first three appear to inhibit signal transduction through the canonical signaling pathways for the HER2 receptor, but may vary in their degree of ras-MAPK versus PI3K-AKT pathway inhibition. This may largely be due to different degrees of inhibition of the coreceptors HER1, 3, and 4 that have a different predilection for each pathway. For instance, lapatinib inhibits both HER2 and EGFR (HER1) with a greater effect on the ras-MAPK pathway. Pertuzumab interferes with the HER3 heterodimer and hence has more effect on the AKT pathway. The new targeted therapy TDM-1 is an antibody–drug conjugate, and its effects are more cytotoxic than signal transduction. All three antibody therapies are thought to activate natural killer cells involved in antibody-dependent cellular cytotoxicity (ADCC); however, there is little evidence from clinical studies to support this or any mechanism of action. As a result, mechanisms of resistance are poorly understood; current hypotheses include activation of alternate receptors (e.g., IGF-1R, c-met) or the AKT pathway via a loss of phosphatase and tensin homolog (PTEN) or PI3K mutation (see Fig. 78.2).^{78,79,81,82}

Ras And Phosphatidylinositol 3-Kinase Pathways

Redundancies and cross-talk of numerous different signaling pathways are a common theme. Several downstream messengers, however, bear special consideration due to their functional importance and therapeutic implications. Recent data from TCGA Breast Cancer publication suggest that the PI3K/AKT and ras-MAP kinase pathways are particularly relevant in breast cancer based on frequent mutation, amplification, and/or activation of these pathways as measured by genomic technologies.⁴⁰

PI3K-AKT is a central signaling pathway downstream of many receptor tyrosine kinases and regulates cell growth and proliferation (see Fig. 78.2B). Activating mutations in the gene encoding

the p110 α catalytic subunit of PI3K (*PI3CA*) may be an important contributing factor to mammary tumor progression, and the site of mutation differs depending on the breast cancer molecular subtype as noted previously. Activating mutations of the AKT gene family are seen in 2% to 4% of breast cancers, excluding the basal-like subtype, where they are rare.⁴²

PTEN dephosphorylates—and therefore inactivates—the p110 catalytic domain of PI3K and is either mutated or underexpressed (e.g., via methylation) in many breast cancers. Activation of the PI3K pathway, in turn, results in the 3-phosphoinositide-dependent kinase-mediated activation of several known kinases, including AKT1, AKT2, and AKT3. Interestingly, activated AKT1 appears to be antiapoptotic but also plays an anti-invasive role in tumor formation. In addition to the AKTs, downstream proliferative effectors of the PI3K pathway also include the mTOR complex 1 (TORC1), which consists of mTOR, raptor, and mLst8. It is currently believed that TORC1 mediates its pro-growth effects through the activation of S6-kinase 1 and suppression of 4E-BP1, an inhibitor of cap-dependent translation. These observations all point to mTOR-raptor as a critical target in cancer therapy, and indeed, several mTOR inhibitors known as rapamycin analogs (e.g., CCI-779, RAD-001, AP-23576) are in clinical trials, and temsirolimus (Afinitor) has been approved for use with aromatase inhibitor therapy.

The ras/raf/MEK/MAPK pathway is also a critical signaling pathway for numerous growth factor receptors (see Fig. 78.2A). Thus far in breast cancer, agents that target the MEK pathway (e.g., raf inhibitor sorafenib) have had modest success as single agents, but studies in combination with other treatments hold more promise.

Angiogenesis

Angiogenesis is normally a tightly regulated process of vessel formation during physiologic events, such as wound healing and pregnancy. It has also been shown to be an important part of tumor growth and spread. In contrast to physiologic angiogenesis, tumor-associated angiogenesis is highly dysregulated with disorganized and distorted vasculature and increased vascular permeability. Thus, in recent years, angiogenesis has become a frequent target for the treatment of many cancers.

Central to this process is the proangiogenic factor, vascular endothelial growth factor (VEGF), which together with its receptors, regulate endothelial cell growth and new vessel formation.⁸¹ VEGF receptors (VEGFR), like EGFRs, are also tyrosine-kinase receptors. VEGF-A binds to both VEGFR1 (Flt-1) and VEGFR2 (KDR/Flk1). VEGFR2 appears to mediate most of the known cellular responses to VEGFs, whereas the function of VEGFR1 is less well defined. Bevacizumab, a humanized monoclonal antibody directed against VEGF-A, has been the most extensively studied thus far. To date, three large randomized trials have shown a statistically significant benefit in progression-free survival when bevacizumab was added to a variety of different chemotherapies in the first-line metastatic setting. However, the lack of survival advantage in any study has led to the withdrawal of bevacizumab's approval, and studies in early stage breast cancer are required to be positive in order to reconsider its use in breast cancer. Multitargeted VEGFR tyrosine-kinase inhibitors such as sunitinib (VEGFR, platelet-derived growth factor receptor (PDGFR), and c-kit blockade) and sorafenib (VEGFR and RAF kinase blockade) have also been studied extensively in breast and other cancers. Despite the success of some of these agents, the identification of predictive factors for an antiangiogenic response have thus far proven to be elusive.

SUMMARY

Breast cancer is a heterogeneous malignancy, with multiple molecular subtypes and clinical presentations ranging from aggressive

to indolent, and varying in distribution by age, menopausal status, and racial group. Recent molecular analyses have shed light on this heterogeneity by mapping patterns that correspond to clinical phenotypes. These studies include, but are not limited to, the study of germ-line variations in breast cancer susceptibility genes, gene expression, copy number and somatic mutations, epigenetic

modifications, and alterations in protein pathways associated with the malignant phenotype. This review attempts to summarize the current state of the science with an emphasis on the insights provided by these studies on prognosis and prediction for therapy and potential new therapeutic targets. It is only through ongoing research that this disease will one day be cured.

79 Malignant Tumors of the Breast

Monica Morrow, Harold J. Burstein, and Jay R. Harris

INTRODUCTION

Breast cancer is a major public health problem for women throughout the world. In the United States, breast cancer remains the most frequent cancer in women and the second most frequent cause of cancer death. In 2012, it was estimated there were 226,870 new cases of breast cancer, with 39,510 deaths.¹ Worldwide, breast cancer is the most frequently diagnosed cancer and the leading cause of cancer death among females, accounting for 23% of the total cancer cases and 14% of the cancer deaths, although there is a five-fold variation in incidence between high-incidence areas such as the United States and Western Europe, and low incidence areas such as Africa and Asia.² Since 1990, the death rate from breast cancer has decreased in the United States by 24%, and similar reductions have been observed in other countries.^{3,4} The adoption of screening mammography, and the use of adjuvant therapy, have contributed approximately equally to this improvement.⁵ Although breast cancer has traditionally been less common in nonindustrialized nations, its incidence in these areas is increasing.⁶ This chapter examines the salient features of breast cancer, stressing practical information of importance to clinicians and the results of prospective randomized trials that guide therapeutic decisions.

ANATOMY OF THE BREAST

The adult female breast lies between the second and sixth ribs, and between the sternal edge and the midaxillary line. The breast is composed of skin, subcutaneous tissue, and breast tissue, with the breast tissue including both epithelial and stromal elements. Epithelial elements make up 10% to 15% of the breast mass, with the remainder being stroma. Each breast consists of 15 to 20 lobes of glandular tissue supported by fibrous connective tissue. The space between lobes is filled with adipose tissue, and differences in the amount of adipose tissue are responsible for variations in breast size. The blood supply of the breast is derived from the internal mammary and lateral thoracic arteries. The breast lymphatic drainage occurs through a superficial and deep lymphatic plexus, and >95% of the lymphatic drainage of the breast is through the axillary lymph nodes, with the remainder via the internal mammary nodes. The axillary nodes are variable in number and have traditionally been divided into three levels based on their relationship to the pectoralis minor muscle, as illustrated in Figure 79.1. The sentinel axillary node is almost always found in the level 1 axillary nodes. The internal mammary nodes are located in the first six intercostal spaces within 3 cm of the sternal edge, with the highest concentration of internal mammary nodes in the first three intercostal spaces.

RISK FACTORS FOR BREAST CANCER

Multiple factors are associated with an increased risk of developing breast cancer, but the majority of these factors convey a small to moderate increase in risk for any individual woman. It has been

estimated that approximately 50% of women who develop breast cancer have no identifiable risk factor beyond increasing age and female gender. The importance of age as a breast cancer risk factor is sometimes overlooked. In 2009, it was estimated that 18,640 invasive breast cancers and 2,820 breast cancer deaths occurred in US women under age 45 compared with 173,730 cancers and 37,350 deaths in women aged 45 years and older.⁷

Familial Factors

A family history of breast cancer has long been recognized as a risk factor for the disease, but only 5% to 10% of women who develop breast cancer have a true hereditary predisposition. Many women with a family history overestimate their risk of developing breast cancer or harboring a predisposing genetic mutation. Overall, the risk of developing breast cancer is increased 1.5-fold to 3-fold if a woman has a mother or sister with breast cancer. Family history, however, is a heterogeneous risk factor with different implications depending on the number of relatives with breast cancer, the exact relationship, the age at diagnosis, and the number of unaffected relatives. Even in the absence of a known inherited predisposition, women with a family history of breast cancer face some level of increased risk, likely from some combination of shared environmental exposures, unexplained genetic factors, or both.

Inherited Predisposition to Breast Cancer

Mutations in the breast cancer susceptibility genes *BRCA1* and *BRCA2* are associated with a significant increase in the risk of breast and ovarian carcinoma, and account for 5% to 10% of all breast cancers. These mutations are inherited in an autosomal dominant fashion and have varying penetrance. As a result, the estimated lifetime risk of breast cancer development in mutation carriers ranges from 26% to 85%, and the risk of ovarian cancer from 16% to 63% and 10% to 27%, respectively, in carriers of *BRCA1* and *BRCA2*.⁸ In a meta-analysis of 10 international studies, the cumulative risks to age 70 for breast cancer were 57% for *BRCA1* and 40% for *BRCA2* carriers.⁹ More than 700 different mutations of *BRCA1* and 300 different mutations of *BRCA2* have been described, and the position of the mutation within the gene has been shown to influence the risk of both breast and ovarian cancers.

Other cancers associated with *BRCA1* or *BRCA2* mutations include male breast cancer, fallopian tube cancer, and prostate cancer. Carriers of *BRCA2* may also have an elevated risk of melanoma and gastric cancer. Management strategies available for risk reduction in *BRCA1/2* mutation carriers include intensive surveillance, chemoprevention with selective estrogen receptor modulators (SERM), and prophylactic (breast and salpingo-ovarian) surgery, and these are discussed in a later section. There is a great interest in the role of environmental and lifestyle factors in the modification of cancer risk among *BRCA1* or *BRCA2* carriers; at present, however, the available data are inconsistent. It is worth

Figure 79.1 Lymphatic drainage of the breast showing lymph node groups and levels. 1, Internal mammary artery and vein; 2, substernal cross-drainage to contralateral internal mammary lymphatic chain; 3, subclavius muscle and Halsted ligament; 4, lateral pectoral nerve (from the lateral cord); 5, pectoral branch from thoracoacromial vein; 6, pectoralis minor muscle; 7, pectoralis major muscle; 8, lateral thoracic vein; 9, medial pectoral nerve (from the medial cord); 10, pectoralis minor muscle; 11, median nerve; 12, subscapular vein; 13, thoracodorsal vein. Internal mammary lymph nodes (A), apical lymph nodes (B), interpectoral (Rotter) lymph nodes (C), axillary vein lymph nodes (D), central lymph nodes (E), scapular lymph nodes (F), external mammary lymph nodes (G). Level I lymph nodes: lateral to lateral border of pectoralis minor muscle; level II lymph nodes: behind pectoralis minor muscle; level III lymph nodes: medial to medial border of pectoralis minor muscle.

noting that women with a significant family history of breast cancer (i.e., two or more breast cancers under the age of 50 years, or three or more breast cancers at any age), but who test negative for *BRCA* mutations have approximately a four-fold risk of breast cancer.¹⁰ In contrast, women in families where a *BRCA* mutation is present who test negative for the mutation are not at increased risk for breast cancer development in the absence of other risk factors, and do not require special surveillance.¹¹

Women with *BRCA1* mutations have a higher incidence of triple-negative/basal-like breast cancers (see the following), and cancers are more likely to be grade 3 tumors and to lack expression of the estrogen receptor (ER), progesterone receptor (PR), and *HER2* overexpression than sporadic cancers.¹² The phenotype of *BRCA2* cancers does not differ from that seen in sporadic cancers. The presence of a *BRCA1* or *BRCA2* mutation may be suggested by the family history on either the maternal or paternal side of the family. The features considered by the 2005 US Preventive Services Task Force¹³ are listed in Table 79.1. Less-rigorous criteria for referral for genetic counseling are used for individuals of Ashkenazi Jewish ancestry, because the carrier frequency of specific *BRCA1* (187delAG, 5385 ins C) and *BRCA2* (6174delT) mutations in this group is 1:40, compared with 1:500 in the general population. These guidelines are particularly useful for individuals not affected with breast cancer. In the patient with newly diagnosed breast cancer, young age at diagnosis (≤ 40 years), bilateral breast cancer, Ashkenazi ancestry, or a malignancy consistent with the *BRCA1* phenotype all constitute reasons for referral to a genetic counselor, particularly in the woman with a small number of female relatives. Models are available to estimate the likelihood of a *BRCA1* or *BRCA2* mutation based on family history. The implications of genetic testing for both individuals and their family members are considerable, and these issues should be discussed prior to undertaking genetic testing.

Other genetic mutations have been associated with breast cancer risk, although with a lower prevalence or penetrance than *BRCA1* and *BRCA2*. *TP53* and *PTEN* each account for $<1\%$ of cases, while mutations in *CDH1* are associated with an autosomal dominant predisposition to diffuse gastric cancer and lobular breast cancer.¹⁴ Young women with *TP53* mutations (Li-Fraumeni syndrome) seem to have a greater propensity for *HER2*⁺ breast cancers.¹⁵ Mutations in low-penetrance genes are thought to account for a significant number of non-*BRCA1* or -*BRCA2* breast

cancers. A specific mutation of the checkpoint kinase 2 (*CHEK2*) gene was found in 11.4% of families with three or more cases of breast cancer diagnosed before age 60,¹⁶ but in a large study of 10,860 unselected breast cancer patients from five countries, the *CHEK2* mutation was identified in only 1.9% of cases¹⁷ and 0.7% of controls (odds ratio, 2.34), and testing for *CHEK2* is not routine. The increasing availability of next-generation sequencing has already resulted in commercially available panels of high and moderate penetrance genes, and is likely to change the approach to genetic screening in future years.

Hormonal Factors

The development of breast cancer in many women appears to be related to female reproductive hormones, particularly endogenous estrogens. Early age at menarche, nulliparity or late age at first full-term pregnancy, and late age at menopause increase the risk of developing breast cancer. In postmenopausal women, obesity and postmenopausal hormone replacement therapy (HRT), both of which are positively correlated with plasma estrogen levels and

TABLE 79.1

Factors Suggestive of *BRCA1* or *BRCA2* Mutation

- Non-Ashkenazic Jewish women
 - Two first-degree relatives^a with breast cancer, one diagnosed ≤ 50 y
 - Three or more first- or second-degree relatives with breast cancer, any age
 - Breast and ovarian cancer among first- and second-degree relatives
 - First-degree relative with bilateral breast cancer
 - Breast cancer in a male relative
 - Two or more first- or second-degree relatives with ovarian cancer
- Ashkenazic Jewish women
 - First-degree relative with breast or ovarian cancer
 - Two second-degree relatives with breast or ovarian cancer

^a Relatives on the same side of the family.

plasma estradiol levels, are associated with increased breast cancer risk. Most hormonal risk factors have a relative risk (RR) of ≤ 2 for breast cancer development.

The age-specific incidence of breast cancer increases steeply with age until menopause, and then plateaus. There is substantial evidence that estrogen deprivation via iatrogenic premature menopause can reduce breast cancer risk. Premenopausal women who undergo oophorectomy without hormone replacement have a markedly reduced risk of breast cancer later in life, with an increasing magnitude of risk reduction as the age at oophorectomy decreases.¹⁸ Data from women with *BRCA1* and *BRCA2* mutations suggest that early oophorectomy has a substantial protective effect on breast cancer risk in this population also.¹⁹

Age at menarche and the establishment of regular ovulatory cycles are strongly linked to breast cancer risk; the total duration of exposure to endogenous estrogens seems important. There appears to be a 20% decrease in breast cancer risk for each year that menarche is delayed. Of note, hormone levels through the reproductive years in women who experience early menarche may be higher than in women who undergo a later menarche.²⁰ Additionally, late onset of menarche results in a delay in the establishment of regular ovulatory cycles, which may contribute to protective effects.

The relationship between pregnancy and breast cancer risk appears more complicated. Women whose first full-term pregnancy occurs after age 30 have a two- to five-fold increase in breast cancer risk in comparison with women who have a first full-term pregnancy before approximately age 18.^{20,21} Nulliparous women are at greater risk for the development of breast cancer than parous women, with a RR of about 1.4. Breast cancer risk increases transiently for the 10 years after a pregnancy, but then declines.²¹ Abortion, whether spontaneous or induced, does not increase breast cancer risk.²² Breastfeeding, particularly for longer duration, lowers the risk of breast cancer diagnosis. The combined effects of reproductive history and breastfeeding may account for substantial fractions of the difference in breast cancer risk between developed and developing nations.

The use of combined estrogen and progestin HRT also increases breast cancer risk. In the Women's Health Initiative, use of combined estrogen and progestin HRT was associated with a hazard ratio (HR) of 1.24 ($p < 0.001$) for breast cancer development as compared to placebo.²³ The effects of HRT were noted after a relatively short duration of use. An excess of abnormal mammograms was observed after 1 year of HRT use and persisted throughout the study, and an increase in breast cancer incidence was noted after 2 years. The cancers occurring in HRT users were larger and more likely to have nodal or distant metastases than those occurring in the placebo group (25.4% versus 16%; $p = 0.04$), although they were of similar histology and grade.²³ The observational UK Million Women Study found that current use of HRT was associated with a RR of breast cancer development of 1.66 ($p < 0.001$) and a RR of breast cancer death of 1.22 ($p = 0.05$).²⁴

Dietary and Lifestyle Factors

Observational studies suggested that high-fat diets were associated with higher rates of breast cancer than low-fat diets. However, a meta-analysis of eight prospective epidemiologic studies failed to identify an association between fat intake and breast cancer risk in adult women in developed countries.²⁵ Consistent with these findings, a randomized dietary modification in 48,835 women in the Women's Health Initiative study did not result in a statistically significant reduction in breast cancer incidence after 8 years of follow-up.²⁶ Breast cancer risk increases linearly with the amount of alcohol consumed.²⁷ Decreased intake of nutrients such as vitamin C, folate, and β -carotene may enhance the risk related to alcohol consumption.

Obesity is associated with both an increased risk of breast cancer development in postmenopausal women and increased breast cancer mortality. Women with a body mass index of ≥ 31.1 have a 2.5-fold greater risk of developing breast cancer than those with a body mass index of ≤ 22.6 .²⁵ Weight and weight gain appear to play an important but complex role in breast cancer risk. During childhood, rapid growth rates decrease the age of menarche, an established risk factor, and result in greater attained stature, which has been consistently associated with increased risk. During early adult life, obesity is associated with a lower incidence of breast cancer before menopause, but no reduction in breast mortality. Weight gain after age 18 is associated with a graded and substantial increase in postmenopausal breast cancer, particularly in the absence of HRT.²⁸

Benign Breast Disease

Benign breast lesions are classified as proliferative or nonproliferative. Nonproliferative disease is not associated with an increased risk of breast cancer, whereas proliferative disease without atypia results in a small increase in risk (RR = 1.5 to 2.0). Proliferative disease with atypical hyperplasia is associated with a greater risk of cancer development (RR = 4.0 to 5.0).²⁹ Dupont and Page³⁰ found a marked interaction between atypia and a family history of a first-degree relative with breast cancer. This subgroup of patients had a risk 11-fold that of women with nonproliferative breast disease, and an absolute risk of breast cancer development of 20% at 15 years, compared with 8% in women with atypical hyperplasia and a negative family history of breast carcinoma. Proliferative breast disease appears to be more common in women with a significant family history of breast cancer than in controls, further supporting its significance as a risk factor. Of note, however, the majority of breast biopsies done for clinical indications demonstrate nonproliferative disease. In the study of 10,000 breast biopsies by Dupont and Page,³⁰ 69% had nonproliferative changes and only 3.6% demonstrated atypical hyperplasia.

Breast Density

Mammographic breast density has emerged as an important predictor of breast cancer risk, and makes detection of cancer more difficult. A significant component of breast density is genetically determined, although density has also been shown to vary with the initiation and discontinuation of postmenopausal HRT. Women with $>75\%$ breast density have 4.7-fold increase in the odds of breast cancer development compared with those with $>10\%$ breast density.³¹ The risk was apparent even after adjustment for other risk factors.

Environmental Factors

Exposure to ionizing radiation increases breast cancer risk, and the increase is particularly marked for exposure at a young age. This pattern has been observed in survivors of the atomic bombings, those undergoing multiple diagnostic X-ray examinations, and in women receiving therapeutic irradiation. A markedly increased risk of breast cancer development has been reported in women who received mantle irradiation for the treatment of Hodgkin lymphoma before age 15 years.³² Additionally, in women with Hodgkin lymphoma who develop unilateral breast cancer, the risk of a contralateral cancer approximates the level of risk seen in *BRCA* mutation carriers.³² Well-conducted studies do not suggest that exposure to electromagnetic fields and organochlorine pesticides increase breast cancer risk. A summary of the magnitude of risk associated with known breast cancer risk factors is provided in Table 79.2.

TABLE 79.2

Magnitude of Risk of Known Breast Cancer Risk Factors

Relative Risk <2	Relative Risk 2–4	Relative Risk >4
Early menarche Late menopause	One first-degree relative with breast cancer	Mutation <i>BRCA1</i> or <i>BRCA2</i> LCIS
Nulliparity	<i>CHEK2</i> mutation	Atypical hyperplasia
Estrogen plus progesterone	Age >35 y for first birth	Radiation exposure before 30
HRT	Proliferative breast disease	
Alcohol use	Mammographic breast density	
Postmenopausal obesity		

LCIS, lobular carcinoma in situ; HRT, hormone replacement therapy.

MANAGEMENT OF THE HIGH-RISK PATIENT

There is no formal definition of what constitutes *high risk*. Without question, women who carry mutations in either *BRCA1* or *BRCA2*, or who have a family history consistent with genetically transmitted breast cancer, are considered to be at higher risk than those in the general population. Other high-risk groups include women who have received mantle irradiation, usually for treatment of Hodgkin lymphoma, and those with lobular carcinoma in situ (LCIS) or atypical hyperplasia. Although a variety of hormonal factors (e.g., early menarche, late age at first full-term pregnancy) affect breast cancer risk on a population basis, these conditions have a relatively small effect on risk for any individual woman.

Many women overestimate their risk of developing breast cancer, so providing an accurate assessment of breast cancer risk will often allay anxiety and facilitate management decisions. It can be helpful to provide women who are concerned about their breast cancer risk with a numeric risk estimate. The Gail et al. model,³³ which calculates a woman's risk of developing breast cancer based on age at menarche, age at first live birth, number of previous breast biopsies, the presence or absence of atypical hyperplasia, and the number of first-degree female relatives with breast cancer, has been used in the National Surgical Adjuvant Breast and Bowel Project (NSABP) breast cancer prevention trials. Efforts to validate the Gail et al. model in different settings have produced variable results. It was highly accurate in the NSABP P1 prevention trial,³⁴ with a ratio of observed to predicted cancers in study participants of 1.03. In general, the Gail et al.³³ model is thought to underestimate risk in women with strong family histories, at least in part because it only incorporates a family history in first-degree relatives and does not include ovarian carcinoma. The Claus et al.³⁵ model takes into account both first- and second-degree relatives, although it does not include other risk factors, and may be more useful for women at risk on the basis of family history.

Management strategies available for high-risk women include intensive surveillance, chemoprevention with endocrine agents, and prophylactic surgery. Surveillance, consisting of monthly breast self-examination, annual screening mammography, and clinical breast examinations once or twice yearly, did not clearly result in early detection in high-risk women in the placebo arm of the NSABP P1 prevention trial where 29% of the women who developed breast cancer had axillary node metastases at diagnosis.³⁴ Women at risk as a result of known or suspected *BRCA1* or *BRCA2* mutations warrant screening with magnetic resonance imaging (MRI), which results in earlier detection of breast cancer than conventional surveillance strategies, and has a higher specificity and sensitivity among high-risk women.³⁶ Because the cancers detected by MRI are smaller and less likely to be associated with nodal positivity, it is likely that a survival benefit is present. However, there is no benefit for MRI screening in women

with atypical hyperplasia or LCIS.³⁷ An expert panel convened by the American Cancer Society in 2007 to develop guidelines for MRI screening recommended the use of MRI in addition to mammography for a small group of women at very high risk of breast cancer development, either due to genetic factors or a history of prior thoracic irradiation (Table 79.3). It has been estimated that only 1% of the population would be eligible for MRI screening using these criteria.³⁸ For women with a <15% risk of breast cancer development, the American Cancer Society recommended against the use of MRI screening.³⁹ In the remainder, they thought that the evidence was insufficient to recommend for or against MRI screening. Chemoprevention is an option in addition to surveillance strategies. Two SERMs, tamoxifen and raloxifene, have been shown to reduce the incidence of ER⁺ breast cancer. Four prospective, randomized trials have examined the effect of tamoxifen on breast cancer incidence (Tables 79.4 and 79.5).^{34,40–42} There is considerable heterogeneity in outcome among the trials, much of which can be attributed to differences in the populations studied. In an overview of the four studies, tamoxifen produced a 38% reduction in breast cancer incidence (95% confidence interval [CI], 8 to 46; *p* < 0.001), and a 48% reduction in the incidence of ER⁺ breast cancers.⁴³ No effect on the incidence of ER⁻ cancers was seen in any of the trials, and the cancers occurring in women taking tamoxifen were not

TABLE 79.3

American Cancer Society Guidelines for Magnetic Resonance Imaging Screening

- Annual MRI recommended based on evidence
 - *BRCA* mutation
 - Untested first-degree relative of *BRCA* carrier
 - Lifetime risk of breast cancer 20% to 25%
- Annual MRI recommended based on expert opinion
 - Radiation to chest between age 10 and 30 y
 - Li-Fraumeni syndrome and first-degree relatives
 - Cowden and Bannayan-Riley-Ruvalcaba syndromes and first-degree relatives
- Insufficient evidence to recommend for or against MRI
 - Lifetime breast cancer risk 15% to 20%
 - Lobular carcinoma in situ
 - Atypical hyperplasia (lobular or ductal)
 - Extremely or heterogeneously dense breasts on mammogram
 - Personal history of breast cancer, including ductal carcinoma in situ

MRI, magnetic resonance imaging.

found to have had more positive nodes or to be larger in size than those in the placebo arm, providing reassurance that tamoxifen chemoprevention does not result in the occurrence of biologically more-aggressive cancers.

In the largest of these studies, the NSABP P1 trial, a 49% risk reduction was seen with tamoxifen, with 43.4 cancers per 1,000 women occurring in the placebo arm compared with 22.0 per 1,000 in the tamoxifen arm.³⁴ The benefits of tamoxifen were observed for both invasive and noninvasive carcinoma, and were seen in women of all ages. A particular benefit was seen in those at risk because of atypical hyperplasia, with an 84% reduction in cancer incidence in this group. The risk reductions were similar in those at risk on the basis of a family history of breast cancer and those at risk from other factors. Controversy exists over the benefit of tamoxifen in BRCA mutation carriers,^{44,45} but it appears that it is the likelihood of expressing the ER that determines the efficacy of tamoxifen as a chemopreventive agent rather than the presence of a BRCA mutation.

The side effects of tamoxifen were well known from its use as a cancer treatment and were again observed in the prevention trials. In the combined analysis of the four studies, the RR of thromboembolic events in tamoxifen users was 1.9 (95% CI = 1.4 to 2.6; $p < 0.0001$) and the RR of endometrial cancer was 2.4 (95% CI = 1.5 to 4.0; $p = 0.0005$).⁴³ Significant elevation in endometrial cancer and thromboembolic events was limited to postmenopausal women. Thus, women most likely to have a favorable risk-benefit ratio for tamoxifen prevention include premenopausal women, younger postmenopausal women without a uterus, and those at risk on the basis of atypical hyperplasia or LCIS. Despite the proven efficacy, use of tamoxifen as chemoprevention has been limited because of concerns about side effects and the small absolute differences in outcomes.

Raloxifene is a SERM used for the treatment and prevention of osteoporosis that was noted to reduce the incidence of ER⁺ breast cancer in this population. The NSABP P2 trial, the Study of Tamoxifen and Raloxifene (STAR) trial, directly compared

the chemopreventive actions and side effects of tamoxifen and raloxifene in 19,747 postmenopausal women at increased risk of breast cancer development.³⁶ No difference in the incidence of invasive cancer was seen between women taking tamoxifen and those taking raloxifene (RR = 1.02; 95% CI = 0.82 to 1.28). More cases of noninvasive cancer were noted in the raloxifene group, with a cumulative incidence of 11.7 per 1,000 compared with 8.1 per 1,000 in the tamoxifen group at 6 years (RR = 1.4; $p = 0.052$). A more favorable side-effect profile was seen for raloxifene, with a reduction in the number of hysterectomies and endometrial cancers in the raloxifene group (RR = 0.62; 95% CI = 0.35 to 1.08), although the difference did not reach statistical significance. Significantly fewer thromboembolic events and cataracts occurred with raloxifene. Raloxifene is thus a viable alternative to tamoxifen for the chemoprevention of breast cancer in postmenopausal women at increased risk for the disease. In addition, the use of raloxifene in women with osteoporosis has the potential to lower breast cancer incidence in a group of women not considered at high risk.

Trials of aromatase inhibitors (AI) for breast cancer prevention suggest qualitatively similar results as seen with SERMs. The MAP.3 trial examined the use of the AI exemestane in postmenopausal women with a Gail risk score of 1.66, atypical hyperplasia, LCIS, or unilateral ductal carcinoma in situ (DCIS) treated with mastectomy. After a median follow-up of 3 years, a 65% reduction in invasive breast cancer was seen with exemestane ($p = 0.002$).⁴⁶ The reduction in cancer incidence was also limited to ER⁺ cancers. At present, there are no chemopreventive agents that have been proven to be effective in reducing the incidence of ER⁻ breast cancer.

The 2013 American Society of Clinical Oncology (ASCO) guideline on pharmacologic agents for breast cancer risk reduction⁴⁷ recommends discussion of tamoxifen for breast cancer risk reduction with premenopausal women age 35 and older at increased risk for breast cancer development, and discussion of tamoxifen, raloxifene, and exemestane with high-risk

TABLE 79.6

Outcome of Bilateral Prophylactic Mastectomy in High-Risk Women

Author ^(Ref.)	Population	No. of Women	Follow-Up (y)	Risk Reduction (%)
Hartmann et al. ⁴⁸	Women with a family history of breast cancer	639	14 (median)	90–94
Meijers-Heijboer et al. ⁴⁹	<i>BRCA1/2</i> mutation carriers	139	3 (mean)	100
Rebbeck et al. ⁵⁰	<i>BRCA1/2</i> mutation carriers	105	6.4 (mean)	90–95

postmenopausal women. Histories of deep vein thrombosis, stroke, pulmonary embolism, or transient ischemic attacks are considered contraindications to the use of both tamoxifen and raloxifene.

Prophylactic surgery, in the form of bilateral mastectomy or bilateral salpingo-oophorectomy, is another option for breast cancer risk reduction. The efficacy of prophylactic mastectomy has never been studied in a prospective, randomized trial. In a retrospective study of 639 women who had bilateral prophylactic mastectomy due to a family history of breast cancer,⁴⁸ a 90% to 94% reduction in breast cancer incidence (95% CI = 71% to 99%) and an 81% to 100% reduction in breast cancer mortality with prophylactic mastectomy compared to unaffected sisters or Gail model predictions was observed. Prospective studies in *BRCA* mutation carriers (Table 79.6) demonstrate similar levels of risk reduction.^{48–50}

Prophylactic bilateral salpingo-oophorectomy is an alternative risk-reduction strategy in women at risk on the basis of *BRCA* mutations, which has the added benefit of reducing the risk of ovarian carcinoma, a disease for which effective screening is not available. In a prospective study of the benefits of prophylactic salpingo-oophorectomy in 170 *BRCA* mutation carriers, Kauff et al.¹⁹ observed that the HR for breast cancer was reduced to 0.32 (95% CI = 0.08 to 1.20) and to 0.25 for gynecologic cancer (95% CI = 0.08 to 0.74) at a mean follow-up of 24 months. In a meta-analysis⁵¹ of risk-reduction estimates associated with risk-reducing salpingo-oophorectomy in *BRCA1* or *BRCA2* mutation carriers, statistically significant reductions in breast cancer (HR = 0.49; 95% CI = 0.37 to 0.65 with similar risk reductions in *BRCA1* and *BRCA2* mutation carriers) and in the risk of *BRCA1/2*-associated ovarian or fallopian tube cancer (HR = 0.21; 95% CI = 0.12 to 0.39) were observed. More recently, recognition that *BRCA*-associated cancers arise in the fallopian tube rather than the ovary has led some to propose bilateral salpingectomy, with ovarian preservation, as a risk-reducing strategy, but the efficacy of this approach is uncertain.

DIAGNOSIS AND BIOPSY

The presence or absence of carcinoma in a suspicious clinically or mammographically detected abnormality can only be reliably determined by tissue biopsy. An abnormal MRI does not reliably indicate the presence of cancer, and a nonworrisome MRI does not reliably exclude carcinoma.⁵² Available biopsy techniques include fine needle aspiration (FNA), core needle biopsy, and excisional biopsy. Needle biopsy techniques (FNA or core biopsy) are preferred because they are more cost-effective than surgical excision, and because most breast lesions are benign, they avoid a surgical scar and potential cosmetic deformity.

FNA is easily performed, but requires a trained cytopathologist for accurate specimen interpretation and does not reliably distinguish invasive cancer from DCIS, a particular drawback for nonpalpable abnormalities, which are often DCIS. Core-cutting needle biopsy has many of the advantages of FNA, but provides a histologic specimen suitable for interpretation by any pathologist, and facilitates ER, PR, and *HER2* testing. False-negative results from sampling error may occur with both core-cutting needle biopsy and FNA. When concordance between the core biopsy or

FNA diagnosis, and the clinical and imaging findings is not present, additional tissue should be obtained, usually by excisional biopsy. Concerns about the false-negative rate of image-guided core biopsy have been resolved with the availability of large, vacuum-assisted biopsy devices that increase the extent of lesion sampling, coupled with the development of clearly defined indications for follow-up surgical biopsy. False-negative rates of core biopsy are now reliably <1%. Indications for surgical biopsy following core biopsy are listed in Table 79.7. Although the finding of atypical ductal hyperplasia on a core biopsy is uniformly accepted as an indication for open surgical biopsy, the need for surgical excision of all lesions showing atypical lobular hyperplasia (ALH) or LCIS remains controversial (discussed in the section “Lobular Carcinoma in Situ”). Papillary carcinoma in situ cannot always be readily distinguished from benign papillary lesions on a core biopsy, and radial scar may be difficult to distinguish from tubular carcinoma without complete removal of the lesion.

The use of core biopsy for the diagnosis of mammographic abnormalities is cost-effective and increases the likelihood that the patient will be able to undergo a single surgical procedure for definitive cancer treatment.⁵³ Excisional biopsy as a diagnostic technique should be reserved for patients with imaging abnormalities that cannot be targeted for core biopsy. A core biopsy diagnosis permits a complete discussion of treatment options prior to the placement of an incision on the breast and allows the breast procedure and the axillary surgery to take place at a single operation.

When excisional biopsy is performed for diagnosis, a small margin of grossly normal breast should be excised around the tumor, orienting sutures should be placed, and the specimen should be inked to allow margin evaluation.

LOBULAR CARCINOMA IN SITU

In 1941, Foote and Stewart⁵⁴ published their landmark study of LCIS, describing a relatively uncommon entity characterized by an “alteration of lobular cytology.” They hypothesized that LCIS was a precursor lesion of invasive cancer, and, based on this, treatment with mastectomy was recommended. More recently, the term ALH has been introduced to describe morphologically

TABLE 79.7

- Diagnosis of atypical lobular hyperplasia or lobular carcinoma in situ^a
- Lack of concordance between imaging findings and histologic diagnosis
- Radial scar
- Papillary lesions

^a See text for details.

similar, but less well-developed, lesions. Some centers use the term *lobular neoplasia* (LN) to cover both ALH and LCIS. Morphologically, LN is defined as “a proliferation of generally small and often loosely cohesive cells originating in the terminal duct-lobular unit, with or without pagetoid involvement of terminal ducts.”⁵⁵

In the past, LCIS was most frequently diagnosed in women aged 40 to 50, a decade earlier than DCIS, but recent literature indicates that the incidence in postmenopausal women is increasing.⁵⁶ Determining the true incidence of LCIS is difficult, as there are no specific clinical or mammographic abnormalities associated with the lesion and the diagnosis of LCIS is often made as an incidental, microscopic finding in a breast biopsy performed for other indications. The prevalence of LN in an otherwise benign breast biopsy has been reported as between 0.5% and 4.3%.⁵⁷ LCIS is both multifocal and bilateral in a large percentage of cases.

In an analysis of nine studies including 172 patients with LCIS who were treated by biopsy alone, 15% developed invasive carcinoma in the ipsilateral breast and 9.3% carcinoma in the contralateral breast after 10 years of follow-up.⁵⁸ This corresponds to a risk of development of invasive carcinoma of about 1% to 2% per year, with a lifetime risk of 30% to 40%. In this study (conducted prior to effective breast imaging), 5.7% of the patients developed metastatic breast cancer. In a more recent study of 776 women with LCIS followed in a high-risk screening program at Memorial Sloan-Kettering Cancer Center, King et al.⁵⁷ reported that 13% had developed cancer at a median follow-up of 58 months, a rate similar to that seen in older studies. Cancers were detected at a median size of 0.8 cm (0.1 cm to 3.5 cm), and 78% were node negative. MRI screening had no significant impact on cancer stage at diagnosis in this cohort. Subsequent cancers are more often invasive ductal carcinoma than invasive lobular carcinoma (ILC), but the incidence of subsequent ILC is substantially increased compared with women without LCIS. Although the risk for development of breast cancer is bilateral, subsequent ipsilateral carcinoma is more likely than contralateral breast cancer, supporting the view that ALH and LCIS act both as precursor lesions and as risk indicators. The RR for development of subsequent breast cancer is lower in women diagnosed with ALH compared with LCIS. Therefore, although LN is a helpful term for collectively describing this group of lesions, specific classification into ALH and LCIS is preferable in terms of risk assessment and management.

LCIS is typically positive for ER and PR staining and negative for *HER2/neu* staining. LN (and ILC) characteristically lacks expression of E-cadherin, an epithelial cell membrane molecule involved in cell-cell adhesion. E-cadherin negativity serves as a fairly reliable means of distinguishing ductal from lobular disease, both in situ and invasive. Pleomorphic LCIS is a relatively uncommon variant of LCIS characterized by medium-to-large pleomorphic cells containing eccentric nuclei, prominent nucleoli, and eosinophilic cytoplasm. As with classic LCIS, it is usually ER⁺ and negative for E-cadherin; it also tests positive by immunohistochemistry (IHC) for gross cystic disease fluid protein-15. Pleomorphic LCIS can be associated with central necrosis, may be associated with mammographic microcalcifications, and may be difficult to distinguish from DCIS. Although pleomorphic LCIS has a more aggressive histologic appearance than classic LCIS, the relative rarity of this lesion and the lack of uniform diagnostic criteria make it difficult to know if pleomorphic LCIS has a different natural history than classic LCIS.

Genetic changes in LN have been evaluated in a number of studies using comparative genomic hybridization. In both ALH and LCIS, there was loss at 16q21-q23.1, an altered region previously identified in invasive carcinoma.⁵⁹ This genomic signature, common to LN and ILC, further suggests that LN is a precursor lesion in some women.

Management of LN must address the bilateral risk, and options therefore include surveillance, chemoprevention, and prophylactic bilateral mastectomy. Surveillance is the strategy selected by most patients. Mammographic screening is the standard breast

imaging technique for patients selecting surveillance. Breast MRI has been used, but, as noted previously, existing evidence does not support its routine use for patients with LCIS. Prophylactic mastectomy reduces breast cancer risk among high-risk women by approximately 90%. Chemoprevention with tamoxifen in patients with LCIS has been evaluated as part of the NSABP P1 study.³⁴ Overall, tamoxifen reduced the incidence of breast cancer by 49% ($p < 0.00001$), and a similar level of risk reduction was seen in the 826 participants with a history of LCIS. In the NSABP P2 (STAR) trial,³⁶ 893 participants gave a history of LCIS, and their rates of subsequent breast cancer were similar with tamoxifen and raloxifene. Benefit for exemestane in women with LCIS was also seen in the MAP.3 study.⁴⁶

In the past, the finding of LN on a core needle biopsy usually led to a recommendation for surgical biopsy to rule out coexisting DCIS or invasive cancer. Recent studies have demonstrated that when the diagnosis of LN is concordant with the imaging findings, upgrade rates with surgical excision are $\leq 3\%$.⁶⁰ Discordance between the pathology and imaging, and the presence of pleomorphic LCIS in a core biopsy remain indications for surgical excision. The recent recognition that, in some cases, LCIS may be a precursor lesion has led to confusion as to whether it should be treated like DCIS (i.e., excised to negative margins and irradiated). At this time, there are no data indicating that the incidence of subsequent cancer is reduced with this approach. When LCIS is seen on an excised tissue, it is not necessary to obtain negative margins of resection, and there is no established role for radiation therapy in patients with LN.

DUCTAL CARCINOMA IN SITU

DCIS is defined as the proliferation of malignant-appearing mammary ductal epithelial cells without evidence of invasion beyond the basement membrane. Prior to the widespread use of screening mammography, <5% of mammary cancers were DCIS. At present, 15% to 30% of the cancers detected in mammography screening programs are DCIS, and the greatest increase in the incidence of DCIS has been seen in women aged 49 to 69 years. DCIS can present as a palpable or nonpalpable mass, Paget disease of the nipple, an incidental finding at biopsy, or, most commonly, as mammographically detected calcifications.

A central problem in the management of DCIS is the lack of understanding of its natural history and the inability to determine which DCIS will progress to invasive carcinoma during a woman's lifetime. The concordance between risk factors for DCIS and invasive carcinoma suggests that they are part of the same disease process.⁶¹ Attempts to better characterize the natural history of DCIS on the basis of pathologic features have not been particularly successful. The traditional morphologic classification into comedo, papillary, micropapillary, solid, and cribriform types is confounded by the observation that as many as 30% to 60% of DCIS lesions display more than one histologic pattern. To overcome this difficulty, a number of classifications based on nuclear grade and the presence or absence of necrosis have been developed. No single classification scheme has been widely adopted and, most importantly, none of the classification systems have been prospectively demonstrated to predict the risk of development of invasive carcinoma. Molecular profiling studies in DCIS have been limited by the need for histologic examination of the entire lesion to reliably exclude the presence of invasive carcinoma. The Oncotype DX (Genomic Health, Redwood City, CA) assay using paraffin-embedded tissue was modified for DCIS, and an initial study suggested usefulness in predicting the risk of invasive in-breast recurrence. This finding has not been validated in other populations, nor has this test been shown to predict the benefit of radiotherapy (RT).⁶² The available data indicate that DCIS lesions share many of the genetic alterations of invasive carcinoma, but predictors of progression to invasion remain to be identified.

Treatment of the Breast

Cancer-specific survival for the woman diagnosed with DCIS exceeds 95%, regardless of the type of local therapy employed.^{63,64} Mastectomy, excision and RT, and excision alone have all been proposed as management strategies for DCIS. The appropriate therapy for the woman with DCIS depends on the extent of the DCIS lesion, the risk of local recurrence (LR) with each form of treatment, and the patient's attitude toward the risks and benefits of a particular therapy.

Total or simple mastectomy is curative in approximately 98% of patients regardless of age, DCIS presentation, size, or grade.⁶⁵ The primary medical indication for mastectomy in DCIS is a lesion too large to be excised to negative margins with a cosmetically acceptable outcome.⁶⁶ The extent of DCIS is most accurately estimated preoperatively with the use of magnification mammography.⁶⁷ Studies indicate that MRI both overestimates and underestimates the size of DCIS lesions, does not improve surgical planning when compared with diagnostic mammography, and does not decrease the rate of ipsilateral breast tumor recurrence (IBTR).⁶⁸

For women with localized DCIS, management by excision alone and excision plus RT have both been employed. Four published prospective, randomized trials have directly compared these two approaches in >4,500 patients.^{63,64,69,70} In all four trials, the majority of participants had mammographically detected DCIS, and in all but the Swedish trial,⁷⁰ negative margins (no ink on tumor) were required. A dose of 50 Gy of radiation was delivered to the whole breast in 25 fractions, and a boost dose to the tumor bed was not required. The results of these trials are summarized in Table 79.8. No differences in overall survival (OS) were seen between treatment arms. In all four studies, the use of RT resulted in a highly significant reduction in the risk of an IBTR, with proportional risk reductions ranging from 47% to 63%.^{40,63} Consistent with observations from many retrospective studies, approximately 50% of the recurrences in both groups were invasive carcinoma, and a benefit for RT was seen in the reduction of both invasive and noninvasive recurrences.

A meta-analysis by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) provides a concise overview of RT effect following lumpectomy for DCIS.⁷¹ With a median follow-up of 8.9 years, RT approximately halved the rate of ipsilateral breast events (rate ratio = 0.46; standard error [SE] = 0.05; $2p < 0.00001$). RT was effective in all subgroups. There were 291 "low-risk" cases of DCIS that were low-grade, >20 mm in size, and with negative surgical margins identified. Among them, the

10-year risk of an ipsilateral event in those allocated to lumpectomy alone was substantial at 30.1%, and even with this relatively small number of women, the effect of RT was highly significant (rate ratio = 0.48; SE = 0.17; $2p = 0.002$), with a 10-year absolute gain of 18.0% (SE = 5.5%).

The Radiation Therapy Oncology Group (RTOG) study 9804 sought to determine RT benefit after lumpectomy for patients with low-risk DCIS.⁷² In comparison to the other randomized trials, RTOG 9804 enrolled patients with smaller lesions, all low- or intermediate-grade DCIS, and had a much higher rate of adjuvant tamoxifen use (62%). Recurrence rates were 6.7% in the observation arm, compared to 0.9% in the RT arm, after a median follow-up of 7.2 years (HR = 0.11; 95% CI = 0.03 to 0.47; $p = 0.0003$).⁷² This suggests that even in low-risk DCIS, RT can lower the risk of in-breast recurrence. LR rates after excision and RT have decreased over time due to improvements in imaging and pathologic analysis. In a retrospective review of 246 consecutive patients treated at Dana-Farber Cancer Institute and Brigham and Women's Hospital from 2001 to 2007, there were no LRs with a median follow-up time of 58 months.⁷³

Despite the clear benefit of RT seen in these five trials, there was considerable interest in identifying patients who could be spared RT for DCIS. The Dana-Farber/Harvard Cancer Center conducted a single-arm, prospective trial of wide excision alone from 1995 to 2002 among 158 patients.⁷⁴ Entry criteria included DCIS of predominant grade 1 or 2 with a mammographic extent of no greater than 2.5 cm and final margin width of at least 1 cm. Tamoxifen was not permitted. The study was closed to further accrual because the number of LRs ($n = 13$) met the predefined stopping rules. The median patient age was 51 years, and 94% had mammographically detected DCIS. The median follow-up was 11 years, and 143 patients were followed for >8 years. Nineteen patients developed an LR. Fourteen recurrences were in the same quadrant as the initial DCIS, and five were elsewhere in the ipsilateral breast. A total of 32% recurred with invasive disease. No patient developed distant metastasis. The 10-year cumulative incidence of LR was 15.6%.

Similar results were seen in the Eastern Cooperative Oncology Group single-arm trial of excision alone for DCIS. Eligibility criteria for this study included DCIS at least 3 mm in size, excised with a margin width of ≥ 3 mm as determined by sequential sectioning, and complete embedding. The study enrolled patients with low- or intermediate-grade DCIS ≤ 2.5 cm in size and high-grade DCIS (defined as nuclear grade 3 with necrosis) up to 1 cm in size. A postexcision mammogram was required for

all patients. At a median follow-up of 8.8 years, the 10-year LR rate was 19.0% for patients with high-grade DCIS, and 14.6% for those with low- or intermediate-grade DCIS.⁶² Taken together, these prospective studies indicate that even patients with small low- to intermediate-grade DCIS treated with excision to widely negative margins of resection have about a 15% 10-year risk of a LR in the absence of RT. No reduction in recurrence was observed for patients excised to margins of ≥ 1 cm compared to those with margins of 3 to 9 mm.

The 2014 National Comprehensive Cancer Network (NCCN) Guidelines[®] endorse lumpectomy and whole breast radiation therapy or total mastectomy as category 1 recommendations, and lumpectomy without RT as a category 2B recommendation.⁶⁶ Clearly, patients should be included in the treatment decision making to learn what magnitude of risk reduction is meaningful to them. A detailed discussion of the pros and cons of the various treatment options is needed to allow each woman with DCIS to make an informed treatment choice.

Treatment of the Axilla

In situ carcinoma by definition does not metastasize, so theoretically, axillary staging should be unnecessary for DCIS. Studies of axillary dissection (ALND) in DCIS have demonstrated axillary nodal metastases in only 1% to 2% of patients, presumably due to unrecognized microinvasion. Data from the NSABP B-17 and B-24 studies confirm that the risk of isolated axillary recurrence with no axillary surgery is $<0.1\%$, regardless of whether RT and tamoxifen are administered.⁷⁵ These low rates of axillary recurrence argue against routine use of sentinel lymph node biopsy in DCIS. Selective use of sentinel node biopsy in patients with DCIS who are at significant risk of having coexistent invasive carcinoma is appropriate. Approximately 15% of patients diagnosed as having DCIS with large vacuum-assisted biopsy devices are found to have invasive cancer after complete excision of the lesion. The diagnosis of DCIS in a palpable breast mass and pathologic interpretation of a core biopsy specimen as suspicious, but not diagnostic, of microinvasion are circumstances in which invasive cancer is frequently found when the lesion is completely examined and so sentinel node biopsy should be considered.

Because patients undergoing mastectomy forfeit the opportunity for sentinel node biopsy if not performed concurrently, patients receiving mastectomy for DCIS should undergo sentinel node biopsy.

Endocrine Therapy

The ER is present in about 80% of DCIS lesions and is more frequent in noncomedo than comedo DCIS.⁷⁶ Endocrine therapy might reduce LR after breast-conserving therapy (BCT) and prevent development of new primary breast cancers in the contralateral breast. Two trials have examined the use of tamoxifen in women with DCIS. In the NSABP B-24 trial,⁶⁴ patients with DCIS were treated with excision and RT and randomized to tamoxifen 20 mg daily or a placebo for 5 years. Patients in the tamoxifen arm had a 32% reduction in the risk of an invasive LR ($p = 0.025$), a 16% reduction in the risk of a DCIS LR ($p = 0.33$), and a 32% reduction in contralateral breast cancer ($p = 0.023$) compared to the patients in the placebo arm. In the subset of women with ER⁺ DCIS, tamoxifen reduced the risk of any breast cancer event by 51% (RR = 0.41; 95% CI = 0.25 to 0.65; $p = 0.0002$); there was no benefit seen if the DCIS lesion was ER⁻.⁷⁶ The United Kingdom/Australia New Zealand trial⁶⁹ that randomized women to tamoxifen or to no tamoxifen and with a median follow-up of 12.7 years found that tamoxifen reduced ipsilateral events (HR = 0.78; 95% CI = 0.62 to 0.99), but more significantly, reduced contralateral events (HR = 0.44; 95% CI = 0.25 to 0.77) (In a subset analysis, the benefit of tamoxifen appeared restricted to

patients who did not receive RT.) Taken together, these trials suggest that tamoxifen modestly reduces ipsilateral events with or without RT, and substantially reduce contralateral events. The addition of tamoxifen to RT is particularly attractive in young patients with ER⁺ DCIS, in whom the risk of LR is higher and the toxicity of tamoxifen is less than in older patients.

Evidence that the AIs reduce the incidence of contralateral breast cancer to a greater extent than tamoxifen has led to interest in their use in DCIS. Ongoing trials (NSABP B53 and IBIS II) are comparing tamoxifen with an AI; however, at present, there are no data for use of AIs in management.

In summary, patients with localized DCIS have treatment options ranging from simple excision to mastectomy, all of which have high survival rates but different risks of LR. Patient preference plays a major role in treatment selection, but available evidence indicates that patients have limited understanding of the nature of DCIS. In one study, women with DCIS estimated their risk of breast cancer death to be 39%.⁷⁷ Perhaps related to this, Katz et al.⁷⁸ found that although patients reported that their surgeon infrequently recommended mastectomy for DCIS, greater involvement of patients in the decision-making process was associated with higher rates of mastectomy.

STAGING

The staging system for breast cancer was last updated in 2010.⁷⁹ The American Joint Committee on Cancer (AJCC) system is both a clinical and pathologic staging system, and is based on the TNM system in which “T” refers to tumor, “N” to nodes, and “M” to metastasis. The current version is the seventh edition of the system and is provided in the following.⁷⁹

The major changes in this edition were the inclusion of a new classification system for patients after neoadjuvant therapy and the creation of a new M0(i+) category for patients found to have circulating tumor cells, tumor in the bone marrow, or incidentally detected tumor deposits in other tissues not exceeding 0.2 mm in size. Patients in this category are staged according to T and N, and are not classified as stage IV.

The AJCC staging system provides a strategy for grouping patients with respect to prognosis. However, TNM staging, while still important, has been superseded by rapidly evolving molecular characterizations of breast cancers, which more precisely define subgroups with different outcomes, both in terms of prognosis and response to specific treatments. Increasingly, multigene diagnostic tests, such as Oncotype DX and MammaPrint (Agendia Inc. USA, Irvine, CA), are employed as part of treatment decision making for invasive breast cancer.

Tumor, Node, and Metastases Definitions

Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements are used, such as mammographic or pathologic measurements, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1 cm increment. The AJCC TNM staging system is illustrated in Table 79.9. Stage IIIC breast cancer includes patients with any T stage who have pN3 disease. Patients with pN3a and pN3b disease are considered operable and are managed as described in the section on stage I, II, IIIA, and operable IIIC breast cancer. Patients with pN3c disease, in which the ipsilateral supraclavicular nodes are affected by cancer, are considered inoperable and are managed as described in the section on inoperable stage IIIB or IIIC or inflammatory breast cancer (IBC).⁷⁹ Pathologic stage after neoadjuvant therapy is designated with the prefix “yp.” Complete response is defined as the absence of invasive carcinoma in the breast and axillary nodes.

TABLE 79.9

American Joint Committee on Cancer Staging

Primary Tumor (T)

- TX: Primary tumor cannot be assessed
- T0: No evidence of primary tumor
- Tis: Carcinoma in situ
 - Tis: DCIS
 - Tis: LCIS
 - Tis (Paget): Paget disease of the nipple NOT associated with invasive carcinoma and/or carcinoma in situ (DCIS and/or LCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget disease are categorized based on the size and characteristics of the parenchymal disease, although the presence of Paget disease should still be noted.
- T1: Tumor ≤ 20 mm in greatest dimension
 - T1mi: Tumor ≤ 1 mm in greatest dimension
 - T1a: Tumor > 1 mm but ≤ 5 mm in greatest dimension
 - T1b: Tumor > 5 mm but ≤ 10 mm in greatest dimension
 - T1c: Tumor > 10 mm but ≤ 20 mm in greatest dimension
- T2: Tumor > 20 mm but ≤ 50 mm in greatest dimension
- T3: Tumor > 50 mm in greatest dimension
- T4: Tumor of any size with direct extension to the chest wall and/or to skin (ulceration or skin nodules). (Note: Invasion of the dermis alone does not qualify as T4.)
 - T4a: Extension to chest wall, not including only pectoralis muscle adherence/invasion
 - T4b: Ulceration and/or ipsilateral satellite nodules and/or edema (including peau d'orange) of the skin, which do not meet the criteria for inflammatory carcinoma
 - T4c: Both T4a and T4b
 - T4d: Inflammatory carcinoma

Regional Lymph Nodes (N)

- NX: Regional lymph nodes cannot be assessed (e.g., previously removed)
- N0: No regional lymph node metastases
- N1: Metastases to movable ipsilateral level I, II axillary lymph node(s)
- N2: Metastases in ipsilateral level I, II axillary lymph nodes that are clinically fixed or matted; or in clinically detected^a ipsilateral internal mammary nodes in the *absence* of clinically evident lymph node metastases
- N2a: Metastases in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures.
- N2b: Metastases only in clinically detected^a ipsilateral internal mammary nodes and in the *absence* of clinically evident level I, II axillary lymph node metastases
- N3: Metastases in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement; or in clinically detected^a ipsilateral internal mammary lymph node(s) with clinically evident level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
- N3a: Metastases in ipsilateral infraclavicular lymph node(s)
- N3b: Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
- N3c: Metastases in ipsilateral supraclavicular lymph node(s)

Pathologic (pN)^b

- pNX: Regional lymph nodes cannot be assessed (e.g., previously removed, or not removed for pathologic study)
- pN0: No regional lymph node metastasis identified histologically
- [Note: ITC clusters are defined as small clusters of cells not > 0.2 mm, or single tumor cells, or a cluster of < 200 cells in a single histologic cross-section. ITCs may be detected by routine histology or by IHC methods. Nodes containing only ITCs are excluded from the total positive node count for purposes of N classification but should be included in the total number of nodes evaluated.]
- pN0(i-): No regional lymph node metastases histologically, negative IHC
- pN0(i+): Malignant cells in regional lymph node(s) no > 0.2 mm (detected by H&E or IHC including ITC)
- pN0(mol-): No regional lymph node metastases histologically, negative molecular findings (RT-PCR)
- pN0(mol+): Positive molecular findings (RT-PCR), but no regional lymph node metastases detected by histology or IHC
- pN1: Micrometastases; or metastases in one to three axillary lymph nodes; and/or in internal mammary nodes with metastases detected by SLNB but not clinically detected^c
 - pN1mi: Micrometastases (> 0.2 mm and/or > 200 cells, but none > 2.0 mm)
 - pN1a: Metastases in one to three axillary lymph nodes, at least one metastasis > 2.0 mm
 - pN1b: Metastases in internal mammary nodes with micrometastases or macrometastases detected by SLNB but not clinically detected^d
 - pN1c: Metastases in one to three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLNB but not clinically detected
- pN2: Metastases in four to nine axillary lymph nodes; or in clinically detected^d internal mammary lymph nodes in the *absence* of axillary lymph node metastases
 - pN2a: Metastases in four to nine axillary lymph nodes (at least one tumor deposit > 2.0 mm)
 - pN2b: Metastases in clinically detected^d internal mammary lymph nodes in the *absence* of axillary lymph node metastases
- pN3: Metastases in 10 or more axillary lymph nodes; or in infraclavicular (level III axillary) lymph nodes; or in clinically detected^d ipsilateral internal mammary lymph nodes in the *presence* of one or more positive level I, II axillary lymph node(s); or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLNB but not clinically detected^e; or in ipsilateral supraclavicular lymph nodes

(continued)

TABLE 79.9

American Joint Committee on Cancer Staging (continued)

- pN3a: Metastases in 10 or more axillary lymph nodes (at least one tumor deposit >2.0 mm); or metastases to the infraclavicular (level III axillary) lymph nodes
- pN3b: Metastases in clinically detected^d ipsilateral internal mammary lymph nodes in the *presence* of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLNB but not clinically detected^c
- pN3c: Metastases in ipsilateral supraclavicular lymph nodes

Distant Metastases (M)

- M0: No clinical or radiographic evidence of distant metastases
- cM0(i+): No clinical or radiographic evidence of distant metastases, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no greater than 0.2 mm in a patient without symptoms or signs of metastases
- M1: Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven >0.2 mm

Anatomic Stage/Prognostic Groups

<i>Stage 0</i>	<i>Stage IIIA</i>
Tis, N0, M0	T0, N2, M0
<i>Stage IA</i>	T1, ^e N2, M0
T1, ^e N0, M0	T2, N2, M0
<i>Stage IB</i>	T3, N1, M0
T0, N1mi, M0	T3, N2, M0
T1, ^e N1mi, M0	<i>Stage IIIB</i>
<i>Stage IIA</i>	T4, N0, M0
T0, N1, ^f M0	T4, N1, M0
T1, ^e N1, ^f M0	T4, N2, M0
T2, N0, M0	<i>Stage IIIC</i>
<i>Stage IIB</i>	Any T, N3, M0
T2, N1, M0	<i>Stage IV</i>
T3, N0, M0	Any T, Any N, M1

DCIS, ductal carcinoma in situ; LCIS, lobular carcinoma in situ; ITC, isolated tumor cells; IHC, immunohistochemical; H&E, hematoxylin and eosin stain; RT-PCR, reverse transcriptase-polymerase chain reaction; SLNB, sentinel lymph node biopsy.

^a Clinically detected is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination. Confirmation of clinically detected metastatic disease by fine needle aspiration without excisional biopsy is designated with an (f) suffix, for example, cN3a(f). Excisional biopsy of a lymph node or biopsy of a sentinel node, in the absence of assignment of a pT, is classified as a clinical N, for example, cN1. Information regarding the confirmation of the nodal status will be designated in site-specific factors as clinical, fine needle aspiration, core biopsy, or SLNB. Pathologic classification (pN) is used for excision or SLNB only in connection with a pathologic T assignment.

^b Classification is based on axillary lymph node dissection with or without SLNB. Classification based solely on SLNB without subsequent axillary lymph node dissection is designated (sn) for "sentinel node" [for example, pN0(sn)].

^c "Not clinically detected" is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

^d "Clinically detected" is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination.

^e T1 includes T1mi.

^f T0 and T1 tumors with nodal micrometastases only are excluded from stage IIA and are classified as stage IB.

PATHOLOGY OF BREAST CANCER

Historically, classification of invasive breast cancers has been based on the morphologic appearance of the cancer as seen by light microscopy.⁸⁰ The most widely used such classification is that of the World Health Organization (second edition),⁵⁵ based on the growth pattern and cytologic features of the invasive tumor cells. Although the classification system recognizes invasive "ductal" and "lobular" carcinomas, this is not meant to indicate that the former originates in the ducts and the latter in the lobules of the breast. Most invasive breast cancers arise in the terminal duct lobular unit, regardless of histologic type.

The most common histologic type of breast cancer is invasive (infiltrating) ductal carcinoma, comprising 70% to 80% of cases. The diagnosis of invasive ductal carcinoma is a diagnosis by exclusion (i.e., this tumor type is defined as a type of cancer not classified into any of the other special categories of invasive mammary carcinoma, such as invasive lobular, tubular, mucinous,

medullary, and other special types). To emphasize this point, most classification systems use the term *infiltrating ductal carcinoma, not otherwise specified* (NOS) or *infiltrating carcinoma of no special type*. In practice, the terms invasive ductal carcinoma, infiltrating ductal carcinoma, and infiltrating or invasive carcinoma of no special type are used interchangeably.

Special types of cancers comprise approximately 20% to 30% of invasive carcinomas. At least 90% of a tumor should demonstrate the defining histologic characteristics of a special type of cancer to be designated as that histologic type. Breast cancer histologic classifications recommended by the *AJCC Staging Manual* include NOS; ductal; inflammatory; medullary, NOS; medullary with lymphoid stroma; mucinous; papillary (predominantly micropapillary pattern); tubular; lobular; Paget disease and infiltrating; undifferentiated; squamous cell; adenoid cystic; secretory; and cribriform. Tumor subtypes that occur in the breast, but that are not considered to be typical breast cancers, include cystosarcoma phyllodes, angiosarcoma, and primary lymphoma.

Invasive breast cancers can be further subclassified based on microscopic features. The most common subclassification has been grading, based either solely on nuclear features (nuclear grading) or on a combination of architectural and nuclear characteristics (histologic grading). In nuclear grading, the appearance of the tumor cell nuclei is compared with those of normal breast epithelial cells, and the tumor nuclei are classified as well differentiated, intermediately differentiated, or poorly differentiated. In current practice, histologic grading is the most commonly used method of grading. In histologic grading, breast carcinomas are categorized based on the evaluation of (1) tubule formation, (2) nuclear pleomorphism, and (3) mitotic activity. The grading system by Elston and Ellis,⁸¹ a modification of the grading system proposed by Bloom and Richardson in 1957, is recommended as part of AJCC staging. Tubule formation (>75%, 10% to 75%, and <10%), nuclear pleomorphism (small and uniform, moderate variation in size and shape, and marked nuclear pleomorphism), and mitotic activity (per field area) are each scored on a scale of 1 to 3. The sum of the scores for these three parameters is the overall histologic grade. Tumors with a sum of the scores of 3 to 5 are designated grade 1 (well differentiated), those with sums of 6 and 7 are designated grade 2 (moderately differentiated), and those with sums of 8 and 9 are designated grade 3 (poorly differentiated). Histologic grading, particularly the distinction between grades 1 and 3, has prognostic significance as discussed in the section “Prognostic and Predictive Factors in Breast Cancer.” In addition, breast cancers with pure tubular, mucinous, papillary, or cribriform features are recognized to have a more favorable outcome than the more common types of breast cancer.⁸⁰ Micropapillary tumors are a recently recognized entity with a high incidence of lymphatic and vascular invasion, and systemic recurrence.⁸²

LOCAL MANAGEMENT OF INVASIVE CANCER

The evaluation of the patient newly diagnosed with breast cancer begins with a determination of operability. The presence of distant metastases at diagnosis has traditionally been considered a contraindication to surgery. Some retrospective studies have suggested a survival benefit for surgery of the primary tumor in the patient presenting with metastatic disease,^{83,84} but systemic therapy remains the initial therapeutic approach. Extensive evaluations to look for metastatic disease are not warranted in asymptomatic patients with stage I and II cancer because of the low likelihood of identifying metastatic disease.⁸⁵ In patients with stage III disease, occult metastases are more frequent, often estimated at 20% of cases, and staging studies are recommended.⁸⁵

Patients with T4 tumors and those with N2 or N3 nodal disease are also not candidates for surgery as the first therapeutic approach and should be treated with systemic therapy initially (discussed in the section “Locally Advanced Breast Cancer and Inflammatory Breast Cancer” on page 1147). In the patient with clinical stage I, II, and T3N1 disease, the initial management is usually surgical. In these patients, the evaluation consists of a determination of their suitability for BCT and a discussion of the options of mastectomy with and without reconstruction. Initial systemic therapy may be used to shrink the primary tumor to allow BCT in a woman who would otherwise require mastectomy, but is not mandatory, as it is for women with locally advanced and inflammatory carcinoma. The current status of management approaches for primary operable breast cancer is discussed in detail in the following sections.

Breast-Conserving Therapy

The goal of BCT using conservative surgery (CS) and RT is to provide survival equivalent to mastectomy with preservation of the cosmetic appearance and a low rate of recurrence in the treated

breast. Because of the wide acceptance of the Halstedian dogma, a relatively large number of randomized clinical trials were conducted comparing mastectomy and BCT, and they demonstrated equivalent survival. The long-term stability of this equivalence was confirmed by the 20-year follow-up reports of the two largest studies, the NSABP B-06 and Milan I trials.^{86,87} An overview of all the trials has also demonstrated comparable survival,⁸⁸ indicating that survival for most patients with breast cancer does not depend on the choice of mastectomy versus BCT.

Medical contraindications to BCT are infrequent. In a population-based study of 1984 patients with DCIS, stage I and II breast cancer, only 13.4% were advised by their surgeon that mastectomy was medically necessary.⁸⁹ In the 1,459 women in whom BCT was attempted, conversion to mastectomy occurred in 12%, and re-excision was not attempted in the majority. Thus, the available data indicate that a minority of patients have contraindications to BCT, and these are readily identified with standard clinical tools. Patient participation in the surgical decision-making process is an important factor in mastectomy use. In a population-based study of patients diagnosed with breast cancer in 2002 in two large metropolitan areas (Los Angeles and Detroit), more patient involvement in decision making was associated with a *greater* likelihood of undergoing mastectomy.^{90,91} The incidence of LR after BCT has declined over time, from 10-year rates of 8% to 19% seen in retrospective studies and the initial randomized trials of BCT, to 2% to 7% in patients excised to negative margins in more recent studies. Table 79.10 shows the 10-year rates of LR in node-negative NSABP trials.⁹² This decrease in LR rates is the result of a combination of improved mammographic and pathologic evaluation, and the more frequent use of adjuvant systemic therapy (discussed in detail in the section “Risk Factors for Local Recurrence Following Conservative Surgery and Radiation Therapy” on page 1129). In contrast, rates of LR after mastectomy have remained stable over the same time period.

Recurrences in the breast are typically classified by their location in relation to the original tumor. Recurrences at or near the primary site (presumably representing a recurrence of the original tumor) are classified as either a *true recurrence* (within the boosted region), a *marginal miss* (adjacent to the boosted region), or *elsewhere* in the breast (occurring at a distance from the original tumor and presumably representing a new primary). The time course to LR in the patient undergoing BCT is prolonged. In one study, the annual incidence rate for a true recurrence/marginal miss recurrence was between 1.3% and 1.8% for years 2 through 7 after treatment and then decreased to 0.4% by 10 years after

TABLE 79.10

Ten-Year Local Recurrence Rates in Recent National Surgical Adjuvant Breast and Bowel Project Trials

Trial	Systemic Therapy	ER Status	10-Year LR (%)
B-13	No chemo	–	13.3
	Chemo	–	3.5
B-14	No tamoxifen	+	11.0
	Tamoxifen	+	3.6
B-19	Chemo	–	6.5
B-20	Tamoxifen	+	4.7
B-23	Chemo	–	4.3

ER, estrogen receptor; LR, local recurrence; chemo, chemotherapy. From Anderson SJ, Wapnir I, Dignam JJ, et al. Prognosis after ipsilateral breast tumor recurrence and locoregional recurrences in patients treated by breast-conserving therapy in five National Surgical Adjuvant Breast and Bowel Project protocols of node-negative breast cancer. *J Clin Oncol* 2009;27:2466–2473.

treatment. The annual incidence rate for recurrence elsewhere in the breast increased slowly to a rate of approximately 0.7% per year at 8 years and remained stable. It also appears that just as the time to development of distant metastases is more rapid in patients with ER⁻ or HER2⁺ cancers than in those with ER⁺ and PR⁺ cancers, the time to LR also varies with receptor status. (These results have been contrasted to those seen after mastectomy, in which most LRs occur in the first 3 to 5 years after surgery.) In the Milan I trial, after 20 years of follow-up, the risk of any type of recurrence in the treated breast was 0.63 per 100 woman-years compared with a risk of 0.66 per 100 woman-years for contralateral cancer.⁸⁷ This suggests that although whole-breast irradiation (WBI) is effective at eradicating subclinical multicentric foci of breast carcinoma present at the time of diagnosis, it does not prevent the subsequent development of new cancers. Thus, patients who elect BCT require lifelong follow-up to screen for the development of new cancers in both the treated and the contralateral breast.

Risk Factors for Local Recurrence Following Conservative Surgery and Radiation Therapy

Risk factors for recurrence after CS and RT can be subdivided into patient, tumor, and treatment factors.

Patient Risk Factors

The most important patient risk factors for LR recurrence are age and inherited susceptibility. Age (<35 or 40) is associated with an increased risk of LR after BCT. Young patient age is associated with an increased frequency of various adverse pathologic features, such as lymphatic vessel invasion, grade 3 histology, absence of ER/presence of HER2, and the presence of an extensive intraductal component (EIC). However, even when correction is done for the differing incidence of the pathologic features of the primary tumor between the age groups, young age is still associated with an increased likelihood of recurrence in the breast.⁹³ However, young age is also a risk factor for LR after mastectomy and should not be considered a contraindication to BCT.

An *inherited susceptibility* to breast and ovarian cancer, and other cancers has been mainly linked to germline mutations in BRCA1 and BRCA2. Patients with breast cancer with a mutation have a substantial risk of contralateral and late ipsilateral breast cancers. In a retrospective study, outcome following CS and RT was compared for 302 stage I-III patients with breast cancer with germline BRCA1 or BRCA2 mutations and 353 stage I-III patients treated with mastectomy.⁹⁴ With a follow-up time of 8.2 and 8.9 years for BCT and mastectomy patients, respectively, LR was significantly more likely in those treated with BCT compared to mastectomy, with a cumulative estimated risk of 23.5% versus 5.5%, respectively, at 15 years ($p < 0.0001$); the 15-year estimate in carriers treated with BCT and chemotherapy was 11.9% ($p = 0.08$ when compared to mastectomy). Most LR events appeared to be second primary cancers. The risk of contralateral breast cancer was high in all groups, exceeding 40%. It is important to consider genetic testing in a patient with newly diagnosed breast cancer with a personal and family history suggestive of a BRCA1 or BRCA2 germline mutation. In patients with a mutation, the option of bilateral mastectomy should be strongly considered to avoid the long-term risk of a second breast cancer in either breast. Patients with breast cancer most likely to benefit from bilateral mastectomy are those who are young and have early-stage disease. Given the high risk of a contralateral breast cancer, unilateral mastectomy is generally not performed in a patient who is a candidate for BCT.

Tumor-Based Risk Factors

An important *tumor risk factor* is the *margin of resection*. A negative margin is defined by absence of cancer cells at inked surfaces, but

there is no standard definition of a close margin. Margins need to be interpreted in conjunction with the operative findings. A close deep margin is not significant if the breast resection was carried down to the pectoral fascia; the same is true for a close anterior margin if the resection extended to the deep dermal surface. Patients with negative margins of excision have low rates of LR after treatment with CS and RT. The impact of close margins of resection on LR has been more controversial, resulting in the frequent use of re-excision to obtain margins more widely clear than no ink on tumor. A 2013 multidisciplinary consensus panel considered a meta-analysis of margin width and IBTR from a systematic review of 33 studies including 28,162 patients. The results of randomized trials, reproducibility of margin assessment, and current patterns of multimodality care were also considered. The panel concluded that positive margins (ink on invasive carcinoma or DCIS) were associated with a two-fold increase in the risk of IBTR compared to negative margins. This increased risk was not mitigated by favorable biology, endocrine therapy, or a radiation boost. The panel also concluded that more widely clear margins beyond “no ink on tumor” do not significantly decrease the rate of IBTR. There is no evidence that more widely clear margins reduce IBTR for young patients, unfavorable biology, lobular cancers, or cancers with an EIC. (When an EIC is present, young age and multiple close margins are associated with an increased risk of IBTR and can be used to select patients who might benefit from re-excision). Therefore, the use of no ink on tumor as the standard for an adequate margin in invasive cancer in the era of multidisciplinary therapy is associated with low rates of IBTR and has the potential to decrease re-excision rates, improve cosmetic outcomes, and decrease health-care costs.⁹⁵

The underlying molecular subtype of the tumor is the most significant determinant of the likelihood of LR after BCT (and mastectomy), particularly among those treated in the modern era with surgery to achieve negative margins.⁹⁶⁻⁹⁸ Higher risks of LR are observed in patients with triple-negative breast cancer than in those with other subtypes, regardless of whether they are treated with BCT or mastectomy.⁹⁹

There is interest in identifying molecular predictors of the risk of LR. The 21-gene recurrence score (Oncotype DX) predicts local-regional recurrence (LRR) in node-negative, ER⁺ breast cancer, regardless of type of surgery.¹⁰⁰ The 10-year LR rate was 4.3% for patients with a low recurrence score (<18), 7.2% with an intermediate recurrence score (18 to 30), and 15.8% with a high recurrence score (>30).

Treatment-Based Risk Factors

Other important *treatment risk factors* are the use of a boost and the use of adjuvant systemic therapy. A *boost* or supplementary irradiation to the area of the primary site is generally used. It is standard in RT after lumpectomy for patients to receive 45 to 50 Gy of WBI followed by a 10 to 16 Gy boost to the region of the tumor bed (Fig. 79.2). The use of a boost is supported by the large European Organisation for Research and Treatment of Cancer (EORTC) trial in which 5,318 patients with negative margins were randomized to a boost of 16 Gy or no boost following 50 Gy to the whole breast.¹⁰¹ With a median follow-up of 10.8 years, the cumulative incidence of ipsilateral breast recurrence was 10.2% without a boost and 6.2% with a boost ($p < 0.0001$). This 41% proportional reduction in LR was similar in all age groups; however, the absolute benefit of the boost was greatest in young patients aged 40 years or less (24% decreased to 14%) and was smallest in patients over age 60 (7% decreased to 4%). Severe fibrosis was increased from 2% to 4% with the boost. Survival at 10 years was the same in both arms. A clinicopathologic study was performed on 1,616 patients in the EORTC trial. In multivariate analysis, high-grade invasive ductal carcinoma was associated with an increased risk of LR (HR = 1.67; $p = 0.026$), and the boost was effective in reducing LR in this subgroup.¹⁰²

The use of *adjuvant systemic therapy* is a very important factor associated with recurrence in the treated breast in conjunction

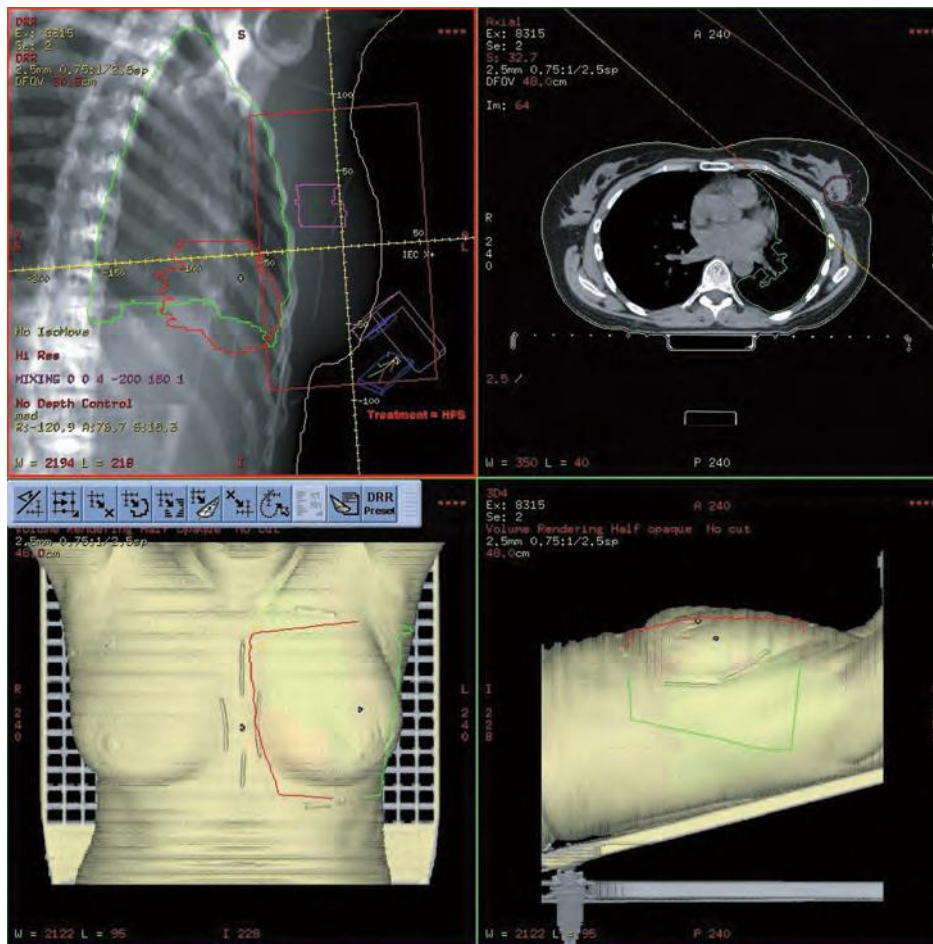

Figure 79.2 Computed tomography simulation for a left-sided breast cancer with medial and lateral tangential fields. Left upper is the beam's eye view with the large rectangle being the treatment field. The area of the primary in the upper outer quadrant is contoured in magenta and the heart is contoured in red. Note that for the actual treatment a block was used to block irradiation of her heart, which also blocked out some breast tissue well away from the primary cancer. Right upper is an axial view of the treatment fields in the center of the treatment fields. Left lower shows (in red) the medial tangent borders on the patient's skin. Right lower shows (in green) the lateral tangent borders on the patient's skin.

with CS and RT. This effect is clearly demonstrated in three randomized clinical trials. In the NSABP B-14 trial, node-negative, ER⁺ patients were randomized to receive tamoxifen or to a placebo. The 10-year rate of recurrence in the ipsilateral breast was 14.7% without tamoxifen and only 4.3% with tamoxifen.¹⁰³ A similar result was seen in the Stockholm Breast Cancer Study Group among node-negative patients randomized to receive tamoxifen or a placebo.¹⁰⁴ In the NSABP B-21 trial, patients with node-negative breast cancer measuring ≤ 1 cm treated with lumpectomy were randomized to tamoxifen alone, RT, or RT and tamoxifen. With a mean follow-up of 87 months, the 8-year rate of ipsilateral LR was 9.3% in the patients treated with RT and 2.8% in the patients treated with RT and tamoxifen.¹⁰⁵ Similar results are seen with adjuvant chemotherapy. In the NSABP B-13 trial, node-negative, ER⁻ patients were randomized to chemotherapy or to a no-treatment control group. Among the 235 patients treated with CS and RT, the 8-year rate of recurrence in the ipsilateral breast was 13.4% without chemotherapy and only 2.6% with chemotherapy given concurrently with the RT.¹⁰⁶ The net result of the benefit of systemic therapy on local control is that between 1990 and 2011, LRR decreased from 30% to 15% of all recurrences seen in a population of 86,598 women enrolled in 53 randomized phase 3 trials.¹⁰⁷

The standard approach is to use sequential chemotherapy and RT. Given the primary importance of preventing systemic relapse, it has been the standard to use initial chemotherapy followed by RT. Although concerns have been expressed about an increased rate of LR with this approach, the results of clinical trials in patients with negative margins have not shown this to be a problem even following 6 months of chemotherapy as with four cycles of doxorubicin and cyclophosphamide followed by four cycles of taxol, both given every 3 weeks.¹⁰⁸

Preservation of a Cosmetically Acceptable Breast

A major goal of BCT is the preservation of a cosmetically acceptable breast. When modern treatment techniques are used, an acceptable cosmetic outcome can be achieved in almost all patients (without compromise of local tumor control) (Fig. 79.3). Treatment-related changes in the breast stabilize at around

Figure 79.3 Cosmetic outcome of breast-conserving therapy. Other than the surgical scar, there is minimal difference between the treated and the untreated breast.

3 years. Evolution of the untreated breast, such as change in size because of weight gain and the normal ptosis seen with aging, continue to affect the symmetry. The major factor determining the cosmetic result is the extent of surgical resection.¹⁰⁹ A variety of factors must be considered together (the size of the patient's breast, the size of the tumor, the depth of the tumor within the breast, and the quadrant of the breast in which the tumor is located) to judge the feasibility of a cosmetically acceptable resection. For example, although the removal of a large tumor in the lower portion of the breast often results in distortion of the breast contour, this is only apparent with the arms raised and is acceptable to most women. A similar distortion in the upper inner quadrant of the breast, which is visible in most types of clothing, might not be as acceptable.

Guidelines for Patient Selection

Because of the potential options for treatment of early-stage breast cancer, careful patient selection and a multidisciplinary approach are necessary. Critical elements in patient selection for BCT are (1) history and physical examination, (2) mammographic evaluation, (3) histologic assessment of the resected breast specimen, and (4) assessment of the patient's needs and expectations.

Recent (i.e., usually within 3 months) preoperative mammographic evaluation is necessary to determine a patient's eligibility for BCT by defining the extent of a patient's disease, the presence or absence of multicentricity, and other factors that might influence the treatment decision. If the mass is associated with microcalcifications, an assessment of the extent of the calcifications within and outside the mass should be made using magnification views. Mammography of the contralateral breast is also standard at the time of diagnosis to exclude synchronous lesions.

There is controversy regarding the role of additional imaging studies, particularly MRI of the breast, in selecting patients for BCT. A meta-analysis of 3,112 patients in nine studies with comparison cohorts treated with and without MRI found no difference in the need for re-excision or unexpected conversion to mastectomy, after age adjustment, in patients managed with and without MRI.¹¹⁰ The age-adjusted rate of initial mastectomy was increased three-fold in patients having MRI. Several other studies have shown an association between MRI use and greater, but unwarranted, use of mastectomy.^{111,112} MRI frequently identifies additional areas of involvement in the breast, but long-term clinical experience has demonstrated that the majority of this disease is controlled with RT. In addition, MRI has a substantial false-positive rate. Ideally, prospective trials demonstrating a clinical benefit in patients selected for BCT with MRI are needed before these examinations are routinely used for patient selection.

The patient and her physician must discuss the benefits and risks of mastectomy compared with those of BCT in her individual case. The following factors should be discussed:

1. The absence of a long-term survival difference between treatments
2. The possibility and consequences of LR with both approaches
3. Psychological adjustment (including the fear of cancer recurrence), cosmetic outcome, sexual adaptation, and functional competence

Psychological research comparing patient adaptation after mastectomy with that after BCT shows no significant differences in global measures of emotional distress. However, women whose breasts are preserved have more positive attitudes about their body image and experience fewer changes in their frequency of breast stimulation and feelings of sexual desirability. In addition, patients treated with BCT have better physical functioning compared with patients treated with mastectomy at the end of primary treatment.¹¹³

Absolute and Relative Contraindications to Breast-Conserving Therapy (National Comprehensive Cancer Network 2014)

Contraindications for BCT requiring radiation therapy include the following:

Absolute:

- Radiation therapy during pregnancy
- Diffuse suspicious or malignant-appearing microcalcifications
- Widespread disease that cannot be incorporated by local excision through a single incision that achieves negative margins with a satisfactory cosmetic result
- Positive pathologic margin

Relative:

- Active connective tissue disease involving the skin (especially scleroderma and lupus)
- Tumors >5 cm
- Focally positive margin
- Women with a known or suspected genetic predisposition to breast cancer:
 - May have an increased risk of ipsilateral breast recurrence or contralateral breast cancer with BCT
 - Prophylactic bilateral mastectomy for risk reduction may be considered

Preoperative Systemic Therapy for Operable Cancer

Women who desire BCT but are not candidates for the procedure because of a large tumor relative to the size of the breast should be considered for preoperative or neoadjuvant therapy. This approach does not allow BCT for patients with multicentric carcinoma or those with an EIC that precludes a cosmetic resection. Patients most likely to be converted to BCT with neoadjuvant chemotherapy are those with unicentric, higher-grade, *HER2*⁺ or triple-negative cancers, as such cancers often respond dramatically to chemotherapy.

Pathologic complete response (pCR)—defined as the absence of residual invasive cancer in the breast and axilla following preoperative therapy—is a common endpoint for clinical trials of preoperative treatment. Multiple studies have shown that patients who experience pCR with neoadjuvant treatment have, on average, better long-term outcomes, with lower risk of cancer recurrence, than women with residual cancer following neoadjuvant chemotherapy. The US Food and Drug Administration has recently indicated that pCR may be a surrogate for accelerated drug approval in neoadjuvant treatment of operable breast cancer.¹¹⁴

Prospective, randomized trials of patients with operable breast cancer have demonstrated that clinical response rates to neoadjuvant chemotherapy are high, ranging from 50% to 85% in many studies. pCRs in the breast range from 15% to 40%. Despite these high response rates, only 25% to 30% of patients who were not candidates for BCT at presentation were able to undergo the procedure after preoperative therapy.^{115,116} This is a reflection of both the difficulty of assessing the extent of residual viable tumor after preoperative chemotherapy and the often patchy nature of cancer cell death in response to chemotherapy. This type of response significantly decreases the total number of viable tumor cells, but viable tumor remains scattered throughout the same volume of breast tissue, precluding BCT. MRI is better than mammography or ultrasonography in evaluating the extent of viable tumor and its distribution, but may both underestimate and overestimate the extent of residual disease.

In patients who overexpress *HER2*, the preoperative administration of anti-*HER2* therapy in combination with chemotherapy has been associated with high rates of pCR. Clinical trials have

confirmed that adding trastuzumab to chemotherapy improves the pCR rate among women with *HER2*⁺ breast cancer receiving neoadjuvant therapy and improves long-term survival,¹¹⁷ consistent with the survival benefit observed for trastuzumab when given with chemotherapy in the adjuvant setting.

In 2013, the US Food and Drug Administration approved concurrent use of a second anti-*HER2* antibody, pertuzumab, for use in combination with trastuzumab and chemotherapy in women receiving neoadjuvant therapy for *HER2*⁺ breast cancer, after it was shown that pertuzumab enhanced the rates of pCR.¹¹⁸

A meta-analysis of nine randomized trials of preoperative chemotherapy demonstrated no increase, or decrease, in survival with preoperative compared with postoperative treatment,¹¹⁹ but an elevated risk of LRR (RR = 1.22; 95% CI = 1.04 to 1.45) was noted. Some of the increase in LR was due to the inclusion of studies in the meta-analysis in which patients who had a clinical complete response did not have surgery. Even in patients undergoing surgery, an elevated risk of LR has been observed. In the NSABP B-18 study,¹¹⁵ LR rates were 15% in patients who required chemotherapy to undergo BCT compared with only 7% in those who were initially candidates for BCT. The increased rates of LR after neoadjuvant therapy likely reflect that in this setting, a negative margin may still be associated with a clinically significant residual tumor burden that is unlikely to be controlled by RT. Thus, an evaluation of both surgical margins and the extent of viable tumor elsewhere in the specimen is essential and may dictate resection of additional breast tissue even when margins are apparently tumor-free. Among women who have mastectomy after neoadjuvant chemotherapy, a pCR is a favorable prognostic finding, associated with a far lower risk of LRR than seen in women with residual cancer.¹²⁰ Percutaneous placement of marker clips within the primary tumor prior to the initiation of chemotherapy will provide a landmark for localization and excision should a clinical and radiographic complete response occur. The lack of a survival benefit for neoadjuvant therapy and the increased complexity in determining the appropriate extent of resection suggest that for women who are candidates for breast conservation at presentation, neoadjuvant therapy outside the context of a clinical trial offers little benefit.

Neoadjuvant endocrine therapy has also been used to increase rates of BCT. In trials of postmenopausal women with ER⁺ cancers who were not considered candidates for BCT at presentation, roughly 30% to 40% of those who received 4 months of endocrine therapy were able to undergo BCT.^{121,122} These studies indicate that in postmenopausal women with hormone receptor-positive tumors, the preoperative use of an AI or tamoxifen significantly increases the likelihood of breast conservation. However, despite the proven survival benefit seen with adjuvant endocrine therapy, pCR is rare with the short duration of treatment used in the neoadjuvant setting. Patients who experience substantial tumor shrinkage with endocrine therapy, even short of pCR, may also have a more favorable prognosis.¹²³ For women with ER⁺ breast cancer, a small randomized trial has suggested that either endocrine or chemotherapy can be equally effective.¹²⁴ In clinical practice, neoadjuvant endocrine therapy is typically reserved for women not considered to be candidates for neoadjuvant chemotherapy.

Conservative Surgery Without Radiation Therapy

An unresolved question is whether RT is necessary in all patients with invasive breast cancer after CS. It is well known that RT after CS reduces LR by about 70%, but there has been uncertainty about whether this improvement in LR is important to survival and whether there is a subgroup of patients with a low risk of LR following CS alone. The impact of improving local control on overall long-term survival was greatly clarified with the findings of the EBCTCG meta-analysis¹²⁵ first published in 2005, and updated in 2011.¹²⁵ In this updated analysis, 17 trials including

10,801 women, 3,143 deaths, and 9.5 median woman-years at risk were included. Importantly, the EBCTCG moved from assessing the effect of RT on LR to its effect on first failure (or first recurrence, either LR or distant metastasis). (Although commonly employed in studies on the local treatment of breast cancer, actuarial calculation of time to LR is, strictly, not statistically valid.) RT proportionally reduced the annual rate of any failure (LR or distant metastases) over the first 10 years by about half (RR = 0.52) and proportionally reduced the annual rate of breast cancer death by about one-sixth. The absolute benefit of RT was greater in patients with the greater risk of recurrence. In node-negative patients, the absolute benefit was strongly correlated with age (inversely), tumor grade and size, and ER status, with very small absolute benefit seen in some subgroups. The updated EBCTCG analysis still demonstrates that RT after CS is not only important for local control, but also for maximizing long-term survival.

Attempts to identify a subgroup of patients (based on various clinical and histologic features) within the available clinical trials who have a low risk of LR after CS alone have been unsuccessful. LR rates are generally lower in trials that use more extensive surgery than in those using lumpectomy, and in older patients than in younger patients. The Joint Center for Radiation Therapy in Boston conducted a prospective single-arm trial of wide excision alone for patients with a tumor size of ≤2 cm, histologically negative axillary nodes, absence of either lymphatic vessel invasion or an EIC in the cancer, and no cancer cells within 1 cm of inked margins.¹²⁶ The median age of patients in this trial was 66 years, 75% of cancers were detected by mammography alone, and the median pathologic size of the cancers was 9 mm. None of the patients received adjuvant endocrine therapy or chemotherapy. This trial was stopped shortly before it reached its accrual goal of 90 patients because of stopping rules ensuring against an excessively high LR rate. With a median follow-up time of 86 months among the 81 eligible patients, the crude rate of LR was 23%. The average LR rate was 2.8% per year. Of note, of the six patients with a tubular cancer, three had an LR. Examination of subsets of patients by age and tumor size did not find any statistically significant differences. Similar results were seen in a small randomized clinical trial from Finland. Based on the results of these prospective studies, it was concluded that even highly selected patients with breast cancer (based on patient and tumor characteristics) have a substantial risk of early LR after treatment with wide excision alone. Newer markers are needed to more reliably identify patients who can be safely treated with wide excision alone.

More recently, there have been five trials that have compared tamoxifen with and without RT after breast-conserving surgery (BCS; largely in ER⁺ patients), and their details are shown in Table 79.11.^{105,127-130} The LRR rates for these trials are shown in Table 79.12. The 5-year results seem reasonable, but the rate of LR appears increased after 5 years. In the Canadian trial,¹²⁸ LR was 7.7% at 5 years, but 17.6% at 8 years. This raises the question of whether tamoxifen is merely delaying LR. As previously discussed,

TABLE 79.11

Trials of Tamoxifen with or without Radiotherapy After Breast-Conserving Therapy

the combination of tamoxifen and RT provides a very low rate of LR. Tamoxifen alone has its greatest appeal in older patients (older than 70 years)¹²⁹ where competing risks of other illnesses are substantial. In a prospective randomized trial of 636 patients age 70 and above with stage 1, ER⁺ breast cancers treated by lumpectomy and randomized to tamoxifen or tamoxifen plus WBI, no differences in OS or rates of breast preservation were observed at 10 years. WBI reduced the incidence of LRR from 10% to 2% in this population.¹²⁹ In elderly patients, it is critical for the clinician to assess the patient's particular cancer characteristics (especially tumor grade) as well as her comorbid illnesses and individual value system in determining the advisability of adding RT. (The website ePrognosis.com is useful in estimating life expectancy in older patients.)

Hypofractionated Whole-Breast and Accelerated Partial-Breast Irradiation

There have been a growing number of studies attempting to decrease the overall treatment time for RT after lumpectomy through the administration of fewer, but larger daily doses (hypofractionation) of RT delivered to the whole breast or only to the portion of the breast containing the primary tumor, typically given twice a day (accelerated).

Hypofractionated WBI was studied¹³¹ among women with invasive breast cancer who had undergone BCS and in whom resection margins were clear and axillary lymph nodes were negative. Women were randomly assigned to receive WBI either at a standard dose of 50 Gy in 25 fractions over a period of 35 days (the control group) or at a dose of 42.5 Gy in 16 fractions over a period of 22 days (the hypofractionated-radiation group). The risk of LR at 10 years was 6.7% with standard irradiation as compared to 6.2% in the hypofractionated regimen (95% CI = -2.5 to 3.5). At 10 years, 71.3% of women in the control group compared with 69.8% of the women in the hypofractionated-radiation group had a good or excellent cosmetic outcome. In a subset analysis, conventional fractionation had better results in patients with high-grade cancers. This trial was initiated before the value of a boost was established, and it is not clear how best to give a boost in patients treated with hypofractionated WBI. As noted previously, the value of a boost is very small in patients aged 60 years and greater, so at a minimum, it seems reasonable to treat patients aged 60 and greater with grade 1 or 2 node-negative breast cancer with accelerated WBI without a boost. A task force of the American Society for Radiation Oncology (ASTRO) developed guidelines for the use of hypofractionated WBI in 2011.¹³² The task force favored a dose schedule of 42.5 Gy in 16 fractions ("Canadian") and its use in patients aged 50 years or older with pT1-2N0 cancer treated with BCS, and not treated with

adjuvant chemotherapy where the dose homogeneity is within $\pm 7\%$ and the heart can be excluded from direct irradiation. There was no agreement on the use of a boost.

Ten-year results are now available from the similar START-B trial fully corroborating the results of the Canadian trial.¹³³ In START-B, a regimen of 50 Gy in 25 fractions over 5 weeks was compared with 40 Gy in 15 fractions over 3 weeks. START-B enrolled 2,215 women. A boost dose was allowed in this trial. Median follow-up was 9.9 years, after which 95 LRRs had occurred. The proportion of patients with LRR at 10 years did not differ significantly between the 40 Gy group (4.3%; 95% CI = 3.2 to 5.9) and the 50 Gy group (5.5%; 95% CI = 4.2 to 7.2; HR = 0.77; 95% CI = 0.51 to 1.16; $p = 0.21$). In START-B, breast shrinkage, telangiectasia, and breast edema were significantly less-common normal tissue effects in the 40 Gy group than in the 50 Gy group. It is anticipated that the use of hypofractionated WBI will increase.

There are several potential benefits for accelerated partial-breast irradiation (APBI), including the following: (1) the quality of life of patients could be improved by relieving patients of the necessity of daily treatments for 5 to 6 weeks, (2) the underutilization of BCT could be reduced by making it more feasible for patients to receive RT, (3) the integration of local and systemic therapies could be simplified, and (4) long-term complications of RT could be decreased by limiting the volume of critical structures irradiated to high dose. The rationale for APBI is based on studies of the patterns of recurrence after standard whole-breast RT and after excision alone that demonstrate that the large majority of recurrences are in the immediate vicinity of the tumor bed.¹³⁴ In addition, pathologic studies on the distribution of tumor cells in relation to the primary tumor demonstrate in most cases that the vast majority of tumor cells in the breast are found near the primary tumor.

These are a number of different APBI techniques, including interstitial brachytherapy, (three-dimensional conformal) external-beam irradiation, intracavitary brachytherapy, and intraoperative limited RT. At present, there are few long-term data, especially from randomized clinical trials, for APBI, and appropriate patient selection remains controversial. Successful application of this approach requires technical expertise. Two cooperative group studies—the recently completed NSABP/RTOG phase 3 trial comparing conventional RT versus APBI (allowing implant or external-beam techniques) and the National Cancer Institute of Canada RAPID study, which permitted external beam technique—will answer important questions about APBI. To provide some direction during this time of uncertainty, an ASTRO expert panel has defined a "suitable" group, for whom APBI outside a clinical trial was acceptable, as being patients¹³⁵ meeting all of the following criteria: age 60 years or greater, BRCA1/2 mutation not present, unicentric invasive ductal carcinoma measuring ≤ 2 cm, margins negative by at least 2 mm, without lymphatic vessel invasion or an EIC, ERs present, and node-negative on pathologic examination. The panel also identified "cautionary" and "unsuitable" groups.

The most widely used form of APBI is with external beam irradiation. There is controversy whether cosmetic results are compromised relative to conventional whole breast external beam treatment. An interim cosmetic and toxicity analysis from the RAPID trial was published in 2013.¹³⁶ Between 2006 and 2011, 2,135 women had been randomly assigned to APBI or WBI. Median follow-up was 36 months. Adverse cosmesis at 3 years was increased among those treated with APBI compared with WBI as assessed by trained nurses (29% versus 17%; $p < 0.001$), by patients (26% versus 18%; $p = 0.0022$), and by physicians reviewing digital photographs (35% versus 17%; $p < 0.001$). Grade 3 toxicities were rare in both treatment arms (1.4% versus 0%), but grade 1 and 2 toxicities were increased among those who received APBI compared with WBI ($p < 0.001$). The authors concluded that external beam APBI increased rates of adverse cosmesis and late radiation toxicity compared with standard WBI.

The first results of a trial from the European Institute of Oncology in Milan testing APBI using intraoperative radiation with electron beam versus conventional whole-breast radiation were published in 2013. A total of 1,305 patients were randomized, and after a median follow-up of 5.8 years, the 5-year rate of LR (IBTR) was 4.4% in the APBI arm and only 0.4% in the conventional whole breast arm (HR = 9.3; 95% CI = 3.3 to 26.3). OS did not differ.¹³⁷

Toxicities of Breast Radiotherapy

Breast RT is generally very well tolerated with very few long-term toxicities. Evidence has long been accumulating that RT involving the heart can result in premature ischemic heart disease, but interest peaked in 2013 when a case-control study found an increased risk for cardiac-related deaths in patients with breast cancer who received RT.¹³⁸ This was a population-based case-control study involving 2,168 Scandinavian women treated between 1958 and 2001. It found that rates of major coronary events increased linearly with the mean dose to the heart by 7.4% per Gy ($p < 0.001$), with no apparent threshold. The increase started within the first 5 years after RT and continued into the third decade after RT. The proportional increase in the rate of major coronary events per Gy was similar in women with and without cardiac risk factors at the time of RT, but the absolute increase was greater in patients with cardiac risk factors. The overall average of the mean doses to the whole heart in this study was 4.9 Gy.

It is important to note the major limitations of the study; mainly, it is a case-control study and as such, it does not provide the highest level of evidence. Also, there were limitations in design. The investigators developed virtual simulations of RT dose based on CT scans of patients with "typical anatomy," which they used to construct idealized radiation fields and with which they estimated the doses to the heart.

It is also important to emphasize that despite the proportional relationship between RT dose to the heart and heart disease, the *absolute* increase was very small. For 50-year-old women without cardiac risk factors, the lifetime increased risk was 0.5% after 0.5 Gy, 0.2% after 1 Gy, and just 0.5% after 3 Gy delivered as a mean heart dose. Today, for most node-negative women having BCT, the mean heart dose is only about 1 Gy, although higher doses (still only about 2 Gy) are more common for women with left-sided postmastectomy RT.

It should also be noted that any cardiac mortality risk in current practice is small compared to the survival benefit from RT both in the setting of BCT and PMRT. The survival benefit seen for RT in these older trials includes the deleterious effects on the heart seen with doses as high as 10 Gy. This means that using current techniques that spare the heart, RT will provide even greater survival benefit. The issue of cardiac irradiation, however, has more importance in patients with DCIS, where the survival impact of RT is small at best.

Notwithstanding these study limitations and improvements in technique, radiation oncologists should operate on the principle that there is no totally safe radiation dose to the heart, and that the heart dose should be kept as low as possible. A number of maneuvers, such as using cardiac blocks, prone techniques, and deep inspiration breath holds, make radiation delivery much safer in current practice.

Mastectomy

Mastectomy, with or without immediate breast reconstruction, is the surgical approach for the patient with breast cancer who has contraindications to BCT or who prefers treatment with mastectomy. The mastectomy used today is a total or complete mastectomy, with removal of the breast tissue from the clavicle to the rectus abdominus and between the sternal edge and the latissimus

dorsi muscles. A total mastectomy also removes the nipple-areolar complex (NAC), the excess skin of the breast, and the fascia of the pectoralis major muscle. When accompanied by an ALND, the procedure is termed a *modified radical mastectomy*. Mastectomy is an extremely safe operation. The 30-day mortality is approximately 0.25%, and the 30-day incidence of major complications is about 5%, the majority of which are related to wound healing. In contemporary American practice, roughly 30% of women underwent mastectomy for breast cancer owing to either contraindications to BCT or patient choice.⁹⁰

Advances in plastic surgical technique have made immediate reconstruction an option for most patients who undergo mastectomy. There have been no prospective trials comparing mastectomy alone with mastectomy with immediate reconstruction, but the available retrospective data do not support concerns about the incidence or detection of LR in the reconstructed patient. The majority of postmastectomy recurrences occur in the skin or subcutaneous fat of the chest wall and present as palpable masses in the skin flap, so detection is not affected by the presence of the reconstruction.¹³⁹ Skin-sparing mastectomy in which skin excision is limited to the NAC and the excisional biopsy scar (if present) is now routinely used to preserve the skin envelope of the breast and facilitate reconstruction. The reported rates of LR after skin-sparing mastectomy are comparable to those of patients treated with conventional mastectomy. This finding is consistent with prior observations that the extent of skin removal in patients treated with mastectomy alone is not a major determinant of the risk of chest wall recurrence. Traditionally, skin-sparing mastectomy has included resection of the NAC due to the need to leave breast tissue on the NAC to provide a blood supply and the risk of leaving behind malignancy within the ducts of the nipple. Nipple sparing mastectomy (NSM) preserves the NAC and is being used with increasing frequency due to the excellent cosmetic results that can be obtained with this technique. Intraoperative frozen section of the tissue beneath the nipple is often used to minimize the risk of residual cancer. To date, most studies of this procedure have consisted of highly selected patients who had relatively short follow-up periods, making the long-term safety of NSM, particularly in high-risk women such as those with BRCA mutations, difficult to ascertain. The reported incidence of occult involvement of the NAC in patients with known breast cancer ranges from 0% to 58%.¹⁴⁰ Despite this, a review of 10 studies including 1,148 NSMs reported a 2.8% rate of LRR after a median follow-up of only 2 years.¹⁴¹ In a large series from the European Institute of Oncology, including 772 patients with invasive cancer, and 162 with DCIS treated with NSM and intraoperative RT to the NAC, at a median follow-up of 50 months, the 5-year rate of LR was 4.4% in the invasive cancer group and 7.8% in patients with DCIS.¹⁴² The majority of recurrences were at a distance from the NAC, suggesting that the more difficult exposure with this operation may result in retained breast tissue on the skin flaps. These studies indicate that NSM may be a viable option in highly selected women, specifically, patients with small, peripherally located, node-negative tumors with favorable histologic features. Most women in this category, however, are candidates for conventional BCT. The eligible population for NSM is further limited by the requirement that the nipple be in the appropriate position on the reconstructed breast. This is rarely the case for women with large, ptotic breasts, further limiting the application of this procedure.

In summary, immediate reconstruction with preservation of the skin envelope of the breast has not been shown to alter the outcome of mastectomy or to delay the administration of systemic therapy. Immediate reconstruction has the advantages of avoiding the need for a second major operative procedure and the psychological morbidity of the loss of the breast. The two major reconstructive techniques involve the use of implants and/or tissue expanders or the use of myocutaneous tissue flaps to create a new breast mound. The advantages and disadvantages

TABLE 79.13

Common Reproductive Options After Mastectomy

Type	Advantages	Disadvantages
Implant	One-stage procedure, minimal prolongation, hospitalization, or recovery Low cost	Poor symmetry if skin removed or in large ptotic breasts Capsular contracture, leakage, rupture possible
Tissue expander	Short operative time Hospitalization, recovery not prolonged Low cost	Multiple physician visits postoperatively Poor symmetry large or ptotic breasts Capsular contracture, leakage rupture possible
Latissimus dorsi flap	Very low risk of flap loss Natural contour with autogenous tissue	Donor site scar Usually requires an implant Moderate prolongation hospitalization and recovery
TRAM flap	Natural contour Good match for large or ptotic breasts Abdominoplasty	Donor site scar Fat necrosis, flap loss possible Abdominal wall weakness plus hernia Significant prolongation hospitalization plus recovery
DIEP flap	Natural contour Muscle-sparing Abdominoplasty	Donor site scar Need for microsurgeon Flap loss possible Moderate prolongation hospitalization plus recovery
Superior gluteal artery perforator flap	Natural contour Alternative donor site	Donor site scar Need for microsurgeon Flap loss possible Moderate prolongation hospitalization plus recovery

TRAM, transverse rectus abdominis myocutaneous; DIEP, deep inferior epigastric perforator.

of the techniques are summarized in Table 79.13. Implant reconstructions are best suited for women with small- to moderate-sized breasts with minimal ptosis, while flap reconstructions allow more flexibility in the size and shape of the reconstructed breast (Fig. 79.4). In the past, most breast implants were filled with silicone gel. However, after reports from uncontrolled studies suggested an increased incidence of connective tissue disease in women with silicone implants, the US Food and Drug Administration declared a moratorium on their use. Since that time, several epidemiologic studies have failed to demonstrate an increased incidence of connective tissue disorders in women with implants compared with matched control populations. Silicone implants are again available for use in patients with breast cancer, but many patients opt for saline implants or flap reconstructions as a result of the adverse publicity surrounding silicone implants.

Reconstructive choices may be influenced by the possible need for postmastectomy RT. As indications for postmastectomy RT have expanded, the impact of RT on reconstruction has also become an issue. Immediate reconstruction can negatively impact the technical delivery of RT, possibly resulting in greater irradiation of the heart (in left-sided cancers) and lung, and undercoverage of the chest wall.¹⁴³ There are a variety of strategies that have been proposed for selecting the type of reconstruction for a patient with a significant likelihood of requiring postmastectomy RT. There is considerable variability in outcome reported in the medical literature for the same approaches, and there are no prospective studies reported to date. The use of RT in patients who have been reconstructed with implants is associated with a higher risk of encapsulation and implant loss than in nonirradiated patients. In one study, however, Cordeiro et al.¹⁴⁴ reported that after a mean follow-up of 34 months in 68 patients reconstructed with tissue expanders or implants who received RT, 80% had good to excellent aesthetic results and 72% would have chosen the same form of reconstruction again. The figures for nonirradiated patients were 88% ($p =$ not significant) and 85%, respectively. Implant loss occurred in 11% of patients with irradiated implants and 6% of nonirradiated pa-

tients. The finding that the majority of patients who require RT after implant reconstruction have good cosmesis and are satisfied with their reconstruction choice has led some to advocate insertion of an expander at the time of mastectomy, which is inflated during chemotherapy and exchanged for a permanent implant prior to RT. In patients who are satisfied with the cosmetic outcome

Figure 79.4 Cosmetic outcome of transverse rectus abdominis muscle flap reconstruction after skin-sparing mastectomy.

after RT, no further surgery is required. In patients with significant cosmetic deformity, a secondary flap reconstruction is performed. This approach has the advantage of allowing preservation of the breast skin and providing the patient with a breast mound during what may be a prolonged course of postoperative cancer therapy. However, additional favorable experience with irradiation of expanders or implants at other institutions is needed.

A primary flap reconstruction is another alternative for the patient who may require postmastectomy RT. Variable outcomes have been reported for patients who receive RT after transverse rectus myocutaneous flap or latissimus dorsi flap reconstruction. Complete flap loss is rare, but fat necrosis, fibrosis, and volume loss can occur. As in the native breast, the full cosmetic impact may not be evident until 3 years posttreatment. In one study, the 5-year incidence of major complications after transverse rectus myocutaneous reconstruction was 0% ($n = 35$) and 5% after tissue expander/implant ($n = 50$) reconstruction followed by RT.¹⁴⁵ In contrast, 4 of 47 (9%) patients reconstructed with flaps and 6 of 15 (40%) implant patients underwent major corrective surgery a median of 8 months after RT in another series.¹⁴⁶ An alternative approach is to perform sentinel node biopsy prior to mastectomy to identify patients with nodal involvement at highest risk for requiring postmastectomy RT and delay reconstruction in this subset of women until after the completion of oncologic therapy. This is an area that continues to evolve, and multidisciplinary consultation between the oncologic surgeon, reconstructive surgeon, and radiation oncologist will help to ensure optimal patient outcomes.

MANAGEMENT OF THE AXILLA

For many years, standard management of the axilla for patients with invasive breast carcinoma consisted of a complete ALND. Initially, this was thought to be a critical component of the surgical cure of breast cancer. This changed when studies such as the NSABP B-04 trial, in which clinically node-negative patients were randomized to radical mastectomy, total mastectomy with RT to the regional lymphatics, or total mastectomy with observation of the axillary nodes and delayed ALND if nodal metastases developed, showed no survival benefit for the axillary surgery.¹⁴⁷ ALND came to be regarded as a staging procedure that provided prognostic information and maintained local control in the axilla. However, the observation that 25% to 30% of long-term survivors treated with radical mastectomy alone had positive nodes,¹⁴⁸ coupled with the decreased survival observed after inadequate axillary treatment in the Guys Hospital trial,¹⁴⁹ suggested that ALND was therapeutic for some patients with axillary nodal metastases.

Lymphatic mapping and sentinel node biopsy has replaced ALND as the staging procedure of choice in clinically node-negative women. A sentinel node can be identified in 97% of women.^{150,151} In the American College of Surgeons Oncology Group (ACOSOG) Z10 trial, participating surgeons chose the method of lymphatic mapping, and no significant differences were seen in the rate of sentinel node identification with the use of blue dye alone, radiocolloid alone, or the combination of the two.¹⁵⁰ Increasing body mass index, increasing age, and <50 patients accrued to the trial were all associated with a significant decrease in sentinel node identification rate, but a sentinel node was successfully identified in >95% of patients in all groups. Complications of sentinel node biopsy are infrequent, with anaphylaxis to lymphazurin blue dye observed in 0.1% of patients in the ACOSOG Z10 trial¹⁵² and axillary paresthesias 6 months postoperatively in 8.6%. Lymphedema can occur after sentinel node biopsy, but at a much lower rate than after ALND. In the randomized Axillary Lymphatic Mapping Against Nodal Axillary Clearance trial, the absolute incidence of lymphedema in the sentinel node biopsy group was 5% at 12 months, with an RR of 0.37 (95% CI = 0.23 to

0.60) compared with the axillary clearance group in an intention-to-treat analysis.¹⁵³

The majority of patients with stage I and II cancer are candidates for sentinel node biopsy. Contraindications to the procedure include pregnancy, lactation, and locally advanced breast cancer (LABC). Care should be taken to excise any palpably abnormal nodes intraoperatively because lymph nodes that contain a heavy tumor burden may not take up the mapping agent. In the patient with clinically positive nodes, confirmation of metastases preoperatively with needle biopsy allows an immediate ALND. Caution should be used in proceeding directly to dissection without pathologic confirmation because the false-positive rate of physical examination is approximately 20%. Multicentric cancers and T3 primary tumors were initially thought to be contraindications to lymphatic mapping, but studies have shown that sentinel node biopsy is accurate in these circumstances.¹⁵⁴ Early in the experience with sentinel node biopsy, the false-negative rates of approximately 10%, determined by completing an ALND after the sentinel node(s) were removed, were a source of concern. However, three randomized studies directly comparing the identification of axillary metastases with ALND and sentinel node biopsy found no difference in the likelihood of identifying nodal disease.^{151,153,155} Follow-up studies of patients treated by sentinel node biopsy alone demonstrate that the rate of LR in the axilla is extremely low if the sentinel node does not contain metastases, despite the 10% false-negative rate. In one study with a median follow-up of 31 months, isolated axillary first failure was seen in only 3 of 4,008 patients (0.07%) who had a sentinel node biopsy.¹⁵⁶

In clinically node-negative patients receiving neoadjuvant chemotherapy, sentinel node biopsy after chemotherapy offers the patient the potential benefit of axillary downstaging and avoidance of ALND. A meta-analysis of 27 studies involving 2,148 patients undergoing sentinel node biopsy after chemotherapy reported a sentinel node identification rate of 90.5% (95% CI = 88% to 92%) and a false-negative rate of 10.5% (8% to 14%), comparable to what is seen in the primary surgical setting,¹⁵⁷ and in the NSABP B18 trial,¹⁵⁸ the rate of nodal positivity was reduced from 57 to 41% with neoadjuvant chemotherapy ($p < 0.001$). The accuracy of sentinel node biopsy in patients with clinically evident axillary nodal metastases at presentation who receive neoadjuvant therapy with resolution of clinically apparent adenopathy has been addressed in two multi-institutional prospective studies, as summarized in Table 79.14.^{159,160} These studies demonstrate false-negative rates <10% only when three or more sentinel nodes are identified, a circumstance present in only 28% of patients in the German multi-institutional Sentinel Neoadjuvant trial.¹⁶⁰ These findings suggest that ALND should remain the standard approach for patients presenting with clinically evident nodal involvement unless three or more sentinel nodes are identified. Ongoing trials are examining whether nodal irradiation could replace ALND in this setting.

The ability to perform a more detailed examination of the sentinel node has significantly increased the identification of small tumor deposits in the axillary nodes. The presence of isolated tumor cells (<0.2 mm deposits) and micrometastases (>0.2 mm, <2.0 mm) was initially thought to identify patients at increased risk for distant metastases. However, prospective trials in the modern era, including systemic therapy, have failed to identify an OS difference associated with micrometastases.^{161,162} A prospective randomized trial addressing the need for completion ALND in patients with sentinel node micrometastases¹⁶³ found no significant difference in local, regional, or distant recurrence rates among patients with sentinel node micrometastases treated with sentinel node biopsy alone versus completion ALND, despite the finding of additional nodal metastases in 13% of the ALND group. Based on these findings, the routine use of serial sections and IHC to detect micrometastases is not warranted.

ALND has been the standard approach to patients with axillary nodal metastases. Studies comparing sentinel node biopsy with ALND have provided important information on the morbidity of the procedure. In the Axillary Lymphatic Mapping Against Nodal Axillary Clearance trial, moderate to severe lymphedema was reported by 13% of patients 12 months after ALND as well as sensory loss in 31%.¹⁵³ Decreases in shoulder flexion and abduction were present 1 month after surgery but resolved rapidly after that time. ALND provides excellent long-term local control, with only 1.4% of patients treated by radical mastectomy in the NSABP B-04 trial¹⁴⁷ having an isolated axillary recurrence at 10-year follow-up. The use of axillary irradiation as an alternative to ALND was studied in the presentin node era in a randomized trial in clinically node-negative patients performed at the Institute Curie. After 15 years of follow-up, the axillary failure rate was 3% in the radiated group and 1% in the surgical group ($p = 0.03$),¹⁶⁴ indicating that this is an acceptable alternative in patients with contraindications to axillary surgery or those who refuse the procedure. The recognition that patients in the modern era who are eligible for BCT often have smaller cancers with lower nodal disease burdens, coupled with the recognition that systemic therapy significantly reduces LR,¹⁶⁵ led to the ACOSOG Z0011 trial, a prospective randomized study to address the need for ALND in clinically node-negative women found to have macrometastases in less than three sentinel nodes. The study was designed to identify a 5% difference in survival between patients undergoing a completion ALND and those treated with sentinel node biopsy alone. It closed prematurely because of a low event rate, but 891 patients were randomized. After a median follow-up of 6.2 years, the 5-year nodal recurrence rate was 0.5% in the dissection arm and 0.9% in the sentinel node biopsy alone arm ($p = 0.11$). No difference in 5-year DFS or OS was seen between groups, and no evidence of a trend toward a survival benefit for dissection, which might have been evident with a larger sample size, was observed. Morbidity, including wound infection, paresthesia, and patient-reported lymphedema, was significantly lower in the sentinel node group. All patients in this study were treated with BCT, 97% received some type of systemic therapy, and irradiation of an axillary field was not permitted, but it is likely that the low rate of axillary failure in the sentinel node biopsy alone group is at least in part related to irradiation of the low axilla with the breast tangents.¹⁶⁶ These findings do not apply to women with clinically positive nodes or extensive nodal involvement, or those undergoing partial breast irradiation or treatment with mastectomy. Investigators from Memorial Sloan-Kettering Cancer Center applied the ACOSOG Z0011 eligibility criteria to a consecutive series of 287 women, and ALND was avoided in 84%.¹⁶⁷ Patient age, hormone receptor status, and HER2 status did not differ between patients requiring ALND and those who did not.

The After Mapping of the Axilla: Radiotherapy or Surgery trial examined alternative management approaches for the patient with a positive sentinel node, in this case, irradiation of the axillary and supraclavicular fields instead of dissection.¹⁶⁸ At

DFS	No	No	Yes
OS	No	No	No

ACOSOG, American College of Surgeons Oncology Group; AMAROS, After Mapping of the Axilla: Radiotherapy or Surgery; MA, National Cancer Institute of Canada MA; BCS, breast-conserving surgery; ALND, axillary lymph node dissection; SN, sentinel node; RT, radiotherapy; SC, supraclavicular; IM, internal mammary; DFS, disease-free survival; OS, overall survival.

5 years, axillary recurrence was seen in 0.54% of patients undergoing ALND and 1.03% of those having RT, without significant differences in 5-year DFS. There was a lower risk of lymphedema among women treated with axillary RT instead of surgery (14% versus 28%, $p < 0.0001$). This study indicates that RT is an alternative to dissection, but does not prove that all patients with metastases to one or two sentinel nodes require nodal irradiation as similar rates of local control were observed in ACOSOG Z0011 after sentinel node biopsy alone. In marked contrast to these two studies are the results of the MA.20 trial, a study randomizing patients with T1 and T2 tumors undergoing WBI to ALND or ALND plus nodal RT. The majority of patients included in the study (85%) had involvement of one to three axillary nodes. The 5-year LR-free survival was improved from 94.5% to 96.8% ($p = 0.02$) with the addition of nodal RT, the distant DFS was improved from 87% to 92.4% ($p = 0.002$), and OS from 90.7% to 92.3% ($p = 0.07$).¹⁶⁹ These trials are summarized in Table 79.15. At present, the optimal approach to the patient with positive sentinel nodes treated with BCS and whole-breast RT is a matter of debate, but ALND should no longer be considered the standard approach for all patients. Future research to clarify which subsets of patients are best managed with sentinel node biopsy alone versus sentinel node biopsy and axillary RT, and which high-risk groups require dissection and nodal RT, is needed.

POSTMASTECTOMY RADIATION THERAPY

The use of postmastectomy radiation therapy (PMRT) is in evolution based on emerging data from clinical trials. The 2005 publication from the EBCTCG suggested a 4:1 ratio between reduction in LRR at 5 years and improved mortality at 15 years with RT both after BCS and after mastectomy, and confirmed that LRR was reduced by 70% with RT after either BCS or mastectomy.⁸⁸ This established LRR as a convenient intermediate endpoint for the survival benefit of PMRT.

ASTRO¹⁷⁰ and ASCO¹⁷¹ have endorsed the routine use of PMRT in women with four or more involved nodes and node-positive women with tumors >5 cm, who have a high (>20% to 25%) risk of LRR without RT. There is uncertain benefit of PMRT in patients with T1/T2 primaries and one to three positive nodes (stage II) in whom the risk of LRR is intermediate (around 10% to 20%). Current NCCN guidelines give a category I

TABLE 79.16

Five-Year Local-Regional Recurrence Rates and Fifteen-Year Breast Cancer Mortality Rates in the Three Groups for Patients Randomly Assigned to Postmastectomy Radiation Therapy or Not

Prognostic Group	Five-Year LRR No RT	Five-Year LRR RT	Fifteen-Year Breast Cancer Mortality – No RT	Fifteen-Year Breast Cancer Mortality – RT
Good	11%	0%	33%	22%
Intermediate	26%	5%	61%	50%
Poor	50%	14%	81%	81%

LRR, local-regional recurrence; RT, radiotherapy.

recommendation for PMRT for patients with four or more positive nodes and a category 2A recommendation for PMRT for patients with one to three positive nodes.

However, in more recent analyses, the EBCTCG has focused on first recurrence of any type (LRR or distant) rather than LRR as a first event.¹²⁵ This difference was partly because it is now clear that RT after BCT or mastectomy reduces breast cancer death, so it must also reduce distant recurrence. In addition, it is because women with a higher risk of LRR also have a higher risk of distant recurrence (i.e., the probabilities of LRR and of distant recurrence are not statistically independent), so valid estimates of the separate effects of RT on LRR and distant recurrence cannot be obtained.¹⁷² As a practical matter, this means that LRR is not an intermediate endpoint for the survival benefit of RT and that the survival benefit can only be learned in long-term follow-up of clinical trials testing RT.

This interplay between LRR and distant recurrence and its effect on survival was illustrated in a post hoc analysis of the Danish PMRT trials.¹⁷³ Patients were assigned to one of three prognostic groups based on number of positive axillary nodes, tumor size, histologic grade, and receptor status. The 5-year LRR rates and the 15-year breast cancer mortality rates were analyzed in the three groups for patients randomly assigned to PMRT or not (Table 79.16). It is noteworthy that the “poor” group had the biggest absolute reduction in LRR with RT (36%), but had no improvement in 15-year breast cancer mortality. In contrast, the “good” group had the smallest absolute reduction in LRR with RT (11%), but the biggest absolute reduction in 15-year breast cancer mortality (11%). The EBCTCG data on trials of PMRT was updated in 2007.¹⁷⁴ Although the data are still preliminary, they demonstrate that the benefit of PMRT was greater in the patients with one to three positive nodes than in patients with four or more positive nodes. In the subgroup of patients with one to three positive lymph nodes, the 15-year gain in breast cancer mortality was 10.2% (51.3 versus 41.1%, $2p < 0.0001$), and the 15-year gain in all-cause mortality was 7.3% (57.2% versus 49.9%, $2p = 0.004$) with PMRT. The reduction in the rate of any first recurrence in the one to three positive node group at 10 years was 13.5% ($2p < 0.0001$). In contrast, the reduction in the rate of any first recurrence in the four or more positive node group at 10 years was 11.5% ($2p < 0.0001$). Thus, these and other data demonstrated that reduction in LRR is not a valid intermediate endpoint for the benefit in long-term survival and that the biggest benefit for PMRT might be in intermediate-risk, not high-risk, patients.

A critically important but unresolved issue is whether the use of effective adjuvant systemic therapy makes PMRT more or less useful. It is clear that effective adjuvant systemic therapy reduces the risk of LRR, but if this is no longer an important endpoint, then this does not provide a justification for less PMRT. We and others have argued that it is in context of effective systemic therapy that eradicates micrometastatic disease that improved local therapy might be most beneficial.¹⁷⁵

A number of preliminary findings support the use of regional RT in intermediate-risk patients. The MA.20 trial¹⁶⁹ randomized high-risk node-negative or node-positive patients to WBI alone or WBI plus regional RT including internal mammary node and medial supraclavicular (IM-MS) fields after BCS. Most patients had one to three positive nodes. With a median follow-up of 62 months, the addition of IM-MS RT improved LR DFS (LR DFS, 96.8% versus 94.8%), distant DFS (distant DFS, 92.4% versus 87%; $p = 0.002$), and overall DFS (DFS, 89.7% versus 84.0%), and had a borderline effect on OS (91.9% versus 89.5%). The HR reduction with RT for DFS was 0.67 ($p = 0.003$) and the HR reduction with RT for survival was 0.76 ($p = 0.07$).

The EORTC randomized patients to WBI plus IM-MS RT versus WBI alone.¹⁷⁶ The patients in this trial were more heterogeneous than in the Canadian trial: 76% had BCT and 24% had mastectomy, and 44% were pN0, 43% were pN1, and 10% were pN2. With a median follow-up of 10.9 years, IM-MS RT improved DFS and distant DFS, and had a borderline effect on OS, the primary endpoint; but the magnitude of benefit in this larger study with longer follow-up was less than that seen in the MA.20 trial. The HR reduction with RT for DFS was 0.89 ($p = 0.04$) and the HR reduction with RT for survival was 0.87 ($p = 0.056$).

It will be important to examine the data in published manuscripts, but the evolving evidence suggests that a serious discussion of PMRT is warranted in the majority of women with intermediate-risk breast cancer treated with mastectomy, including those with one to three positive lymph nodes. There are a number of points about PMRT worth stressing. One is that, similar to the previous discussion on BCT, minimizing cardiac irradiation is critical but can be more difficult in PMRT, because unlike in BCT, the target volume includes the whole chest wall. The use of the deep inspiration breath hold technique is encouraged for left-sided patients. The other point relates to the multidisciplinary collaboration needed when reconstruction, particularly immediate reconstruction, is planned.

PROGNOSTIC AND PREDICTIVE FACTORS IN BREAST CANCER

The AJCC staging system reviewed elsewhere in this chapter⁷⁹ is based on established clinical and pathologic prognostic factors, and stage—particularly the *extent of axillary lymph node involvement* by breast cancer—is the most established and reliable prognostic factor for subsequent metastatic disease and survival. Tumor size and histologic grading also have established prognostic significance. *Tumor size* is typically given as the microscopic size of the invasive cancer. *Histologic grade* is best determined by an established methodology, such as the Nottingham combined histologic grading system. However, persistent challenges in interpretation of grade either under the microscope or in genomic assays, especially intermediate grade, tend to diminish some of its prognostic impact.¹⁷⁷

Estrogen and progesterone receptor expression are important and useful predictive factors. Patients with invasive breast cancer whose tumors are totally lacking in ER and PR do not derive benefit from hormonal treatment. Assays for ER and PR are performed using IHC techniques. Laboratories need to adhere to well-described techniques to ensure accurate determination of ER and PR as a centerpiece for quality care in breast cancer.¹⁷⁸ Using tumor size and grade, ER status, and the number of involved axillary nodes, online services such as Adjuvant Online (www.adjuvantonline.com) can give accurate estimates of recurrence risk and treatment benefit.¹⁷⁹

Patient age has also consistently been shown to be a prognostic factor. Very young breast cancer patients (≤ 35 years) have a poorer prognosis than older patients. The cancers in these patients tend to be higher grade, less often ER/PR⁺, and more likely to have lymphovascular invasion than cancers in older patients—differences that likely explain much of the worse outcomes in very young patients.^{180,181} A retrospective review of patients in clinical trials examining prognosis based on age, ER, PR, and *HER2* status found that patients < 35 years of age with ER/PR⁺, *HER2*⁻ tumors had no different risk of local or distant relapse than their older counterparts, but differences in LRR and survival persisted among other subgroups.¹⁸²

Approximately 20% of patients with breast cancer have *HER2/neu* gene amplification, which results in glycoprotein overexpression. Approximately 5% of patients have overexpression without gene amplification, but otherwise, gene amplification and expression are highly correlated. *HER2* amplification or overexpression has been associated with higher tumor grade, lower expression or lack of hormone receptors, higher levels of tumor proliferation, heavier nodal tumor burden, and poorer prognosis. *HER2* status is the major predictive factor for benefit from anti-*HER2* targeted therapies, which is discussed later in this chapter. There is some evidence that suggests that *HER2* status is predictive for benefit from anthracycline-based chemotherapy, although this relationship is not certain, particularly with the availability of trastuzumab.¹⁸³ Measurements of *HER2* can be performed by either IHC or fluorescent in situ hybridization. Similar to ER, laboratories need to adhere to well-described techniques to ensure accurate determination of *HER2*. In clinical practice, tumors that are considered *HER2* 3⁺ by IHC, or show evidence of *HER2* gene amplification with ratios ≥ 2 , warrant treatment with anti-*HER2* therapies.¹⁸⁴

Involvement of lymphovascular spaces is associated with a greater likelihood of lymph node metastases and is an independent adverse prognostic factor in both node-negative and node-positive patients. Rigid pathologic criteria are required for this factor to be reliable.

Other Factors

Numerous other prognostic and predictive factors have been evaluated, but have not been widely adopted in routine clinical use in the United States and include (1) markers of *proliferation*, such as S-phase fraction, the percentage of cells labeling with thymidine or bromodeoxyuridine or cellular expression of Ki-67 or MIB-1 (which measure the percentage of cells in the G₁ phase of the cell cycle), and mitotic index; (2) measures of the *plasminogen activator system*, such as the concentrations of urokinase plasminogen activator and its inhibitor, plasminogen activator inhibitor-1; and (3) the detection of *occult micrometastases* in the bone marrow using IHC techniques.¹⁸⁵ Sources are available for a more detailed discussion of these and other factors.¹⁸⁶

Molecular and Genomic Factors

Breast cancer is a heterogeneous disease, and it has long been appreciated that tumors with different biologic features have different clinical outcomes and responses to therapy. At present,

prognosis and treatment selection in breast cancer are based on characterization of tumor growth factor receptor status—ER, PR, and *HER2*. These markers can be used to define four functional groups of tumors: hormone receptor-positive, *HER2*⁻, hormone receptor-negative, *HER2*⁻ (“triple-negative” tumors), and *HER2*-overexpressing tumors with or without hormone receptor expression.

Recent advances in molecular biology have resulted in further refinement of these breast cancer subsets. Sorlie et al.¹⁸⁷ and Perou et al.¹⁸⁸ were able to classify breast cancers into tumor subtypes that had different prognoses using complementary DNA microarrays. These studies used hierarchical clustering analysis to identify tumor subtypes with distinct gene expression patterns. The differences in gene expression patterns among these subtypes reflect basic differences in the cell biology of the tumors and are manifest in differences in clinical outcome; clinicians are increasingly viewing these molecular subtypes as separable diseases. The subtypes are luminal A, luminal B, *HER2/neu*, and basal-like (or basaloid, or triple-negative). The subtypes are commonly approximated using routine tumor markers, such as luminal A: ER and/or PR⁺/*HER2*⁻; luminal B: ER and/or PR⁺/*HER2*⁺; *HER2*⁺: ER⁻/PR⁻/*HER2*⁺; and basal-like ER⁻/PR⁻/*HER2*⁻ and/or CK5/6⁺ and/or epidermal growth factor-positive. Differences in gene expression pattern affecting hundreds of genes are found between the various subgroups; these differences appear to persist through the natural life history of the breast cancer,¹⁸⁹ and neoadjuvant treatment of breast tumors appears to have little bearing on the gene expression patterns that contribute to the intrinsic tumor subtype.^{188,190} Subgroup affects both the likelihood and timing of cancer recurrence.¹⁹¹ Triple-negative/basal-like, *HER2*-associated, and luminal B breast cancers are at greater risk for early recurrence relative to luminal A cancers, which have a longer latency period of possible recurrence.

Complete genetic sequencing of human breast cancers has reinforced the idea that discrete subtypes of breast cancer exist.¹⁹² There is strong correlation between histologic subtypes of breast cancers, genomic profiles, and mutations identified by genomic sequencing. This information is beginning to influence clinical practice in breast cancer management.

In addition to defining biologic tumor subsets, gene expression profiling has been used to stratify tumors as having good-risk or poor-risk prognostic signatures.^{193,194} Several of these assays are now commercially available. MammaPrint is a 70-gene signature developed in the Netherlands.¹⁹³ Prosigna (NanoString Technologies, Seattle, WA) is a 50-gene intrinsic subtype classifier that categories cancers into luminal A, luminal B, *HER2*, or basal-like subtypes.¹⁹⁵ Retrospective analyses suggest that these gene signatures contribute independent prognostic information above and beyond that achieved with use of traditional pathologic markers, such as stage, grade, lymphovascular invasion, and ER/PR/*HER2* status.

One molecular test that is of use clinically is the Oncotype DX recurrence score. The recurrence score is based on a quantitative assessment of 21 genes thought to be relevant to breast cancer biology, including hormone receptors, Ki67, and *HER2*, among others. In contrast to gene expression profiles that classify tumors into specific subsets or dichotomize tumors into good/poor prognostic groups, the recurrence score calculates a continuous, numeric result that correlates with distant metastatic recurrence in tamoxifen-treated patients with node-negative breast cancer,¹⁹⁶ and has been shown to be a prognostic marker in postmenopausal women with node-negative or node-positive tumors receiving either tamoxifen or an AI.¹⁹⁷ Although the recurrence score tends to correlate with features like tumor grade, size, nodal status, and quantitative levels of hormone receptor expression, multivariate analyses demonstrate that the score provides significant independent prognostic information. Oncotype DX has been applied to a common clinical question: whether a patient with ER⁺ breast cancer should receive chemotherapy in addition to hormonal therapy. Retrospective analyses from NSABP B-20—a trial of tamoxifen alone versus tamoxifen plus chemotherapy for ER⁺, node-negative

patients—demonstrated that the recurrence score was a predictive factor for benefit from chemotherapy. Patients with tumors that had a low recurrence score had a very favorable overall prognosis that was not meaningfully improved by chemotherapy, while patients with high recurrence scores derived a substantial benefit from chemotherapy.¹⁹⁸ Qualitatively similar findings were seen in the Southwest Oncology Group (SWOG) 8814 study, a randomized trial of tamoxifen alone or tamoxifen plus cyclophosphamide/doxorubicin/5-fluorouracil chemotherapy for postmenopausal women with ER⁺, node-positive breast cancer, although the overall prognosis in this node-positive cohort was less favorable than in node-negative cases.¹⁹⁹

There is substantial overlap between the various molecular diagnostic assays used to gauge prognosis and treatment for early-stage breast cancer.²⁰⁰ In particular, many assays appear capable of distinguishing node-negative, lower-grade tumors that are strongly ER⁺ and HER2⁻, and are unlikely to benefit from adjuvant chemotherapy²⁰¹ (Table 79.17). Collectively, these molecular tools have led to the evolution of specific treatment algorithms based on subtype classification, and clinical trials are increasingly designed for specific tumor types.

ADJUVANT SYSTEMIC THERAPY

The goal of adjuvant systemic therapy is to prevent the recurrence of breast cancer by eradicating occult, micrometastatic deposits of tumor present at the time of diagnosis. The rationale for adjuvant treatment stems from the systemic hypothesis of breast tumorigenesis, which argues that in the early stages of breast cancer development, tumor cells are disseminated throughout the body. To a large extent, this hypothesis has been validated through decades of clinical investigation, and approximately half of the

recent decline in breast cancer mortality in the United States and Western Europe has been attributed to the widespread use of adjuvant therapy.⁵

In current practice, three systemic treatment modalities are widely used as adjuvant therapy for early-stage breast cancer. These modalities are (1) endocrine treatments such as tamoxifen, AIs, or ovarian suppression; (2) anti-HER2 therapy with the humanized monoclonal antibody, trastuzumab; and (3) chemotherapy. Selection of adjuvant treatment is determined by the biologic features of the breast cancer (Table 79.18). Patients with tumors that are hormone receptor positive (either for ER, PR, or both) are candidates for adjuvant endocrine therapy; patients with tumors that are HER2 overexpressing are candidates for trastuzumab. Chemotherapy is used for tumors that are hormone receptor negative, alongside trastuzumab in HER2⁺ tumors, and in addition to endocrine therapy in ER⁺ patients, based largely on features such as tumor size, nodal status, and the patient's other health considerations.

Adjuvant Endocrine Therapy

Tamoxifen is the historic standard for adjuvant endocrine therapy for breast cancer. The EBCTCG has performed an overview of the randomized trials of adjuvant tamoxifen therapy.²⁰² These results reflect data with 15 years of follow-up, from over 60 adjuvant trials including >80,000 women. Tamoxifen administered for 5 years results in a 41% reduction in the annual rate of breast cancer recurrence (HR = 0.59) and a 34% reduction in the annual death rate (HR = 0.66) for women with ER⁺ breast cancer. The gains associated with tamoxifen are achieved independent of patient age or menopausal status, with and without the use of adjuvant chemotherapy, and are durable, contributing to improved survival through at least 15 years of follow-up. Shorter durations of tamoxifen therapy are also beneficial, but appear to have less impact than

TABLE 79.18

Overview of Adjuvant Treatment Approaches in Breast Cancer

Tumor HER Status	Tumor Hormone Receptor Status	
	Positive	Negative
HER2 negative/normal	Endocrine therapy ± chemotherapy	Chemotherapy
HER2 positive/overexpressed	Endocrine therapy + chemotherapy + trastuzumab	Chemotherapy + trastuzumab

5-year treatment duration. Until recently, data had suggested that the optimal duration of tamoxifen therapy was 5 years; extending tamoxifen therapy beyond 5 years in patients with no evidence of tumor recurrence had not led to further improvements in DFS or OS.²⁰⁵ However, the Adjuvant Tamoxifen: Longer Against Shorter trial compared 10 years versus 5 years of adjuvant tamoxifen, and found an improvement in overall and DFS with the longer duration of tamoxifen treatment.²⁰⁴ This finding is of particular relevance for premenopausal women who lack the option of receiving extended adjuvant endocrine therapy with an AI (see the following). Based on the Adjuvant Tamoxifen: Longer Against Shorter trial, premenopausal women should consider longer duration of tamoxifen up to 10 years as adjuvant endocrine treatment. Tamoxifen is not effective in preventing recurrence of hormone receptor–negative breast cancer.^{205,206}

Multiple clinical trials have examined the role of AIs as adjuvant endocrine therapy for early breast cancer. Although tamoxifen works by binding to the ER, AIs function through inhibition of the aromatase enzyme that converts androgens into estrogens,²⁰⁷ resulting in profound estrogen depletion. In postmenopausal patients, where only nonovarian, baseline levels of aromatase activity are present, AIs lower estrogen production by 90% to nearly undetectable levels.²⁰⁸ AIs are not appropriate for premenopausal patients, as residual ovarian function can lead to enhanced production of aromatase and thus overcome the effects of AIs.

Major trials have studied whether the incorporation of an AI improves the results seen with 5 years of tamoxifen in postmenopausal women with hormone receptor–positive breast cancer (Table 79.19). AI treatment has been explored as primary or up-front therapy *instead* of tamoxifen,^{209–211} as *sequential* therapy after 2 or 3 years of tamoxifen,^{212,213} and as *extended* therapy after 5 years of tamoxifen.^{214–216} In each setting, the use of an AI achieved modest improvements in DFS as a result of a lower risk of both distant metastasis as well as of in-breast recurrences and contralateral tumors. Two trials, BIG 1-98²¹⁷ and the Tamoxifen and Exemestane in Early Breast Cancer study,²¹⁸ have compared up-front use of an AI against a sequential treatment with tamoxifen followed by an AI. These studies demonstrate equal rates of tumor recurrence with either 5 years of an AI or 2 to 3 years of tamoxifen followed by 2 to 3 years of an AI for a total of 5 years of therapy. Randomized trials have shown no important clinical differences between nonsteroidal or steroidal AIs as adjuvant therapy, demonstrating that different commercially available AIs can be used interchangeably.²¹⁹

For women who begin taking an AI at the time of diagnosis, the appropriate duration of endocrine treatment is unknown, although at present, a maximum of 5 years is the only duration for which safety and efficacy data exist. Studies are ongoing to address this question. The option of starting with either an AI or tamoxifen appears reasonable for any patient. The up-front trials^{210,211}

limited treatment to a total of 5 years' duration, and the sequential trials^{212,213} used AI therapy for only 2 or 3 years as part of a total of 5 years of adjuvant endocrine treatment. The studies of extended endocrine therapy beyond 5 years^{204,214,216} underscore the long natural history of hormone receptor–positive breast cancer and demonstrate that antiestrogen treatments have ongoing benefits well beyond 5 years after diagnosis.

The recently updated ASCO guidelines on adjuvant endocrine therapy recommend that postmenopausal women consider an AI at some point in their treatment program as either initial therapy or as sequential therapy after several years of tamoxifen.²²⁰ Differences in side effect profiles between tamoxifen and AI therapy may inform treatment selection. Tamoxifen is associated with rare risks of thromboembolism and uterine cancer.^{205,210,211} AI treatment is associated with accelerated osteoporosis and an arthralgia syndrome²²¹; patients receiving AI therapy require serial monitoring of bone mineral density.²²² Both treatments are associated with menopausal symptoms, such as hot flashes, night sweats, and genitourinary symptoms, including sexual dysfunction. Postmenopausal women who are intolerant of either tamoxifen or AI therapy should be offered the alternative type of treatment. Because AI therapy is only effective in postmenopausal women, tamoxifen remains the treatment of choice in women who are pre- or perimenopausal, or in whom there is question of residual ovarian function. In particular, women with chemotherapy-induced amenorrhea may have recovery of ovarian function and are not suitable candidates for AI treatment.²²³

Despite longstanding interest in ovarian suppression as adjuvant therapy, its role in addition to tamoxifen or chemotherapy remains unclear because of confounding clinical factors. Early studies of ovarian suppression were not limited to patients with hormone receptor–positive tumors, did not necessarily include tamoxifen, and frequently included chemotherapy, which led to a high incidence of chemotherapy-induced menopause.²²⁴ Thus, despite the fact that multiple randomized trials have demonstrated that ovarian suppression can be effective adjuvant therapy for premenopausal women²⁰² and have demonstrated that ovarian suppression is frequently at least as effective as adjuvant chemotherapy in preventing breast cancer recurrence,²²⁵ there remains little consensus on whether ovarian suppression adds meaningfully to results seen with tamoxifen with or without adjuvant chemotherapy.

Very young women—typically those <35 years of age—who do not routinely experience amenorrhea with adjuvant chemotherapy, appear to have a substantially worse prognosis than patients who do enter menopause with chemotherapy.²²⁶ A randomized trial has compared chemotherapy alone, chemotherapy plus ovarian suppression and tamoxifen, and ovarian suppression plus tamoxifen as adjuvant treatment. The addition of tamoxifen clearly

improved results compared to chemotherapy with or without ovarian suppression. In subset analyses, younger women (<40 years of age) who were less likely to experience chemotherapy-induced amenorrhea did appear to benefit from ovarian suppression in addition to chemotherapy.²²⁷ The Adjuvant Breast Cancer Ovarian Ablation or Suppression Trial compared tamoxifen alone versus tamoxifen with ovarian suppression in premenopausal women and did not show a substantial improvement in DFS with the addition of ovarian suppression.²²⁸ However, in this study, only 40% of patients were known to have ER⁺ breast cancer, and 80% of patients additionally received adjuvant chemotherapy, profoundly limiting study interpretation. Ongoing trials are specifically testing the role of ovarian suppression in addition to tamoxifen for premenopausal patients.

Tamoxifen is metabolized by the cytochrome P-450 system into biologically active metabolites. Pharmacogenomic variation in P-450 alleles or the concurrent use of tamoxifen and P-450 inhibitors might affect tamoxifen metabolism, with clinically significant effects.^{229–233} Larger retrospective studies have not found consistent relationships between CYP2D6 metabolism and long-term outcomes with tamoxifen treatment.^{234,235} At present, neither the full significance of pharmacogenomic allelic variation nor the adequacy of testing for such variation is well characterized.

Multiple studies have documented high rates of noncompliance and early termination of adjuvant endocrine treatments.²³⁶ Factors associated with limited compliance or adherence to tamoxifen and AIs include age, treatment-related symptoms, costs of therapy, and patient-specific perceptions of therapeutic benefit. While the precise impact of noncompliance or nonpersistence with adjuvant endocrine treatment is unclear, clinicians should inquire about treatment utilization given the importance of these agents at improving survival.

Adjuvant Chemotherapy

Adjuvant chemotherapy consisting of multiple cycles of polychemotherapy is well established as an important strategy for lowering the risk of breast cancer recurrence and improving survival. Initial studies of adjuvant chemotherapy were conducted in women with higher-risk, lymph node–positive breast cancer. Subsequent trials have extended the benefits of adjuvant chemotherapy into lower risk, node-negative patient populations.²³⁷ Long-term follow-up from the EBCTCG overview demonstrated benefit from chemotherapy for women irrespective of age, tumor ER status, or whether patients also receive adjuvant endocrine therapy. In addition, the overview suggests that there are advantages for multiple cycles (four to eight) of chemotherapy compared with single-cycle regimens, and demonstrates the superiority of taxane-based and anthracycline-based chemotherapy over cyclophosphamide, methotrexate, 5-fluorouracil (CMF)-based, nonanthracycline regimens.

Multiple cycles of adjuvant chemotherapy, typically including taxanes and anthracyclines as part of the regimen, are recommended for the majority of patients with node-positive and higher-risk node-negative tumors.²³⁸ The current challenges in adjuvant chemotherapy treatment are to select subsets of patients that might preferentially benefit from chemotherapy or conversely be spared adjuvant chemotherapy and to optimize the dosing and scheduling of chemotherapy to achieve the best clinical results and improve the side effect profile of treatment.

The introduction of taxanes into early-stage breast cancer treatment constitutes an important advance over the historic experience with alkylator and anthracycline-based chemotherapy. The first report on adjuvant taxane therapy, Cancer and Leukemia Group B 9344, demonstrated that the addition of sequential paclitaxel therapy improved both DFS and OS among women with node-positive breast cancer compared to women receiving four cycles of cyclophosphamide-doxorubicin (AC) chemotherapy.²³⁹ Since that time, nearly one dozen studies have reported on breast

cancer outcomes with the incorporation of taxanes—either paclitaxel or docetaxel—either as substitutes or sequential additions to anthracycline-based regimens. Studies to define the optimal taxane-based regimen have yielded the following important results. The Cancer and Leukemia Group B 9741 trial compared AC followed by paclitaxel given either every 3 weeks or every 2 weeks at the same doses and schedules.²⁴⁰ Accelerated, every 2-week treatment (so-called dose-dense) led to lower risk of recurrence and improved survival. A randomized comparison of AC followed by either docetaxel or paclitaxel, with taxanes given either every 3 weeks or on a weekly schedule, did not show significant differences between the taxanes with respect to breast cancer recurrence, though weekly paclitaxel was the best tolerated option.²⁴¹ Sequential therapy with anthracyclines/alkylators followed by taxanes proved superior to concurrent taxane-anthracycline-alkylator treatments.²⁴² Sequential dose-dense AC followed by paclitaxel was at least as effective, and better tolerated, than concurrent docetaxel/doxorubicin/cyclophosphamide chemotherapy.²⁴³

Meanwhile, neither additional chemotherapy doses nor agents have improved outcomes. Multiple studies have failed to demonstrate that dose escalation of cyclophosphamide²⁴⁴ or doxorubicin²³⁹ results in a lower risk of recurrence. The addition of capecitabine or gemcitabine to anthracycline- and taxane-based chemotherapy regimens did not improve efficacy.^{243,245}

For women who warrant chemotherapy, sequential anthracycline- and taxane-based treatment remains the “gold standard.” While multiple possible variations on this regimen exist, the experience to date has not demonstrated that any regimen is better tolerated or more effective than AC for four cycles followed by paclitaxel chemotherapy, with paclitaxel given as either four cycles every 2 weeks, or as 12 weeks of weekly therapy.

There is growing interest in adjuvant chemotherapy regimens that might spare patients exposure to anthracycline-based chemotherapy. Historical options include CMF chemotherapy, which was shown to be equivalent to doxorubicin/cyclophosphamide.²⁴⁰ The two-drug combination regimen of docetaxel plus cyclophosphamide was superior to doxorubicin/cyclophosphamide (each regimen given for a total of four cycles)²⁴⁶ in a trial of 1,016 women with node-negative or one to three positive lymph nodes, establishing docetaxel plus cyclophosphamide as an option for these intermediate-risk patients. Six cycles of chemotherapy with AC or taxanes is not better than four cycles of the same regimen.²⁴⁷ Among higher-risk patients, it is unclear that anthracyclines can be safely omitted.

Clinical studies have shown that chemotherapy can be of benefit to women with node-positive and node-negative breast cancers, with tumors that are either hormone receptor–positive or –negative, regardless of age or menopausal status. Retrospective analyses have even shown that chemotherapy can be beneficial to women with tumors as small as ≤ 1 cm, including both ER⁺ and ER[–] tumors.²⁴⁸ However, not all patients warrant chemotherapy. While chemotherapy often leads to statistically significant risk reduction, the differences in the absolute risk of recurrence for patients, especially patients with small cancers²⁴⁹ or ER⁺ cancers who also receive adjuvant endocrine therapy, tend to be very small (single percentage points). Third, most benchmark trial results did not take into account the existence of molecularly defined breast cancer subsets and may overestimate the benefits of chemotherapy in certain subtypes of breast cancer, while underestimating the benefits in others. Finally, for patients in whom the absolute advantages of chemotherapy are modest, efforts to weigh patient preferences and directly quantify chemotherapy benefits for specific patients, as opposed to large cohorts in clinical trials, have led to further individualization of chemotherapy choices.

Hormone receptor status may be an important predictor of benefit from chemotherapy. Tumors that are low or nonexpressors of ER derive substantial benefit from the addition of chemotherapy to tamoxifen; by contrast, tumors with high quantitative levels of ER do not appear to gain substantially from adding chemotherapy

to endocrine therapy.²⁰⁵ A retrospective review of trials for node-positive breast cancer found the gains associated with chemotherapy innovations in anthracycline- and taxane-based treatments were most noticeable among patients with ER⁻ tumors, while patients with ER⁺ tumors derived more limited benefit.²⁵⁰ However, not all retrospective studies have shown a clear relationship between ER status and the benefit of chemotherapy,²⁵¹ and precise thresholds of ER expression and chemotherapy benefit are not well established.

HER2 is also a marker that has been widely studied as a predictor of benefit from adjuvant chemotherapy. HER2 overexpression is associated with a relative benefit from anthracycline-based chemotherapy,²⁵² and HER2⁻ tumors do not selectively benefit from anthracyclines, as opposed to CMF-type chemotherapy treatments. Other retrospective work based on characterizing both HER2 status and ER status of tumors suggests that chemotherapy with taxanes may be especially critical in tumors that either lack ER expression or express HER2.²⁵³ However, these chemotherapy trials all predate the widespread use of adjuvant trastuzumab, which may render moot the details of chemotherapy selection for HER2⁺ tumors.

Molecular assays that integrate larger numbers of biomarkers can clarify the role of chemotherapeutic agents in adjuvant treatment. The 21-gene recurrence score (Oncotype DX, discussed in the section “Prognostic and Predictive Factors in Breast Cancer” on page 1138) predicts outcome for ER⁺, node-negative breast cancers treated with tamoxifen¹⁹⁶ or tamoxifen plus chemotherapy in node-negative¹⁹⁷ and node-positive¹⁹⁹ patients. Patients with tumors with higher recurrence scores derive substantial benefit from the addition of chemotherapy to endocrine treatment, while patients with low recurrence scores have both a more favorable overall prognosis and do not appear to benefit meaningfully from the addition of chemotherapy. Pathologic features such as low or no expression of hormone receptors, expression of HER2, and high tumor grade all tend to be predictors of likely sensitivity of tumors to chemotherapy.^{177,200} Tumors at the other end of the molecular spectrum—low grade, high levels of hormone receptors, lack of HER2 expression—tend to be more sensitive to endocrine therapies and less sensitive to adjuvant chemotherapy. Various chemotherapy regimens have distinctive side effect profiles that can inform regimen selection for an individual patient. For example, anthracyclines are associated with a low risk of cardiomyopathy and may not be appropriate for patients with previous anthracycline exposure or preexisting cardiac disease. Taxane-based treatments are associated with neuropathy that may be worse in patients with preexisting peripheral neuropathy.

Patients and doctors should gauge the absolute gains associated with chemotherapy by considering rigorously the tumor stage, comorbid conditions, age of the patient, and the biologic features

of the tumor. Adjuvant!, an online tool that quantifies the benefits of adjuvant treatment, integrates tumor size and biomarker information, patient age and health status, and the relative benefits of chemotherapy as measured in clinical trials, and reports in bar graph format the absolute benefits that the given patient is likely to achieve with adjuvant chemotherapy.^{179,254} There are limitations to Adjuvant!, which neither factors into account intrinsic subtypes, nor the efficacy of adjuvant trastuzumab for HER2⁺ tumors. Nonetheless, Adjuvant! can be valuable for framing the realistic benefits of chemotherapy for a variety of clinical situations. Patient surveys, inevitably performed after patients have endured adjuvant chemotherapy, suggest that many women would prefer adjuvant chemotherapy for extraordinarily small gains (1% improvement in outcome), and most women would accept chemotherapy for modest differences on the order of a 3% to 5% improvement in chance of recurrence.²⁵⁵

Adjuvant Trastuzumab Therapy for HER2-Overexpressing Breast Cancer

HER2 expression was historically an adverse prognostic factor associated with a higher risk of recurrence, lack of or lower levels of ER expression, and relative resistance to endocrine therapy and CMF-based chemotherapy.^{256,257} In 2005, reports became available from five randomized clinical trials that examined the addition of trastuzumab, the humanized monoclonal antibody against the HER2 protein, to chemotherapy as adjuvant treatment for HER2-overexpressing breast cancer (Table 79.20).^{258–261} Although these trials used a variety of different adjuvant chemotherapy regimens and employed trastuzumab in different schedules and sequences, they all showed significant improvements in DFS (reduction in risk of 50% on average) and OS. Subset analyses demonstrated comparable RR reduction regardless of tumor size, nodal status, or hormone receptor status, resulting in the rapid incorporation of trastuzumab into standard treatment recommendations for women with HER2⁺ breast cancer.

Cardiomyopathy is a novel side effect of trastuzumab therapy.²⁶⁰ Cardiac dysfunction is more frequent in patients receiving anthracycline-based than nonanthracycline adjuvant chemotherapy (2% versus 1%) in addition to trastuzumab. Other risk factors for cardiac dysfunction with adjuvant trastuzumab include preexisting cardiac disease, such as borderline normal left ventricular ejection fraction or hypertension, and age >65 years. All patients being considered for adjuvant trastuzumab require baseline determination of left ventricular ejection fraction and serial monitoring of cardiac function.

Adjuvant trastuzumab is only known to be effective in tumors with aberrant expression of HER2.²⁶² The optimal duration of

trastuzumab therapy is 1 year. While short exposure (9 weeks) of concurrent chemotherapy-trastuzumab treatment is better than no trastuzumab,²⁵⁸ a comparison of 6 months versus 12 months of trastuzumab therapy showed superiority for the 12 month duration.²⁶⁵ The HERA (Herceptin Adjuvant) trial compared 1 year versus 2 years of therapy and found no benefit for a second year of treatment.^{259,264}

Trastuzumab is active when delivered sequentially after chemotherapy (as done in the HERA trial²⁵⁹) or concurrently with chemotherapy (as done in the NSABP B-31/North Central Cancer Treatment Group N9831,²⁶⁰ and Breast Cancer International Research Group trials²⁶¹). However, concurrent trastuzumab-chemotherapy administration yielded superior results compared to sequential therapy.²⁶⁵ All of the adjuvant trastuzumab trials gave chemotherapy; there are no data on whether trastuzumab would be effective without adjuvant chemotherapy.

The optimal chemotherapy backbone for trastuzumab-based adjuvant treatment is uncertain.²⁶⁶ Most patients treated on the extant clinical trials received sequential anthracyclines and taxane-based treatment, with concurrent use of trastuzumab during taxane treatment. The results from Breast Cancer International Research Group 006 suggest that the nonanthracycline trastuzumab/docetaxel/carboplatin regimen is superior to chemotherapy given without trastuzumab.²⁶¹ However, the study was not powered to adequately compare trastuzumab/docetaxel/carboplatin against the doxorubicin and cyclophosphamide followed by docetaxel and trastuzumab treatment arms, and numerically, the anthracycline-based regimen followed by trastuzumab was associated with a lower risk of cancer recurrence.²⁶¹ Trastuzumab/docetaxel/carboplatin is an important treatment option, particularly in patients with contraindications to anthracycline-based treatment. Concomitant RT and maintenance trastuzumab can be safely delivered after chemotherapy.

Most of the patients in the major trastuzumab trials had node-positive or high-risk, node-negative breast cancers. The role of trastuzumab treatment for women with smaller, node-negative tumors, particularly tumors <1 cm, remains unproven in randomized trials. Historical studies have suggested that these smaller, *HER2*⁺ breast cancers still carried a substantial risk of tumor recurrence (on the order of 15% to 20% through 5 to 10 years of therapy).²⁶⁷ Recent retrospective analyses of small *HER2*⁺ tumors suggest a benefit may exist for this subgroup with the addition of trastuzumab.²⁶⁸ A prospective trial of 12 weeks of paclitaxel plus trastuzumab, followed by conclusion of 1 year of adjuvant

trastuzumab, yielded a remarkably low risk of recurrence when studied in stage I, *HER2*⁺ breast cancers.²⁶⁹ Patients with *HER2*⁺ tumors ≥ 5 mm are likely to benefit substantially from adjuvant chemotherapy and trastuzumab.

INTEGRATION OF MULTIMODALITY PRIMARY THERAPY

Current consensus recommendations for adjuvant therapy are summarized in Table 79.21. The majority of women with breast cancer receive some form of adjuvant therapy, which requires integration of systemic treatments with local therapy including surgery and RT. Low rates of LR are seen regardless of the sequence of RT and chemotherapy.²⁷⁰ A nonsignificant trend toward a greater risk of distant recurrence in patients receiving RT first was seen in one study,²⁷⁰ and because of the primary importance of preventing distant relapse, the convention has been to administer chemotherapy first. Tamoxifen therapy should not be given concurrently with chemotherapy because in one randomized study, concurrent tamoxifen and chemotherapy was associated with greater risk of recurrence than sequential treatment of chemotherapy followed by tamoxifen.²⁷¹ There are no compelling data that the concurrent administration of endocrine therapy and RT has deleterious consequences, nor that it has particular advantages.²⁷² The timing of surgery either before (neo) or after adjuvant chemotherapy does not alter long-term survival for women with breast cancer.¹¹⁹ Thus, patients may comfortably proceed in a linear fashion of treatment, receiving one therapeutic modality (surgery, RT, chemotherapy, biologic therapy) after another, as they receive definitive treatment for early-stage breast cancer.

FOLLOW-UP FOR BREAST CANCER SURVIVORS

Following initial treatment for breast cancer, patients require surveillance for local-regional tumor recurrence, contralateral breast cancer, and the development of distant metastatic disease. In addition, medical follow-up allows clinicians to monitor for late effects of chemotherapy, RT, or surgery, to gauge ongoing side effects from cancer treatments, such as antiestrogen therapies, and to facilitate opportunities to update patients on new developments that

ER, estrogen receptor.

may affect their treatment plan.²⁷³ Although the greatest risk of recurrence is in the first 5 years after breast cancer diagnosis, women remain at risk for many years after their treatment, especially those with hormone receptor–positive breast cancer. (These experiences justify ongoing follow-up with breast cancer specialists, although particularly in later years, follow-up is often shared with primary care physicians.)

LR and new contralateral cancers are potentially curable, so women should undergo regular breast examinations and annual mammography, with supplemental breast imaging as clinically indicated. LR is often associated with concurrent metastatic disease, and evaluation for distant metastases is indicated prior to local therapy in this setting. By contrast, it is not clear that early detection of distant metastatic disease contributes to substantial improvement in clinically important end points. Most distant recurrences are detected following patient-reported symptoms, such as bone discomfort, lymphadenopathy, chest wall/breast changes, or respiratory symptoms; asymptomatic detection through screening laboratory tests or radiology studies occurs in only a modest fraction of patients, even with intensive surveillance.²⁷³ Randomized trials have compared vigorous surveillance with radiologic imaging (chest radiography, bone scanning, and liver ultrasound) and laboratory testing (blood counts, liver function tests, and serum tumor markers) against standard care consisting of regular physical examination and mammography, with additional testing performed only if indicated by symptoms or physical examination.^{274,275} More intensive surveillance achieved modest gains in early detection of metastatic breast cancer, with a small increase in the fraction of patients diagnosed while asymptomatic, but no improvement in OS was noted.

Based on these data, ASCO has issued surveillance guidelines for women with early-stage breast cancer²⁷⁶ (Table 79.22). These guidelines emphasize the importance of a careful history and examination to elicit symptoms or signs of recurrent breast cancer, but minimize the role of routine imaging studies including plain films and CT scans, and do not recommend routine laboratory testing in the absence of symptoms. Patients should be encouraged to perform breast self-examination and to contact their physicians if they develop symptoms possibly suggestive of breast cancer recurrence. Understandably, patients often request additional testing to provide reassurance and to “catch” early recurrences. Clinical experience suggests, however, that patients respond well to discussions regarding optimal testing strategies, the role of surveillance for breast cancer recurrence, the challenges of false-positive and

false-negative test results, and the limited need for testing in the absence of symptoms or physical examination findings.²⁷⁷

SPECIAL THERAPEUTIC PROBLEMS

Paget Disease

Paget disease represents in situ carcinoma in the nipple epidermis. The classic pathologic finding is the presence of Paget cells (large cells with clear cytoplasm and atypical nuclei) within the epidermis of the nipple. The clinical manifestations of Paget disease include eczematoid changes, crusting, redness, irritation, erosion, discharge, retraction, and inversion. Rarely, Paget disease is bilateral or occurs in a male patient.

Paget disease may occur in the nipple (1) in conjunction with an underlying invasive cancer (staged by the invasive cancer), (2) with underlying DCIS (staged Tis), or (3) alone without any underlying invasive breast carcinoma or DCIS (also staged Tis). The associated underlying cancer may be located centrally in the breast adjacent to the nipple or it may be located peripherally. It is uncertain whether the origin of Paget disease is primarily an in situ intraepidermal malignancy with secondary extension to adjacent structures (intraepidermal theory) or migration of tumor cells into the nipple epidermis from an underlying carcinoma of the breast (epidermotropic theory).

The age-adjusted incidence rates of female Paget disease peaked in 1985 and have decreased yearly thereafter through 2002,²⁷⁸ perhaps because of earlier detection of breast lesions by mammography prior to the development of pagetoid changes. More recently, Paget disease has been observed as a form of recurrence after nipple-sparing mastectomy.

The workup for the patient with Paget disease includes mammography and physical examination of the breast to rule out an underlying invasive cancer or DCIS. In patients with negative findings on physical examination and mammogram, breast MRI should be considered for patients who are candidates for BCT.

Historically, Paget disease was treated with mastectomy. Prognosis is determined by the stage of the underlying malignancy, if present. Small studies examining the use of excision and WBI for Paget disease have reported LR rates of 5% to 8%^{279,280} and no survival differences between BCT and mastectomy, suggesting that BCT with WBI is a reasonable alternative to mastectomy. Local excision alone, without RT, has been used to treat a small number

TABLE 79.22

Breast Cancer Follow-Up

Recommended for Routine Surveillance

History/physical examination	Every 3 to 6 mo for the first 3 y, every 6 to 12 mo y 4 and 5, annually thereafter
Mammography	Annually, beginning no earlier than 6 mo after radiation therapy
Breast self-examination	All women should be counseled to perform monthly
Pelvic examination	Annually
Coordination of care	Continuity of care with breast cancer specialist and appropriate other health care providers

Not Recommended for Routine Surveillance

Routine blood tests	Complete blood cell count and liver function tests are not recommended
Imaging studies	Chest radiograph, bone scans, liver ultrasound, computed tomography scans, fluorodeoxyglucose-positron emission tomography scans, and breast magnetic resonance imaging are not recommended for routine breast cancer surveillance
Tumor markers	Cancer antigen 15-3, 27.29, and carcinoembryonic antigen are not recommended

Adapted from Khatcheressian JL, Wolff AC, Smith TJ, et al. American Society of Clinical Oncology 2006 update of the breast cancer follow-up and management guidelines in the adjuvant setting. *J Clin Oncol* 2006;24:5091–5097.

of patients. In one series of 33 patients prospectively treated with local excision alone, the LR rate was 33%²⁸¹ and 10 of 11 recurrences were invasive carcinoma. Because of the small numbers of patients treated without RT and the high rate of local failure, such treatment must be considered as nonstandard at the present time.

For patients treated with BCT, surgery should include excision of the full NAC with a cone of underlying retroareolar tissue and complete excision of any tissue with abnormal radiologic findings. For patients with positive margins after central lumpectomy, additional surgery is indicated. Patients with negative surgical margins should undergo irradiation based on criteria generally used to select patients with DCIS and invasive cancer for RT and discussed previously. The decision for axillary node surgery should be based on the presence of an invasive breast cancer; sentinel node biopsy has been used successfully in this setting. Recommendations for adjuvant systemic therapy are based on the final pathology.

Occult Primary with Axillary Metastases

Axillary metastases in the absence of a clinically or mammographically detectable breast tumor are an uncommon presentation of breast carcinoma, seen in <1% of cases. The initial evaluation should include a detailed history and physical examination, bilateral mammogram, breast MRI (if the mammogram is unrevealing), and a chest radiograph. The presence of ER, PR, or *HER2* overexpression is strongly suggestive of metastatic breast carcinoma, although their absence does not exclude a primary breast tumor. MRI identifies the primary tumor in the breast in a significant number of patients with a normal mammogram and breast examination. In a meta-analysis of 220 patients with occult primary tumors, MRI identified a suspicious lesion in 72% with a sensitivity of 90% and a specificity of 31%. The size of tumors identified on pathologic exam ranged from 5 mm to 16 mm.²⁸² The identification of the primary tumor within the breast simplifies local management, allowing these patients to be treated with BCT or mastectomy according to standard guidelines.

In cases in which a primary tumor cannot be identified, treatment has traditionally been with mastectomy. This strategy was based on the observation that approximately 50% of patients who do not receive therapy to the breast will develop clinically evident disease in the breast. In addition, prior to the era of modern mammography and the availability of MRI, the occult cancers found in the breast at mastectomy were sometimes quite large.²⁸³ More recently, WBI has been used in these patients. Fourquet et al.²⁸³ treated 54 patients with WBI without removal of the primary tumor. The 5- and 10-year rates of IBTR were 7.5% and 20%, respectively. Other small studies antedating the use of MRI confirm that although rates of LR after BCT are higher than in patients treated with excision of a known primary tumor and a boost dose of RT to the tumor bed, WBI with a dose of about 50 Gy is an acceptable alternative to mastectomy in this patient population.

Regardless of the management approach chosen for the breast, ALND should be carried out because of the limited ability of radiation to control gross axillary disease. OS for women with occult primary tumors is similar to that of patients with comparable axillary involvement and a known primary tumor, and some investigators have suggested that survival is actually superior for those with occult primary tumors.²⁸⁴ Because of the small size of most studies of occult primary cancer, the heterogeneous treatments employed, and the variable durations of follow-up, this claim is difficult to substantiate. Systemic treatment for patients with occult primary breast cancer and axillary involvement should follow the current guidelines for patients with node-positive breast cancer.

Breast Cancer and Pregnancy

Breast carcinoma is one of the most commonly diagnosed malignancies during pregnancy. Older studies estimated that breast

cancer developed in 2.2 in 10,000 pregnancies²⁸⁵; however, the trend toward later age at first childbirth has increased the number of breast cancer cases coexistent with pregnancy, and breast cancer is now estimated to occur in 1 in 1,000 pregnancies.²⁸⁶ Delay in diagnosis remains a problem due to the nodularity of the pregnant breast and the assumption that new breast masses are normal physiologic changes. Dominant breast masses developing during pregnancy require biopsy before assuming that they are benign. This can be readily accomplished with a core-cutting needle biopsy in the majority of women. If excisional biopsy is necessary, it should be undertaken; concerns about the development of a milk fistula appear to be overstated.²⁸⁷ Mammography is not as useful in pregnant patients as in those who are not pregnant because of the increased density in the breast parenchyma associated with pregnancy. Ultrasound may be helpful in confirming the presence of a dominant mass, but, as in the nonpregnant patient, normal imaging studies should not lead to a decision to forgo biopsy in the patient with a dominant breast mass.

After a diagnosis is made, the initial evaluation should include an assessment of the extent of the disease. Computed tomography and bone scans are not recommended during pregnancy because of concerns about radiation exposure to the fetus. In patients with symptoms suggestive of metastases, MRI without contrast can be used to evaluate bony sites and the intra-abdominal viscera.²⁸⁷

Breast cancers occurring during pregnancy are usually high-grade infiltrating ductal carcinomas. In a prospective study of 38 pregnant women who developed breast cancer, only 28% had ER⁺ tumors and 24% had PR⁺ tumors.²⁸⁸ In general, the characteristics of cancers occurring during pregnancy are similar to those of nonpregnant women of the same age. Data from retrospective case-control series suggest that after adjusting for age and disease stage, the prognosis of women with breast cancer occurring during pregnancy differs little from that of nonpregnant patients.²⁸⁷

For women diagnosed in the first or second trimester, the question of pregnancy termination is inevitably raised. Although some treatment approaches are feasible during pregnancy, others are contraindicated. Depending on the patient's specific situation, continuing the pregnancy may or may not compromise the breast cancer treatment. Even when deviations from standard treatment are required, it is unclear to what extent such changes or delays affect a woman's odds of remaining free from recurrent breast cancer. The concerns about compromising care must be balanced by the woman, her family, and her physicians, with the desire to continue the pregnancy. The woman facing these issues must also consider the possibility that if she receives chemotherapy, her ability to conceive another child could be compromised.²²⁴ There is no clear evidence that pregnancy termination changes OS.²⁸⁹

Breast surgery can be safely performed during any trimester of pregnancy. Mastectomy is the treatment that has traditionally been undertaken because of the inability to safely deliver RT to the breast without excessive fetal exposure during any trimester. The effect of delaying RT on LR, in the absence of systemic therapy, is unknown and is of concern. Guidelines for BCS⁶⁶ consider this an appropriate approach for cancers diagnosed in the third trimester and one that must be considered on a case-by-case basis for cancers diagnosed earlier in pregnancy. In the woman who will receive systemic chemotherapy, the delay in the delivery of RT is often no greater than in the nonpregnant patient. The success rate of lymphatic mapping and sentinel node biopsy in the pregnant woman is unknown. Isosulfan blue dye is not approved by the US Food and Drug Administration for use during pregnancy. The radiation exposure to the fetus from the use of technetium has been estimated to be low, and it has been suggested that mapping with technetium alone could be discussed with patients as an appropriate management strategy.²⁹⁰ In the absence of definitive data on the safety and accuracy of sentinel node biopsy in the pregnant woman, ALND remains the standard management strategy.

The risk of congenital malformation from cytotoxic chemotherapy varies with the fetal age at exposure and the agent used.

Exposure in the first trimester is associated with risks of 10% to 20% and should be avoided. Risks decline to <2% with exposure in the second and third trimesters, enabling chemotherapy administration in those trimesters.²⁹¹ Chemotherapy during pregnancy may also contribute to intrauterine growth retardation, and the long-term consequences of exposure remain uncertain. In a prospective study of 24 pregnant women treated with fluorouracil, doxorubicin, and cyclophosphamide during the second and third trimesters of pregnancy, no complications were observed for the fetus or infant.²⁹² Experience with the taxanes in pregnancy is limited, but appears feasible after the first trimester.²⁹³

The use of trastuzumab in pregnancy is associated with oligohydramnios,²⁹⁴ and more information on the safety of this agent in pregnancy is needed. Methotrexate should be avoided during pregnancy because of the risk of abortion and severe fetal malformation. Similarly, tamoxifen should be withheld until after delivery because its safety is uncertain. When chemotherapy or tamoxifen is given postpartum, breastfeeding should be avoided, as these agents may be excreted in the breast milk.

The management of breast cancer during pregnancy is difficult, as there is often a conflict between optimal therapy for the mother and the fetus. Multidisciplinary management by a team including medical, surgical, and radiation oncologists, an obstetrician, a maternal-fetal medicine specialist, and a psychologist will facilitate the development of a strategy that optimizes the outcome for both mother and child.

Male Breast Cancer

The incidence of male breast cancer varies on a worldwide basis, with the highest rates in some sub-Saharan countries. In the United States, it is estimated that in 2012, 2,190 men were diagnosed with breast cancer, and 410 died of the disease. Worldwide, the female to male incidence ratio is 122:1.²⁹⁵ In recent years, as the incidence of female breast cancer has declined by 42%, a 28% decline in male breast cancer has been observed.²⁹⁶ The risk of male breast cancer is related to an increased lifelong exposure to estrogen (as with female breast cancer) or to reduced androgen. The strongest association is in men with Klinefelter syndrome (XXY); they have a 14- to 50-fold increased risk of developing male breast cancer and account for about 3% of all male breast cancer cases. Also, men who carry a *BRCA1* or, particularly, a *BRCA2* mutation, have an increased risk of developing breast cancer. The following conditions have been reported to be associated with an increased risk of breast cancer in men: chronic liver disorders, such as cirrhosis, chronic alcoholism, and schistosomiasis; a history of mumps orchitis, undescended testes, or testicular injury; and feminization, genetically or by environmental exposure. In contrast, gynecomastia alone does not appear to be a risk factor.²⁹⁷

The clinical presentation of male breast cancer is similar to that of female breast cancer, but the median age of onset is later than in women (60 years versus 53 years). Because the diagnosis of breast cancer is often not considered as promptly in men and screening mammography is not used, men often present with more advanced stage than do women. All known histopathologic types of breast cancer have been described in men, with infiltrating ductal carcinoma accounting for at least 70% of cases. However, ILC in men is rare. A majority of male breast cancers are ER/PR⁺, and the percentage positive is greater than for female breast cancer. As for women, stage is the predominant prognostic indicator, and most studies report that stage for stage, men with breast cancer have the same outcome following treatment as women with breast cancer. A recent study, however, from the Veterans Affairs reports a worse prognosis for men than women in early-stage breast cancer.²⁹⁸ There appears to be a substantial negative disparity in outcome for blacks with male breast cancer compared with whites.²⁹⁹

Primary local treatment is typically total mastectomy. In some patients with early disease, BCT can be considered. However, the

subareolar location of most male breast cancers and the small amount of breast tissue present in most men limits eligibility for BCT. The same considerations regarding nodal surgery pertain for men as for women, with sentinel node biopsy the preferred treatment in clinically node-negative patients. The use of postmastectomy RT follows the same guidelines as for female breast cancer. Similarly, the use of systemic therapy follows the same guidelines as for women with postmenopausal breast cancer. Adjuvant systemic chemotherapy is used in men, although no controlled trials have confirmed its value.³⁰⁰ Tamoxifen is the mainstay for adjuvant systemic therapy in ER⁺ male breast cancer; a study of 257 male breast cancer patients demonstrated a 1.5-fold increase in mortality in those treated with an AI versus tamoxifen.³⁰¹ Metastatic breast cancer in men is treated identically to metastatic disease in women.

Phyllodes Tumor

The term *phyllodes tumor* includes a group of lesions of varying malignant potential, ranging from completely benign tumors to fully malignant sarcomas. Clinically, phyllodes tumors are smooth, rounded, usually painless multinodular lesions that may be indistinguishable from fibroadenomas. The average age at diagnosis is in the fourth decade. Skin ulceration may be seen with large tumors, but this is usually due to pressure necrosis rather than invasion of the skin by malignant cells. Histologically, phyllodes tumor, like fibroadenoma, is composed of epithelial elements and a connective tissue stroma.

Phyllodes tumors are classified as benign, borderline, or malignant on the basis of the nature of the tumor margins (pushing or infiltrative) and presence of cellular atypia, mitotic activity, and overgrowth in the stroma. There is disagreement about which of these criteria is most important, although most experts favor stromal overgrowth. The percentage of phyllodes tumors classified as malignant ranges from 23% to 50%. Local excision to negative margins is an appropriate management strategy for both benign and malignant phyllodes tumors if this can be accomplished with a satisfactory cosmetic outcome. The optimal margin width is not known, but wider excisions appear to reduce the risk of LR. Approximately 20% of phyllodes tumors recur locally if excised with no margin or a margin of a few millimeters of normal breast tissue, regardless of whether they are benign or malignant.³⁰² In a review of 821 patients with nonmetastatic malignant phyllodes tumors reported to the Surveillance, Epidemiology, and End Results registry between 1983 and 2002, 52% were treated with mastectomy and the remainder with local excision. The 10-year cause-specific survival was 89%, and no survival benefit for mastectomy was observed.³⁰²

The role of RT and systemic therapy in phyllodes tumor is unclear. RT is not used for benign or borderline lesions, but has been combined with wide excision in the management of malignant phyllodes tumors. When phyllodes tumors metastasize, they tend to behave like sarcomas, with the lung as the most common site. Axillary metastases are seen in <5% of cases, and axillary surgery is not indicated unless worrisome nodes are clinically evident. When systemic therapy is used for malignant phyllodes tumors, treatment is based on the guidelines for treating sarcomas.

Locally Advanced Breast Cancer and Inflammatory Breast Cancer

LABC and IBC refer to a heterogeneous group of breast cancers without evidence of distant metastases (M0) and represent only 2% to 5% of all breast cancers in the United States. The term LABC encompasses patients with (1) operable disease at presentation (clinical stage T3N1), (2) inoperable disease at presentation (clinical stage T4 and/or N2-3), and (3) IBC (clinical stage

T4dN0-3, also inoperable). (All stages refer to the *AJCC Cancer Staging Manual*, seventh edition, 2010).⁷⁹ Subdividing patients into these three broad groups facilitates clinical management.

Comparison of studies of LABC and IBC is problematic due to a high degree of heterogeneity within T and N classification, small numbers of patients in stage subgroups, and variation in the definition of LABC according to AJCC staging criteria over time.⁷⁹ For example, supraclavicular lymphadenopathy, now classified as N3 disease, was previously classified as M1.³⁰³ IBC accounts for 1% to 5% of all cases of breast cancer in the United States and is an aggressive variant of LABC. IBC is a clinicopathologic entity characterized by diffuse erythema and edema (peau d'orange) of the skin of the breast, often without a discreet, underlying palpable mass, although the breast is usually diffusely thickened. IBC typically has a rapid onset and is often initially mistaken as infection and treated with antibiotics before the diagnosis is established. The clinical presentation results from tumor emboli in the dermal lymphatics. According to the AJCC staging rules,⁷⁹ IBC is primarily a clinical diagnosis. Involvement of dermal lymphatics in the absence of clinical findings does not indicate IBC. A skin biopsy may be performed to confirm the clinical impression of IBC, but the absence of dermal lymphatic involvement does not affect staging. IBCs are more likely to be high-grade, *HER2*-overexpressing, and lacking in hormone receptor expression compared with other presentations of breast cancer. Because both LABC and IBC are associated with substantial risk of metastatic disease, patients with these cancers should undergo full workup for distant metastases prior to initiation of therapy.

Patients with LABC or IBC should be evaluated by a multidisciplinary team (ideally, around the time of diagnosis). Treatment typically includes neoadjuvant chemotherapy, surgery, and RT. Prior to the use of neoadjuvant chemotherapy, long-term survival was uncommon. Long-term survival has been greatly improved with aggressive trimodality treatment. As with early-stage breast cancer, biologic tumor markers should affect treatment selection: patients with *HER2*⁺ cancers should receive trastuzumab-based therapy, and patients with hormone receptor-positive cancers should receive adjuvant endocrine therapy. Anthracycline- and taxane-based chemotherapy regimens are appropriate as induction chemotherapy for women with LABC or IBC. The vast majority of patients will have clinical response to therapy, and roughly 15% to 25% will experience a pCR. The addition of paclitaxel to anthracycline-based therapy appears to improve long-term disease outcomes for women with LABC and IBC.³⁰⁴ There are no studies of trastuzumab specifically for LABC/IBC; however, by extrapolation of results using trastuzumab for early-stage breast cancer, it should be incorporated into the treatment of women with *HER2*⁺ LABC or IBC. As with other experiences using neoadjuvant chemotherapy, complete pathologic eradication of the tumor is associated with superior outcomes among women with LABC or IBC.³⁰⁵ However, even among patients with pCR to neoadjuvant chemotherapy, those with LABC or IBC at baseline have a higher risk of recurrence than patients with earlier-stage breast cancer at baseline.³⁰⁶ Patients with LABC or IBC should be routinely treated with postmastectomy RT, regardless of the pathologic response.³⁰⁷

Some women with LABC may be candidates for BCT following neoadjuvant chemotherapy. In one series, local-regional control following this approach appeared to be excellent except in patients with one or more of the following features: (1) clinical N2-3 disease, (2) lymphovascular invasion, (3) residual primary pathologic size >2 cm and (4) multifocal residual disease.³⁰⁸ However, there is still limited experience with this approach. In contrast, BCT is contraindicated in patients with IBC, even after a complete clinical response to neoadjuvant therapy. In a small study of 13 patients with IBC treated with preoperative chemotherapy and BCT, 7 of 13 experienced LR.³⁰⁹ This, coupled with the diffuse nature of IBC, indicates that BCT is contraindicated in women with this diagnosis.

Although most women have a clinical response to neoadjuvant chemotherapy, some patients will experience tumor progression

or remain inoperable. Such patients may be candidates for non-cross-resistant chemotherapy or novel treatments. Surgery is contraindicated in IBC unless there is complete resolution of the inflammatory skin changes. In modern studies, 85% to 90% of patients become operable after initial chemotherapy.³¹⁰ RT may facilitate conversion of inoperable to operable disease. Despite modern multimodality therapy, approximately 20% of patients with IBC treated with chemotherapy, surgery, and RT will experience LRR.³¹⁰ Patients with chest wall recurrence after chemotherapy, surgery, and RT are at high risk for both extensive local-regional tumor spread and for developing metastatic disease to visceral organ sites, and are treated according to guidelines for metastatic breast cancer.

MANAGEMENT OF LOCAL-REGIONAL RECURRENCE

LRR after primary therapy for breast cancer includes in-breast recurrence after BCS, chest wall recurrence after mastectomy, and regional nodal recurrences, and accounts for about 15% of all breast cancer recurrences.¹⁰⁷ Predictors of LR include higher initial tumor stage, young patient age involved, surgical margins, and intrinsic subtype (greater risk with basal-like, luminal B, or *HER2*⁺ cancers). More than 60% of patients with LRR after either BCT or mastectomy will eventually develop metastatic disease.^{311,312} Short disease-free intervals, lymph node recurrence, skin lesions, and tumor lack of ER expression all portend greater risk of disseminated cancer. Patients with LRR warrant comprehensive restaging to exclude concurrent metastatic disease.

Despite the high-risk nature of LRR, patients are treated with curative intent in multidisciplinary fashion, with treatment plans individualized based on the nature of the LRR, prior local therapy, and prior adjuvant systemic therapy. The initial management step is usually surgical resection. Women previously treated with BCS are offered salvage mastectomy. Patients with localized chest wall recurrences should undergo surgical excision, while ALND is indicated for axillary nodal recurrences occurring after sentinel lymph node biopsy. RT to sites of regional recurrence and additional regional lymph nodes is standard. Patients with prior RT after either BCS or mastectomy need careful planning to minimize overlap with prior RT fields.

Current treatment standards for LRR recommend introduction of systemic therapy following local management. Recurrences that are ER⁺ warrant introduction or switching of endocrine therapy. Patients with recurrence on tamoxifen should consider treatment with AIs. Patients who have recurrences on AI therapy may consider tamoxifen or fulvestrant. Patients with *HER2*⁺ tumors should consider initiation or re-institution of anti-*HER2* therapy in an adjuvant fashion. The role of chemotherapy in the management of LRR has been controversial, especially among those previously treated with adjuvant chemotherapy. The Chemotherapy as Adjuvant for Locally Recurrent Breast Cancer study was a randomized trial of "adjuvant" chemotherapy following optimal resection of LRR.³¹³ Chemotherapy reduced the risk of subsequent cancer recurrence and improved OS, especially in ER⁻ tumors, though modest benefits were seen among patients with ER⁺ tumors. Patients without prior chemotherapy exposure would be suitable for any standard adjuvant chemotherapy regimen. Those patients with prior chemotherapy treatment may consider nonoverlapping regimens.

METASTATIC DISEASE

Metastatic (stage IV) breast cancer is defined by tumor spread beyond the breast, chest wall, and ipsilateral regional lymph nodes. The most common sites for breast cancer metastasis include the bone, lung, liver, lymph nodes, chest wall, and brain. However,

case reports have documented breast cancer dissemination to almost every organ in the body. Hormone receptor–positive tumors are more likely to spread to bone as the initial site of metastasis; hormone receptor–negative and/or *HER2*⁺ tumors are more likely to recur initially in viscera.³¹⁴ Lobular (as opposed to ductal) cancers are more often associated with serosal metastases to the pleura and abdomen. Most women with metastatic disease will have been initially diagnosed with early-stage breast cancer, treated with curative intent, and then experience metastatic recurrence. Only about 10% of patients with newly diagnosed breast cancer in the United States have metastatic disease at presentation; this proportion is far higher in areas where screening programs are not available.

Symptoms of metastatic breast cancer are related to the location and extent of the tumor. Common symptoms or physical examination findings include bone discomfort, lymphadenopathy, skin changes, cough or shortness of breath, and fatigue. These clinical findings are all nonspecific, and appropriate evaluation is warranted in patients with breast cancer with new or evolving symptoms. In some cases, physical examination or radiologic findings will demonstrate unequivocal evidence of metastatic breast cancer. In instances when radiologic or clinical findings are equivocal, tissue biopsy is imperative. If a biopsy is performed, ER, PR, and *HER2* should be redetermined.

The treatment goals in women with advanced breast cancer include prolongation of life, control of tumor burden, reduction in cancer-related symptoms or complications, and maintenance of quality of life and function. Therapy is not generally considered curative. A small fraction of patients, often those with limited sites of metastatic disease or bearing tumors with exquisite sensitivity to treatment, may experience very long periods of remission and tumor control. Treatment of metastatic breast cancer, like treatment of early-stage breast cancer, is based on consideration of tumor biology and clinical history. Thus, characterization of tumor ER, PR, and *HER2* status is critical for all patients, and a detailed assessment of past treatment, including timing of therapies as well as patient symptoms and functional assessment, is essential. Patients with endocrine-sensitive tumors, particularly those with minimal symptoms and limited visceral involvement, are candidates for initial treatment with endocrine therapy alone; initial treatment using combined chemoendocrine therapy has not been shown to improve survival compared with sequential treatment programs. Patients with hormone receptor–negative tumors or those with hormone receptor–positive tumors progressing despite the use of endocrine therapy are candidates for chemotherapy. If the tumor is *HER2*⁺, then anti-*HER2* treatment is employed in combination with chemotherapy.

Well-established clinical factors can inform the likelihood of response to therapy and long-term outcomes in women with metastatic breast cancer. Patients who have received less therapy, a longer disease-free interval since initial diagnosis, soft tissue or bone metastases, fewer symptoms and better performance status, and tumors that are hormone receptor–positive or *HER2*⁺ are likely to experience longer survival with metastatic disease than more heavily treated patients with shorter intervals since treatment, visceral metastases, and greater symptoms.

In clinical trials, the measured end points for defining efficacy of therapy for metastatic breast cancer are response rate, time to tumor progression, and OS. These landmarks are important for guiding clinical practice as well, although formal measures of response/progression are often difficult to apply owing to inconsistencies in imaging studies, the prevalence of nonmeasurable disease such as bone lesions, subcentimeter tumor deposits, and pleural effusions or ascites. The art of treating patients with metastatic breast cancer involves careful, thoughtful repetition of a process of treatment initiation, evaluation including assessment of patient functional status and symptom profile, and serial measurement of tumor burden and response to therapy, through multiple lines of therapy. Clinical guidelines for the management of

metastatic carcinoma⁶⁶ are often quite open-ended, acknowledging the multiple treatment pathways that might be legitimately pursued, arguing for judicious use of clinical decision making and treatment selection based on tumor biology, and focusing clinicians on the continuous considerations of patient preference and illness experience.

Endocrine Therapy for Metastatic Breast Cancer

Endocrine treatment is a key intervention for women with hormone receptor–positive, metastatic breast cancer. Table 79.23 lists available endocrine drugs for treating advanced breast cancer. Single-agent therapy is the standard approach; combining endocrine agents has not in general been shown to improve outcomes. Many women will be candidates for multiple lines of endocrine therapy to control metastatic breast cancer. On average, first-line treatment is associated with 8 to 12 months of tumor control, and second-line treatment with 4 to 6 months. Individual patients may experience substantially longer time to progression. Sequential single-agent second- and third-line endocrine treatments are often effective, although typically for shorter durations than initial therapy. Patients with either overt tumor shrinkage or stabilization of disease in response to endocrine treatment can have equivalent long-term tumor control. Endocrine therapy can cause regression of soft tissue and bone and visceral metastases.

Recently, several studies have examined the combined use of an AI with fulvestrant for de novo or progressive, ER⁺, metastatic breast cancer.^{315–317} In treatment-naïve patients, the SWOG 0226 trial suggested that combining anastrozole with fulvestrant improved progression-free survival and OS. By contrast, in patients who had received prior tamoxifen in the SWOG and Fulvestrant and Anastrozole Combination Therapy trials, or prior AI therapy in the Study of Faslodex vs Exemestane with/without Arimidex trial, the combination of fulvestrant plus an AI was not superior to monotherapy approaches. Thus, the combined use of an AI with fulvestrant is appropriate primarily among women with endocrine-naïve cancers.

Eventually, most women with hormone receptor–positive metastatic breast cancer will progress despite first-line endocrine therapy, and be candidates for second-, third-, and even subsequent lines of endocrine therapy. Resistance to treatment does not seem to be associated with loss of hormone receptor expression by the tumor cells. The results of the Breast Cancer Trials of Oral Everolimus-2 trial have recently led to the approval of the mammalian target of rapamycin inhibitor everolimus in the advanced setting.³¹⁸ In this randomized clinical trial, patients with advanced disease resistant to letrozole or anastrozole were assigned to exemestane plus everolimus or placebo. The combination of exemestane and everolimus extended progression-free survival, but

TABLE 79.23

Endocrine Therapies for Metastatic Breast Cancer

- Ovarian suppression/ablation (premenopausal women)
- Selective estrogen receptor modulators (tamoxifen, toremifene)
- Aromatase inhibitors (anastrozole, letrozole, exemestane; postmenopausal women)
- Antiestrogens (fulvestrant; postmenopausal women)
- Progestins (megestrol and medroxyprogesterone)
- Other steroid hormones (high-dose estrogens, androgens; principally of historical interest)

was associated with significant side effects, including stomatitis, hyperglycemia, and pneumonitis.

Indications for chemotherapy include symptomatic tumor progression, pending visceral crisis, or resistance to multiple endocrine therapies. Patients presenting with extensive visceral metastases or profound symptoms from breast cancer may benefit from induction chemotherapy, which should then be followed with endocrine therapy.

Tamoxifen was the historic standard as treatment for ER⁺ metastatic breast cancer, associated with a 50% response rate and median duration of response of 12 to 18 months among treatment-naïve patients. A “tamoxifen flare” reaction, typically characterized by intensification of bone pain, transient tumor progression, and hypercalcemia, can arise in 5% to 10% of patients within the first days or weeks of tamoxifen treatment. Flare reactions are often harbingers of exquisite tumor sensitivity to endocrine manipulation, but must be distinguished from overt tumor progression. Flare reactions are not frequently seen with other endocrine therapies.

In premenopausal women with metastatic breast cancer, combined endocrine therapy with ovarian suppression and tamoxifen can improve survival compared with treatment with either tamoxifen or ovarian suppression alone.³¹⁹ Thus, the first intervention for premenopausal women with breast cancer recurrence is ovarian suppression or ablation, with initiation of tamoxifen treatment. Premenopausal women with metastatic tumor despite tamoxifen use are candidates for ovarian suppression/ablation and AI therapy. Postmenopausal women are candidates for either tamoxifen, AIs, fulvestrant, or progestational agents as palliation for metastatic breast cancer. AIs appear to be the preferred initial agents for women who received prior tamoxifen treatment in the adjuvant setting,^{319,320} and may have modest clinical advantages over tamoxifen as initial treatment for metastatic disease.^{321,322} Fulvestrant appears to have comparable activity to AIs in women previously treated with tamoxifen.^{323,324}

The optimal sequencing of endocrine therapy for postmenopausal women treated with adjuvant AIs is not clear, as few trials have rigorously explored different treatments among such patients. Tamoxifen, fulvestrant, progestins, and possibly different AIs are all reasonable options among such patients.

Chemotherapy for Metastatic Breast Cancer

Cytotoxic chemotherapy remains a mainstay of treatment for women with metastatic breast cancer, irrespective of hormone receptor status, and is the backbone of many novel treatments incorporating biologic therapy.³²⁵ Chemotherapy has substantial side effects, including fatigue, nausea, vomiting, myelosuppression, neuropathy, diarrhea, and alopecia, making for tradeoffs between cancer palliation and toxicities of therapy. Chemotherapy is used in patients with hormone-refractory or hormone-insensitive tumors.

Tumor response to chemotherapy is a surrogate for longer cancer control and survival.^{326,327} First-line chemotherapy is associated with higher response rates and longer tumor control than second-line, and so forth. There are relatively few studies of fourth or higher lines of chemotherapy, although patients often receive many lines of treatment. Trials have demonstrated palliative benefits of chemotherapy in patients with refractory tumors receiving third-line or subsequent chemotherapy treatment, but the magnitude of such gains must be realistically weighed against the side effects of treatment. Chemotherapy treatment can be interrupted in patients who have had significant response or palliation following initiation of therapy and reintroduced when there is tumor progression or symptom recurrence.

Since the advent of chemotherapy administration for metastatic breast cancer, it has been debated whether single-agent sequential treatment or combination treatment with multiple agents is the best strategy. Combination chemotherapy may be associated with higher response rates and improved time to progression compared with single-agent therapy. However, studies that have specifically planned for crossover treatment with second-line sequential therapy have not shown improved survival compared with a sequential treatment program.³²⁸ Patients with extensive visceral disease or pending visceral crisis may preferentially require initiation of combination chemotherapy, but this has not been demonstrated in prospective studies. Because single-agent chemotherapy facilitates better understanding of which drugs are contributing to benefit or side effects and is generally associated with less toxicity, it remains the preferred approach.

A large number of chemotherapy agents and combinations are effective in treatment of metastatic breast cancer (Table 79.24).⁶⁶

TABLE 79.24

Common Chemotherapy Agents and Combinations for Advanced Breast Cancer

Single Agents	Combination Regimens
Anthracyclines (doxorubicin, epirubicin, pegylated liposomal doxorubicin)	Cyclophosphamide/anthracycline ± 5-fluorouracil regimens (such as AC, EC, CEF, CAF, FEC, FAC)
Taxanes (paclitaxel, docetaxel, albumin nano-particle bound paclitaxel)	CMF
5-fluorouracil ^a (continuous-infusion 5-fluorouracil, capecitabine)	Anthracyclines/taxanes (such as doxorubicin/paclitaxel or doxorubicin/docetaxel)
Vinca alkaloids (vinorelbine, vinblastine ^a)	Docetaxel/capecitabine
Gemcitabine	Gemcitabine/paclitaxel
Platinum salts (cisplatin, carboplatin)	Taxane/platinum regimens ^b (such as paclitaxel/carboplatin or docetaxel/carboplatin)
Ixabepilone	Ixabepilone/capecitabine ^b
Cyclophosphamide	
Eribulin	

A, doxorubicin; C, cyclophosphamide; E, epirubicin; F, 5-fluorouracil; M, methotrexate; NCCN, National Comprehensive Cancer Network.

^a Not listed in NCCN Guidelines as a single agent.

^b Combination not listed in NCCN Guidelines.

A variety of specific drugs and combinations are considered preferred based on a large historical experience, results from randomized trials, and consideration of toxicity profiles. A single “best” approach for all patients with metastatic cancer is not supported by the literature. Although anthracycline- and taxane-based treatments are generally considered to be among the most active in treatment of metastatic breast cancer, their utility has led to their incorporation into adjuvant chemotherapy regimens. Thus, many women with metastatic breast cancer will already have been treated with anthracyclines and/or taxanes, diminishing the utility of these agents in the palliation of metastatic disease.

Capecitabine is an orally available fluoropyrimidine, metabolized in tissues into 5-fluorouracil. Capecitabine has clinical activity in anthracycline- and taxane-resistant breast cancer,³²⁹ and improves response and survival as first-line treatment when added to single-agent docetaxel.³²⁹ The antimetabolite gemcitabine similarly yields higher response rates and survival when paired with paclitaxel compared with paclitaxel therapy alone.³³⁰ Ixabepilone, an epothilone chemotherapy agent, has substantial activity as a single agent or in combination with capecitabine in patients previously treated with anthracyclines and taxanes.^{331,332} Eribulin, a synthetic analog of halochondrin B, is a nontaxane microtubule dynamics inhibitor that was evaluated against physician’s choice of chemotherapy in a randomized phase 3 study, the 30-Day Cardiac Event Monitor Belt for Recording Atrial Fibrillation After a Cerebral Ischemic Event trial,³³³ and led to improved OS in patients with locally recurrent or metastatic breast cancer with at least two prior regimens.

Dose escalation of taxane therapy with paclitaxel has not been shown to result in clinically important improvements. However, weekly administration of paclitaxel therapy does appear to improve response rate and time to progression compared with less frequent, every-3-week administration.^{334,335}

As a strategy to overcome chemotherapy resistance, many investigators in the 1990s explored high-dose chemotherapy with autologous bone marrow or stem cell support as treatment for breast cancer. Preliminary studies suggested favorable clinical outcomes, prompting both widespread use of high-dose chemotherapy in clinical practice and randomized trials for patients with either metastatic or high-risk, node-positive breast cancer. Despite initial hopes, clinical trials found no difference in outcome between standard chemotherapy followed by treatment with either high-dose chemotherapy and autologous stem cell rescue or maintenance chemotherapy at conventional doses.³³⁶ There is no current role for bone marrow or stem cell transplant in management of either early- or late-stage breast cancer.

Anti-HER2 Therapy for Metastatic Breast Cancer

First-Line Treatment

Just as hormonal therapy radically alters that natural history of ER⁺ metastatic breast cancer, so has anti-HER2 treatment revolutionized outcomes for patients with HER2⁺ breast cancer. Trastuzumab, the humanized anti-HER2 monoclonal antibody, was the first anti-HER2 agent to enter clinical practice. When added to first-line chemotherapy for HER2⁺ metastatic breast cancer, trastuzumab improved response rates, time to progression, and OS.^{337,338} Cardiomyopathy is a known side effect of trastuzumab therapy, and concurrent administration of trastuzumab and anthracyclines should be avoided. Serial determinations of left ventricular ejection fraction should be performed to screen for changes related to trastuzumab.³³⁹

Pertuzumab is a different anti-HER2 antibody than trastuzumab, which binds to both HER2 and HER3 proteins, and is believed to prevent dimerization of those receptors. Clinically, the activity of pertuzumab seems dependent on coadministration of

trastuzumab.³⁴⁰ The Placebo + Trastuzumab + Docetaxel in Previously Untreated HER2-positive Metastatic Breast Cancer study compared docetaxel/trastuzumab versus docetaxel/trastuzumab/pertuzumab as first-line treatment for HER2⁺ breast cancer, and showed improvement in both progression-free survival and OS with the addition of pertuzumab.³⁴¹

As the first anti-HER2 agent, trastuzumab has served as the model for treatment principles for anti-HER2-based therapy. While responses can be seen with either single-agent trastuzumab or trastuzumab plus pertuzumab anti-HER2 therapy,^{340,342} the major benefits of these therapies have only been proven in combination with chemotherapy. The addition of anti-HER2 treatments to endocrine therapy yields modest improvements in progression-free survival.^{343,344} After an induction phase of therapy, the chemotherapy can be withheld, and endocrine therapy initiated (if appropriate), while continuing maintenance treatments with the antibodies. Currently, data for use of pertuzumab and trastuzumab are limited to concurrent administration with taxane-based chemotherapy. A variety of chemotherapy agents have shown clinical activity and safety when paired with trastuzumab, including taxanes, vinorelbine, and platinum analogs.

Refractory, HER2⁺ Breast Cancer

A variety of clinical approaches are used to treat trastuzumab-refractory, HER2⁺ metastatic breast cancer. Continuation of trastuzumab treatment beyond progression is associated with improvements in time to progression,^{344,345} and justifies the practice of continued anti-HER2 blockade in association with multiple lines of treatment for HER2⁺ metastatic breast cancer. Lapatinib is a dual-kinase inhibitor that targets both the HER2 and EGFR tyrosine kinase signaling pathways. Lapatinib has been studied as second-line anti-HER2 therapy for patients progressing after chemotherapy and trastuzumab.³⁴⁶ In comparison with the administration of capecitabine chemotherapy alone, the combination of lapatinib plus capecitabine was associated with a longer period of tumor control and improvement in response rate, but not survival.

Trastuzumab emtansine (TDM1) is a novel antibody-drug conjugate in which the trastuzumab antibody has been linked chemically to a potent chemotherapy moiety. The resulting conjugated antibody has been shown to have substantial activity in trastuzumab-refractory breast cancer, without the traditional side effects of chemotherapy, such as neutropenia or alopecia.³⁴⁷ In a randomized trial of trastuzumab-resistant breast cancer, TDM1 was found to be superior to the combination of lapatinib/capecitabine with respect to progression-free survival, OS, and tolerability.³⁴⁸ A study of first-line therapy for HER2⁺ breast cancer found that TDM1 was more effective than docetaxel/trastuzumab, and led to dramatic improvements in quality of life.³⁴⁹ Ongoing studies are examining the combination of TDM1 with pertuzumab, and assessing whether treatment beyond progression will prove clinically valuable.

Patients with HER2⁺ metastatic breast cancer continue to receive clinical benefit from multiple lines of anti-HER2 therapy,³⁵⁰ and can have tumor responses even following progression on TDM1.³⁵¹

Emerging Options for BRCA1- or BRCA2-Associated Breast Cancer

A novel class of therapeutics, drugs that inhibit the poly(adenosine diphosphate-ribose) polymerase (PARP) enzyme, are emerging as potentially valuable drugs in treatment of advanced breast cancer, particularly in hereditary breast cancer. In a proof of principle open-label phase 2 study, the PARP inhibitor olaparib was studied in patients with BRCA1- or BRCA2-associated cancers. This select group of patients was chosen because of preclinical data that suggested that tumors with BRCA deficiency might be particularly dependent on the DNA repair function of the PARP

enzyme complex, and thus suitable targets for PARP inhibition. Initial observations have suggested robust responses among BRCA-associated breast cancers when patients are given single-agent therapy with olaparib.^{352,353} In addition to PARP inhibitors, platinum-based chemotherapy may have a clinical role in hereditary breast cancers. Limited experience using platinum-based chemotherapy as neoadjuvant treatment for early-stage breast cancer has shown dramatic rates of pCR.³⁵⁴ It remains unclear how important these findings are for either the long-term natural history of BRCA-associated breast cancer or treatment of metastatic disease.

Treatment of Special Metastatic Sites in Patients with Breast Cancer

Specialized treatment options are available for patients with breast cancer with metastases to selective anatomic sites. Patients with lytic bone metastases should receive bone targeted therapy either with intravenous bisphosphonate therapy, such as pamidronate or zoledronic acid, or the RANK-ligand inhibitor, denosumab.³⁵⁵ These agents lessen the pain associated with bone lesions and prevent complications of skeletal metastases, including fracture and hypercalcemia.³⁵⁶ Extended therapy can be associated with osteonecrosis of the jaw, so patients should be monitored for atypical oral lesions. Patients with focal pain at sites of skeletal metastases, pending fracture, or pathologic fracture may also benefit from external-beam RT at selected tumor sites and, when necessary, surgical stabilization or repair of the bone or joint.

Improvements in survival in metastatic breast cancer achieved through chemotherapy and trastuzumab-based treatment have led to an increase in the incidence of central nervous system metastases, especially those with HER2-overexpressing or hormone receptor-negative tumors.³⁵⁷ Therapy for brain metastases remains inadequate, but generally includes WBI. Patients with isolated lesions, dominant masses, or recurrence after WBI may additionally be candidates for surgical resection or stereotactic RT to specific lesions. Patients with leptomeningeal disease may achieve symptomatic improvement with WBI or, in some cases, intrathecal chemotherapy with methotrexate or cytarabine. Very limited clinical experience suggests that some

systemic therapies, including endocrine treatments, chemotherapy agents including anthracyclines, alkylators, and capecitabine, and lapatinib, may have antitumor activity in the brain.³⁵⁸ However, none of these are a substitute for local therapy to the brain.

Some patients with breast cancer will have limited sites of metastatic disease, such as isolated pulmonary nodules, isolated contralateral lymph node recurrence, or bone lesions. Single-institutional experience from the MD Anderson Cancer Center suggests that a fraction of such patients may be treated “aggressively” with curative intent, with favorable long-term results.³⁵⁹ In a cohort of patients without previous adjuvant therapy and with oligometastatic disease that could be definitively treated with local therapy, “stage IV–NED” (no evidence of disease) the use of adjuvant chemotherapy, and, where appropriate, endocrine therapy resulted in 25% to 30% of patients remaining free of further recurrence through 10 years of follow-up.³⁵⁹

The treatment of the primary tumor in the breast in women who present with metastatic disease is another area of controversy. Historically, surgery or RT to the breast was limited to patients with local tumor complications, such as pain or skin erosion, and systemic drug therapy was the primary form of treatment. An analysis of 16,023 patients presenting with stage IV disease and an intact primary tumor compared outcomes between patients having surgery of the primary tumor to negative margins or no surgery. In a multivariate analysis adjusting for known prognostic factors, surgery reduced the HR for death to 0.61 (95% CI = 0.58 to 0.65).⁸³ Multiple other retrospective studies from single institutions, registries, and population-based cohorts have confirmed this initial observation, but it is uncertain whether these studies reflect a real benefit for surgery or consistent selection bias. Three prospective randomized trials are examining the role of surgery in patients presenting with stage IV disease and an intact primary tumor. While awaiting the results of these trials, it is not known precisely how or when to integrate such surgical management into standard medical therapy for metastatic breast cancer or which patients in particular are most likely to benefit from such treatment. Local therapy should not be used as an initial approach to the patient with metastatic disease, but may be considered in a highly selected group of patients with a good response to systemic therapy and a limited number of metastatic sites.

80 Genetic Testing in Breast Cancer

Kristen M. Shannon and Anu Chittenden

INTRODUCTION

Women in the United States have a 12% lifetime risk of developing breast cancer.¹ Although only about 5% to 10% of all cases of breast cancer are attributable to a highly penetrant cancer predisposition gene, individuals who carry a mutation in one of these genes have a significantly higher risk of developing breast cancer, as well as other cancers, over their lifetime compared with the general population. The ability to distinguish those individuals at high risk allows health-care providers to intervene with appropriate counseling and education, surveillance, and prevention with the overall goal of improved survival for these individuals. This chapter focuses on the identification of patients at high risk for breast cancer and provides an overview of the clinical features, cancer risks, causative genes, and medical management for the most clearly described hereditary breast cancer syndromes.

IDENTIFICATION OF HIGH-RISK INDIVIDUALS

An accurate and comprehensive family history of cancer is essential for identifying individuals who may be at risk for inherited breast cancer. As with any family history, it is important to gather a three-generation family history with information on both maternal and paternal lineages.^{2,3} Particular focus should be on individuals with malignancies (affected), but those family members without a personal history of cancer (unaffected) should also be included. It is also important to include the presence of nonmalignant findings in the proband and family members, as some inherited cancer syndromes have other physical characteristics associated with them (e.g., trichilemmomas with Cowden syndrome [CS]).

When taking the family history, the accuracy of the information obtained from an individual patient should be considered. Many factors can influence an individual's knowledge of his/her family history, and errors in the reporting of family history have been documented.^{4,5} A recent study indicates that individuals are often confident that a family member has had cancer but are typically unsure of the details surrounding that diagnosis.^{6,7} Reports of breast cancer tend to be accurate, whereas reports of ovarian cancer are less trustworthy.^{8,9} It is important to note that family histories can change over time, with clinically relevant diagnoses arising in family members, especially between the ages of 30 and 50 years.¹⁰ Finally, the physical examination of the proband and family members can be incredibly helpful in the identification of some inherited breast cancer syndromes, such as CS.

GENETIC TESTING

Although some published guidelines for genetic testing exist, much of the time the decision to offer genetic testing is based on clinical judgment. The National Comprehensive Cancer Network® (NCCN®) provides guidelines for individuals who should

be offered genetic testing for some of the genes mentioned in this text (NCCN 2011). In the end, however, it is up to the individual provider's judgment as to whether genetic testing is indicated.

Genetic testing for breast cancer susceptibility is rapidly changing. The classic method includes pursuing genetic testing for individual cancer predisposition gene(s) that the clinical suspects may be the cause of breast cancer in the family. In this scenario, finding the appropriate laboratory to perform the testing is very important because laboratory techniques (as well as sensitivity of the technique) vary. Most genetic testing includes sequencing of the gene in question. However, there are emerging data that suggest deletion/duplication studies are imperative for genetic testing as the mutational spectra include various rare, yet important genomic rearrangements.¹¹

Recent changes in genetic testing, and specifically the advent of next-generation sequencing tests, have led various genetic testing companies to establish "panel" testing for multiple breast cancer susceptibility genes. In this scenario, up to 14 different breast cancer susceptibility genes are analyzed from one blood specimen. These genes vary in clinical significance from the very highly penetrant breast cancer susceptibility gene *TP53* to the low penetrant breast cancer gene *CHEK2*. How this testing will evolve and the role it will play in clinical care remains to be seen.

BRCA1 AND BRCA2

Description

Mutations in the *BRCA1* and *BRCA2* genes give rise to the "classic" inherited breast cancer syndrome "hereditary breast and ovarian cancer (HBOC) syndrome." The vast majority of cases of HBOC are due to mutations in the *BRCA1* and *BRCA2* genes,^{12,13} which were cloned in 1994 and 1995, respectively.^{14,15} *BRCA1* and *BRCA2* mutations are rare in most populations, occurring in approximately 1 of 400 individuals, but much more common in the Ashkenazi Jewish population in which 1 of 40 individuals carries one of three main disease-causing mutations: two in *BRCA1* (185delAG and 5382insC) and the 6174delT mutation in *BRCA2*.^{16,17} Other founder mutations have been identified, but the utility of these in the US population is minimal.^{18,19}

There has been a great deal of research into the tumor biology associated with *BRCA1/2* mutation carriers. *BRCA2*-associated breast cancers are similar in phenotype and clinical behavior in comparison to sporadic cancers.^{20,21} *BRCA1*-related breast cancers are often of higher histologic grade, show an excess of medullary histopathology, and are more likely than sporadic tumors to be "triple negative" (i.e., estrogen receptor–negative, progesterone receptor–negative, and are less likely to demonstrate HER2/neu overexpression).²² Serous papillary ovarian carcinoma is a key feature of hereditary cancers in *BRCA1* mutation carriers; it is less common in *BRCA2* carriers. Endometrioid and clear-cell subtypes of ovarian cancer have been observed,²³ but borderline ovarian tumors do not seem to be a part of the phenotype.²⁴ Both primary tumors of the

fallopian tubes and peritoneum occur with increased frequency in mutation carriers.²⁵ The prognosis of ovarian cancer in *BRCA1* and *BRCA2* carriers is better than age-matched controls.^{23,26,27}

Identifying *BRCA1/2* Carriers

Identifying those individuals at highest risk for harboring a mutation in *BRCA1* or *BRCA2* is of utmost importance so that they can benefit from surveillance and prevention options. There exist various models designed to estimate the likelihood of identifying a mutation in the *BRCA1* or *BRCA2* gene^{13,28–31}; these models have strengths and limitations that health-care providers need to be familiar with to use and interpret them appropriately.^{32–34} The BRCAPRO model, likely the most often used in clinical cancer genetics, estimates the probability that an individual is a carrier of a *BRCA* mutation using family history and Bayes theorem.²⁸ It is important when using these risk models to understand the limitations of these risk calculations and to place risk estimates into the appropriate context. It is important to note that risk estimates calculated by different models may vary, a factor that complicates the use of quantitative thresholds for making screening recommendations.³⁵ The health-care provider should use clinical judgment in conjunction with estimates from models to provide the most precise risk assessment for an individual patient.

Cancer Risks

The penetrance associated with mutations in *BRCA1* and *BRCA2* remains an active area of research. The risks of developing specific cancers can be found in Table 80.1. The range of breast cancer risk is influenced by the population under study: Higher risk estimates have come from studies with affected families and somewhat lower risk estimates from studies in populations. Also, the risk of ovarian cancer is not the same for all *BRCA2* mutations, with mutations in the central ovarian cancer cluster region conferring a higher lifetime risk.⁴² Other factors, such as birth cohort, oral contraceptive use, age at first pregnancy, and exercise, have all been shown to influence penetrance risk in populations.³⁶ There has been a report of increased risk of gallbladder and bile duct cancer, stomach cancer, and melanoma with *BRCA2* mutation, none of which seem to be clinically actionable.^{37,43}

TABLE 80.1

***BRCA1/2* Cancer Risks**

Management

The current recommendations for the screening of women at risk for HBOC is based on the best available evidence and is expected to change as more specific features of *BRCA1*- and *BRCA2*-related disease become available. The current screening recommendations for women are listed in Table 80.2.

Risk-reduction mastectomies are an appropriate consideration for women at the highest hereditary risk for breast cancer. Studies have shown a 90% to 95% reduction in breast cancer risk following prophylactic mastectomy.^{44–47} The evidence for the use of tamoxifen or raloxifene as a chemopreventive agent in *BRCA* carriers is limited; however, tamoxifen has been shown to reduce the risk of contralateral breast cancers in *BRCA* carriers.^{48,49} Two recent studies support the role of risk-reducing salpingo-oophorectomy: The hazard ratio for ovarian cancer for women who underwent prophylactic surgery and that for those who chose close surveillance were 0.15 and 0.04, respectively.^{50,51} Women should be informed about the potential for the subsequent development of peritoneal carcinomatosis, which has been reported up to 15 years after risk-reducing bilateral salpingo-oophorectomy.^{25,52} Combination oral contraceptives containing estrogen and progestin result in a protective effect against ovarian cancer in some studies, but not in others.^{53–55}

Male *BRCA* mutation carriers are advised to undergo training in breast self-examination with regular monthly practice and semi-annual clinical breast examinations, and workup of any suspected breast lesions is recommended. The NCCN Clinical Practice Guidelines In Oncology (NCCN Guidelines[®]) also recommend that a baseline mammogram be considered, with an annual mammogram if gynecomastia or parenchymal/glandular breast density is identified on baseline study.⁵⁶ The NCCN Guidelines[®] recommend that male *BRCA* mutation carriers should adhere to the current prostate cancer screening guidelines.^{56,57}

Psychosocial Considerations

The psychosocial needs of *BRCA*-positive women have been studied fairly widely. Studies have shown that although there is slight worsening of distress symptoms following cancer genetic counseling in *BRCA1/BRCA2* mutation carriers, these symptoms were minimal, did not affect everyday life activities, and had almost disappeared at 1-year follow-up.^{58–62} Approximately 20% of *BRCA1/2* mutation carrier women experience high distress after learning their test result.^{63,64} Factors that are related to high posttest distress include a high level of pretest anxiety, higher pretest perceived risk, and whether they are opting for prophylactic surgery to reduce their risk.⁵ It is important to note, however, that even in women who experienced distress after receipt of genetic test information, women do not “regret” their decision to be tested.⁶⁶ It has been suggested that health-care providers consider including a brief pretest psychological assessment before initiating genetic testing for *BRCA1* and *BRCA2*⁶⁷ so that these women can be targeted for more comprehensive support once test results are available.⁶⁸

The anxiety-associated symptoms reported by *BRCA1/2* carriers include sleeplessness and “bad mood.”^{60,69,70} One other psychosocial issue reported by single women with *BRCA1/2* mutations is that they experience increased urgency at finding a life partner capable of handling the emotional strain of the cancer world and open to pursuing multiple paths toward parenthood.⁷¹

Various studies have suggested that existing social support networks are inadequate for *BRCA1/2* mutation carriers and that formal services are unavailable or underutilized.^{66,70,72} To address this lack of formal support services, a retreat for *BRCA1/2* carriers that includes educational updates about medical management, genetic privacy, and discrimination and addresses psychological and family issues may provide a valuable opportunity for *BRCA* carriers and their families to receive updated medical information, share personal experiences, provide and receive support, and change health behaviors.⁷³

TABLE 80.2

National Comprehensive Cancer Network Guidelines for Management of BRCA1/2 Carriers

Women

- Breast awareness starting at age 18 y
- Clinical breast examination, every 6–12 mo, starting at age 25 y
- Breast screening
 - Age 25–29 y, annual breast magnetic resonance imaging (MRI) screening (preferred) or mammogram if MRI is unavailable or individualized based on earliest age of onset in family.
 - Age ≥30–75 y, annual mammogram and breast MRI screening.
 - Age >75 y, management should be considered on an individual basis.
- Discuss option of risk-reducing mastectomy and counsel regarding degree of protection, reconstruction options, and risks
- Recommend risk-reducing salpingo-oophorectomy, ideally between 35 and 40 y and upon completion of childbearing, or individualized based on earliest age at onset of ovarian cancer in the family; counseling includes a discussion of reproductive desires, extent of cancer risk, degree of protection for breast and ovarian cancer, management of menopausal symptoms, possible short-term hormone replacement therapy to a recommended maximum age at natural menopause, and related medical issues
- Address psychosocial, social, and quality-of-life aspects of undergoing risk-reducing mastectomy and/or salpingo-oophorectomy.
- For those patients who have not elected risk-reducing salpingo-oophorectomy, consider concurrent transvaginal ultrasound (preferably days 1–10 of menstrual cycle in premenopausal women) and CA-125 (preferably after day 5 of menstrual cycle in premenopausal women), every 6 mo starting at age 30 y or 5–10 y before the earliest age at first diagnosis of ovarian cancer in the family
- Consider chemoprevention options for breast and ovarian cancer, including discussing risks and benefits
- Consider investigational imaging and screening studies, when available (e.g., novel imaging technologies and more frequent screening interval[s] in the context of a clinical trial)

Men

- Breast self-examination training and education starting at the age of 35 y
- Clinical breast examination, every 6–12 mo, starting at the age of 35 y
- Consider baseline mammogram at the age of 40 y; annual mammogram if gynecomastia or parenchymal/glandular breast density on baseline study
- Starting at age 40:
 - Recommend prostate cancer screening for *BRCA2* carriers
 - Consider prostate cancer screening for *BRCA1* carriers

Distress in male *BRCA* carriers has not been studied quite as widely, but one study noted that high distress after disclosure of the result was reported by one of four male mutation carriers.⁷⁴

TP53

Description

Germline mutations in the *TP53* gene give rise to a disease called Li-Fraumeni syndrome (LFS), which is a rare cancer predisposition syndrome thought to be responsible for ~1% of breast cancers.⁷⁵ LFS is often thought of as a hereditary predisposition to cancer in general, involving many tumor types and occurring at any point in an individual's lifetime, including childhood. The majority of cases of LFS are due to mutations in the *p53* gene.^{76–79} The component tumors of LFS include bone sarcomas (primarily osteosarcomas and chondrosarcomas), soft tissue sarcomas, breast cancer, brain tumors, leukemia, and adrenocortical carcinomas.⁸⁰ The classic component tumors are thought to account for 63% to 77% of cancer diagnoses in individuals with LFS.^{80–83} Breast cancer is the most common tumor in *p53* mutation carriers (24% to 31.2%), followed by soft tissue sarcomas (11.6% to 17.8%), brain tumors (3.5% to 14%), osteosarcomas (12.6% to 13.4%), and adrenocortical tumors (6.5% to 9.9%).^{84,85} Other tumors that have been argued to be component tumors of LFS are listed in Table 80.3.

There are some data regarding common histology of LFS component tumors. Breast cancers are most commonly invasive ductal carcinomas.⁸⁰ Rhabdomyosarcomas account for 55% of soft tissue sarcomas, followed by fibrosarcomas (13%) and then malignant fibrous histiocytomas.⁸⁴ For LFS-associated brain tumors, 69% are astrocytic (astrocytoma or glioblastoma), followed by medulloblastoma/primitive neuroectodermal tumors (17%).⁸⁴

Identifying Li-Fraumeni Syndrome

Li et al.⁸⁰ first defined LFS in 1988 at which point clinical criteria were established, now known as classic LFS criteria (Table 80.4). In 1994, Birch et al.⁷⁷ went on to define less stringent criteria (see Table 80.4) in an attempt to capture families with *p53* mutations

TABLE 80.4

Clinical Criteria for Classic Li-Fraumeni Syndrome

LFL Syndrome and Chompret Criteria

Classic LFS criteria

- Proband diagnosed with a sarcoma before 45 y of age and
- A first-degree relative^a with cancer diagnosed before 45 y of age and
- A first- or second-degree relative^b on the same side of the family with cancer diagnosed before 45 y of age or a sarcoma at any age

LFL syndrome criteria

- Proband with any childhood cancer or sarcoma, brain tumor, or adrenocortical carcinoma diagnosed before 45 y of age and
- First- or second-degree relative with a component LFS cancer (sarcoma, breast cancer, brain tumor, leukemia, or adrenocortical carcinoma) diagnosed at any age and
- One first- or second-degree relative on the same side of the family with any cancer diagnosed before age 60 y

Chompret criteria

- Proband diagnosed with a narrow spectrum cancer (sarcoma, brain tumor, breast cancer, or adrenocortical carcinoma) before the age of 36 y, and at least one first- or second-degree relative affected by a narrow-spectrum tumor (other than breast cancer if the proband was affected by breast cancer) before 46 y or a relative with multiple primary tumors at any age
- A proband with multiple primary tumors, two of which belong to the narrow spectrum and the first of which occurred before 36 y, regardless of family history
- A proband with adrenocortical carcinoma, regardless of age at diagnosis or family history

LFL, LFS-like; LFS, Li-Fraumeni syndrome.

^a First-degree relative is defined as parent, sibling, or child.

^b Second-degree relative is defined as grandparent, aunt, uncle, niece, nephew, or grandchild.

who did not necessarily conform to the classic criteria. Families who met the broader criteria of Birch et al.⁷⁷ were referred to as “LFS-like (LFL)” families. Both classic and LFL criteria are based on family history and fail to recognize potential *p53* mutation carriers who have de novo germline *p53* mutations. Although the de novo rate is not well defined for *p53*, one study showed as high as a 24% rate.⁸⁸

More recently in 2001, Chompret et al.⁸⁹ developed criteria for identifying patients likely to carry *p53* mutations (see Table 80.4) and included criteria that address families who display a collection of component tumors but also address individuals whose personal histories are suggestive of *p53* mutation even in the absence of a suggestive family history. The Chompret criteria were designed to include individuals who may potentially carry de novo *p53* mutations.

Fifty to seventy percent of individuals who meet the classic definition of LFS will have a mutation in *p53*.^{77,89-92} Individuals who meet the LFL criteria are less likely to be *p53* mutation carriers, estimated at 21% to 40%.^{79,90} Twenty percent of individuals meeting the Chompret criteria will be identified as *p53* mutation carriers.⁸⁹

Cancer Risks

Typically, LFS-associated tumors occur at significantly younger ages than when they occur sporadically. However, depending on tumor type, the mean age at diagnosis varies from childhood well into adulthood.⁸⁴ Understanding cancer risk for LFS is somewhat complicated as the ranges of risk vary greatly between studies and depend largely on study population. When pooling studies that examine overall cancer risk in *p53* mutation carriers (both female and male), the risk of developing cancer by ages 15 to 20 years is 12% to 42%, by ages 40 to 45 years is 52% to 66%, by age 50 years is 80%, and by age 85 years is 85%.^{82,83,88,93} When separating out

the sexes, it is apparent that female *p53* mutation carriers have generally a higher lifetime cancer risk in comparison to males.^{83,88,94}

Individuals with a diagnosis of LFS are also at markedly increased risk of developing multiple primary tumors. Hisada et al.⁹⁵ found that, following a first cancer diagnosis, there is a 57% risk for a second primary tumor within 30 years of the first diagnosis, followed by a 38% risk for a third primary tumor within 10 years of the second cancer diagnosis. In addition, it has been widely observed that second, third, and so on primary cancers commonly occur in the radiation field of previously treated cancers.^{76,80,88,95}

Psychosocial Issues

The psychosocial effects of being a member of an LFS family and/or being affected with LFS have not been widely studied.^{96,97} The nature of the disease itself leads to unique psychosocial implications with individual members of LFS families often experiencing many cancer diagnoses (and deaths) in their immediate and extended family. These cancer diagnoses will be throughout the life span, with many parents having to deal with a child's diagnosis and many children needing to deal with a parent's diagnosis. It is likely that these repeated experiences of grief and stress pose a significant psychological burden for the members of LFS families.⁹⁸ Although no data exist, this psychosocial burden may also impact individuals' relationships with their family members including, but not limited to, children and spouses.

Because of the rarity of the syndrome, many individuals with LFS may feel isolated. Other inherited syndromes, in general, and inherited cancer syndromes, in particular, have “support groups” that can help with the coping process when an individual is diagnosed with the disease. Unfortunately, no such group exists in the United States today. An online discussion group/support group for individuals with LFS is available (<http://listserv.acor.org/SCRIPTS/WA-ACOR.EXE?OK=53111E8B&L=LI-FRAUMENI>). Members of the listserv include patients with LFS, health-care providers, and spouses and friends of individuals with LFS. The listserv serves as a place not only to share information about the disease but also to discuss fears, anxiety, grief, and other psychological manifestations of the disease.

COWDEN SYNDROME (PHOSPHATE AND TENSIN HOMOLOG)

Description

CS is a rare hereditary cancer syndrome that is characterized by overgrowth in different organ systems. The incidence of CS is thought to be about 1 in 200,000, but it may be underdiagnosed.⁹⁹ CS belongs to the set of syndromes known as the phosphatase and tensin homolog (PTEN) hamartoma tumor syndromes.¹⁰⁰ *PTEN* mutations are found in the vast majority of patients with CS, although mutations in other genes such as *BMPRIA* and the succinate dehydrogenase genes have been reported in a small number of patients who have features of CS but do not meet diagnostic criteria (CS-like).^{101,102}

Diagnostic Criteria Testing Criteria

Traditionally, one of the hallmark features of CS is the development of multiple hamartomas of the skin and mucosa. A thorough physical examination, including head circumference measurement and examination for skin manifestations, is an important component of assessing for CS. However, a lack of hamartomas does not exclude CS; diagnostic criteria are complicated.¹⁰³ The NCCN's most recent guidelines (v.1.2014) for testing for CS are in Table 80.5.

Identifying Cowden Syndrome

In 2011, the Cleveland Clinic made available an online calculator for risk of a *PTEN* mutation in adults, as well as a set of pediatric criteria (<http://www.lerner.ccf.org/gmi/ccscore/>). Risk estimates

TABLE 80.5

National Comprehensive Cancer Network Guidelines (V.1.2014): Testing Criteria for Cowden Syndrome

Individual from a family with a known <i>PTEN</i> mutation or
Individual meeting clinical diagnostic criteria for CS/PHTS or
<ul style="list-style-type: none"> ■ At risk individual with a relative with a clinical diagnosis of CS/PHTS or BRRS for whom testing has not been performed ■ The at-risk individual must have the following: <ul style="list-style-type: none"> ■ Any one major criterion or ■ Two minor criteria
or
Individual with a personal history of

were based on data from the largest prospective cohort of patients collected with a potential diagnosis of CS. Information on physical findings, specific cancer diagnoses, intestinal polyps, and other benign conditions is collected. If a patient has a risk of mutation greater than 3%, testing for *PTEN* is recommended.¹⁰⁴

TABLE 80.6

Cancer Risks Associated with Cowden Syndrome

	Pilarski et al. ¹⁰⁵ (2009) (%)	Tan et al. ¹⁰⁴ (2012) (%)
Breast cancer risk	25–50	85
Thyroid cancer	3–10	35
Endometrial cancer	5–10	28
Renal cell cancer	Unknown	34
Melanoma	Unknown	6
Colorectal cancer	Unknown	9

Cancer Risks

The highest risk of cancer associated with CS is for female breast cancer. Other cancers that are thought to be a part of the spectrum of cancers seen in CS include thyroid cancer and uterine cancer; more recently, renal cell cancer, melanoma, and colorectal cancer have also been reported. The magnitude of risk for the cancers associated with CS varies widely.^{104,105} A recent article from Cleveland Clinic estimated the lifetime risks of cancer to be much higher than previously reported; however, it is likely that there is significant ascertainment bias present in this cohort.¹⁰⁴ A comparison of two publications reviewing the cancer risks associated with CS is presented in Table 80.6.

Management

CS is a complex diagnosis to make and to receive. Because of the degree of variability in CS, it is difficult for clinicians to make a firm diagnosis except in the most obvious of cases. In situations where there is a high suspicion, a negative genetic test result may be uninformative for the patient and her family. Conversely, a positive result or variant of uncertain significance in an individual without classic features of Cowden can lead to uncertainty regarding how aggressive to be about screening and prevention measures. The NCCN guidelines for management are in Table 80.7.

Psychosocial Issues

There is a dearth of literature addressing the psychological issues for individuals and families with a clinical and/or genetic diagnosis of CS, possibly due to its rarity. However, there are several factors associated with CS that could add to the psychological burden of having a hereditary syndrome. These include variability in clinical presentation, difficulty screening (especially for breast cancer), disfigurement due to mucocutaneous lesions and surgical procedures, the possibility of intellectual disabilities and/or autism in children, lack of knowledge about how often *PTEN* mutations are found de novo versus inherited in a family, a large number of uncertain variants found through genetic testing, and overall lack of knowledge about the syndrome.

Because of the association of CS with autism and macrocephaly, many children are now undergoing genetic testing for alterations in the *PTEN* gene; a small number of them will be found to have CS or a related disorder.¹⁰⁶ When the child is the index case in the family, testing him/her may provide information for adult family members about cancer risks. In addition, parents may find value in knowing that there is an underlying genetic cause to their child's issues and in finding a community with a shared diagnosis. There is also the hope that the development of targeted therapies may help ameliorate the disease in children and, going forward, in adults.

The benefit of testing an asymptomatic child whose parent has a known mutation in *PTEN* is still unknown. Although childhood cancers have been reported in CS, these cancers appear to be rare. Some experts argue that thyroid and other screening is warranted in

TABLE 80.7

National Comprehensive Cancer Network Guidelines (V.1.2014) for Cowden Syndrome Management

Women

- Breast awareness starting at the age of 18 y
- Clinical breast examination, every 6–12 mo, starting at the age of 25 y or 5–10 y before the earliest known breast cancer in the family
- Annual mammography and breast magnetic resonance imaging screening starting at the age of 30–35 y or individualized based on earliest age of onset in family. For endometrial cancer screening, encourage patient education and prompt response to symptoms. Consider annual random endometrial biopsies and/or ultrasound beginning at age 30–35 y
- Discuss option of risk-reducing mastectomy and hysterectomy on a case-by-case basis and counsel regarding degree of protection, extent of cancer risk, and reconstruction options

Men and Women

- Annual comprehensive physical examination starting at the age of 18 y or 5 y before the youngest age at diagnosis of a component cancer in the family (whichever comes first), with particular attention to breast and thyroid examinations
- Annual thyroid ultrasound at the age of 18 y, or 5–10 y before the earliest known thyroid cancer in the family, whichever is earlier
- Colonoscopy starting at the age of 35 y, then every 5 y or more frequently if patient is symptomatic or polyps found
- Consider renal ultrasound starting at age 40 y, then every 1–2 y. Dermatologic management may be indicated for some patients
- Consider psychomotor assessment in children at diagnosis and brain MRI if there are symptoms.
- Education regarding the signs and symptoms of cancer

Risk to Relatives

- Advise about possible inherited cancer risk to relatives and options for risk assessment and management
- Recommend genetic counseling and consideration of genetic testing for at-risk relatives

children for the early detection and prevention of related cancers¹⁰⁷; however, others would say that the psychological burden of screening outweighs any small medical benefit that may be derived from discovering benign lesions that are unlikely to become cancerous at a young age. Testing unaffected children for CS remains controversial.

OTHER GENETIC MUTATIONS AND BREAST CANCER

STK11

Peutz–Jeghers syndrome (PJS) is a rare autosomal dominant gastrointestinal hamartomatous polyposis syndrome. It is estimated that the incidence is approximately 1 in 150,000 in North America and Western Europe.^{108,109} PJS is characterized by the development of Peutz–Jeghers polyps in the intestine in conjunction with pigmentation

TABLE 80.8

Clinical Criteria for Peutz–Jeghers Syndrome and Hereditary Diffuse Gastric Cancer Syndrome

PJS Clinical Diagnostic Criteria

Any one of the following is present

- Two or more histologically confirmed Peutz–Jeghers polyps
- Any number of Peutz–Jeghers polyps detected in one individual who has a family history of PJS in close relative(s)
- Characteristic mucocutaneous pigmentation in an individual who has a family history of PJS in close relative(s)
- Any number of Peutz–Jeghers polyps in an individual who also has characteristic mucocutaneous pigmentation
Beggs et al.¹¹⁰ (2010)

Hereditary Diffuse Gastric Cancer Clinical Criteria

Any of the following:

- Two gastric cancer cases in a family, one individual aged <50 y with confirmed DGC
- Three confirmed DGC cases in first- or second-degree relatives independent of age
- Simplex case (i.e., a single occurrence in a family) of DGC occurring before the age of 40 y
- Personal or family history of DGC and lobular breast cancer, one diagnosed before the age of 50 y

PJS, Peutz–Jeghers syndrome; DGC, diffuse gastric cancer. Fitzgerald RC, Hardwick R, Hunstman D, et al. Hereditary diffuse gastric cancer: Updated consensus guidelines for clinical management and directions for future research. *J Med Genet* 2010;47:436–444.

(brown or bluish spots) around and inside the mouth, nose and lips, and perianal area, as well as other parts of the body. These lesions are often most prominent in childhood and fade with age.

Most families with PJS have mutations in the *STK11* gene, although this gene does not explain all inherited cases of PJS as well as many simplex cases.¹¹⁰ The lifetime risk of breast cancer in females is reported in a wide range, with the most consistent risks being in the 30% to 50% range.^{111,112} Other cancers that can be seen in PJS include cancers of the colon, pancreas, stomach, ovary, small intestine, lung, cervix, testes, uterus, and esophagus.¹¹⁰ Consensus diagnostic criteria were published in 2010 and are listed in Table 80.8.¹¹⁰

CDH1

Hereditary diffuse gastric cancer is a rare autosomal dominant hereditary syndrome characterized by diffuse (or signet ring cell pathology) stomach cancer. The incidence of this syndrome is not well known but likely to be rare. The lifetime risk of stomach cancer is thought to be approximately 80% compared with <1% in the general population.^{114,115} The second most common cancer in families with this syndrome is lobular breast cancer, with a lifetime risk of about 40% in women.^{116–120} Cleft lip and palate have also been reported in some families.¹²¹ The International Gastric Cancer Linkage Consortium published clinical criteria in 2010, shown in Table 80.8.¹¹³ The incidence of *CDH1* mutations in lobular breast cancer cases is thought to be low in the absence of a family history of gastric cancer.¹²² Please see Chapter 59 (“Genetic Testing in Colon Cancer [Nonpolyposis Syndrome]”) for more detailed information.

MODERATE- AND LOW-PENETRANCE BREAST CANCER GENES

There are several genes that have already been described in families with breast cancer including *CHEK2* and *ATM*. The risk of breast cancer associated with alterations in these genes is thought to be

lower than with traditional hereditary breast cancer syndromes; other factors are likely to interact with the effects of changes in these genes and result in a more moderate increase in risk for breast cancer.

Recently, a US group published a study on 12 genes linked to hereditary ovarian cancer, which are also being analyzed in families with hereditary breast cancer.^{123–125} More laboratories are beginning to offer genetic testing for panels of genes that are important in DNA repair pathways.¹²⁶ There are several categories of these genes.

1. Category 1—genes functionally related to *BRCA1* and *BRCA2* (*ATM*, *BARD1*, *CHEK2*, *MRE11A*, *NBN*, *RAD50*, *RAD51D*)
 - *ATM* (ataxia telangiectasia mutated)
 - *BARD1* (*BRCA1*-associated RING domain 1)
 - *CHEK2* (cell cycle checkpoint kinase 2)
 - *MRE11A* (meiotic recombination 11 homolog A)
 - *NBN* (nibrin; aka *NBS1*)
 - *RAD50*
 - *RAD51D*
2. Category 2—(other) genes in the Fanconi anemia pathway that increase breast cancer risk (*BRIPI*, *PALB2*, *RAD51C*)
 - *BRIPI* (*BRCA*-interacting protein C-terminal helicase 1; *FANCI*)
 - *PALB2* (partner and localizer of *BRCA2*; *FANCN*)
 - *RAD51C* (*FANCO*)
3. Category 3—genes involved in hereditary colorectal cancer (*MLH1*, *MSH2*, *MSH6*, *PMS2*, *EPCAM*, *MYH*)

For many of the genes in categories 1 and 2, risks of breast cancer are not well defined, and it is unclear if women who test negative for a mutation that was found in an affected relative (“true negatives”) are really at general population risk.

Lynch Syndrome and MYH-Associated Polyposis

Lynch syndrome (LS) is the most common hereditary form of colorectal cancer, accounting for about 2% to 3% of colorectal cancer cases. It is caused by mutations in genes involved in DNA mismatch repair, including *MLH1*, *MSH2*, *MSH6*, *PMS2*, and, indirectly, *EPCAM*. LS is typically characterized by the development of relatively early-onset colorectal and uterine cancer; risks for other cancers including stomach cancer, cancer of the small

intestine, pancreatic cancer, sebaceous carcinomas, ovarian cancer, and cancers of the urinary collecting tract. Rarely, brain tumors are thought to be increased.¹²⁷ Most studies have not shown a significant increase in breast cancer risk for *MMR* mutation carriers versus noncarriers,¹²⁸ although a more recent article studying a cohort of LS families prospectively did show a fourfold increase in breast cancer risk.¹²⁹ It is clear that defective mismatch repair can be seen in some breast cancers in women from LS families.^{130–131} Whether there is a true increase in risk (and the magnitude of this risk) remains to be seen. Please see “Genetic Testing in Colon Cancer (Nonpolyposis Syndrome)” for more detailed information.

MYH-associated polyposis (MAP) is the lesser known of the adenomatous polyposis syndromes (versus familial adenomatous polyposis). *MYH* is involved in base excision repair; without *MYH*, oxidative DNA damage leads to the formation of 8-oxo-G, which mispairs with adenine. This leads to an increase in G:C>T:A transversions in *APC* and other genes.¹³² MAP is associated with an attenuated phenotype; fewer adenomas (generally in the range of 10 to 100) and a mixture of polyp types (serrated adenomas, hyperplastic polyps) and duodenal polyps are often seen.^{133,134} Extraintestinal manifestations, including breast cancer, have been reported in MAP.^{135,136} However, *MYH* does not appear to be a common cause of breast cancer.¹³⁷ Please see “Genetic Testing in Colon Cancer (Nonpolyposis Syndrome)” for more detailed information.

CONCLUSION

This chapter has provided a synopsis of the genes linked to the most well-defined syndromes associated with breast cancer and an introduction to breast cancer gene panels. It is important for clinicians to be able to identify the classic breast cancer syndromes, know the relevant genes, and understand the medical management and psychosocial issues associated with the syndromes. The advent of whole genome sequencing and the ability to analyze the estimated 22,000 genes in the human genome with cheap and efficient technology bring the hope that all of the genes involved in hereditary and familial breast cancer will be found. However, making this information clinically relevant will require much more research. Elucidating the interaction of mutations in these genes with modifying factors could help clarify risks in families and lead to targeted screening and prevention measures. It is clear that genetic testing will become more complicated over time and that the interpretation of test results will require continuing education and expertise in the field.

81 Molecular Biology of Endocrine Tumors

Samuel A. Wells, Jr.

INTRODUCTION

Over the last two decades, advances in molecular biology have provided a deeper understanding of the etiology and pathogenesis of endocrine diseases. Studies of hereditary endocrinopathies have been particularly instructive in this regard and have led to significant improvements in the diagnosis and treatment of patients with both hereditary and sporadic endocrine cancers. The introduction of a new class of drugs, molecular targeted therapeutics (MTT), has been a particularly notable achievement in the treatment of patients with advanced endocrine cancers, a disease stage for which there had been no effective therapy.

THE MULTIPLE ENDOCRINE NEOPLASIA SYNDROMES

Most endocrine tumors involve a single gland, are usually benign, and occur sporadically. Rarely, however, two or more endocrine tumors occur together in a familial pattern designated as the multiple endocrine neoplasias (MEN) syndromes. The genetic mutations causing the two most common of these disorders, MEN1 and MEN2, have been identified, which led to improved management of patients with these syndromes as well as patients with the related sporadic endocrine tumors.

Multiple Endocrine Neoplasia Type 1

Clinical Features

In 1954, Wermer described a family with hyperparathyroidism and tumors of the pancreatic islet cells and the pituitary gland.¹ This hereditary syndrome has since been named MEN1 (Online Mendelian Inheritance in Man [OMIM] #131100), and it may include over 20 separate endocrine and nonendocrine tumors. The prevalence of MEN1 is 1 per 30,000 to 100,000 persons. Males and females are equally affected, although women are more prone to develop pituitary tumors and men are more prone to develop gastrinomas and thymus tumors.²⁻⁶ MEN1 is characterized by high penetrance but variable expressivity. While parathyroid hyperplasia occurs in virtually all patients by age 40 years, other endocrine tumors develop less frequently. Pancreatic islet cell tumors (usually gastrinomas, less often insulinomas, and rarely glucagonomas, or vasoactive intestinal polypeptide secreting tumors, occur in 50% to 70% of patients) Pituitary tumors (usually prolactinomas, adrenal cortical tumors, and thymus tumors, occur in 20% to 40%, 20% to 40%, and 10% of patients, respectively. The diagnosis of MEN1 is established when a patient with hyperparathyroidism develops a pituitary tumor or a pancreatic islet cell tumor, when a previously unaffected member of a family with MEN1 develops a

single characteristic endocrine tumor, or when a germline *MEN1* mutation is detected in an individual who may or may not have an endocrine tumor associated with MEN1. The severity of the disease is unpredictable; although recently, an interaction between menin and *JunD* was shown to be significantly associated with a higher death rate, primarily due to thymus and pancreatic tumors.⁷

Molecular Genetics of MEN1

Chandrasekharappa et al. discovered *MEN1*, the genetic mutation for MEN1.⁸ The *MEN1* gene spans a 9.8 kb segment of chromosome 11q13 and consists of 10 exons with a 1,830 base pair region that encodes transcripts of 2.7 and 3.1 kb. *MEN1* is a putative tumor suppressor gene, residing in the nucleus of nondividing cells and in the cytoplasm of dividing cells.^{9,10} Homozygous mice null for *MEN1* die during embryogenesis, while heterologous mice, *MEN1*^{+/-}, develop a pattern of endocrine tumors very similar to that occurring in patients with MEN1.¹¹ The transcripts, expressed in almost all tissues, encode a novel, highly conserved, ubiquitously expressed, 610 amino acid, 67kDa protein, named menin. The biochemical mechanism underlying the tumor-suppressing function of menin is unknown, however, it appears to play a critical role in the regulation of gene transcription, apoptosis, and genome stability.¹² Menin's crystal structure indicates that it is a scaffold protein that interacts with distinct partner proteins, approximately 40 of which have been identified, the most common including JunD, MLL1, LEDGF, and H3K4m3.¹³ Epigenetic regulation of gene expression is a central aspect of menin's function, thus alteration of epigenetic targets holds promise for the treatment of MEN1-related tumors.¹⁴

More than 1,000 distinct and presumed pathologic mutations have been identified over the coding region of the *MEN1* gene; approximately 70% are germline mutations and 30% are somatic mutations (Fig. 81.1).¹² The mutations are diverse in type (including frame-shift, deletions or insertions, nonsense, missense, splice-site alterations, in-frame deletions or insertions, and large deletions), and occur throughout the 1,830 base pair coding region with no evidence of clustering or "hot spots," as is seen in MEN2.¹⁵ Although large deletions have been reported in the *MEN1* gene, no mutations have been reported in the promoter region.¹⁶ Screening of the coding region of the *MEN1* gene has identified a heterozygous germline mutation in 70% of sporadic or familial index cases of MEN1.¹⁵ There is no association between genotype and phenotype, and even families with the same base pair deletion can display a wide range of MEN1-associated tumors.¹⁷ The first "hit" leading to tumorigenesis involves small mutations in one or several bases, broadly distributed across the *MEN1* open reading frame. Approximately 75% of first-hit mutations lead to premature truncation of the menin protein. Most often, a large chromosomal rearrangement causes a deletion of the normal *MEN1* gene resulting in loss of heterozygosity, compromising the second hit in the Knudson two-hit hypothesis.¹⁸

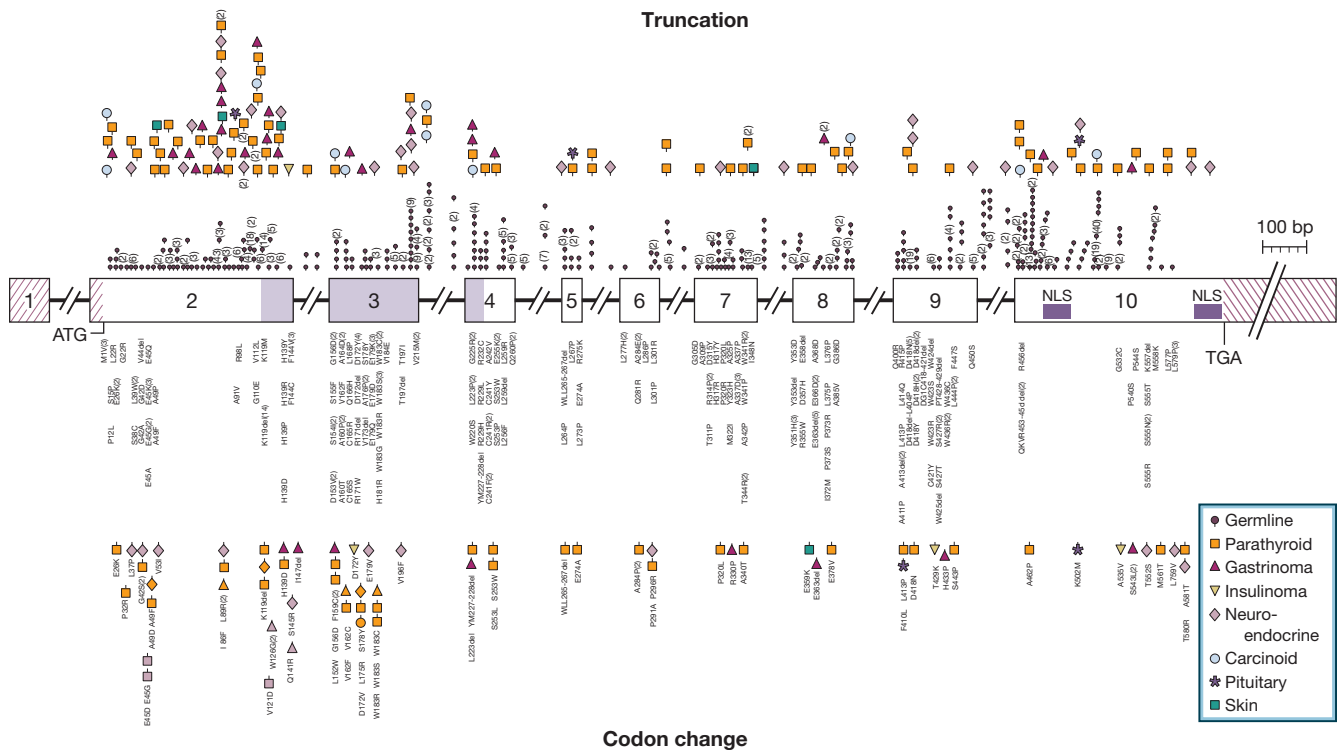

Figure 81.1 Germline and somatic mutations of the *MEN1* gene. Unique germline *MEN1* mutations in families, sporadic cases, and nonhereditary tumors. The figure shows 670 unique mutations identified by 2006. Repeating mutations within the germline or somatic category (common ancestry versus hot spots for mutation) are shown only once, with a small number in parentheses to indicate total occurrences. Germline mutations are shown as *black lollipops* or as code above the messenger RNA (mRNA). Somatic *MEN1* mutations in diverse tumors are shown separately as *flags* along the upper and lower border and as code. *MEN1* mRNA is diagrammed with exons numbered; untranslated regions are *crosshatched*. Truncating mutations (frameshift mutations, splice errors, and nonsense [stop codon] mutations) are shown above the mRNA; they account for 75% of all mutations. Codon change mutations (missense mutations or small in-frame deletions) are shown below the mRNA with their three-letter amino acid code. *Stippling* about exon 3 represents the main zone of menin interaction with JunD. Several large deletions, probably of the entire *MEN1* gene, are not shown. NLS, nuclear localization sequence; ATG, a transcription factor; TGA, a stop codon; bp, base pair. (Reprinted from Melmed S, Polonsky KS, Larsen PR, et al., eds. The multiple endocrine neoplasia syndromes. In: *Williams Textbook of Endocrinology*. 12th ed. Amsterdam: Elsevier; 2011:1728–1756, Figure 41-7. With permission from Elsevier.)

Mutational analysis is important in confirming the diagnosis in patients with clinically evident MEN1 and in identifying first-degree relatives who have inherited, or have not inherited, the MEN1 mutation so that respectively they can either be followed for the development of endocrine tumors or cease to be followed. Half of newly diagnosed index cases are found to have novel mutations, and more than 10% of *MEN1* mutations arise *de novo* and will be passed to subsequent generations.^{17,19,20} It is important to note that the absence of an *MEN1* mutation in a patient with tumors characteristic of MEN1 does not exclude that the patient has MEN1.

The endocrine tumors associated with MEN1 occur more commonly in a sporadic setting, and it is of interest that 25% of gastrinomas, 10% to 20% of insulinomas, 50% of VIPomas, 25% to 35% of bronchial carcinoids, and 20% of parathyroid adenomas express somatic *MEN1* mutations. Conversely, somatic *MEN1* mutations rarely if ever occur in sporadic adrenocortical tumors, pituitary tumors, or thymus tumors.²¹

Hereditary Endocrinopathies, Other than MEN1, Involving the Parathyroid and Pituitary Glands

The Parathyroid Gland

Primary hyperparathyroidism occurs in 1 of every 1,000 persons, and 5% to 10% of cases occur in a familial pattern, most often as MEN1, MEN2A, familial hypocalciuric hypercalcemia (FHH),

the hyperparathyroidism jaw-tumor syndrome (HPT-JT), and familial isolated hyperparathyroidism (FIHP).

Familial Hypocalciuric Hypercalcemia, Neonatal Severe Hyperparathyroidism, Autosomal Dominant Hypoparathyroidism, and Familial Isolated Hyperparathyroidism

Familial Hypocalciuric Hypercalcemia. The calcium-sensing receptor *CASR* gene is a seven-transmembrane-spanning G protein-coupled receptor that is expressed in cells of the parathyroid gland and the kidney tubule. *CASR* plays a critical role in regulating extracellular calcium homeostasis. The discovery of *CASR* was a surprise, since previously no small cation had been shown capable of acting as a ligand for a G-protein coupled receptor.²² The human *CASR*, located on chromosome 3q11.3-q21, is sensitive to changes in the ambient calcium concentration and when activated inhibits parathyroid hormone (PTH) secretion and the renal reabsorption of calcium. With heterogeneous inactivating mutations of the *CASR* gene, the parathyroid cell fails to sense properly an increased serum calcium concentration; the resulting increase in PTH secretion causes FHH (OMIM #145980), an autosomal dominant disease characterized by hypocalcemia, hypercalcemia, mild hypermagnesemia, and parathyroid hyperfunction.²³ Bone density levels are not decreased, and patients are generally asymptomatic. It is important for clinicians to recognize this relatively mild form of familial hyperparathyroidism, as it is not cured by parathyroidectomy.²⁴ More than 250 different mutations have

been reported to affect CASR function, and mutational analysis is utilized to identify family members who have inherited a mutated CASR allele. It is important to note, however, that CASR mutations are detected in only 65% of patients with FHH and additional mapping studies have revealed additional loci on chromosome 19p and chromosome 19q13.3, thereby suggesting genetic heterogeneity for FHH and raising the possibility that additional or signal pathways are involved in calcium homeostasis.²⁵⁻²⁷

Neonatal Severe Hyperparathyroidism. With inactivating mutations in both alleles of the CASR gene, neonatal severe hyperparathyroidism (OMIM #239200) develops with serum calcium levels in the range of 15 to 20 mg/dl, up to 10-fold increases in serum PTH levels, greatly enlarged parathyroid glands, demineralization, and bone fractures. The disease was originally described in consanguineous parents, each with FHH. This disease represents a life-threatening emergency, and urgent parathyroidectomy is usually indicated. Recently, however, there are reports that the calcimimetic cinacalcet produces robust and durable reductions in the serum calcium concentrations of patients with neonatal severe hyperparathyroidism. However, the response is not uniform and appears to depend on the patient's specific CASR mutation.^{24,28}

Autosomal Dominant Hypoparathyroidism. The related syndrome, autosomal dominant hypoparathyroidism (OMIM #146200) results from activating mutations of the CASR gene, causing the parathyroid cells to sense that serum calcium is "elevated" when it is actually normal.²⁹ There is a resulting suppression of PTH secretion (even though it remains within the reference range), enhanced urinary Ca^{++} secretion, hypomagnesemia, and increased fractional excretion of magnesium. More than 70 activating mutations have been reported in autosomal dominant hypoparathyroidism, and both familial cases and sporadic cases with de novo mutations have been described.³⁰

Familial Isolated Hyperparathyroidism. FIHP (OMIM #146200) is a heterogeneous condition, and some kindreds thought to have this disease have been shown to have germline mutations of *MEN1*, *CASR*, *CDC73*, and *CDKN1B* suggesting that the disease represents incompletely expressed forms of *MEN1*, FHH, or the HPT-JT.³¹ Over 100 families with FIHP have been reported, and in most cases the causative genetic mutation is unknown although there are convincing data that it resides on chromosome 2p13.3-14.³²

Hyperparathyroidism-Jaw Tumor Syndrome. HPT-JT (OMIM #145001) is characterized by the autosomal dominant occurrence of hyperparathyroidism, ossifying fibromas of the mandible or maxilla, renal cysts or solid tumors, and uterine fibromas.³³ Approximately 50 families with HPT-JT have been reported, and 80 percent of patients have hyperparathyroidism. In 15% of patients with HPT-JT, the parathyroid tumors are malignant. It is noteworthy that the age-related penetrance of HPT-JT is approximately 40% by age 40 years in contrast to *MEN1* where the age-related penetrance is 98% by age 40.³⁴ Members of kindreds with this disease need lifelong surveillance by physical examination and biochemical evaluation. It has even been suggested that serial ultrasound examination of the neck should be performed beginning at a young age as parathyroid carcinoma has been reported in normocalcemic family members.³⁵

Inactivating mutations of the *HRPT2* tumor suppressor gene, also known as *CDC73*, causes HPT-JT. The gene is located on chromosome 1q25-q31 and codes for the 531 amino acid tumor suppressor protein, parafibromin (named for parathyroid tumors and jaw fibromas).³⁶ The function of parafibromin is unknown but it is thought to regulate posttranscriptional events and histone modification. There is recent evidence that parafibromin has proapoptotic activity, important as a tumor suppressor function.³⁷

The *CDC73* gene consists of 17 exons, and the mutations are scattered throughout the coding region, with the majority resulting

in functional loss through premature truncation.³⁸ Approximately 100 germline and somatic mutations of *CDC73* have been identified but there are no "hot spot" mutations and no relationship between genotype and phenotype.³⁹ Germline *CDC73* mutations occur in the majority of patients with the HPT-JT, and surprisingly they also occur in 20% of patients with apparently sporadic parathyroid carcinomas. Somatic *CDC73* mutations have been detected in 50% to 100% of patients with sporadic parathyroid carcinoma.^{40,41} Mutations in *CDC73* are rarely seen in sporadic parathyroid adenomas, an important diagnostic finding distinguishing benign from malignant parathyroid tumors.^{37,42}

The Pituitary Gland

Familial Isolated Pituitary Adenomas. Approximately 5% of pituitary tumors occur in a familial pattern. Familial isolated pituitary adenomas (FIPA [OMIM #102200]) is an autosomal dominant disease characterized by the occurrence of at least two cases of pituitary tumors in a family that has no features of *MEN1* or the Carney complex.⁴³ In a study of 64 families with FIPA, 55 of 138 affected family members had prolactinomas, 47 had somatotropinomas, 28 had nonsecreting adenomas, and eight had adrenocorticotrophic hormone-secreting tumors.⁴⁴ There are two equally occurring phenotypes, where families are either homogenous, expressing the same type of pituitary tumors, or heterogeneous, expressing different types of pituitary tumors. In heterogeneous families, prolactinomas exhibit more aggressive behavior, compared to their sporadic counterparts, with higher rates of subsella expansion and cavernous sinus invasion. Conversely, somatotropinomas are more aggressive in the homogenous setting.

Germline mutations in the *aryl hydrocarbon receptor interacting protein (AIP)* gene occur in 20% (range 15% to 40%) of patients with FIPA; however, in the remainder, the causative gene is unknown.⁴⁵ The *AIP* gene consists of six exons encoding a 330 amino acid (37 kDa) cytoplasmic co-chaperone phosphoprotein (XAP2).⁴⁶ The gene is located at 11q13, which is 2.7 Mb downstream from the *MEN1* gene. *AIP* forms a complex with the aryl hydrocarbon receptor and two 90-kD heat-shock proteins (HSP90). The aryl hydrocarbon receptor is a ligand-activated transcription factor and also participates in cellular signaling pathways.⁴⁷ The mean age at diagnosis is 13 years earlier in *AIP*-positive FIPA families compared to *AIP*-negative families, and the majority of patients in *AIP*-positive families are male, where there is equal gender balance in *AIP*-negative families. The pituitary tumors in *AIP*-positive patients are large, frequently invade surrounding structures, and respond poorly to somatostatin analogues.^{48,49}

Multiple Endocrine Neoplasia Type 2

Multiple Endocrine Neoplasia Type 2A and Multiple Endocrine Neoplasia 2B

Clinical Features. In 1968, Steiner and associates described a large family with medullary thyroid carcinoma (MTC), pheochromocytomas (PHEO), hyperparathyroidism (HPTH), and Cushing syndrome.⁵⁰ The disease was named MEN type 2, and we now it as MEN2A. Until recently, there were three related syndromes of hereditary MTC: MEN2A (OMIM #171400), MEN2B (OMIM #162300), and familial MTC (FMTC) (OMIM #155240).^{51,52} Most endocrinologists now feel that FMTC represents a variant of MEN2A and should not stand alone as a disease entity. It has recently been suggested that there be two MEN2 syndromes: MEN2A and MEN2B. In addition, within MEN2A, it has been suggested that there be four variants: classical MEN2A, MEN2A with Hirschsprung disease, MEN2A with cutaneous lichen amyloidosis, and FMTC.⁵³

Of patients with hereditary MTC, 95% have MEN2A and 5% have MEN2B. Virtually all patients with these syndromes develop MTC, and up to half of the patients with MEN2A and MEN2B

develop PHEOs. The PHEOs are almost always benign and confined to the adrenal gland. Patients with a unilateral PHEO usually develop a contralateral PHEO within 10 years.⁵⁴ Prior to the development of biochemical and genetic test to establish the early diagnosis of hereditary MTC, PHEO, not MTC, was the most common cause of death in patients with MEN2A.⁵⁵ Approximately 30% of patients with MEN2A develop HPTH, which is usually mild and asymptomatic.

Patients with MEN2B have a typical physical appearance with a Marfanoid habitus and atypical facies. They also have a generalized ganglioneuromatosis and ocular and skeletal abnormalities.

MTC originates from the neural crest-derived C-cells. The MTC cells secrete the polypeptide hormone calcitonin (CTN) and the glycoprotein carcinoembryonic antigen. Serum levels of CTN and carcinoembryonic antigen are excellent tumor markers, most useful in detecting persistent or recurrent disease following thyroidectomy for MTC. The most effective therapy for MTC is thyroidectomy, preferentially performed before MTC develops or while it is still confined to the thyroid gland.

Molecular Genetics of MEN2A and MEN2B. In 1985, Takahashi and associates discovered the *RET* (REarranged during Transfection) protooncogene.⁵⁶ The gene is located in the pericentromeric region of chromosome 10q11.2 and includes 21 exons. *RET* encodes a receptor tyrosine kinase, which is expressed in

neuroendocrine cells (including thyroid C cells and adrenal medullary cells), neural cells (including parasympathetic and sympathetic ganglion cells), urogenital tract cells, and branchial arch cells. *RET* is essential for the development, survival, and regeneration of neuronal cells in the gut, the kidney, and the nervous system.

The *RET* gene has an extracellular portion containing four cadherin-like repeats, a calcium binding site and a cysteine-rich region, a transmembrane portion, and an intracellular portion containing two tyrosine kinase domains.⁵³ Alternate splicing of *RET* produces three isoforms with either 9, 43, or 51 amino acids at the C terminus, referred to as *RET9*, *RET43*, and *RET51*.^{57,58} Mice lacking *RET51* are normal; however, mice lacking *RET9* have renal malformation and defects in innervation of the gut.⁵⁹ *RET51* and *RET9* have transforming activity but *RET51* is the stronger of the two.

A tripartite complex is necessary for *RET* signaling. One of four glial-derived neurotrophic factors (GDNF) family ligands; GDNF, neurturin, persephin, or artemin binds *RET* in conjunction with one of four glycosylphosphatidylinositol-anchored co-receptors, designated GDNF family receptors (GFR): GFR- α 1, GFR- α 2, GFR- α 3, or GFR- α 4.⁶⁰⁻⁶² The GDNF family ligand-GFR complex causes dimerization of *RET* with activation of autophosphorylation and intracellular signaling. The molecular pathways associated with activation of the *RET* protooncogene are shown in Fig. 81.2.⁵³

MEN2A and MEN2B are caused by mutations in the *RET* protooncogene; the most common are shown in Fig. 81.3.^{63,64} In

Figure 81.2 The RET protein. The position of major RET phosphorylation sites (Y905, Y1015, and Y1062) are marked, as are other phosphorylation sites and signaling pathways. SP, signal peptide; CLD, cadherin-like domains; CRD, cysteine-rich domain; TM, transmembrane domain; TK, tyrosine kinase domain; Ki, kinase insert region; GFR α (1-4), GDNF family alpha receptors; GFL, glial derived neurotrophic factor family ligands; GDNF, glial derived neurotrophic factor; NTN, neurturin; ART, artemin; PSP, persephin. (Reproduced from Wells SA Jr, Pacini F, Robinson BG, et al. Multiple endocrine neoplasia type 2 and familial medullary thyroid carcinoma: an update. *J Clin Endocrinol Metab* 2013;98:3149-3164, Figure 1, Copyright 2013; With permission from the Endocrine Society, <http://jcem.endojournals.org/site/author/itoa.xhtml>.)

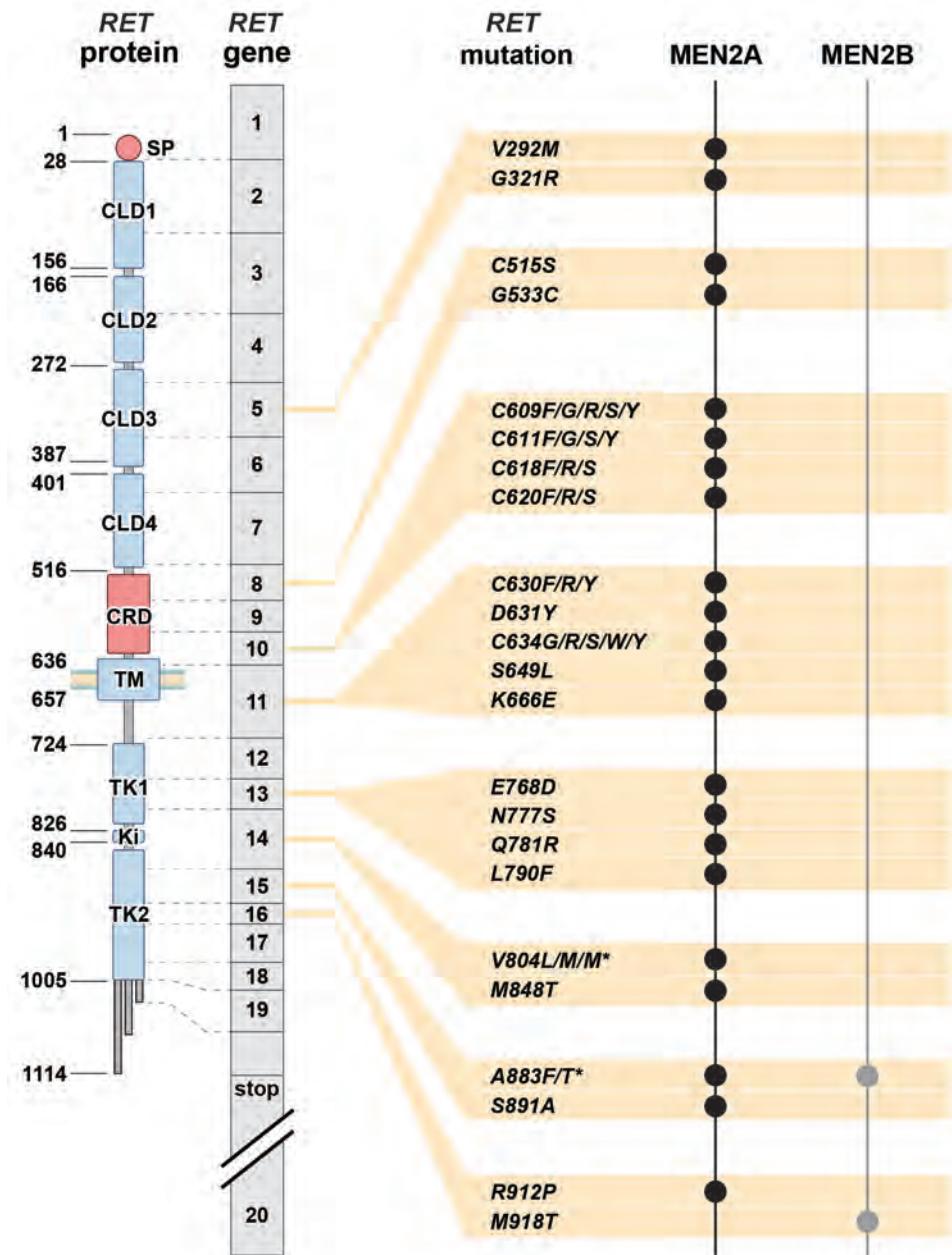

Figure 81.3 The *RET* gene, the RET protein, and *RET* point mutations associated with MEN2A, MEN2B, and FMTC. RET gene structure with coding exons numbered 1–20 is shown as the central figure in gray. Alternative splicing in exon 19 generates two alternative mRNAs, coding for RET-51 (1,114 residues) when exon 19 is spliced to exon 20, or RET-9 (1,072 residues), when exon 19 remains unspliced. Moreover, alternative splicing to a further exon (exon 21) causes the synthesis of the C-terminal part of another less abundant RET isoform, RET-43. In this figure, only RET-51 is represented, while RET-9, RET-43 and the alternative exon 21 are not. The RET protein is represented on the left in blue and red. Amino acid residues, numbered 1–1,114, are shown to the left of the figure. The extracellular RET domain (with the signal peptide [SP], four cadherin-like domains [CLD1–4], and a cysteine-rich domain [CRD]), the transmembrane domain (TM), and the intracellular tyrosine kinase domain (TK) are represented. The RETTK is split into two subdomains (TK1 and TK2) by an insert region (Ki). The positions of reported *RET* point mutations associated with MEN2A, MEN2B, and FMTC are shown to the right of the *RET* gene. The mutations causing MEN2A and MEN2B are shown in black, whereas the mutations for FMTC are shown in red. An asterisk denotes homozygous mutations. Some of the reported RET mutations have no function studies demonstrating that the specific mutation is a bona fide gain-of-function mutation. (Modified from Figure 5 in de Groot JW, Links TP, Plukker JT, et al. RET as a diagnostic and therapeutic target in sporadic and hereditary endocrine tumors. *Endocr Rev* 2006; 27:535–560.)

approximately 50% of patients with MEN2B and 10% of patients with MEN2A, the *RET* mutation arises de novo and virtually always from the paternal allele. Furthermore, in MEN2B there is a gender preference such that the first offspring of transmitting males is almost always an affected female.⁶⁵

In patients with MEN2A, there is a correlation between genotype and phenotype. In 98% of patients with MEN2A, mutations occur in *RET* codons 609, 611, 618, 620, and 634. *RET* codon 634 accounts for 80% of mutations in MEN2A. The frequency of PHEO depends on the *RET* codon mutation: (634 [50%], 609 [4% to 26%], 611 [10% to 25%], 618 [12% to 23%], and 620 [13% to 24%]).^{66,67} A *RET* codon 634 mutation is associated with a 30% incidence of HPTH; however, the frequency ranges between 2% and 10% in patients with mutations in *RET* codons 609, 611, 618, and 620.⁶⁸ Patients with MEN2A may also develop cutaneous lichen amyloidosis, which is almost always associated with a *RET* codon 634 mutation.⁶⁹ Less commonly, patients with MEN2A develop Hirschsprung disease, which is associated with *RET* codon mutations in exon 10: 609 (15%), 611 (5%), 618 (30%), and 620 (50%).⁷⁰

Approximately 95% of patients with MEN2B have mutations in *RET* codon M918T, and most of the remainder have mutations in *RET* codon A833F.^{71,72} Rarely, patients with MEN2B have double mutations appearing in tandem on the same allele involving *RET* codon V804M and either codon Y806C, S904C, E805K, or Q781R. The MEN2B syndrome in patients with these double mutations is atypical, and MTC presents at a later age than in patients with typical MEN2B.^{73–76} Approximately half of the patients with sporadic MTC have a somatic *RET* M918T mutation, which it appears is associated with a more aggressive clinical phenotype.⁷⁷ Recently, it was discovered that the majority of patients with sporadic MTC who have no somatic *RET* mutations have somatic mutations of *HRAS*, *KRAS*, or rarely *NRAS*.⁷⁸ There is no indication that the presence of somatic RAS mutations is associated with a pattern of clinical behavior of the MTC.

Of patients with presumed sporadic MTC, 7% will be found on direct DNA analysis to have germline *RET* mutations, characteristic of MEN2A, meaning that they and their first-degree relatives should be evaluated for the presence of all components of this syndrome.⁷⁹

APPLICATION OF MOLECULAR GENETICS TO CLINICAL MEDICINE

The discovery that mutations in the *RET* protooncogene cause MEN2A, MEN2B, and FMTC changed the management of patients with both sporadic and hereditary MTC and represents a paradigm for personalized genomic medicine.

Prophylactic Thyroidectomy

In patients with MEN2A and MEN2B who are shown to have inherited a mutated *RET* allele, it is important to remove the thyroid before MTC develops or while it is still confined to the gland.⁸⁰ The question in family members with hereditary MTC who have inherited a mutated *RET* allele is not whether the thyroid gland should be removed but at what age? At the MEN Consortium Meeting in 2000, a consensus panel evaluated the relationship between the *RET* codon mutation and the biologic aggressiveness of hereditary MTC.⁸¹ Based on combined clinical data, the panel defined three levels of thyroid cancer severity on which to base the timing of thyroidectomy. Subsequently, three professional organizations published guidelines defining the management of patients with MEN2A and MEN2B, including the timing of recommended thyroidectomy in patients who had inherited a mutated *RET* allele.^{82–84} Generally, the

recommendations among the groups were similar and the timing of thyroidectomy was based on the clinical aggressiveness of patients with a specific *RET* mutation. This was not a problem for patients with some mutations. For example, patients with *RET* M918T mutations, which occur in the large majority of patients with MEN2B, should have thyroidectomy as soon as the diagnosis is established, even in the first months of life. Also, patients with MEN2A who have mutations in codon 634 have an aggressive MTC and the thyroid should be removed at or before 5 years of age. Decisions regarding thyroidectomy in patients with other *RET* mutations are based on knowledge of behavior of MTC in the patient's family, or in other families with the same *RET* mutation, or more importantly on measurements of basal or stimulated serum CTN levels.

Molecular Targeted Therapeutics

There has been no effective therapy for patients with locally advanced or metastatic MTC, as single-agent or combined chemotherapy has been characterized by low response rates of short duration.⁸⁵ With the discovery that the MTT imatinib induced striking and prolonged remissions in patients with chronic myelogenous leukemia, it was hoped that similar therapeutics would be developed for solid tumors, including thyroid cancer, where the specific mutated gene was known and druggable.⁸⁶ In phase 2 clinical trials the MTT vandetanib, known to inhibit RET and vascular endothelial growth factor receptors, showed significant clinical activity in patients with advanced MTC.^{87,88} In a subsequent phase 3 prospective, randomized, clinical trial of patients with locally advanced or metastatic MTC, vandetanib induced significant progression-free survival compared to placebo.⁸⁹ Based on the trial the US Food and Drug Administration (FDA) approved vandetanib for the treatment of patients with advanced MTC. Subsequently, also based on results of a phase 3 clinical trial, the FDA approved the MTT cabozantinib for the treatment of patients with advanced MTC.⁹⁰ Despite the fact that these drugs have shown efficacy in the treatment of advanced MTC, most patients in time become resistant to the drug, and their disease progresses. Hopefully, an understanding at the molecular level of mechanisms of resistance to various MTTs will provide the basis for the development of promising regimens of combinatorial therapy.

THYROID CARCINOMAS

Papillary Thyroid Carcinoma

Malignant tumors of the thyroid gland have a great range of biologic behavior, ranging from the relatively slow-growing papillary thyroid carcinoma (PTC) and follicular thyroid carcinoma (FTC) to the highly aggressive anaplastic thyroid carcinoma (ATC). Over the last three decades, it has become clear that mutations or chromosomal rearrangements in the mitogen-activated-protein kinase (MAPK) and the phosphatidylinositol 3-kinase (PI3K)/protein kinase B pathways cause the most common forms of thyroid cancer (Fig. 81.4). For example, mutually exclusive activating mutations of *HRAS*, *KRAS*, *NRAS*, or *BRAF*, or chromosomal rearrangements of genes encoding *RET* (*RET/PTCs*) or *NTRK1* (*TRK-Ts*) occur in 70% of patients with PTC.⁹¹ The most common mutation, *BRAF*^{V600E}, occurs in approximately 50% of patients with PTC and is most common in patients with classic PTC (60%) and the tall cell variant of PTC (90%). The mutation also occurs in poorly differentiated thyroid carcinomas and ATCs, derived from PTC. Mutations in *HRAS*, *KRAS*, or more commonly *NRAS* occur in 25% of FTCs, 15% of PTCs (almost always the follicular variant of PTC), and 5% of follicular adenomas.⁹² Mutations in

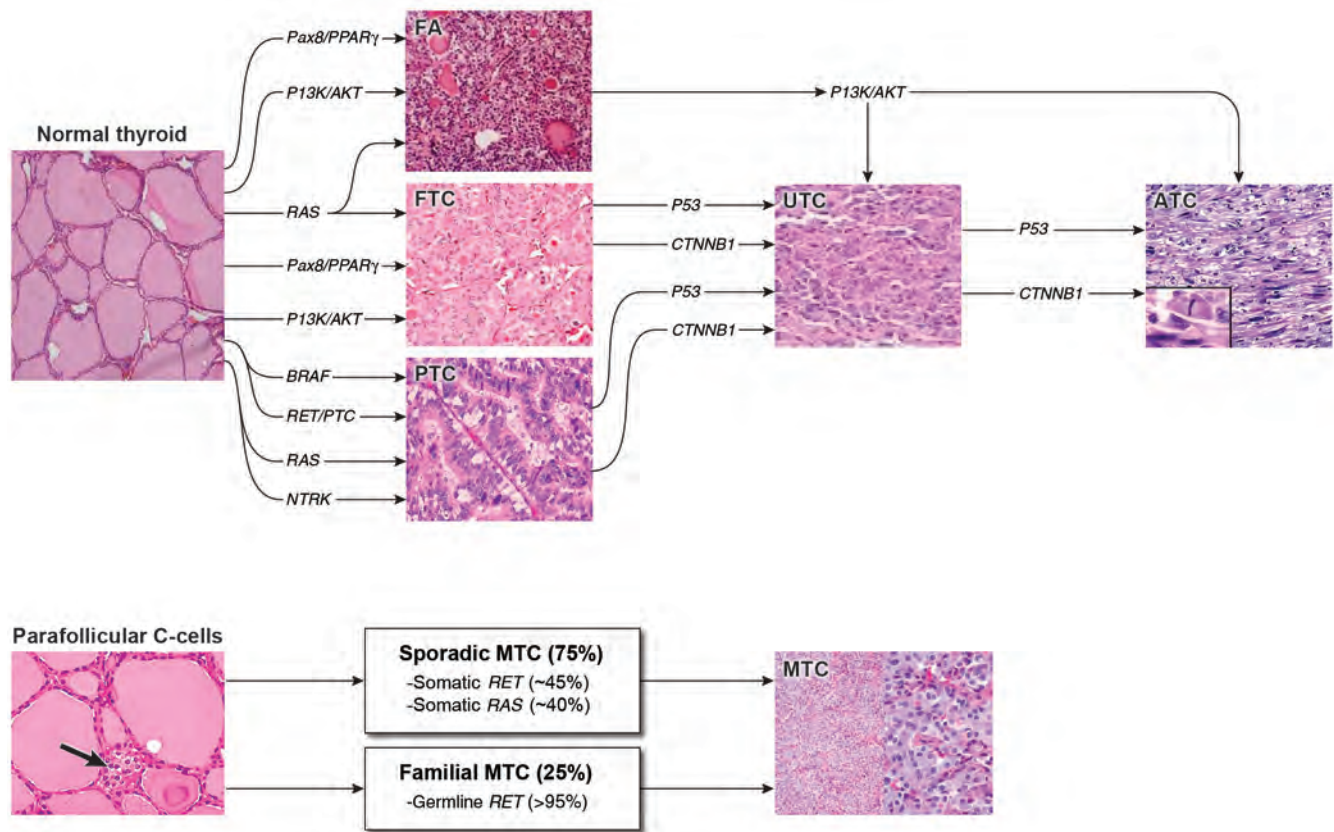

Figure 81.4 Subtypes of thyroid neoplasms, either arising from follicular (*top*) or parafollicular (*bottom*) cells are depicted together with genes bearing the most prevalent oncogenic driving lesions (see text for details). FA, follicular adenoma; FTC, follicular thyroid carcinoma; PTC, papillary thyroid carcinoma; UTC, undifferentiated thyroid carcinoma; ATC, anaplastic thyroid carcinoma; MTC, medullary thyroid carcinoma. Arrow: area of parafollicular thyroid C cells. (Reproduced from Wells SA Jr, Sanoto M. Update: the status of clinical trials of kinase inhibitors in thyroid cancer. *J Clin Endocrinol Metab* 2014;99:1543–1555, Figure 1, Copyright 2013; With permission from the Endocrine Society, <http://jcem.endojournals.org/site/author/itoa.xhtml>.)

p53 and *CTNNB1* (B-catenin) occur commonly in patients with poorly differentiated thyroid carcinoma and ATC.⁹³

The first chromosomal rearrangement associated with thyroid cancer was described in 1985 with the discovery of the *RET* protooncogene.⁵⁶ In 1987, Fusco and associates demonstrated that approximately 30% of PTCs have a chromosomal translocation, resulting in the fusion of the C-terminal *RET* tyrosine kinase-encoding domain to the promoter and N-terminal portion of unrelated genes.⁹⁴ The creation of these heterologous partners results in the illegitimate expression of a constitutively active chimeric oncogene termed *RET/PTC*. Subsequently, more than 15 molecular fusion oncogenes in PTCs have been identified, all of which differ according to the 5'-terminal region of the heterologous gene (Fig. 81.5).⁹⁵ The most common of these chimeric oncogenes are *H4 (CCDC6)-RET*, also known as *RET/PTC1* (60% to 70%), and *ELE1-RET*, also known as *RET/PTC3* (20% to 30%). The prevalence of *RET/PTC* in the thyroid cancers of children is >50%; in youngsters in Kiev and Belarus who developed PTC following exposure to radiation from the Chernobyl accident, the prevalence of such rearrangements is 67% to 87%.^{96,97}

There have been several clinical trials of MTTs in patients with differentiated thyroid carcinoma. Most of the drugs have targeted *BRAF*^{V6003} and have induced partial remissions (modified RECIST) ranging from 0% to 60%.^{98,99} A phase 3 prospective, randomized, clinical trial of sorafenib, compared to placebo, was conducted in patients with progressive, locally advanced or metastatic,

and ¹³¹I refractory differentiated thyroid carcinoma. Based on significantly improved progression-free survival in patients receiving sorafenib compared to placebo, the FDA approved the drug for the treatment of patients with advanced PTC.¹⁰⁰

Follicular Thyroid Carcinoma

The peroxisome proliferators-activated receptor- γ (PPAR- γ), a member of the steroid-nuclear hormone receptor superfamily, is encoded by *PPARG* located on 3p25. Rearrangements involving the thyroid-specific transcription factor paired-box gene 8 (*PAX8*) with the peroxisome proliferators-activated receptor- γ (PPAR- γ) were first identified in FTC as a cytogenetically detectable translocation t (2,3)(q13; p25).¹⁰¹ The *PAX8-PPAR γ* appears to be confined to atypical follicular adenomas and FTC, and has not been detected in PTC or either poorly differentiated or undifferentiated (anaplastic) thyroid carcinomas. In an evaluation of 88 conventional follicular and Hürthle cell tumors analyzed for *RAS* mutations and *PAX8-PPAR γ* re-arrangements, 49 percent of FTC had *RAS* mutations, 36 percent had *PAX8-PPAR γ* rearrangements, and one had both. *RAS* mutations occurred in almost half of the follicular adenomas, and *PAX8-PPAR γ* translocations were present in only 4%. Overt tumor invasiveness was associated with *PAX8-PPAR γ* translocations and not *RAS* mutations.¹⁰²

Even though there have been significant advances with MTTs in the treatment of patients with differentiated thyroid

carcinomas and MTCs, virtually all patients become resistant to the therapy, develop progressive disease, and die. It is hoped that new single-agent therapeutics will improve survival beyond what has been achieved with the current drugs, but clinical investigators need to focus attention on the development of combinatorial therapies based on molecular studies of tumor cells in vitro and in vivo. There have already been examples of successful combined therapies, such as the demonstrated effectiveness of combined imatinib and nilotinib in the treatment of patients with imatinib-refractory blast phase chronic myelogenous leukemia who were initially unresponsive to, or intolerant of, either agent alone.^{103,104}

FUTURE DIRECTIONS

Advances in molecular genetics have elucidated the oncogenic event(s) of many solid tumors; this is nowhere more evident than in endocrine tumors. The discovery of the mutations causing MEN1 and MEN2 has been most important as it has led to an understanding of the pathogenesis, not only of the component hereditary tumors but their sporadic counterparts as well. These discoveries have already been of great benefit in the diagnosis and treatment of patients with endocrine tumors, as evidenced most clearly in families with hereditary MTC.

Another therapeutic benefit of the molecular research has been the identification of molecular targets for MTTs. Recently, prospectively randomized placebo controlled trials have been completed in patients with differentiated thyroid carcinoma and MTC. With the demonstration of progression-free survival in treated patients, compared to controls, in each of these trials, the FDA approved the drugs for the treatment of patients with advanced thyroid cancer, a stage of disease for which there had been no effective therapy. The use of MTTs for the treatment of patients with endocrine tumors will expand with the introduction of new more potent compounds and with the design of effective combinatorial regimens.

82 Thyroid Tumors

Caroline J. Davidge-Pitts and Geoffrey B. Thompson

ANATOMY AND PHYSIOLOGY

The name “thyroid” is derived from the Greek term “shield-shaped,” which was first introduced by Thomas Wharton in 1656 due to the shape of the nearby thyroid cartilage. The thyroid is one of the largest endocrine organs weighing between 10 and 25 g. This bilobed gland is derived from foregut endoderm that finds its final position in the anterior neck after fusion with the ventral aspect of the fourth ventral pouch. The thyroglossal duct is formed during the thyroid’s caudal descent into the neck, a canal between the gland and the pharyngeal floor. The duct subsequently undergoes degeneration, leaving behind the foramen cecum at the base of the tongue. The distal duct differentiates into thyroid tissue that becomes the pyramidal lobe. Parafollicular or C cells are derived from neural crest cells in the ultimobranchial body that fuse with the thyroid diverticulum during the descent into the neck. By gestational age 18 to 20 weeks, thyroid hormone is produced.

The thyroid is made up of two lobes, connected by the isthmus. Each lobe is approximately 2 cm thick and 4 cm in length, although the right lobe may be larger than the left. The gland is made up of follicular cells arranged in a spherical manner (follicles) that are filled with a proteinaceous substance called colloid. The principle function of the thyroid gland is to produce thyroid hormone (thyroxine [T₄] and 3,5,3'-triiodothyronine [T₃]), which is synthesized by the follicular cells. Production of thyroid hormone by the thyroid gland is controlled by thyrotropin-stimulating hormone (TSH) secreted from the anterior pituitary in response to thyrotropin-releasing hormone secreted by the hypothalamus. C cells are found in the thyroid interstitium surrounding the follicles, and secrete calcitonin. Additional cells within the thyroid include lymphocytes, fibroblasts, and adipocytes.

The thyroid is a very vascular gland (Fig. 82.1), with the right lobe exhibiting more vascularity than the left. Arterial supply is from the superior and inferior thyroid arteries. The thyroid drains into the superior, middle, and inferior thyroid veins through a venous plexus on the surface of the gland. These veins then drain into the internal jugular and innominate veins. The thyroid is innervated by the middle and inferior cervical ganglia of the sympathetic nervous system.

THYROID NODULES

A thyroid nodule is defined as a discrete lesion in the thyroid gland that is radiologically distinct from the surrounding parenchyma.¹ Thyroid nodules are very common in the general population, ranging from 20% to 76%. Nodules discovered at autopsy typically reflect this prevalence.² Nodules are more common with increasing age, particularly in women.¹ Up to 90% of women older than 70 years and 60% of men older than 80 years have thyroid nodules. Other risk factors include radiation exposure, particularly during childhood, family history of thyroid nodules, and iodine deficiency. Nodules may also occur in the setting of Hashimoto disease, where chronic inflammation leads to destruction of the

thyroid gland with a rise in TSH in response to reduction in thyroid hormone. This rise in TSH stimulates growth of thyroid cells, forming nodules.

Thyroid nodules may be discovered by palpation during a physical exam in 3% to 7% of patients.^{3,4} Nodules may also be found incidentally on imaging studies such as neck ultrasounds, computed tomography (CT) scans, and deoxy-2[¹⁸F]fluoro-d-glucose positron emission tomography (¹⁸FDG-PET) scans performed for unrelated reasons. Risk of malignancy is the same in nodules discovered by palpation and those discovered incidentally.⁵

The proportion of thyroid nodules that prove to be malignant is 10% to 15%.⁶ Part of determination of malignancy is evaluation of individual risk assessment, which includes a detailed history and examination. Patients with the following histories may be at increased risk for malignancy:

1. Age. Patients age >70 years and <14 years have increased risk of malignancy.⁷ Nodules discovered during childhood have a three- to four-fold higher risk of malignancy than adults.⁸
2. Head and neck radiation, particularly during childhood. Nodules carry a 33% to 37% chance of malignancy.⁹
3. ¹⁸FDG-PET–positive lesion. See “Incidental ¹⁸FDG-PET Positive Lesions.”
4. Family history of thyroid cancer, particularly first-degree relatives.
5. Personal history of genetic syndromes commonly associated with thyroid cancer (multiple endocrine neoplasia 2, familial papillary thyroid cancer, familial polyposis coli, Gardner syndrome, and Cowden disease; Table 82.1).
6. Physical examination findings of a fixed, hard, solid nodule, cervical lymphadenopathy, and vocal cord paralysis.

In addition to history and physical examination, a TSH level should be performed on discovery of a thyroid nodule. If the TSH is suppressed, then a radionuclear thyroid scan should be performed to ascertain whether the nodule is hyperfunctioning. Hyperfunctioning nodules are rarely malignant; therefore, further cytologic evaluation is not needed if the patient’s risk profile is otherwise low.⁷ It is generally accepted that if a cold nodule is present on radionuclear thyroid scan, cytologic assessment is performed. If the TSH is in the upper range of normal, there may be an increased risk of malignancy,¹⁰ although this association is poorly understood.

Routine measurement of calcitonin is controversial but is supported by the European Thyroid Association.¹¹ The American Thyroid Association (ATA) cannot recommend for or against routine testing of calcitonin.¹ It seems reasonable to perform, however, if there is a history of familial medullary thyroid cancer (MTC) as measurement may provide earlier diagnosis and more focused operative management.

A real-time two-dimensional, high-resolution ultrasound of the neck should be performed if thyroid nodules are discovered or suspected. Certain features may help distinguish benign from malignant lesions, although these signs are not independently predictive. These features include presence of microcalcifications, nodular hypoechogenicity, irregular borders, nodular vascularity, and a nodule that is taller than wide on transverse view.¹ Purely

Figure 82.1 The thyroid gland and its arterial supply. (Drs. L.J. Rizzolo and W.B. Stewart, Section of Anatomy, Department of Surgery, Yale University School of Medicine, are acknowledged for providing the figure. With permission from Springer, Berlin-Heidelberg-New York.)

cystic nodules are likely to be benign.¹² Solitary nodules may not have a higher malignant risk than a nodule embedded in a multinodular goiter^{13,14}; however, this still remains controversial.

Fine needle aspiration (FNA) is a very sensitive, low-risk procedure to help distinguish benign from malignant nodules.

According to the Mayo Clinic experience from 1979 to 1990, FNA reduced the proportion of operations for benign nodules by 50% and increased detection of malignancy.¹⁵ The nondiagnostic rate is lower when performed in conjunction with neck ultrasound. Accuracy of the FNA will rely on an experienced team, and the cytopathologist should have an interest in thyroid disease. The ATA and American Association of Clinical Endocrinologists have provided guidelines to help clinicians decide which nodules require biopsy. Generally, routine FNA is recommended if the nodule is >1 cm with solid, hypoechoic features. Smaller nodules should also be considered for FNA if the nodule has suspicious features as described previously or if the patient has risk for thyroid cancer based on history or physical examination. The cytopathology may be reported as benign (60% to 80%), malignant (3.5% to 10%), suspicious for papillary thyroid cancer (2.5% to 10%), suspicious for follicular lesion/neoplasm or indeterminate (10% to 20%), and nondiagnostic (10% to 15%).⁷ Follicular or Hürthle cell adenomas and carcinomas appear identical on cytologic examination. Malignancy is found in approximately 20% of these neoplasms. Capsular or vascular invasion seen in the surgical specimen needs to be present for diagnosis of follicular or Hürthle cell carcinoma (HCC).

The use of genetic markers could help improve diagnostic accuracy of indeterminate lesions.^{16,17} Many centers now use these markers routinely to help guide management of indeterminate lesions, particularly in patients who do not want to undergo surgery. If the molecular profile suggests a low rate of malignancy (<5%), then observation may be recommended over surgical intervention.¹⁸ Long-term follow up studies are still needed before this technology is widely adopted.

Figure 82.2 shows the evaluation of thyroid nodule in a euthyroid patient based on FNA results. Benign nodules can be followed conservatively by physical examination or ultrasound, unless there are compressive symptoms such as dysphagia or respiratory compromise, at which time surgical management should be considered. Lesions suspicious for follicular or Hürthle cell neoplasm typically are treated at Mayo Clinic with thyroid lobectomy and intraoperative frozen section. If the lesion is benign, no further thyroid resection is needed. If the lesion is malignant, completion thyroidectomy is performed. Molecular profiling can also be used to guide management decisions as described previously.

TABLE 82.1

Clinical and Genetic Characteristics of Familial Thyroid Follicular Cell Carcinoma Susceptibility Syndromes

Syndrome	Chromosome Linkage/Gene	Characteristics
Papillary thyroid carcinoma with papillary renal neoplasia	1q21/?	Associated with papillary renal neoplasia Autosomal dominant with partial penetrance
Familial nonmedullary thyroid carcinoma	2q21/? and 19p13/?	Two genetic loci identified Autosomal dominant with partial penetrance
Familial thyroid tumors with cell oxyphilia	19p13.2/?	Characteristic oxyphilic cells Autosomal dominant with partial penetrance
Familial adenomatous polyposis	5q21–22/APC	Papillary thyroid carcinoma with ~10× increased prevalence Colorectal carcinoma, ampullary carcinoma, hepatoblastoma, medulloblastoma Autosomal dominant
Cowden disease (multiple hamartoma syndrome)	10q23.3/PTEN	Follicular and papillary thyroid carcinoma Multiple hamartomas, breast and endometrial cancer Autosomal dominant
Carney complex 1	17q/PRKAR1A	Follicular and papillary thyroid carcinoma Skin pigmentation, and cardiac, endocrine, cutaneous, and neural myxomatous tumors Autosomal dominant

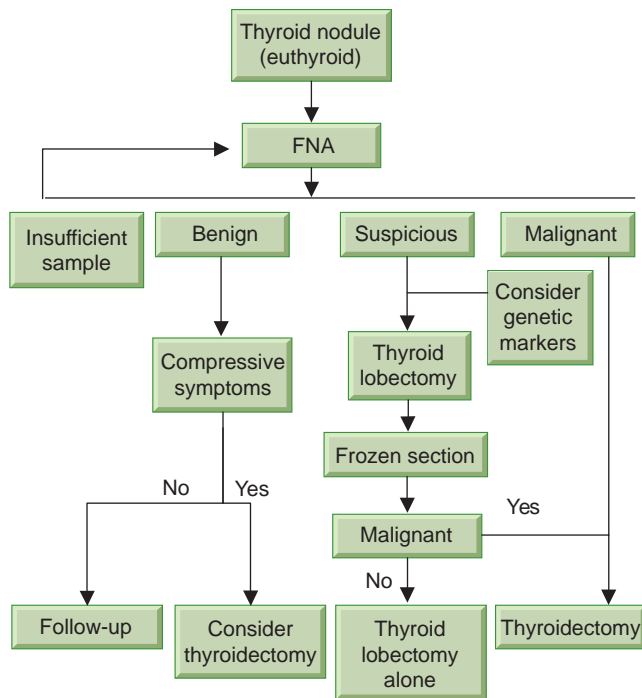

Figure 82.2 Flow diagram for the evaluation of thyroid nodule based on the results of fine needle aspiration (FNA) biopsy.

Nondiagnostic specimens require repeat FNA, particularly if there are suspicious features on ultrasound. Repeated nondiagnostic FNAs may lead to surgical excision in order to obtain a diagnosis. Malignant lesions will be discussed in the chapter to follow.

Incidental ^{18}F FDG-PET Positive Lesions

Fluorodeoxyglucose whole-body positron emission tomography is frequently used in oncology to evaluate and follow-up malignancies. High concentrations of ^{18}F FDG occur in most malignant tumors; however, high glucose uptake may also be nonspecific. Normal thyroid tissue has diffuse, low accumulation of ^{18}F FDG. Incidental focal increased uptake in the thyroid may occur and has been reported in 1.1% of ^{18}F FDG-PET imaging in a recent series.¹⁹ Both primary and secondary thyroid malignancies have increased metabolic activity including lymphoma; therefore, an ^{18}F FDG-PET-positive solitary thyroid lesion has increased risk of malignancy of approximately 30% to 50%^{19–22} compared to the 5% risk of malignancy of an incidental thyroid nodule found by other imaging. Therefore, solitary ^{18}F FDG-PET-positive thyroid lesions should be referred for ultrasound-guided FNA to exclude a primary or metastatic lesion in the thyroid. Hot nodules have also been reported to have increased ^{18}F FDG uptake; therefore, if the TSH is suppressed, further imaging with a thyroid uptake and scan may be indicated. Some studies have advocated the use of maximum standardized uptake value to differentiate benign from malignant lesions^{20,21,23,24}; however, this approach has not been supported by all studies.^{19,25} Diffuse thyroid uptake that does not correlate to a lesion on CT or ultrasound may be seen in autoimmune thyroid disease such as Hashimoto²⁶ or Graves thyroiditis,²⁷ and often do not require further evaluation unless other risk factors for malignancy are present.

Malignancies of the Thyroid

Risk Factors for Thyroid Malignancy

Although many risk factors have been evaluated in thyroid cancer, few clear associations have been found. Exposure to radiation,

particularly in childhood, is associated with an increased risk of well-differentiated thyroid cancer.⁹ Relative risk is related to exposure dose, starting as low as 0.1 Gy.⁹ The latency period after childhood exposure is at least 3 to 5 years, and the risk remains apparent even 40 years after the radiation exposure.⁹ The majority of cases occur between 20 and 40 years after exposure. However, even after 40 years, the relative risk as compared to a nonirradiated population is still increased. In addition to those who are exposed to radiation for medical reasons, patients who have been exposed to nuclear disasters or who are atomic bomb survivors are also at increased risk for thyroid cancer. On the other hand, ^{131}I for treatment of positive thyroid scans or hyperthyroidism has not been associated with this risk.

Family history is also an important risk factor, particularly if well-differentiated cancer is present in first-degree relatives²⁸ or there is a family history of thyroid cancer syndromes as mentioned previously (see Table 82.1). MTC is also associated with distinct familial syndromes, which will be discussed in more detail later in the chapter.

The only known risk factor for thyroid lymphoma is Hashimoto's thyroiditis,²⁹ particularly the non-Hodgkin lymphoma derived from mucosa-associated lymphoid tissue.

THYROID TUMOR CLASSIFICATION AND STAGING SYSTEMS

The follicular cells give rise to well-differentiated cancers and anaplastic thyroid cancer (ATC). The C or parafollicular cell gives rise to medullary thyroid carcinoma. Immune cells and stromal cells of the thyroid are responsible for lymphoma and sarcoma, respectively. A total of 90% are well-differentiated cancers, 5% to 9% are medullary, 1% to 2% are anaplastic, 1% to 3% are lymphoma, and <1% are sarcomas or other rare tumors.³⁰

Thyroid carcinoma can be categorized as tumors derived from follicular epithelium including differentiated thyroid carcinoma (DTC; papillary thyroid carcinoma, follicular carcinoma, including more aggressive forms such as HCC, some rare variants of papillary carcinoma, including the tall cell variant, columnar cell variant, and diffuse sclerosing variant), poorly differentiated thyroid carcinoma, and anaplastic carcinoma. Medullary thyroid carcinoma is derived from the C cells.

Many systems have been proposed for staging thyroid cancer. In the absence of a universally accepted system, it is recommended that the TNM (tumor-node-metastasis) staging system, introduced by the International Union Against Cancer and promoted by the American Joint Committee on Cancer, the American Cancer Society, the National Cooperative Cancer Network, and the American College of Surgeons, be adopted as the international staging system (Table 82.2). The system stages the malignant lesions based on tumor size, invasiveness, nodal spread, and distant metastases. Based on this system, all patients younger than 45 years of age with papillary or follicular carcinoma are stage I unless distant metastases are present. Patients older than 45 years of age with papillary or follicular microcarcinoma without nodal disease are stage I, whereas any tumor >2 cm is considered stage II. Stage III is classified in older patients with nodal disease or extrathyroidal invasion. Staging of MTC is similar, although there are no age distinctions and extrathyroidal invasion is classified as stage II. In papillary, follicular, and MTC, distant metastases are considered stage IV disease.

DIFFERENTIATED THYROID CANCER

Incidence and Prognosis

In the United States, the diagnosis of thyroid cancer has tripled in the past three decades, likely secondary to increased detection rates. Papillary thyroid cancer (PTC) is by far the most

TABLE 82.2

American Joint Committee on Cancer Classification of Thyroid Cancer, Seventh Edition (2010)

Primary Tumor (T) ^a							
TX	Primary tumor cannot be assessed						
T0	No evidence of primary tumor						
T1	Tumor ≤2 cm confined to the thyroid						
T1a	Tumor ≤1 cm confined to the thyroid						
T1b	Tumor 1–2 cm confined to the thyroid						
T2	Tumor >2 cm and <4 cm confined to the thyroid						
T3	Tumor >4 cm confined to the thyroid or tumor of any size with minimal extrathyroid extension						
T4a	Moderately advanced disease; tumor of any size extending beyond the thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve or intrathyroidal anaplastic carcinoma ^b						
T4b	Very advanced disease; tumor invades prevertebral fascia or encases carotid artery or mediastinal vessels or extrathyroidal anaplastic carcinoma ^b						
Regional Lymph Nodes (N) (Central Compartment, Lateral Cervical, and Upper Mediastinal)							
NX	Regional lymph nodes cannot be assessed						
N0	No regional lymph node metastasis						
N1	Regional lymph node metastasis						
N1a	Metastasis to level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)						
N1b	Metastasis to unilateral, bilateral, or contralateral cervical (levels I, II, III, IV, or V) or retropharyngeal or superior mediastinal lymph nodes (level VII)						
Distant Metastasis (M)							
MX	Distant metastasis cannot be assessed						
M0	No distant metastasis						
M1	Distant metastasis						
Stage Groupings							
PAPILLARY AND FOLLICULAR							
Under 45 y of age				Medullary carcinoma			
Stage I	Any T	Any N	M0	Stage I	T1	N0	M0
Stage II	Any T	Any N	M1	Stage II	T2	N0	M0
45 y of age and over					T3	N0	M0
Stage I	T1	N0	M0	Stage III	T1	N1a	M0
Stage II	T2	N0	M0		T2	N1a	M0
Stage III	T3	N0	M0		T3	N1a	M0
	T1	N1a	M0	Stage IVA	T4a	N0	M0
	T2	N1a	M0		T4a	N1a	M0
	T3	N1a	M0		T1	N1b	M0
Stage IVA	T4a	N0	M0		T2	N1b	M0
	T4a	N1a	M0		T3	N1b	M0
	T1	N1b	M0		T4a	N1b	M0
	T2	N1b	M0	Stage IVB	T4b	Any N	M0
	T3	N1b	M0	Stage IVC	Any T	Any N	M1
	T4a	N1b	M0	Anaplastic carcinoma			
	T4a	N1b	M0	Stage IVA	T4a	Any N	M0
Stage IVB	T4b	Any N	M0	Stage IVB	T4b	Any N	M0
Stage IVC	Any T	Any N	M1	Stage IVC	Any T	Any N	M1

^a All categories may be subdivided: (a) solitary tumor, (b) multifocal tumor (the largest determines the classification).

^b All anaplastic carcinomas are considered T4 tumors.

common (80% to 85%) compared to 10% to 15% follicular and 3% to 5% HCC.³¹

Several databases define prognostic risk factors for well-differentiated thyroid cancer.³² Most prognostic indicators are derived from uncontrolled retrospective trials. The most widely used systems include AGES (age, tumor grade, tumor extent, tumor size), AMES (age, metastatic disease, extrathyroidal extension, size), and MACIS (metastasis, patient age, completeness of resection, local invasion, and tumor size) (Table 82.3). Evaluation of 859 patients treated at Mayo clinic between 1946 and 1970 revealed that age of the patient, histologic grade of the tumor, and extent and size of the tumor were associated with worse prognosis.³³ These variables were combined into a prognostic score (AGES) with high-risk patients having a score ≥ 4 and low risk patients < 4 . Cause-specific mortality in low-risk patients was 1.1% at 20 years compared to 39% in the high-risk group. The AMES system was developed after a subsequent analysis of 821 patients with DTC treated at Lahey Clinic between 1941 and 1980.³⁴ This system was based on age, distant metastases, and extent and size of

primary tumor. Twenty-year mortality rates were 1.2% and 39.5% for low- and high-risk patients, respectively. Worse prognostic indicators included male sex, older age, major capsular invasion for follicular carcinoma, tumors > 5 cm in size, extrathyroidal extension of the tumor, and distant metastases at presentation. Mayo Clinic developed the MACIS system after analyzing 1,779 patients with PTC.³⁵ A low-risk score is considered < 6 with a 20-year mortality of 1%. This scoring system is the current predominant system to determine risk of death and postoperative outcome at Mayo Clinic, and is the only system to take gross residual disease after primary resection into account. These three staging systems allow the clinician to determine risk following the initial cancer operation.

Lymph node status has not been associated with cause-specific mortality; however, positive nodal involvement at presentation increases the risk of locoregional recurrence.³⁶

A single point mutation (V600E) of the BRAF protooncogene is recognized as the initiating oncogenic trigger in up to 40% to 50% of PTC.³⁷⁻³⁹ Less commonly, RET rearrangements and RAS mutations may be present.^{40,41} When compared to papillary cancers that do not have BRAF mutations, PTCs with this mutation are more advanced at the time of diagnosis, more likely to be invasive beyond the thyroid capsule, more likely to metastasize to regional lymph nodes, more likely to exhibit distant metastatic spread, and therefore less likely to be surgically curable.^{37,42-46} It remains unclear whether BRAF V600E status provides incremental prognostic information beyond that available based on surgical and pathologic information obtained at the time of initial surgery. Nevertheless, some investigators suggest that assessment of V600E BRAF status could be a standard part of the workup for patients with PTC.⁴⁷ For further discussion on the clinical and molecular genetics of endocrine tumorigenesis, see Chapter 81.

The majority (35% to 70%) of patients with follicular cell carcinoma and HCC present with stage II disease. In patients older than 45 years of age, stage III disease accounts for 4% to 7% of follicular thyroid carcinoma (FTC) and 8% to 10% of HCC. Stage IV disease with distant metastases is seen in 7% to 15% of FTC and 4% to 6% of HCC. Predictors of cause-specific mortality include age > 50 years, marked vascular invasion, and metastatic disease at presentation.³² A retrospective review from Memorial Sloan-Kettering from 1930 to 1985⁴⁸ showed that age > 45 years, Hürthle cell subtype, extrathyroidal extension, tumor > 4 cm, and distant metastases were associated with worse prognosis. Patients were divided into low-, intermediate-, and high-risk groups. The 10-year survival for low-, intermediate-, and high-risk groups were 98%, 88%, and 76%, respectively. HCC is considered a more aggressive subtype, and studies evaluating flow cytometry show that tumors with DNA aneuploidy are associated with increased tumor-related mortality.⁴⁹ Although originally designed for PTC, prognostic scoring systems AMES and AGES have been used in FTC, although it is important to point out that these scoring systems do not include important prognostic factors just described, namely vascular invasion or flow cytometry.

TABLE 82.3

Prognostic Scoring Systems for AGES, AMES, and MACIS

AGES (age, tumor grade, tumor extent, tumor size)

Prognostic score = $0.05 \times \text{age}$ (if age ≥ 40 y)
 + 1 (if grade 2)
 + 3 (if grade 3 or 4)
 + 1 (if extrathyroid)
 + 3 (if distant spread)
 + $0.2 \times \text{tumor size}$ (cm maximum diameter)

Survival by AGES score (20-y):

$\leq 3.99 = 99\%$
 4–4.99 = 80%
 5–5.99 = 67%
 $\geq 6 = 13\%$

AMES (age, metastatic disease, extrathyroidal extension, size)

Low risk: Younger patients (men ≤ 40 y, women ≤ 50 y) with no metastases
 Older patients (intrathyroid papillary, minor capsular invasion for follicular lesions)
 Primary cancers < 5 cm
 No distant metastases
 High risk: All patients with distant metastases
 Extrathyroid papillary, major capsular invasion follicular
 Primary cancers ≥ 5 cm in older patients (men > 40 y, women > 50 y)

Survival by AMES risk groups (20-y):

Low risk = 99%
 High risk = 61%

MACIS (metastasis, patient age, completeness of resection, local invasion, and tumor size)

Score = 3.1 (if age < 40 y) or $0.08 \times \text{age}$ (if age ≥ 40 y)
 + $0.3 \times \text{tumor size}$ (cm maximum diameter)
 + 1 (if incompletely resected)
 + 1 (if locally invasive)
 + 3 (if distant spread)

Survival by MACIS score (20-y):

$< 6 = 99\%$
 6–6.99 = 89%
 7–7.99 = 56%
 $\geq 8 = 24\%$

Adapted from Dean DS, Hay ID. Prognostic indicators in differentiated thyroid carcinoma. *Cancer Control* 2000;7(3):229–239. Reprinted with permission by *Cancer Control: Journal of the Moffitt Cancer Center*.

Pathology

PTC constitutes approximately 80% to 85% of malignant epithelial thyroid tumors. Grossly, papillary carcinomas have a variable appearance, from subcapsular white scars to large tumors > 5 to 6 cm that invade nearby structures outside the thyroid gland. Cystic change, calcification, and even ossification may be identified. Microscopically, papillary carcinomas are characterized by the presence of papillae, but some variants contain no papillary areas, are totally follicular in pattern, and are identified as a follicular variant. Biologically, all these tumors, independent of their degree of follicular pattern, show similar clinical characteristics. The major cytologic feature shared by all members of this papillary group is the characteristic nucleus containing

Orphan-Annie nuclei, nuclear grooves, and intranuclear pseudoinclusions. Because the nuclei are enlarged, they frequently overlap one another. Papillary carcinoma has a propensity to invade lymphatic spaces and, therefore, leads to microscopic multimodal lesions in the gland as well as a high incidence of regional lymph node metastases.

In contrast to the overall indolent behavior of the classical DTC, subtypes of these tumors have been identified as being more aggressive. These tumors comprise approximately 10% to 15% of all thyroid cancers.⁵⁰ These include HCCs (oncocyctic, oxyphilic) as well as variants of PTC such as the tall cell variant, columnar cell variant, and diffuse sclerosing variant. These variants exhibit unique histopathologic features. However, they do share some commonalities, such as a high rate of extrathyroidal extension and nodal metastasis at diagnosis, as well as locoregional recurrence and development of synchronous and metastatic disease.⁵⁰

True FTC is a tumor comprising approximately 5% to 10% of thyroid malignancies in nonendemic goiter areas of the world.⁵¹ Most of the follicular pattern of thyroid malignancies represent the follicular variant of papillary carcinoma and share the biologic features, natural history, and prognosis of PTC.⁵² FTC is unifocal, thickly encapsulated, and shows invasion of the capsule and/or vessels.

The Hürthle cell neoplasm is considered by most to be a variant of follicular neoplasms. Historically, all such lesions, despite the histologic features, were considered to be malignant; hence, it was recommended that they all be treated aggressively. However, many studies have evaluated the clinical pathologic features of thyroid Hürthle cell tumors and have shown that, on average, only 20% to 33% show histologic evidence of malignancy or invasive growth and may metastasize.⁵² However, the size of the lesion is related to the risk of malignancy, and 65% of tumors >4 cm are found to be malignant.⁵² Hürthle cell tumors that do not demonstrate invasion microscopically behave as adenomas and may be treated conservatively.

TREATMENT OF DIFFERENTIATED THYROID CANCER

Surgery

Mayo Clinic has been observing the treatment of PTC since 1940.⁵³ Over the decades, our management of PTC has become more aggressive. Seventy percent of patients treated for PTC in the 1940s underwent unilateral lobectomy. By the 1950s, the frequency dropped to 22% and by the 1960s, only 5% of patients with PTC underwent unilateral lobectomy. In contrast, by the 1980s, total or near-total thyroidectomy was performed in 92% of patients with PTC.⁵³ In current day practice, a patient diagnosed with PTC will undergo either total or near-total thyroidectomy as the preferred initial treatment.

Preoperative ultrasonography of the neck allows for evaluation of suspicious neck node metastases (NNM) that should be resected with a modified neck dissection at time of initial thyroidectomy (Fig. 82.3). Of 1,916 patients undergoing primary surgery for PTC at Mayo Clinic during 1940 through 1991, 23% of patients had suspicious nodes by palpation. More than 50% of those with PTC had neck nodes removed at surgery; 38% of the patients with PTC had nodes that were positive for metastatic disease. Only 4% of patients with FTC and 6% of those with HCC had NNM at initial surgical diagnosis.⁵⁴ Patients with DTC may be found to have recurrent NNM on long-term follow-up after initial surgery. The proportion of patients who present with these recurrences varies among histologic types of DTC. In 2,172 patients with DTC who underwent complete surgical resection at Mayo during 1940 to 1991, neck node recurrence occurred in 8% of PTC (1,801), 2% of FTC (124), and 18% of HCC (87) by 20 years. Definition of recurrence was 180 days after initial surgery.⁵⁴ In 2,370 patients with PTC treated with curative intent during 1940 to 2000 at Mayo Clinic, the cumulative occurrence rates for postoperative NNM at both 25 and 40 years were 10%.⁵⁵

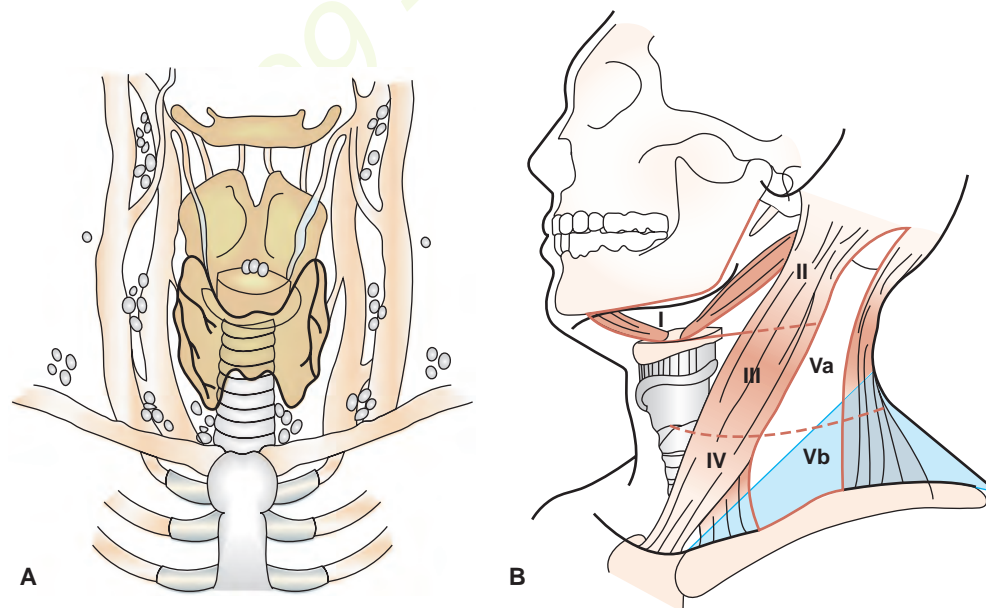

Figure 82.3 The thyroid gland and lymphatic node basins. **(A)** Schematic representation of the lymphatic node basins of the neck. The lateral neck lymph node compartments (levels II to V) and the central neck compartment (level IV). **(B)** Schematic illustration of the anatomic borders of the central neck compartment (level VI). The superior margin is at the level of the hyoid bone, the inferior margin is at the level of the brachiocephalic vessels, and the lateral margins are at the medial aspect of the common carotid arteries **(A)**. The central neck (level VI) contains the precricoid (Delphian), pretracheal, paratracheal, and perithyroidal nodes, including those along the recurrent laryngeal nerves, and the external branch of the superior laryngeal nerve. The parathyroid glands are also normally located in the central neck **(B)**.

According to the European Thyroid Association,¹¹ ATA,¹ and National Comprehensive Cancer Network,¹⁸ therapeutic neck dissection is performed with initial thyroidectomy for patients with PTC with NNM. Prophylactic lateral neck dissection is not recommended; however, prophylactic central neck dissection remains controversial. At Mayo Clinic, we routinely dissect the central neck compartment at time of initial thyroidectomy considering the high risk of NNM in DTC. Contrast-enhanced CT scanning is indicated in patients with locally advanced disease or vocal cord paralysis to rule out invasion of the aerodigestive tree which will alter surgical management.

Adjuvant Therapy

Adjuvant therapy includes postoperative TSH suppression with thyroxine therapy, usually to a level around 0.1 mIU/L. If the patient is considered low risk, TSH levels are acceptable into the low range of normal. High-risk patients are often maintained at ≤ 0.1 mIU/L. This has been standard practice in PTC and FTC for many years; however, risks of thyroid hormone suppression should be weighed against individual patients' cardiovascular risk.

The trends in surgical management of DTC have been described previously. Similar changes have been seen in the management of DTC with radioactive iodine (RAI), particularly with respect to postoperative radioiodine remnant ablation (RRA) in low-risk patients. At Mayo Clinic, approximately 60% of patients underwent RRA within 6 months of initial surgery in the 1980s. This is in comparison to only 6% in the 1970s.⁵³ The ATA guidelines recommend RRA for patients with stage II disease older than 45 years of age and patients with stage III and IV disease. Only selected patients with stage I disease should be considered for RRA (aggressive histologies, multifocal disease, nodal metastases, extrathyroidal or vascular invasion).¹ Analysis of 1,163 patients at Mayo Clinic with low-risk PTC (defined as MACIS ≤ 6) between 1970 and 2000 showed no statistical difference was seen in 20-year tumor recurrence and cause-specific mortality between those that received surgical treatment alone versus those who received surgical treatment with RRA.⁵³ In addition, the National Thyroid Cancer Treatment Cooperative Study group⁵⁶ and a multivariate analysis performed in Toronto, Canada,⁵⁷ did not show improvement in recurrence and cause-specific mortality in patients with low-risk disease. It has therefore become clearer that RRA in low-risk disease does not change long-term outcomes and should be reserved for higher risk patients. At Mayo Clinic, we reserve postoperative RRA for patients with high-risk PTC (MACIS > 6) or patients with a diagnosis of follicular or HCC. In those elected to receive RAI, quantitation of uptake is assessed by whole-body ¹³¹I scan and customization of dose is decided based on this quantitation and distribution of disease.

Postoperative RRA is typically performed approximately 6 weeks after near-total or total thyroidectomy. Most centers perform a pretherapy whole-body iodine scan. If performed, a pretherapy scan should use a low dose of ¹³¹I (1 to 3 mCi) or ¹²⁵I. To optimize uptake by both normal residual thyroid and thyroid cancer, patients are rendered hypothyroid with a goal of increasing serum TSH. To accomplish this, thyroid replacement after thyroidectomy is often performed with the administration of triiodothyronine (T₃), as it has a much shorter half-life than thyroxine (T₄), and it is discontinued 2 weeks before treatment. In response to this hypothyroid state, TSH must be > 30 mU/L to obtain optimal uptake of radioiodine. It is also recommended that a serum thyroglobulin level is obtained during this period of hypothyroid state (see "Long-Term Surveillance"). A low-iodine diet is recommended 1 to 2 weeks before scanning or ablative ¹³¹I therapy to enhance the uptake and retention of radioiodine. Alternatively, imaging and treatment employing TSH stimulation with recombinant human TSH (rhTSH; Thyrogen, Genzyme, Cambridge, MA) is presently performed with increased frequency. This way is preferred if rendering the

patient frankly hypothyroid is potentially hazardous, for example, metastatic PTC in the central nervous system. Posttherapy whole-body iodine scanning is typically performed 1 week after ¹³¹I treatment to identify metastases.

The most common side effects from radioiodine therapy include sialadenitis, nausea, and temporary bone marrow suppression. Women undergoing ¹³¹I treatment should be advised to avoid pregnancy during and 6 to 12 months after treatment due to risk of miscarriage and fetal malformation. There is a weak, but dose-dependent relationship between ¹³¹I therapy and the development of second malignancies, such as bone and soft tissue tumors, colorectal cancer, salivary tumors, and leukemia.⁵⁸

Papillary Thyroid Microcarcinoma

Papillary thyroid microcarcinomas (PMC) are defined as PTC with a maximum diameter of ≤ 10 mm.⁵⁹ In contrast with ATC with a poor prognosis, PTC generally has an excellent prognosis, with majority of patients with small primary tumors alive at 20 years. Prior to the advent of high-resolution ultrasound, most PTCs were discovered by palpation. With improved ultrasound imaging techniques and the ability to perform guided biopsies in the office setting, subclinical papillary cancers are now being discovered. In addition, these micropapillary carcinomas are often incidentally found on imaging performed for other reasons. Autopsy studies reveal an incidence of 6% to 36%.⁶⁰ The treatment of these microcarcinomas remains very controversial in the thyroid field. Mayo Clinic reported treatment outcomes of 900 patients with PMC over 60 years.⁶¹ Prognosis was excellent with cause-specific mortality of only 0.3%. A total of 30% of patients had cervical lymph node involvement, with only 0.3% having distant spread at the time of diagnosis. Bilateral lobar resections were performed in 86% with unilateral lobectomy performed in 14%. By 20 years, 5.7% of patients recurred within the neck or at distant sites. Eighty percent of recurrences occurred within cervical lymph nodes, whereas the remainder occurred in the nonresected contralateral lobe or soft tissues of the thyroid bed. However, cervical recurrences were not associated with increased mortality. Of the recurrences, 4% were to distant sites. Higher recurrences were seen in patients with multifocal tumors and positive NNM at primary resection. Recurrence rates did not differ whether primary resection included bilateral or unilateral lobar resection. RRA did not improve mortality or recurrence rate. In summary of this large series, as long as complete resection is possible, more extensive surgery and RRA do not seem to influence recurrence risk or mortality. The most common site of recurrent disease is the cervical lymph nodes, and central compartment exploration can be performed at the time of initial surgery to remove involved nodes. Future recurrence is higher in those with positive nodes at initial resection, and those with multifocal disease.

In a Japanese observational study of 1,395 patients with PMC, patients were given the choice of surgery versus observation if no unfavorable features were present.⁶² Less than a quarter chose observation, and these patients were followed with frequent ultrasounds over an average of 74 months. Tumor enlargement was considered growth of ≥ 3 . At 5- and 10-year follow-up, the proportion of patients with tumor growth was 6.4% and 15.9%, respectively. Eighteen of the thirty-one patients with tumor enlargement underwent surgery after observation, two of which were found to have lymph node metastases. Of the 13 patients who continued with observation, 7 tumors decreased in size. Tumor enlargement was not related to the original size of the tumor, multicentricity, or TSH suppression. Tumors of patients under the age of 45 tended to enlarge, but this did not reach statistical significance. The proportion of patients with new node metastases at 5- and 10-year follow-up was 1.4% and 3.4%, respectively. This author therefore summarized that observation of papillary microcarcinoma without unfavorable characteristics is a potential therapeutic option, with

progression to surgical resection if tumor enlargement or lymph node metastases occur.

Treatment of PMC is largely based on observational and epidemiologic studies. Further large trials are needed to rest this controversy. Recently, authors have advocated for a change in the name of PMC to try and prevent overtreatment of these small tumors.⁶³ However, it is important to note that not all PMCs may be “created equal,” with more aggressive variants of PTC possibly behaving differently.⁶⁴ It is currently unknown whether these aggressive variants change survival risk.

Long-Term Surveillance

The goal of long-term surveillance is to identify recurrence in patients thought to be free of disease. Thyroglobulin (Tg), an important serum tumor marker in the surveillance of patients with thyroid cancer, is the protein that provides a matrix for thyroid hormone synthesis within thyroid follicles and is critical in the storage of thyroid hormone within the thyroid gland. After successful thyroidectomy and ablation of residual normal or malignant thyroid tissue by radioiodine, the Tg should be in the athyreotic range. Both normal thyroid tissue as well as follicular cell–derived thyroid cancer will produce Tg. Levels above the athyreotic range are indicative of persistent, functioning thyroid tissue or carcinoma.

Follow-up protocols have also been a controversial issue in the management of PTC. At Mayo Clinic, we typically order a TSH with Tg testing (including Tg tumor marker and antibody) yearly for at least 5 years as this is the period of time where most recurrences occur. The presence of autoantibodies to Tg, which occurs in 25% of patients with thyroid cancer and 10% of the general population, will falsely lower serum Tg levels. Thus, such antibodies should quantitatively be determined at every measurement of serum Tg levels. We do not routinely order a TSH-stimulated Tg level. In patients with low-risk disease, a TSH-suppressed Tg level <0.5 ng/mL likely represents absence of clinically relevant disease.

In addition to Tg and TSH monitoring, follow-up imaging after initial surgery and adjuvant therapy is required. High-sensitivity ultrasonography has become the mainstay of imaging surveillance in patients with low-risk disease, with the ability to pick up small NNM that are millimeters in size. Neck ultrasound should be performed 6 and 12 months after surgery, and then annually for 3 to 5 years, depending on the patient's risk for recurrence and Tg status.¹ At Mayo Clinic, routine posttherapeutic radioiodine whole-body scanning (WBS) in the absence of recurrence by ultrasound or positive Tg is not performed. A report from Mayo Clinic Jacksonville looked at 194 patients with follicular cell–derived thyroid cancer with a TSH suppressed Tg of 0.1 ng/mL who subsequently underwent TSH stimulation and radioiodine scanning.⁶⁵ The Tg rarely stimulated above 2 ng/mL and none of the 194 patients had radioiodine scanning that was positive for locoregional recurrence or distant metastases. Therefore, radioiodine scanning is reserved for patients with recurrence or metastatic disease that may be amenable to therapeutic doses of RAI.

Management of Local Recurrence and Distant Metastasis

Patients with significant nodal locoregional recurrence in the neck should undergo modified radical neck dissection or central compartment (level VI) neck dissection, depending on the location of the recurrence. More aggressive surgery may be warranted in selected patients with invasion of the aerodigestive tract.⁶⁶ Tracheal stents and tracheotomy can be used as palliative measures in the case of unresectable disease or poor performance status. For smaller regional lymph node metastasis or patients who are not amenable to surgical therapy or have distant metastasis, locoregional disease control can also be achieved using

ultrasound-guided percutaneous ethanol ablation, which will be discussed in more detail in the following.

Metastatic disease that is detected with whole-body iodine scan, and is considered radioiodine avid, is treated with ¹³¹I therapy. Similar to the discussion of initial treatment, no consensus exists regarding dosing of ¹³¹I, although most authors use a high dose ranging between 150 to 300 mCi. Pulmonary metastases are frequently detected exclusively on radioiodine scanning and tend to respond to ¹³¹I treatment. Treatment can be performed every 6 to 12 months as long as the disease continues to respond. It should be noted, however, that pulmonary fibrosis may limit further ¹³¹I treatment.⁶⁷ For select patients with incurable pulmonary disease, palliative treatments using metastasectomy, laser ablation, and external beam radiation therapy (EBRT) may be considered. Complete surgical resection of isolated symptomatic bone metastases and ¹³¹I treatment for radioiodine avid, widespread disease have both been associated with an increased survival and are recommended especially in younger patients.⁶⁷ A combination of treatments may be considered for symptomatic bone lesions when surgery or ¹³¹I treatment is not possible nor effective. Similarly, complete surgical resection of central nervous system metastasis seem to be the most efficacious treatment, whereas EBRT and gamma knife therapy may be considered in those not candidates for surgery.

There has been a great deal of debate regarding the optimal management of patients who are Tg positive with negative imaging including negative whole-body iodine scans and ultrasonography. It is important to rule out technical factors that could lead to a false negative scan including iodine contamination and suboptimal TSH elevation. If the scan is truly negative in the setting of positive Tg, management is controversial. Previous reports have indicated benefit from empiric RAI of 100 to 200 mCi ¹³¹I in these patients.^{68,69} If the posttherapy scan is positive, then repeated RAI is given until the scan is negative. The idea is that metastases may be too small to visualize on pretherapy scan or the tumor has reduced ability to concentrate iodine. A study from Mayo Clinic looking at 24 high-risk patients with detectable Tg and negative WBSs and known macrometastases, treated with RAI between 1997 and 2000, showed that only 2 patients had evidence of uptake on the posttherapy scan.⁷⁰ The study showed that high-risk patients with known metastases who have been treated with RAI for remnant ablation, with subsequent negative WBS and positive Tg, are unlikely to benefit from empiric high-dose RAI due to reduced ¹³¹I accumulation in the persistent disease. In addition, the adverse effects of high-dose RAI should be considered. This study did not look at patients without evidence of metastases on conventional imaging. ¹⁸F-FDG-PET has been used in restaging of residual or recurrent advanced disease in patients with negative WBS but with increased Tg. FDG-avid lesions are associated with increased cancer-associated mortality, with negative ¹⁸F-FDG-PETs indicating a better prognosis.^{71,72} A recent retrospective study by van Dijk et al.⁷³ showed that PET scanning performed early after negative WBS lead to additional tumor localization in 17% (9 of 52 patients). Ninety percent of patients with positive PET scan had a Tg of >2 ng/mL. Due to the retrospective nature of this study, both stimulated and unstimulated Tg were included.⁷³ ¹⁸F-FDG-PET is best performed with a high Tg.⁷⁴

Ultrasound-Guided Percutaneous Ethanol Ablation

Many well-differentiated thyroid carcinomas present with NNM at diagnosis, approaching or exceeding 40% in both medullary and PTC. In addition, NNM may develop many years after the primary surgery, despite complete surgical resection. In the past, these lymph node recurrences have been treated with repeat surgical excision, which may include neck dissection or the less favored “berry picking” approach. High-resolution ultrasound has also allowed us to discover subcentimeter NNM that are too small for

surgical intervention. These small lesions present a dilemma to the treating clinician. Percutaneous ethanol ablation was used to treat benign disease in the 1980s, including parathyroid adenomas and benign thyroid nodules.⁷⁵ In the early 1990s, Mayo Clinic successfully started treating neck node recurrences with ultrasound-guided percutaneous ethanol ablation in both medullary and PTC.^{76,77} This procedure has subsequently been adopted by institutions around the United States and the world.^{78–80} In a series of 14 patients at the Mayo Clinic, 29 NNM were treated with ultrasound-guided percutaneous ethanol ablation between 1993 and 2000. Over a follow-up period of 18 months, all treated nodes reduced in volume, and blood flow within the metastases disappeared.⁷⁶ Long-term studies have revealed similar successes.^{80,81} The procedure can be repeated if needed, either on the same treated node or in new nodes. Figure 82.4 shows an example of a treated NNM in a patient with locoregional recurrence of PTC. We recommend this procedure for patients who are poor surgical candidates, patients who prefer to not undergo repeated neck surgery, or disease that is resistance to radioactive iodine ablation. If performed by an experienced center, the procedure has few complications, with pain at injection being the most common. Hoarseness has also been reported, but this is usually transient.⁷⁶

Systemic Agents

Approximately 25% to 50% of patients with advanced DTC are refractory to radioactive iodine therapy (RAI-R). Five- and ten-year survival may decrease to <50% and <10%, respectively. In these circumstances, systemic therapies should be considered, particularly in patients with rapidly progressive disease. Treatment options for these patients include doxorubicin, palliative EBRT, targeted molecular therapies such as tyrosine kinase inhibitors, and enrollment in clinical trials.

The role of EBRT and chemotherapy in thyroid cancer is limited. EBRT should be considered in patients with unresectable gross residual cervical disease, painful bone metastases, and for metastases in critical locations that are not amenable to surgery and that would likely result in fracture, neurologic, or compressive symptoms (such as metastases in the central nervous system, vertebral bodies, selected mediastinal lymph nodes, and pelvis). Doxorubicin is approved by the US Food and Drug Administration for the treatment of RAI-R DTC; however, significant partial and complete responses are lacking. In addition, doxorubicin has many toxicities, limiting its durability. It is clear that more established evidence is needed in order to provide therapeutic agents that reduce disease progression and increase survival without the burden of cost and morbidity associated with these agents. Anderson et al.⁸²

performed an extensive literature review of current clinical trials involving treatment of advanced thyroid cancer. The majority of evidence came from nonrandomized single arm phase 2 clinical trials, begging for more rigorous trial designs. In the last decade, vascular endothelial growth factor receptor tyrosine kinase inhibitors (TKI) appear to be the most promising agents in the treatment of advanced thyroid cancer, with disease regression seen in many patients. Impact of these agents on quality of life and overall survival is still unknown. Sorafenib was recently approved by the US Food and Drug Administration in November 2013. This was based on a double-blind, placebo-controlled phase 3 trial of 417 patients with locally recurrent or progressive, metastatic DTC that is refractory to radioactive iodine, presented at the American Society of Clinical Oncology annual meeting in June 2013. The majority of the patients had papillary carcinoma (57%); however, patients with follicular (25%) and poorly differentiated carcinomas (10%) were also included. Ninety-six percent of patients had metastases (pulmonary, 86%; lymph nodes, 51%; and bone, 27%). The median progression-free survival was 10.8 and 5.8 months for the sorafenib and placebo arms, respectively, with no complete responses. The overall survival was not significantly different. Another TKI, vandetanib, has shown progression-free survival advantage of 5.2 months in patients with RAI-R DTC,⁸³ and a phase 2 study with pazopanib showed a 49% partial Response Evaluation Criteria in Solid Tumors (RECIST) response rate in patients with RAI-R DTC.⁸⁴ Many questions still remain in the treatment of RAI-R DTC, including adaptation of therapy based on genetic profiling or tumor histology. Also, questions about economic factors, quality of life, overall survival, and disease progression despite treatment with these agents still need to be answered.

Another interesting area of research is the use of MEK inhibitors to “reverse” the loss of RAI avidity seen in many advanced tumors, particularly those with RAS mutations. A recent study published in the *New England Journal of Medicine* showed that the MEK1/MEK2 inhibitor selumetinib induced iodine incorporation into previously RAI-R tumors allowing a therapeutic RAI dose to be delivered to the metastatic lesion. Of 20 patients evaluated, 12 patients had increased uptake of iodine and 8 patients received a therapeutic dose of RAI.⁸⁵

ANAPLASTIC THYROID CARCINOMA

ATC is an undifferentiated thyroid malignancy of the follicular epithelium. ATC is fortunately rare, but is aggressive and has a very poor prognosis with median overall survival of <6 months.⁸⁶ Median age at diagnosis is older than other thyroid cancers, and female

Figure 82.4 Transverse sonogram of a left lateral neck papillary thyroid carcinoma neck node metastasis (indicated markers). (A) Before ultrasound-guided percutaneous ethanol ablation and (B) 1 year after. The lesion has become indistinct and avascular.

patients predominate. All ATCs are classified as stage IV, with stage IVA limited to the thyroid, stage IVB with local invasion, and stage IVC with distant metastases.⁸⁷ Death is mainly caused by distant metastases (51.5%), local complications (24.7%), or both (26.2%).⁸⁶ Only 10% of patients will have intrathyroidal tumors at diagnosis, with 40% having extrathyroidal extension and lymph node involvement and 50% with distant metastases.⁸⁸ Lungs and bones are the most common sites of distant spread.

ATC may occur in synchrony with other thyroid malignancies including papillary, follicular, and HCC,⁸⁹ leading to the question about development of ATC through dedifferentiation of these well-differentiated cancers, possibly through activating mutations of BRAF and RAS. ATC typically presents with a rapidly enlarging thyroid mass, which frequently involves cervical lymph nodes and surrounding neck structures leading to compressive symptoms. Ultrasonography may be helpful to determine lymph node status and invasion; however, there are no specific ultrasound features to ATC. FNA is usually adequate to make the diagnosis, as long as the sample is taken from nonnecrotic areas. If the FNA is non-diagnostic, then core biopsy or incisional biopsy should be performed. Cytopathology shows significant necrosis in addition to morphologic patterns such as pleomorphic giant cell, spindle cell, and squamoid. Once the diagnosis has been established, imaging should be performed to assess local invasion as well as distant metastases. Per the ATA guidelines,⁸⁸ initial imaging includes a neck ultrasound, cross-sectional imaging of the neck and chest, imaging of the brain, and ¹⁸F-FDG-PET. ¹⁸F-FDG-PET has been shown to be very useful in the management of ATC, with intense uptake seen in both primary tumors and metastases.⁹⁰

Treatment involves a multidisciplinary approach involving endocrinologists, surgeons, medical oncologists, and radiation oncologists. Considering the aggressive nature of the disease, palliative care teams should be involved early. The first step in management is to assess if the resectability with the imaging modalities described previously. For patients with locoregional disease and in which a grossly negative margin is achievable, initial appropriate management includes surgical resection. In circumstances when the disease is considered unresectable or high risk, neoadjuvant radiation and/or chemotherapy can be considered permitting delayed primary resection if needed. Resection after neoadjuvant therapy may reduce local relapse.

Adjuvant therapy with radiation, with or without chemotherapy, should be considered in patients with both resectable and unresectable disease and has been shown to improve outcomes in ATC. Due to rapid growth of anaplastic carcinoma, adjuvant therapy should be started as soon as possible after surgery. Palliative radiotherapy can be offered to patients with poor performance status. Traditionally, doxorubicin-based chemotherapy has been used, with or without platin. Encouraging results have also been seen with taxanes (both paclitaxel and docetaxel).⁹¹⁻⁹³ The TKI pazopanib has less activity against ATC than DTC as a single agent; however, ongoing trials are evaluating pazopanib in combination therapy with paclitaxel.⁹⁴

An important decision to make in patients with metastatic disease is aggressiveness of therapy. Although there is no clear evidence that survival is prolonged with the addition of systemic therapy, some therapies may have disease-modifying effects including taxanes, doxorubicin, and possibly the platin. These agents, in single or combination therapies, can be considered first line in patients with advanced ATC who require a more aggressive approach. If a palliative approach is preferred, therapy should be aimed at local disease control to prevent demise from invasion of vital structures such as the trachea, including surgery and/or palliative radiation.

Better understanding of the biology of the ATC has led to investigation into newer targeted agents. Patients should be enrolled in clinical trials if possible. Newer agents include imatinib, an inhibitor of C-kit, platelet-derived growth factor receptor, and Bcr-Abl tyrosine kinases. Imatinib has produced partial remissions in two patients with stable disease in four patients.⁹⁵ Fosbretabulin,

a microtubule disrupting agent, has shown to produce stable disease in 26 patients.⁹⁶ Erlotinib, an epidermal growth factor receptor antagonist, has shown tumor reduction in several patients,^{97,98} and gefitinib led to stable disease in one of five patients for 12 months.⁹⁹ Due to the lack of randomized controlled trials, many management questions unfortunately remain unanswered.

MEDULLARY THYROID CANCER

MTC was first described as a “malignant goiter with amyloid” by Jaquet in the German literature.¹⁰⁰ MTC is derived from the parafollicular or C cells, and is therefore classified as a neuroendocrine tumor. Embryologically, C cells are derived from neural crest and are located in the upper and middle portions of the thyroid. Therefore, most tumors are found in this location. Histologically, MTC resembles other neuroendocrine tumors, such as islet cell tumors.

MTC comprises approximately 4% of thyroid malignancies¹⁰¹ and can be challenging to manage. Radiation is not associated with increased risk of MTC, but rather is associated with distinct familial syndromes. Both sporadic and familial MTC may have mutations in the *RET* (REarranged during Transfection) gene.

Sporadic Medullary Thyroid Cancer

Sporadic MTC comprises the majority of MTC: approximately 80%.¹⁰² In 6% to 7% of cases, a *RET* germline mutation may be present. Up to 60% of MTC tumor cells may have a *RET* somatic mutation that is only limited to the C cells.¹⁰³⁻¹⁰⁵ Tumors with these somatic mutations may have a poorer prognosis.¹⁰⁶

Patients typically present with an asymptomatic thyroid mass but if the disease is locally advanced, patients may develop systemic symptoms such as diarrhea and flushing secondary to calcitonin secretion. Rarely, tumors may be a source of ectopic corticotropin production, leading to clinical evidence of Cushing syndrome.

Unfortunately, many presentations have evidence of local metastases at the time of diagnosis. Local invasion can present with cervical lymph node involvement (50% of patients) or invasion of local structures such as the nerves, trachea, and esophagus. Approximately 5% of patients will have distant metastatic disease; the sites favored include liver, bone, and lungs.¹⁰⁷

Familial Medullary Thyroid Cancer

Autosomal dominant inherited MTC comprises 20% to 25% of MTC.¹⁰² These syndromes consist of multiple endocrine neoplasia (MEN)2A, MEN2B, and familial MTC (FMTC) (Table 82.4). All three genetic syndromes are associated with gain of function mutations in the *RET* proto-oncogene, which leads to overexpression of Ret protein in the affected tissues, subsequent C cell hyperplasia, and progression to MTC over time.¹⁰⁰ MTC associated with familial syndromes is usually bilateral and multicentric. MEN2A is the most common of the MEN2 subtypes and usually presents in the third or fourth decade of life. Ninety five percent will have an identifiable *RET* mutation.¹⁰⁸ MEN2A is comprised of MTC, primary hyperparathyroidism (PHPT), and pheochromocytoma (PHEO), with MTC occurring in 90% of gene carriers.¹⁰⁸ It may be difficult to differentiate MEN2A from FMTC. FMTC has MTC in at least two generations, in the absence of PHPT and PHEO.¹⁰⁹ This is an important distinction to make as PHEOs can be missed if misclassification occurs. Presentation of disease in FMTC is later than MEN2A and has lower penetrance.^{110,111} MEN2B is the more aggressive subtype of MEN2 syndromes, with many patients presenting with more advanced disease. MEN2B comprises of MTC and PHEO, but lacks the PHPT seen in MEN2A. In addition, patients with MEN2B have musculoskeletal abnormalities including marfanoid habitus, ganglioneuromatosis of the gut and oral mucosa, and medullated corneal nerve fibers (see Table 82.3).¹⁰⁰

TABLE 82.4

Clinical and Genetic Characteristics of Familial Medullary Thyroid Cancer Syndromes

Syndrome	Characteristic Features
FMTC	MTC
MEN2A	MTC Adrenal medulla (pheochromocytoma) Parathyroid hyperplasia
MEN2A with cutaneous lichen amyloidosis	MEN2A and a pruritic cutaneous lesion located over the upper back
MEN2A or FMTC with Hirschsprung disease	MEN2A or FMTC with Hirschsprung disease
MEN2B	MTC Adrenal medulla (pheochromocytoma) Intestinal and mucosal ganglioneuromatosis Characteristic Marfanoid habitus

FMTC, familial MTC; MTC, medullary thyroid cancer; MEN, multiple endocrine neoplasia.

Diagnosis and Staging

Ultrasound is a common modality utilized in the diagnosis of thyroid cancer. MTC may appear solid and hypoechoic on ultrasound, with some having microcalcifications as seen in PTC (varying frequency depending on study).¹¹²⁻¹¹⁵ In sporadic MTC, diagnosis is made by FNA of the thyroid mass. Considering the sensitivity of FNA in MTC is 50% to 80%, calcitonin washout of the FNA needle may improve sensitivity.^{116,117}

Once the diagnosis is made, an ultrasound of the neck should be performed to evaluate for nodal disease. In addition, the tumor markers calcitonin and carcinoembryonic antigen (CEA) should be measured, which can be used for comparison in the postoperative period. Additional imaging for metastatic disease should be performed if neck nodal disease is present or if the calcitonin is >400 pg/ml. The additional imaging should concentrate on the lungs, liver, and bones, as these are the most common sites of metastases. Imaging modalities include CT scans of the neck, chest, and abdomen. Bone magnetic resonance imaging can be performed if there is clinical suspicion of bony metastases. MTC does not concentrate iodine; therefore, ¹³¹I thyroid scans are of no utility. Similarly, thallium as well as technetium scans have been used with minimal efficacy.¹¹⁸ ¹⁸F-FDG-PET and octreotide scans have low sensitivity, especially if the calcitonin is not very high; therefore, they are not used in routine metastatic evaluation.

Testing for germline mutations in *RET* proto-oncogene should be considered in all patients diagnosed with C cell hyperplasia or MTC, as mutations may occur in both sporadic and familial MTC. If a germline mutation is present, family members should also be screened for the mutation. In addition, patients with a germline mutation should be screened for other diseases associated with the familial syndromes including PHPT and PHEO, particularly prior to any surgical intervention. This screening will include serum calcium for PHPT and plasma-fractionated metanephrines for PHEO. Plasma-fractionated metanephrines are very sensitive but have a high false positive rate. If abnormal, we recommend confirmation with 24-hour urine-free metanephrines and catecholamines. Screening for PHEO and PHPT is usually not necessary if there is no evidence of *RET* mutation and no family history of MTC.

Prognosis

Recent studies show a 5-year survival between 80% and 90% and 10-year survival between 70% and 80% for combined series of familial and sporadic MTC.¹¹⁹ The natural history and prognosis for the various subtypes of MTC correlate with described genetic changes. Poor prognostic factors include advanced age, large primary tumors, nodal disease, and distant metastases.

Treatment of Medullary Thyroid Cancer

Initial surgical management of MTC includes total thyroidectomy with central compartment node dissection. Total extracapsular thyroidectomy is always indicated in familial MTC due to incidence of bilateral tumors with metastatic disease. As mentioned previously, the anatomic position of primary MTC is in the upper thyroid lobes. This anatomic position of the primary tumor can make complete resection with a difficult due to close proximity of the recurrent laryngeal nerve. The ATA published guidelines on the management of sporadic and familial MTC.¹⁰⁰ The ATA recommends routine level VI compartment dissection with normal ultrasound of the lateral neck. On the other hand, if the lateral compartment has evidence of disease, without distant metastases, or limited distant metastases, level IIA, III, IV, and V neck dissection in addition to the central neck compartment dissection is recommended. At Mayo Clinic, 32% of 182 patients with MTC had palpable nodes and 40% of the patients with MTC had nodes involved with metastatic disease by pathologic examination.⁵⁴

Postoperatively, patients should begin replacement levothyroxine therapy to maintain euthyroidism. Because C cells are not responsive to TSH, suppressive doses of levothyroxine are not indicated. Postoperative radioactive iodine is also not indicated as MTC tissue does not take up iodine. Serum calcitonin and CEA should be measured 3 to 6 months after surgery. It may take a long time for tumor markers to fall after surgery; however, if they remain elevated 6 months after surgery, prognosis is generally poorer. On the other hand, if the postoperative calcitonin and CEA are undetectable, the 5-year recurrence rate is only 5%.¹¹⁹ Calcium stimulation testing has diminished over the years, and pentagastrin is no longer available in the United States. In those patients with evidence of biochemical cure, imaging is repeated 6 to 12 months after surgery to establish a baseline. Calcitonin and CEA should be measured every 6 months for the first 2 years and yearly thereafter.

A challenge in the surgical management of patients with MTC is the approach to patients who have persistently elevated basal or stimulated calcitonin after resection of all gross disease.^{100,118} In many of these cases, imaging studies fail to demonstrate areas of disease. Excision attempts generally do not produce normalization of calcitonin levels. Tisell et al.¹²⁰ advocated meticulous 12-hour neck dissections, often removing 40 to 60 additional cervical lymph nodes in patients with occult MTC. In a series of 11 patients, 4 demonstrated normalization of calcitonin levels, with another 4 who had dramatic improvement in their calcitonin levels. However, even these improvements in the calcitonin levels do not necessarily translate into improved survival. In another report, only 9 of 32 patients developed biochemical cure after microdissection of the central and bilateral compartments.¹²¹⁻¹²³ Prognosis of postoperative hypercalcitonemia is dependent on extent of disease at initial surgery as well as the patient's age, with younger age and lack of nodal metastases having a better prognosis. In a large series of 899 patients, the 10-year survival rate of patients with postoperative hypercalcitonemia was 70% compared to 98% in those patients who had evidence of biochemical cure.¹¹⁹ Therefore, considering biochemical cure is only achieved in approximately 25% of patients with repeat neck dissections, observation should be considered with periodic imaging and tumor marker evaluation in patients with limited locoregional disease. Surgery can be reconsidered if the locoregional disease progresses.

If calcitonin remains detectable but <150 pg/ml, imaging of the neck should be performed to evaluate for persistent disease.

If disease is evident on imaging, repeat neck dissection may be indicated to provide locoregional disease control as long as metastatic disease is not suspected. If imaging of the neck is negative for locoregional recurrence, then calcitonin should be monitored for stability. If the calcitonin remains stable, imaging can be performed yearly. If the calcitonin or CEA begins to rise, further imaging may be required to look for metastatic disease.

If the calcitonin is >150 pg/ml postoperatively, evaluation for distant metastases can be considered, particularly if the calcitonin is >300 pg/ml. Imaging should include CT evaluation of the neck, chest, and abdomen. Bone magnetic resonance imaging can be performed if there are any skeletal complaints. PET scanning is not very sensitive in detecting recurrent disease, with one study reporting a sensitivity of 78% in MTC with calcitonin $>1,000$ pg/ml.¹²⁴

Assessment of tumor progression rate can be evaluated using RECIST or tumor marker surrogates such as calcitonin and CEA doubling time (DT). Barbet et al.¹²⁵ studied 41 patients with MTC with postoperative abnormal calcitonin levels. When the calcitonin DT was <6 months, the 5- and 10-year survivals were 25% and 8%, respectively; when 6 to 24 months, the 5- and 10-year survivals were 92% and 37%, respectively, and all patients with a calcitonin DT of >2 years were alive at the end of the study. Calcitonin DT using the first four measurements is an independent predictor of survival.¹²⁶ Reliable estimates include at least four data points over a minimum of 2 years. However, DT <6 months can be reliably estimated in the first 12 months. A calcitonin DT calculator is available on the ATA website (www.thyroid.org).

If disease is evident on imaging, the goal of treatment is to prevent complications of progressive local or metastatic disease. The first approach to neck nodal metastases may include neck dissection attempting to obtain surgical cure in the setting of limited disease. The second approach includes palliative debulking in the setting of metastatic disease to prevent locoregional complications including compression and pain. Ultrasound-guided percutaneous ethanol ablation of metastatic lymph nodes has been used successfully in patients who are poor surgical candidates (see "Ultrasound-guided Percutaneous Ethanol Ablation").

Systemic Therapy in Medullary Thyroid Cancer

The role of EBRT is limited. EBRT to the neck may be considered in patients who have extensive locoregional disease without complete resection of gross disease as this approach may provide increased time to recurrence or progression.¹²⁷ EBRT may also be used to treat skeletal metastases that are symptomatic or are located in sites prone to fracture.

Systemic therapy may be associated with significant toxicity and should be reserved for patients who have unresectable, locally advanced, or progressive disease (growing diameter $>20\%$ per year). TKIs have been of great interest in the treatment of advanced MTC and have changed the standard approach to therapy. Two TKIs have been recently approved for the treatment of MTC: vandetanib (2011) and cabozantinib (2012). Vandetanib is currently approved in the United States for treatment of unresectable locally advanced or progressive sporadic and familial MTC, and is available to prescribers who are part of the Risk Evaluation Mitigation Strategy (REMS) program. Vandetanib targets vascular endothelial growth factor receptor, RET, and the epidermal growth factor receptor, all of which are responsible for a tumor's ability to proliferate, invade, and metastasize. Approval was based on the phase 3 ZETA trial of 331 patients, with 300 mg of vandetanib daily versus placebo.¹²⁸ Median follow-up was 24 months. Patients treated with vandetanib had increased progression-free survival of 30.5 months compared to 19.3 months. In addition, reduction in calcitonin and CEA was seen. No overall survival benefit has been reported as of yet. Common side effects were present in approximately 20% of patients, including diarrhea, rash, nausea, and fatigue. Severe side effects were present in approximately 5% and included sudden cardiac death and

torsades des pointes. In the phase 3 EXAM trial, 330 patients were randomized to cabozantinib versus placebo.¹²⁹ Median progression-free survival was 11.2 months in the cabozantinib arm compared to 4 months in the placebo arm. Many other TKIs are under investigation in advanced MTC, including sorafenib and sunitinib.

Traditional cytotoxic agents have been used in MTC but the results are disappointing. Chemotherapeutic agents used in the treatment of MTC include doxorubicin, dacarbazine, cyclophosphamide, vincristine, streptozocin, and 5-fluorouracil. Combination regimens are preferred. These agents are considered second-line therapy and should be reserved for patients who fail or cannot tolerate TKIs. Other investigational approaches have included immunotherapy.

THYROID LYMPHOMA

Primary lymphoma of the thyroid is rare, only accounting for 1% to 5% of thyroid malignancies¹³⁰ and 2% of all extranodal lymphomas. There is a strong female predominance, with median age of diagnosis in the seventh decade. Approximately 50% of patients of primary thyroid lymphoma have underlying Hashimoto's thyroiditis, the only known risk factor.²⁹ Patients frequently present with a rapidly enlarging goiter¹³¹; however, smaller tumors may present as a solitary or dominant nodule. Between 10% and 30% of patients report a symptom or combination of symptoms relating to local invasion, including hoarseness, dyspnea with stridor, or dysphagia. Examination may reveal a firm, possibly tender thyroid that may be fixed. Thyroid function may be compromised, with many patients having hypothyroidism, either due to underlying Hashimoto's thyroiditis or due to infiltration of the thyroid with lymphoma. Hyperthyroidism is rare but has been described. Systemic symptoms associated with lymphoma or "B" symptoms including fever, weight loss, and night sweats may be present in 10% of patients with primary thyroid lymphoma.

Diagnosis may be difficult, particularly if the clinical suspicion is not high. Primary thyroid lymphomas may be indistinguishable from Hashimoto's thyroiditis and have low echogenicity on ultrasound. Lesions are commonly described as pseudocystic. Borders may be ill or well defined depending on the underlying lymphoma subtype.¹³² There is no role for other radiographic imaging in differentiating thyroid lymphoma from other thyroid pathologies. However, imaging can be useful in staging once the diagnosis of lymphoma has been made.

FNA has led to great advancement in the diagnosis of thyroid cancer; however, in thyroid lymphoma the FNA is frequently non-diagnostic. If clinical suspicion for lymphoma is high, then core or incisional biopsies should be performed to allow for flow cytometry and immunohistochemical staining to be performed. The most common histologic subtype is diffuse large B cell lymphoma, whereas the remaining are mucosa-associated lymphoid tissue or follicular subtype.^{131,133} The majority of patients with thyroid lymphoma have disease on one side of the diaphragm with approximately 50% confined to the thyroid (stage IE). Approximately 45% have thyroid disease plus cervical or mediastinal lymph nodes (stage IIE). Only 5% have disease both sides of the diaphragm (stage IIIE) or diffuse organ involvement (stage IV).^{29,134,135}

According to the Surveillance, Epidemiology and End Results (SEER) database on thyroid lymphoma, decreased disease-specific survival is associated with advanced age >80 years, advanced stage of disease, lack of chemotherapy and radiotherapy, and diffuse large B cell lymphoma or follicular subtype.¹³⁶ Five-year survival ranges from 52% to 90%.

Surgery is predominantly used as a diagnostic tool in the treatment of primary thyroid lymphoma. In stage IE disease, surgery may help differentiate intrathyroidal tumors from extrathyroidal extension, which is an important distinction to make with respect to treatment decisions. If the tumor remains intrathyroidal, treatment with surgery and radiation alone may be appropriate. If the tumor extends outside the thyroid, combination chemotherapy is

required.¹³⁷ Thyroidectomy in patients with stage IIE or IIIE is less commonly performed as cause-specific survival is not improved in patients who received thyroidectomy with radiation versus those who receive radiation alone.¹³⁸ Diffuse large B-cell lymphoma is treated with three courses of combination chemotherapy, followed by radiation, or six to eight cycles of combination chemotherapy without radiation. In localized, low-grade, or indolent lymphomas, radiation therapy can be used alone unless systemic disease is present, at which time chemotherapy can be used alone.

CHILDREN WITH THYROID CARCINOMA

Differentiated Thyroid Carcinoma

PTC accounts for 1.5% of childhood malignancy but >90% of childhood thyroid cancers.¹³⁹ Due to low incidence, current treatment strategies for pediatric patients with well-differentiated thyroid carcinoma are derived from single institution clinical cohorts, reports of extensive personal experience, and extrapolation of several common therapeutic practices in adults. PTC has a higher incidence of metastases to the lymph nodes and lungs at presentation than in adults.^{140,141} However, PTC in childhood tends to be indolent with low death rates. Children with well-differentiated thyroid carcinoma more often than their adult counterparts have a history of external irradiation to the head and neck, although the majority present without such a history.¹⁴² In the past, >50% of patients had exposure to ionizing radiation. Outside of the Chernobyl accident region, this exposure has dropped to <3% of cases.

Most authors agree that aggressive initial management with total thyroidectomy and cervical lymph node dissection should be performed in most children with well-differentiated thyroid carcinoma. Routine radioactive remnant ablation has become more

controversial over time. A study of 215 patients <21 years of age with PTC at Mayo Clinic showed that the initial surgery had the greatest impact on recurrence that was not further influenced by RRA.¹⁴³ In addition, there is concern about nonthyroid secondary malignancies, which occurred in patients 30 to 50 years after initial treatment, most commonly in patients that were exposed to various forms of radiation. At Mayo Clinic, we therefore restrict adjuvant RAI to patients who are considered high risk with distant metastases or incomplete resection with gross residual disease. Due to the limited experience in the management of thyroid cancer in the pediatric population, consideration should be made for referral to centers with experience in managing these challenging cases.

Medullary Thyroid Carcinoma

With the introduction of genetic screening for *RET* gene mutations, an increasing number of patients are diagnosed with inherited forms of MTC during childhood or even infancy. Depending on genotype, the current recommendations advise that individuals with *RET* gene mutations associated with MEN2A and FMTC undergo prophylactic thyroidectomy between ages 5 to 6 years, whereas affected individuals in kindreds with MEN2B should undergo thyroidectomy during infancy due to the aggressiveness and earlier age at onset of MTC in these patients.¹⁰⁰ At the MD Anderson Cancer Center, 86 patients with inherited MTC were stratified into three *RET* gene mutation risk groups: level 1, low risk for MTC (mutations in codons 609, 768, 790, 791, 804, and 891); level 2, intermediate risk (mutations in codons 611, 618, 620, and 634); and level 3, highest risk (mutations in codons 883 and 918).¹⁰⁰ All patients in the level 3 group (all with MEN2B) had MTC present at initial thyroidectomy performed at a median age of 13.5 years. With increased knowledge of genotype-phenotype correlations, more individualized management can be used in the treatment of familial variants of MTC.

83 Parathyroid Tumors

Marcio L. Griebeler and Geoffrey B. Thompson

INCIDENCE AND ETIOLOGY

Parathyroid tumors are one of the most common endocrine neoplasms. Hyperparathyroidism may be primary, secondary, or rarely, tertiary. Primary hyperparathyroidism (PHP) is one of the most common endocrine disorders along with diabetes mellitus, osteoporosis, thyroid nodules, and the most common cause of hypercalcemia in the outpatient setting.^{1,2}

PHP occurs as a result of inappropriate parathyroid hormone (PTH) secretion from an enlarged gland. A total of 85% of the cases are caused by a parathyroid adenoma, parathyroid hyperplasia involving the four glands (10%), double parathyroid adenoma (2% to 5%), and parathyroid cancer in <1% of the cases.³ Secondary hyperparathyroidism occurs when the parathyroid glands appropriately respond to a reduced level of extracellular calcium and elevated levels of serum phosphorus. It is characterized by an elevation of PTH with normal or low calcium concentration, which usually is associated with renal failure and vitamin D deficiency. Finally, in tertiary hyperparathyroidism there is a continued autonomous hypersecretion of PTH from one or more enlarged parathyroid gland. PHP may also be associated with some familial syndromes, like multiple endocrine neoplasia (MEN) type 1 and type 2A, familial isolated hyperparathyroidism, and the hyperparathyroidism-jaw tumor syndrome (HPT-JT).^{4,5}

PHP was diagnosed less often when the diagnosis was dependent on overt symptoms related to long-standing disease. The epidemiology of this disease has shown significant changes over the last several decades, with the majority of the patients remaining relatively asymptomatic with only mild hypercalcemia, being diagnosed by routine calcium measurements instead of symptoms.⁶ Recent studies from Europe and the United States have demonstrated that the incidence of PHP is higher than previously reported, suggesting that the incidence has increased from 2000 to 2010.⁷⁻⁹ There are approximately 100,000 new cases diagnosed each year in the United States. It is more common in women (1 in 500) than in men (1 in 1,000) and occurs in approximately 0.3% of the general population. PHP occurs most often in perimenopausal or postmenopausal women and is rare in children.

Parathyroid cancer is a rare cause of PHP and one of the rarest of malignancies.¹⁰ The estimated prevalence is 0.005% of all solid malignancies.^{11,12} The majority of cases often coexist with PHP, but there are reports of cancers occurring in secondary hyperparathyroidism and with nonfunctioning tumors. The incidence of parathyroid cancer ranges from 0.5% to 5% of cases of PHP. The majority of studies show a prevalence of <1% of all cases of PHP.^{11,13-15} Variable rates in parathyroid cancer are likely the result of the fact that most studies take place at tertiary referral centers where rare diagnoses are more likely to be encountered. Hundahl et al.,¹⁶ in their review of the National Cancer Data Base, reported 286 cases of parathyroid cancer between the years 1985 and 1995. Lee et al.,¹² who used the Surveillance, Epidemiology and End Results (SEER) cancer registry database for years 1988 through 2003, reported 224 cases of parathyroid cancer. Talat and Schulte¹⁷ recently compiled information on 330 patients collected from case reviews and 706 patients from

other studies providing clustered data between 1961 and February 2009. Based on some of these studies, which capture approximately 60% to 80% of all cancer diagnoses in the United States, between 30 and 50 cases of parathyroid carcinoma occur annually.

The majority of patients with parathyroid cancer present with symptoms, severe hypercalcemia, and metabolic complications of PHP, like bone and renal disease. The levels of PTH are usually very high. The clinical behavior of parathyroid cancer is quite variable but usually the tumor is very aggressive, and most patients develop locoregional recurrence; distant metastasis to lung, bone, and liver occur late. Most patients with parathyroid cancer succumb to uncontrollable hypercalcemia, not to direct tumor burden.

Different than the benign parathyroid tumors (female-to-male ratio of 3 to 4:1), parathyroid cancer occurs with equal frequency in men and women. The male sex is associated with worse overall survival. Parathyroid carcinoma typically will develop between ages 45 to 59 years. More than 75% of patients will present after the age of 45 where the median age of presentation is 55 years old.^{12,16} Patients with benign parathyroid tumors are on average a decade older than patients with parathyroid carcinoma. There is no ethnic or racial disparity in the incidence of parathyroid cancer.^{12,16}

There are few risk factors associated with parathyroid cancer. Genetic syndromes associated with parathyroid cancer include MEN1 and MEN2A, but benign parathyroid tumors remain much more common in these syndromes as well.^{18,19} Another very important genetic syndrome is the HPT-JT syndrome, where up to 15% of affected individuals develop parathyroid cancer. The gene that predisposes to tumor is an inactivating germ line mutation of the *HRPT2* gene (*CDC73*).²⁰ There are a few case reports of carcinoma occurring in patients with a history of neck irradiation and end-stage renal disease; however, there is very little clinical evidence to support this association.^{18,21-23} A retrospective cohort study from Swedish Family Cancer Database reported an association of parathyroid cancer in patients with history of thyroid cancer and parathyroid adenoma, but despite these associations the evidence of parathyroid carcinoma arising from malignant transformation has not been found.^{24,25}

ANATOMY AND PATHOLOGY

It can be difficult to distinguish parathyroid cancer from parathyroid adenoma. At the time of neck exploration, malignant tumors are often large (usually >3 cm), weighing between 2 and 10 g (the combined weight of all four normal parathyroid glands is approximately 150 mg). They are often hard, firm, and whitish-gray, and with invasion or adherence to the adjacent tissues such as the strap muscles, thyroid gland, recurrent laryngeal nerve, trachea, or esophagus.¹¹ For an unequivocal diagnosis of parathyroid cancer, the presence of gross local invasion, lymph node or distant (lung, liver, or bone) metastasis, or local recurrence after complete resection (not as a result of tumor spillage at the initial resection) is needed.

Even by histopathology the diagnosis of parathyroid carcinoma is challenging. In 1973 after 70 cases of parathyroid cancer were examined, Schantz and Castleman²⁵ reported histologic criteria

that are still commonly used. This includes the presence of fibrous bands intersecting the tumors forming trabecular architecture, along with capsular invasion, vascular invasion, and increased mitotic activity. These features are not unique to parathyroid carcinoma and can also be found in benign parathyroid tumors (adenoma, atypical adenoma, parathyromatosis, and hyperplasia). Overall, there is not one histopathologic sign that can distinguish between parathyroid cancer and benign disease; definitive diagnosis can be made only with the presence of loco regional invasion or distant metastases.⁴

Several other markers of malignancy have been studied besides routine hematoxylin and eosin histology to help distinguish parathyroid cancer from parathyroid adenoma. Electron microscopy does not add proof of malignancy when compared to light microscopy.²⁶ Flow-cytometric analysis of parathyroid tumors are more likely to be aneuploid than adenomas (60% versus 9%, respectively). Determination of DNA ploidy may add valuable information to routine histology, even though some studies have shown that variable rates of DNA ploidy can also be seen in parathyroid adenoma.²⁷ Analysis of human telomerase expression in parathyroid tumors may be a helpful adjunct to histology as 100% of parathyroid cancers are positive on immunohistochemistry examination as compared with 6% of parathyroid adenomas (6%).²⁸

Increased Ki-67 and galectin 3 expression in association with absent parafibromin expression may help distinguish parathyroid cancer from benign parathyroid tumors.²⁹ A combination of these three markers showed that 15 of 16 parathyroid cancers were correctly identified with only a 3% false positive rate.⁴ Recently, Starker et al.³⁰ demonstrated that a comprehensive analysis of epigenetic alteration in parathyroid tumors shows distinct DNA methylation profiles between benign and malignant lesions.

Molecular classification of parathyroid cancer by gene expression profiling comes from inherited disorders of PHP, especially HPT-JT syndrome. Identification of the molecular markers associated with parathyroid carcinoma will prove to be an important tool for the improvement of the often difficult diagnostic dilemma. HPT-JT is an autosomal-dominant disease, and the majority of patients are heterozygous for germline CDC 73 mutations, located on chromosome 1q31.2.³¹ The gene encodes parafibromin, a tumor suppressor protein. Parafibromin inhibits mitogenic functions of cyclin D1 and c-myc pathway.³² The most common mutations are frame-shift and nonsense mutations. Patients with HPT-JT syndrome have ossifying fibromas of the maxilla and mandible, less frequently hamartomas and renal cysts, and develop parathyroid tumors that are mostly malignant.³³

Cyclin D1 is an oncogene located on chromosome 11q13 and is involved in cell cycle regulation. Overexpression of the oncogene CCND1 (or BCL1 or PRad1) that encodes cyclin-D1 was found in many benign tumors and the vast majority of parathyroid cancers.^{20,34} Although cyclin D1 overexpression has been seen in parathyroid cancer, it appears that the increase in expression may be related to increased proliferation and not to the pathogenesis of parathyroid cancer.⁵ Furthermore, it appears that parafibromin regulates cyclin D1 and thus may be a downstream effector of parafibromin. P27kip1 (cell-cycle progression regulator) is also downregulated in parathyroid cancer cells.³⁵

The importance of underlying germline mutations in susceptibility genes was recently underscored by the presence of *MEN1*, *CASR*, and *HRPT2/CDC73* gene mutations in about 10% of young patients (<45 years of age) with no family history suggestive of familial hyperparathyroidism.³⁶ Finding mutations in these genes implies that the parathyroid lesion in this specific subset of patient should be treated with a high index of suspicion.

CLINICAL MANIFESTATIONS AND SCREENING

The majority of patients with parathyroid cancer will be hormonally functional, presenting with symptoms of hypercalcemia, while

TABLE 83.1

Sites of Parathyroid Cancer at Presentation and at Recurrence

Initial Presentation	
Local invasion	40%
Lymph node metastases	15%–30%
Distant metastases	1.8%
Recurrence	
Local	33%–82%
Lymph node	17%–32%
Distant	10%–40%

the benign forms of PHP may be relatively asymptomatic.^{15,37} Some of the patients with parathyroid cancer may present already with complications, such as renal (polyuria, renal colic, nephrocalcinosis, nephrolithiasis) and skeletal involvement (bone pain, osteopenia, pathologic fractures). Concomitant renal and bone involvement can be seen in half of the patients and can lead to chronic renal insufficiency. Manifestations of bone disease include osteitis fibrosa cystica, subperiosteal bone resorption, and “salt and pepper” skull.^{38,39} Other symptoms seen in patients with hypercalcemia, like nausea, abdominal pain, peptic ulcer, pancreatitis, psychiatric complaints, fatigue and depression, may also be present. The overall symptoms can be exactly the same for benign parathyroid disease, and the challenge for the physician remains to differentiate between hyperparathyroidism due to benign disease versus parathyroid cancer. Less than 10% of parathyroid carcinomas will be hormonally nonfunctional.⁴⁰ Calcium is markedly elevated, usually >14 mg/dL, and PTH levels may be >5 to 10 times greater than normal levels.^{38,41} Hypercalcemic crisis is not uncommon in parathyroid carcinoma.²⁹ PHP due to benign parathyroid disease usually will have milder elevation of calcium and PTH levels. It should be noted that very high calcium and PTH levels are seen more often in benign disease due to their relative frequency.

On the physical examination, a neck mass is palpable in >40% of patients, while in benign parathyroid disease this is much less frequent¹⁵ (Table 83.1). Lymph node disease occurs in 15% to 30% of the patients at initial presentation.⁴² Most commonly, parathyroid cancer invades the adjacent thyroid lobe, but invasion into the esophagus, trachea, carotid sheath, strap muscles, and mediastinum is not uncommon.^{11,43} Parathyroid cancer may also cause local symptoms such as dysphagia, dyspnea, dysphonia, odynophagia, and/or ear pain from local invasion.³⁹ Recurrent laryngeal nerve paralysis can also be seen, and a preoperative laryngoscopy should be performed in patients with voice change, as a vocal cord paralysis may be present from tumor invasion of the recurrent laryngeal nerve and should be recognized before operative intervention. Common sites of distant metastasis are lung, bone, and liver.

DIAGNOSIS

It is often difficult to diagnose parathyroid cancer prior to surgery as the clinical features are very similar with benign disease. On the other hand, PHP can easily be established with an abnormal level of total calcium and an inappropriate or high level of PTH. As part of the differential diagnosis of PHP, it is important to exclude benign familial hypercalcemic hypocalciuria. This disease will present with hypercalcemia, usually normal PTH levels, and hypocalciuria with calcium to creatinine clearance ration <0.01. Genetic testing is also available for evaluation of *CASR* mutations.

Making a preoperative diagnosis of parathyroid cancer as the cause of PHP is often difficult. As said before, there is no single

laboratory finding that is pathognomonic of parathyroid cancer. Findings of severe hypercalcemia (calcium levels usually >14 mg/dL), extreme elevated levels of PTH (5 to 10 times the upper limit of the normal range), and a palpable neck mass may suggest the diagnosis. About 60% to 65% of patients present with a calcium level >14 mg/dL.^{14,39,44} Patients with parathyroid cancer often have elevated alkaline phosphatase and low serum phosphorus levels. Some tests like human chorionic gonadotropin and N-terminal parathyroid hormone can be ordered, but they can also be elevated in benign parathyroid disease.⁴⁵⁻⁴⁷

Patients that present with severe hypercalcemia, metabolic complications (like bone and renal), and a neck mass have a higher likelihood of parathyroid cancer. Preoperative imaging may help with tumor localization but cannot reliably distinguish benign and malignant disease. A heterogeneous mass with irregular borders may increase the suspicion of malignancy, but these characteristics are not always present in parathyroid cancers.⁴⁸ Fine needle aspiration should be avoided in patients with suspected parathyroid cancer because of the possibility of cutaneous seeding along the needle track.⁴⁹

Parathyroid cancer remains a diagnostic dilemma. There are no definitive histologic diagnostic criteria, and the diagnosis can only be made in a patient who has either locoregional or distant metastasis at the time of initial neck exploration. A patient presenting with severe symptoms, a palpable mass, and metabolic complications has a higher likelihood of having parathyroid cancer, but this is not pathognomonic.¹¹

STAGING

At the present time, there is a lack of a TNM (tumor, node, metastases) staging system available for parathyroid cancer. Shaha and Shah⁵⁰ have proposed a staging system in the past taking in consideration the size of the tumor, invasion to adjacent tissues, lymph node involvement, and distant metastases (Table 83.2). Talat and Schulte¹⁷ in 2010 suggested an anatomy-based TNM system that showed that patient prognosis could be predicted with their model. They used the same principles established for other endocrine tumors.¹⁷

TABLE 83.2

Proposed Staging System

Proposed Staging System	
T1	Primary tumor <3 cm
T2	Primary tumor >3 cm
T3	Primary tumor of any size with invasion of the surrounding soft tissues (thyroid gland, strap muscles, etc.)
T4	Massive central compartment disease invading trachea and esophagus or recurrence parathyroid cancer
N0	No regional lymph node metastases
N1	Regional lymph node metastases
M0	No evidence of distant metastases
M1	Evidence of distant metastases
Stage	
I	T1N0M0
II	T2N0M0
IIIa	T3N0M0
IIIb	T3N0M0
IIIc	Any T, N1M0
IV	Any T, Any N, M1

MANAGEMENT OF PARATHYROID CANCER

Surgery is the treatment of choice for parathyroid cancer. It is helpful to have a high index of suspicion prior to the surgical procedure to better enable the surgeon to perform the appropriate operation, including a complete resection with microscopically negative margins as this offers the best chance of cure. An en bloc resection of the tumor and the involved structure(s) has been associated with decreased risk of recurrent disease. At the very least, the surgical resection should include en bloc removal of the tumor without compromising the tumor capsule. Systemic chemotherapy, embolization, and radiofrequency ablation have been attempted but in general are not effective in patients with parathyroid cancer.

Hypercalcemia can be very challenging to manage and correction of electrolyte imbalance is paramount to avoid irreversible cardiac and renal complications. Several therapies may be instituted including rehydration, repletion of electrolytes, and loop diuretics after adequate hydration to improve urinary excretion of calcium.¹¹ Other treatment options include calcitonin and bisphosphonates in an attempt to lower calcium levels. Less common treatment includes amifostine (agent that inhibits PTH release) but use has been limited due to side effect profile.⁵¹ A new drug called cinacalcet (a calcimimetic) is more effective in lowering serum calcium levels and with fewer side effects. This medication is preferred when compared to the older drugs.

Surgical Treatment

As patients are often not assessed for the risk of parathyroid cancer, the initial surgery may not completely address the need for wide resection. If during the resection the adenoma shows suspicious features like a large mass, whitish capsule, and adherence to adjacent structures, an en bloc resection of the tumor and adjacent structures involving the neck, including the ipsilateral thyroid lobe with gross clear margins should be attempted.^{18,50,52}

En bloc resection is the modality of choice and is associated with improved outcome.¹¹ It includes removal of the parathyroid lesion with avoidance of capsular disruption (rupture can cause tumor spread leading to parathyromatosis)⁵³ and resection of all involved tissues, including the ipsilateral thyroid lobe, trachea, and esophageal wall. Suspicious ipsilateral regional lymph nodes should also be removed. Patients with untreated hypercalcemic crisis should have their surgery delayed until the electrolyte imbalance is corrected. Those with diffuse metastatic disease are less likely to benefit from surgical resection.

Common surgical complications include recurrent laryngeal nerve (RLN) injury, esophageal and tracheal injury, neck hematoma, and infection. If the patient presents with a hoarse voice, invasion of the RLN should be suspected. Preoperative laryngoscopy can confirm vocal cord paralysis. It is appropriate to resect the nerve in symptomatic patients or the ones at high risk of RLN invasion, as the risk of recurrence outweighs the benefit of preserving the nerve.⁵⁴

Patients with poor outcome usually are the ones with incomplete resection, tumor seeding, and a history of recurrence. The finding of positive surgical margins predicts recurrence.⁵⁵ Studies have shown that patients with local excision rather than en bloc resection have poor outcomes.⁵⁶ For localized recurrent tumors, a cervical and/or mediastinal exploration with wide resection is recommended.⁴² Radical surgical procedures will reduce the risk of local recurrence but will not prevent distant metastasis secondary to vascular invasion.

Lymph node metastasis occurs in up to 8% of patients with parathyroid cancer but can be as high as 17% to 32% (see Table 83.1).^{38,44,57} If cervical nodes are involved, a modified neck dissection should be performed. Prophylactic neck dissection does not seem to improve survival and has increased morbidity.⁵⁸ En bloc resection has an 8% local recurrence rate and long-term overall survival rate of 89%.¹⁸ Usually, parathyroid carcinoma will recur 2 to 5 years after surgery with a local recurrence rate of 33%

to 82% at 5 years.¹¹ Metastases may occur via lymphatic spread or hematogenously; the most common sites include lung and liver (40% and 10% incidence, respectively).^{37,52,59}

Radiotherapy

Usually, parathyroid cancer is radioresistant and radiation treatment as primary therapy has not been shown to have any significant effect either locally or at distant sites. External-beam adjuvant radiotherapy may be considered in high-risk patients or those with positive surgical margins.⁶⁰ One study showed that the local recurrence rate is lower with radiation independent of the surgical procedure or stage, in addition to improved disease-free survival. These findings, however, were not statistically significant.⁴³ Another study showed that patients with aggressive tumors who received radiation postsurgery achieved better locoregional disease control, but all patients had negative margins.⁶⁰ Patients with parathyroid cancer have been treated with doses as high as 70 Gy.⁴² The efficacy of radiotherapy is difficult to evaluate as the current evidence in the literature is scarce and most of the studies have a small number of patients. In addition, parathyroid cancer is a rare diagnosis. Resection in bloc with negative margins is still the best chance of cure in parathyroid carcinoma, and the use of adjuvant radiotherapy should be decided on an individual basis. Adjuvant radiation therapy does not affect the survival of patients with parathyroid cancer.

Chemotherapy

There is no standard chemotherapy regimen for parathyroid carcinoma, and such treatment usually is ineffective. Most of the experience comes from a limited number of case reports without randomized clinical trials.^{13,15,37,39} Regimens used include dacarbazine as monotherapy; a combination of fluorouracil, cyclophosphamide, and dacarbazine; or a combination of methotrexate, doxorubicin, cyclophosphamide, and lomustine. There is no survival benefit associated with chemotherapy in patients with parathyroid cancer.

Other Treatment Modalities of Parathyroid Cancer

Patients with parathyroid cancer will usually succumb to the complications of severe hypercalcemia. The primary goal in patients with metastatic disease is controlling the PTH-driven hypercalcemia. Some of the drugs that may be used include bisphosphonates, calcitonin, glucocorticoids, mitramycin, plicamycin, and gallium nitrate as well as hemodialysis in addition to generous hydration. These medications help decrease the calcium levels in the short term, but long-term remission rarely is seen.⁶¹ Studies with intravenous pamidronate and zoledronate have shown good calcium response in the short term, but gradually the effect diminishes with subsequent infusions.⁶¹⁻⁶³ Oral bisphosphonates are not effective.

A new drug called cinacalcet (a calcimimetic) is more effective in lowering serum calcium levels and with less side effects. This drug is preferred when compared to the other drugs. Cinacalcet modulates calcium receptors on the surface of parathyroid cells directly decreasing PTH synthesis and secretion, consequently lowering serum calcium levels. It usually is started at a dose of 30 mg twice daily.⁶⁴⁻⁶⁷ A study showed that cinacalcet decreased serum calcium by 1 mg/dL in 62% of patients with parathyroid cancer.⁶⁶ Patients tolerated total daily doses up to 360 mg. In responders, the magnitude of decrease in calcium levels was greatest in those with the highest baseline calcium levels. Interestingly, decreases in serum calcium have been achieved despite no significant decrease in serum PTH levels.⁶⁶

Other modalities that have been attempted include radiofrequency ablation and transcatheter arterial embolization for diffuse

metastatic disease.^{68,69} These reports showed improved control in both serum calcium and PTH levels after treatment. Use of ultrasound-guided percutaneous alcohol injection for unresectable disease has also been reported.⁷⁰ Another approach is the induction of anti-PTH antibodies by immunization with PTH fragments, with an attempt to shrink tumors and halt the progression of metastases. No clinical trials are available at this time.⁷¹⁻⁷⁴ The adjuvant therapies mentioned previously are described in small case series or cases reports, so insufficient information is available to determine the effects of these therapies on long-term survival. These therapeutic options should be decided on a case-by-case basis.

FOLLOW-UP AND NATURAL HISTORY

Patients with parathyroid cancer will require lifelong follow-up. At least half of patients with parathyroid cancer will develop recurrent disease, the neck being the most common site of recurrence (80%).⁶⁰ The average time to recurrence is slightly over 33 months.³⁷ The rate of recurrence is higher when the diagnosis is not initially known and en bloc parathyroidectomy is not performed. Disruption of the parathyroid capsule also leads to higher rates of recurrence.

PTH and calcium monitoring is the best way to follow these patients. If there is biochemical evidence of persistent disease, high-resolution ultrasound of the neck is the best next approach. Whole-body sestamibi scan and other images like computed tomography or magnetic resonance imaging of the chest, neck, and abdomen can be performed for evaluation of metastatic disease. The most common sites of metastasis include lungs, bone, and mediastinum. A study showed that the ultrasound of the neck has a sensitivity of 69% while the sestamibi, computed tomography, and magnetic resonance imaging have 93%, 79%, and 67%, respectively.⁵⁴

Once biochemical recurrence has been confirmed, the next step is to distinguish between local and distant recurrence. Non-invasive localizing studies are used to rule out lung and bone metastasis. If noninvasive studies are nondiagnostic, selective venous sampling for PTH can be performed in an attempt to localize the site of recurrence. If isolated distant metastases are confirmed, resection might be helpful in controlling disease both clinically and biochemically. Local recurrence is usually treated with reoperation and resection of cervical and/or mediastinal disease. This often helps to improve symptoms and calcium levels in up to 75% of the patients.⁵⁴ Patients with disseminated disease are less likely to benefit. These patients are usually treated with medical management that includes bisphosphonates and, more recently, cinacalcet.

PROGNOSIS

In a mean follow-up of 6.1 years, Talat and Schulte¹⁷ showed that 35% patients died of disease and 64% experienced recurrence. The relative risk of recurrence is 1.7 in males and 4.3 when there is presence of vascular invasion. In addition, failure to perform an oncologic operation (en bloc resection) carries with it a relative risk of 2.0 for reoperative surgery. Studies have shown that recurrence is detected on average 2 to 4 years after the initial operation, and these patients have a median survival of 5 to 6 years after the initial diagnosis.^{37,39,43,44,57} Patients will usually succumb to uncontrolled hypercalcemia and its sequelae. The 10-year survival is quite variable and institution-dependent (Table 83.3). The best survival seems to occur most often in patients presenting with a high index of suspicious for parathyroid carcinoma prior to surgery thus recognizing the need for en bloc resection. Once a patient has recurrent parathyroid cancer, the 5-year survival is <15%. Patients with parathyroid cancer may have long survival but this will typically involve multiple reoperations and a high rate of complications.⁴²

84 Adrenal Tumors

Roy Lirov, Tobias Else, Antonio M. Lerario, and Gary D. Hammer*

INTRODUCTION

The focus of this chapter is the evaluation and management of primary malignant adrenal neoplasia. Other etiologies of adrenal tumors include primary benign neoplasms, which will be discussed briefly, metastatic nonadrenal tumors, and nonneoplastic masses, such as adrenal cysts, tuberculosis, and histoplasmosis.¹⁻⁵ Additionally, many disease processes in close proximity may mimic adrenal tumors.³ Primary benign or malignant neoplasms of the adrenal may derive from the adrenal cortex or medulla. Evaluation and management of adrenal neoplasms depends on clinical suspicion of malignancy and biochemical evidence of autonomous hormone production.^{6,7} Although malignancy is extremely rare, a missed opportunity for appropriate management of early-stage cancer can be devastating. Much more common are functional (hormone-producing) benign lesions, which may be symptomatic or indolent, but can still cause morbidity and mortality unless properly addressed. Therefore, the most important primary adrenal neoplasms to consider are functional adrenocortical adenoma (ACA), adrenocortical carcinoma (ACC), and benign or malignant pheochromocytoma. Surgery is the cornerstone of management in most cases, although therapy is often multimodal and highly individualized. Review by a multidisciplinary team of experts is essential because management algorithms are complex and rapidly evolving. Early referral to specialized centers at tertiary care facilities is recommended.

OVERVIEW AND PATHOPHYSIOLOGY OF THE ADRENAL GLAND

The adrenal cortex and medulla are developmentally and physiologically distinct organs. The adrenogonadal primordium begins to form in the third week of intrauterine life, eventually giving rise to the three-layered adrenal cortex and structures of the gonad. As its outer capsule forms during the eighth week, the gland is infiltrated by cells of the neural crest, which migrate to the center of the gland and differentiate into the chromaffin cells of the adrenal medulla. The gland continues to develop during early life and does not reach its mature form until ages 10 to 20 with formation of the zona reticularis.⁸ The adrenal medulla is closely related to the paraganglia associated with the autonomic nervous system and found in the head, neck, mediastinum, and retroperitoneum. The paraganglia associated with the sympathetic system are often para-aortic⁹; the largest of these is the organ of Zuckerkandl, located anterior and superior to the aortic bifurcation.¹⁰

The adrenals are paired glands of the retroperitoneum with a rich blood supply. Their venous drainage is asymmetric: the right gland drains directly into the inferior vena cava while the left drains into the left renal vein.^{11,12} Steroidogenic cells of the adrenal cortex produce hormones by incremental modifications to cholesterol catalyzed by a complement of enzymes that are specific to each concentric cortical layer. The outer zona glomerulosa synthesizes the mineralocorticoid aldosterone, the middle zona fasciculata synthesizes the glucocorticoid cortisol, and the inner zona reticularis synthesizes the androgen precursor dehydroepiandrosterone sulfate. The synthetic pathway involves multiple intermediate hormones that can sometimes mimic the activity of mature hormones if produced in sufficient quantity by tumors of the adrenal cortex.¹² Norepinephrine is synthesized in the adrenal medulla and peripheral sympathetic nerves from tyrosine or phenylalanine by way of dopa and dopamine intermediates. The adrenal medulla additionally converts norepinephrine into epinephrine.¹³

ACAs are benign neoplasms of the adrenal cortex. The majority are functionally silent, but these tumors can produce steroid hormones, which in excess may cause typical clinical syndromes.¹⁴ Cortisol-producing ACAs are the usual cause of adrenocorticotrophic hormone (ACTH)-independent hypercortisolism.¹⁵ Primary hyperaldosteronism was recently shown to have a prevalence of >10% in unselected patients with newly diagnosed hypertension, and an aldosterone-producing ACA, previously thought to be rare, was identified in almost half of those patients.¹⁶ ACAs rarely produce significant amounts of androgens or estrogens. Hence, the presence of virilization or feminization should alert the clinician to the possibility of ACC.^{6,14}

ACC is a malignant neoplasm of the adrenal cortex. Although classically these are thought to be distinct from ACA, recent evidence suggests that a transition from ACA to ACC can occur, albeit such an event is extremely rare.¹⁷⁻¹⁹ ACC may behave aggressively with high rates of invasion, metastasis, and recurrence.²⁰ Histologically, these tumors can be heterogeneous with atypia, deranged architecture, and chromosomal instability.⁹ They may produce an excess of one or several steroid hormones, including intermediates that may produce a mixed clinical picture.^{21,22}

Pheochromocytoma (PC) is a tumor of the chromaffin cells of the adrenal medulla. These tumors typically produce a combination of epinephrine, norepinephrine, and rarely dopamine.²³⁻²⁵ Paraganglioma (PGL) is an extra-adrenal tumor of the autonomic nervous system. Those of sympathetic origin are typically mediastinal or abdominal and can produce norepinephrine, whereas those of parasympathetic origin are found in the head and neck and are functionally silent.^{23,26} Occasionally PC or PGL can produce dopamine, a feature that might be associated with malignancy. Although these catecholamines can be released intermittently and degraded rapidly, their metabolites normetanephrine and metanephrine are typically released from PC in a less variable fashion and hence are more reliable in the assessment of medullary neoplasms.^{26,27} PGLs are often considered together with PCs (PCPGL) because of their shared neural crest origin, similar histology, pathogenesis, biological behavior, and therapy.^{28,29}

MOLECULAR GENETICS OF ADRENAL NEOPLASMS

The rarity of malignant adrenal neoplasms presents challenges for researchers and clinicians. In recent years, international collaboration and increasingly sophisticated biologic techniques have elucidated many genes that appear to be important in the pathogenesis of these diseases.³⁰⁻⁴²

The association of several important genes with adrenocortical neoplasia, both benign and malignant, derives from the study of heritable syndromes. Studies of families with Carney complex, which can include primary pigmented nodular adrenocortical hyperplasia, identified a mutation in *PRKARIA*, the gene encoding a regulatory subunit of protein kinase A. Although somatic mutations in *PRKARIA* in cortisol-producing ACAs are rare, other disruptions of the protein kinase A pathway in these tumors are frequent.⁴³ High-throughput techniques used in the study of aldosterone-producing ACAs led to the discovery of an inactivating mutation in the potassium-channel gene *KCNJ5* (found in up to 40% of samples), as well as mutations in *ATP1A1*, *ATP2B3*, and *CACNA1D*.⁴⁴⁻⁴⁷ Study of families with syndromes associated with ACC such as Li-Fraumeni syndrome, Beckwith-Wiedemann syndrome, and familial adenomatous polyposis led to recognition of the importance of *TP53*, *IGF2*, and *APC* genes in ACC. Somatic mutations in these genes or their regulatory elements and others are present in many cases of sporadic ACC.⁴⁰ Particularly, the very high expression of *IGF2* as well as methylation changes of its locus on 11p15 have emerged as a molecular hallmark separating benign from malignant tumors.⁴⁸

PCs are classically associated with von Hippel-Lindau disease (*VHL*, often bilateral and norepinephrine producing), neurofibromatosis type 1 (*NF1*), and multiple endocrine neoplasia type 2 (*RET*, almost always epinephrine producing).^{9,30-38,49} PCs and in particular PGLs clinically define the different hereditary PGL syndromes (PGL1 to 5), in which several germline mutations of the genes encoding the succinate dehydrogenase complex (*SDHA*, *SDHB*, *SDHC*, *SDHD*, *SDHAF2*) have recently been discovered (Table 84.1).^{33,34,36,37,39,41} Mutations in the *SDHx* genes lead to slightly different phenotypes in terms of localization, biochemistry, and biologic behavior, with *SDHB* conferring a higher risk of

malignancy.^{37,50} More recently, exome sequencing has identified new germline mutations in *MAX* and *TMEM127* predisposing to PC (see Table 84.1).^{35,38}

INCIDENCE AND EPIDEMIOLOGY

While the overall prevalence of adrenal tumors is estimated to be 3% in those >50 years of age and 6% in those >60 years of age, primary malignancies of the adrenal glands are extremely rare.^{14,51,52} When discovered during imaging for reasons other than an evaluation for suspected adrenal diseases or staging for a different primary tumor, adrenal tumors are referred to as adrenal incidentalomas. The vast majority of adrenal incidentalomas are benign, but up to 15% can be functional, autonomously secreting adrenal hormones leading to clinical or subclinical hormone excess, making clinical exam and biochemical evaluation for hormone excess mandatory.^{3,6,7,14}

The estimated incidence of ACC is 0.5 to 2 per million per year. It has a slight predilection for women (female:male, 1.5:1) with a relative bimodal age distribution peaking in early childhood and in the fifth decade of life.^{3,53,54-56} Although there are no established risk factors for sporadic ACC, smoking and early contraceptive use have been suggested.^{57,58} Up to 10% to 15% of all ACCs arise in patients with familial cancer syndromes, such as Li-Fraumeni syndrome, Lynch syndrome, multiple endocrine neoplasia type 1, and less commonly familial adenomatous polyposis, Beckwith-Wiedemann syndrome, or Carney complex.^{59,60}

The overall rate of PCPGL in the general population has been estimated at between 0.05% to 0.1%.^{61,62} The estimated incidence of malignant PCPGL is 1 to 5 per million per year.²⁶ Between 3% to 36% of PCPGL are malignant, with higher rates of malignancy in children, those with *SDHB* mutations, and those with extra-adrenal tumors.^{26,29,62,63} The average age at presentation is 44 in sporadic cases, compared with 25 for hereditary disease.^{62,64,65} Although historically only 10% of PCs were assumed to be associated with a familial syndrome, this is now estimated at 25% to 30%, particularly when also including PGLs.^{26,63} The relatively high contribution of hereditary conditions predisposing to all adrenal neoplasms warrants evaluation of every patient by a cancer geneticist and genetic counselor.

TABLE 84.1

Pheochromocytoma/Paraganglioma-Associated Syndromes^{41,196-209}

Gene	Syndrome	% Malignant	Clinical Features	Localization			
				Adrenal	Abdominal	Thoracic	Head/Neck
