SCREENING IN SPECIAL POPULATIONS

There are no current screening recommendations for adrenal tumors in the general population. As such, screening should only be considered for patients with a known or suspected familial syndrome that predisposes to adrenal neoplasia. Of all familial syndromes associated with ACC, Li-Fraumeni syndrome has the highest lifetime risk at up to 6.5% to 9%.^{66,67} Adrenal lesions identified in imaging obtained in patients with any of the other predisposing syndromes should be evaluated carefully for signs of malignancy. All patients diagnosed with PCPGL should undergo evaluation for predisposing familial syndromes caused by mutations in *SDHx*, *VHL*, *NFI*, *TMEM127*, *MAX*, and *RET*. Demonstration of a genetic mutation allows for identification of other affected family members and disease-specific screening and surveillance for adrenal neoplasms and other associated tumors in all gene carriers.^{49,68,69}

DIAGNOSIS OF ADRENAL NEOPLASIA

Patients with adrenal neoplasia may seek medical attention because of symptoms related to the size of their mass, hormone excess, or be referred for an incidentally discovered tumor (Fig. 84.1).^{64,70} Evaluation should begin with a thorough history and physical exam, including specific questions regarding symptoms of hormone excess, systemic illness, and a careful family history. The classic symptom triad of PC is headache, palpitations,

and diaphoresis, but presentation is highly variable and the complete triad is not observed in all cases.^{26,64} Patients with functional cortical neoplasms may present with overt hypercortisolism, hyperaldosteronism, virilization, or rarely feminization. Cortisol is the most commonly produced hormone in both benign and malignant functional cortical neoplasms.^{14,15,70} Mild hypercortisolism may be challenging to recognize given the absence of obvious signs.^{6,7} Hypertension may be caused by aldosterone-producing ACA, although aldosterone secretion by ACC is rare. Hypertension in ACC is more often related to mineralocorticoid effects of cortisol or secreted steroid intermediates.^{14,70} Virilization or feminization should increase suspicion for malignancy, as adrenal androgens are the next most common steroid hormone secreted by ACC, and up to half of hormone-producing ACCs produce both cortisol and androgen.⁷⁰ Likewise, hypercortisolism of rapid onset should increase concern for ACC.

Basic laboratory evaluation of a patient presenting with an adrenal mass or syndrome of hormone excess includes a complete blood count and comprehensive metabolic panel with liver enzymes. Those presenting with an incidental adrenal mass require comprehensive hormonal evaluation including tests for hypercortisolism, androgen excess, hyperaldosteronism in hypertensive patients, and catecholamine production in all patients.^{71,72} The most sensitive test for hypercortisolism is a 1 mg dexamethasone suppression test. Overt hypercortisolism is most often associated with morning (8 a.m.) cortisol levels $>5 \mu\text{g/dL}$ following dexamethasone testing, while a value of $<1.8 \mu\text{g/dL}$ excludes endogenous hypercortisolism.⁷ Conversely, spontaneous morning (8 a.m.)

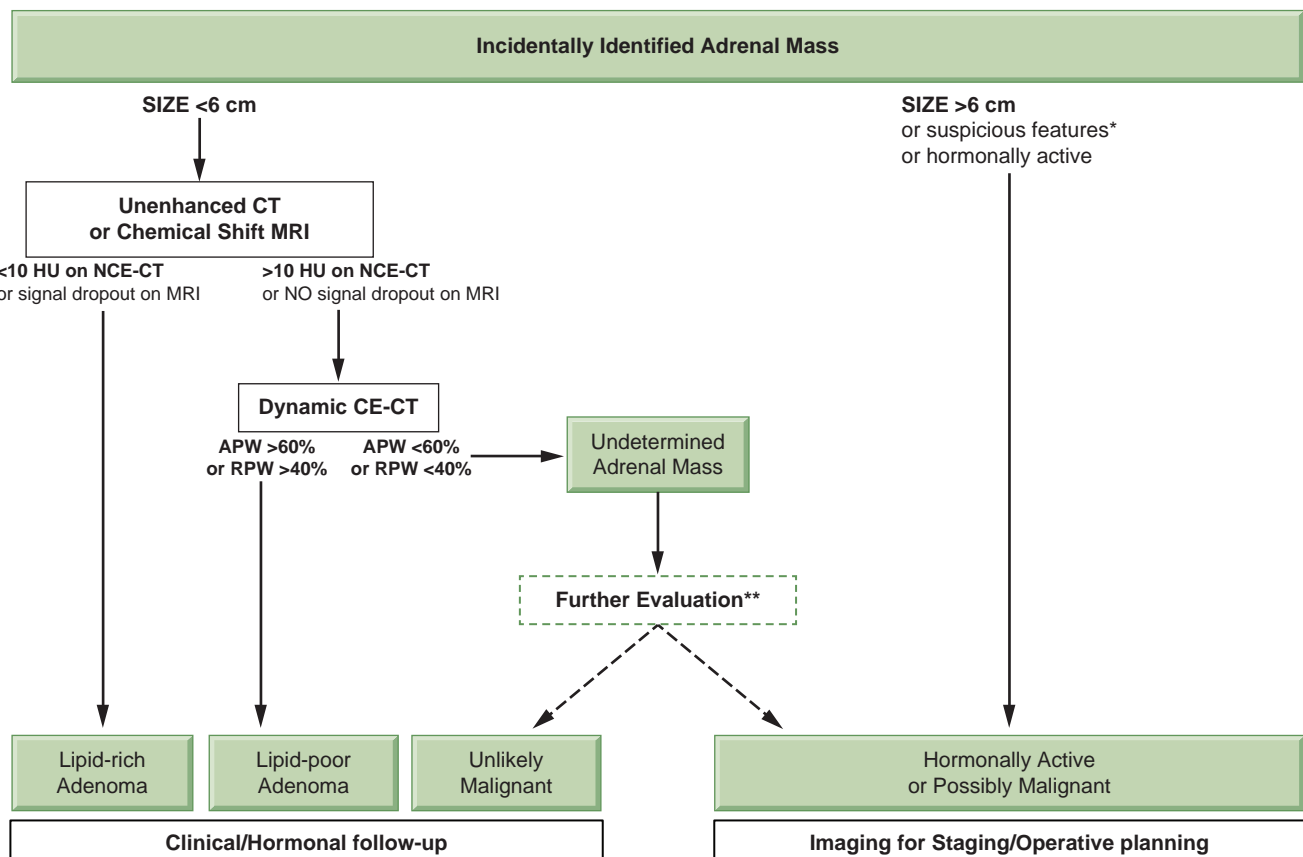

Figure 84.1 Imaging evaluation of an incidentally identified adrenal mass.^{6,7,26,62,71,78-88}

CT, computed tomography; MRI, magnetic resonance imaging; NCE, non-contrast-enhanced; CE, contrast-enhanced; APW, absolute percentage washout; RPW, relative percentage washout.

*Suspicious features include heterogeneity, irregular margins, and calcifications.

**Functional imaging with positron emission tomography/computed tomography or follow-up with magnetic resonance imaging or computed tomography has been described; however, emerging evidence of substantially increased lifetime risk of cancer death related to radiation exposure should be considered when developing a follow-up or surveillance plan.^{194,195}

ACTH levels of <10 pg/ml will be demonstrated for most cortisol-secreting tumors due to suppression of the hypothalamic-pituitary axis (HPA).⁶ Bioavailable or total testosterone and dehydroepiandrosterone sulfate are obtained to evaluate potential androgen excess, the latter produced only in the adrenal gland and therefore helpful in differentiating adrenal from gonadal neoplasia. Hypertensive or hypokalemic patients should have serum aldosterone concentration and plasma renin activity (PRA) measured. Hyperaldosteronism is typically diagnosed with a ratio of serum aldosterone concentration/PRA >20 to 40, provided the absolute level of aldosterone is also elevated, since mineralocorticoid effects of intermediates or volume repletion may also suppress renin.⁷ Plasma free metanephrine and normetanephrine are the most sensitive tests for PCPGL.⁷³ Positive screening hormonal evaluation dictates additional confirmatory hormonal studies, which may include 24-hour urine free cortisol to measure the extent of hypercortisolism,⁶ serum aldosterone levels following saline-infusion or 24-hour urine aldosterone under salt loading conditions, or measurement of additional steroid hormones such as progesterone, androstenedione, estradiol, 17-hydroxyprogesterone, or 17-hydroxypregnenolone for further characterization.^{6,7,72} The initial steroid profile can be useful for surveillance in ACC.^{21,72} For PCPGL, chromogranin A should be obtained, as it can be followed in surveillance.^{26,74-76}

Cross-sectional imaging (Fig. 84.2) with computed tomography (CT) or magnetic resonance imaging (MRI) is important for establishing the extent of disease and identifying features concerning for malignant cortical lesions. Benign cortical lesions tend to be small, fat-containing, and homogeneous, with smooth borders. Conversely, large, heterogeneous lesions with irregular margins and calcifications are strongly suggestive of ACC. The risk of ACC increases with size, and is estimated at $<2\%$ for lesions <4 cm, 2%

to 6% for lesions 4 to 6 cm, and 25% for lesions >6 cm. Lesions with enhancement of <10 Hounsfield units (HU) are indicative of lipid-rich ACA, although up to 30% of ACAs may be lipid-poor with intermediate enhancement between 10 and 30 HU.^{6,7,62,77} Lipid-containing lesions may also be identified on MRI by signal dropout on opposed-phase sequences. PCPGL are often bright as cerebrospinal fluid on T2-weighted MRI, but can be variable in appearance. They tend to be homogeneous when smaller and heterogeneous when larger with features overlapping lipid-poor ACAs, but no imaging features predict malignancy.^{7,26,82}

Suspicious tumors or those with indeterminate characteristics require additional imaging to further characterize the lesion in question and to evaluate for metastatic disease.⁷⁸ If the initial CT was non-contrast enhanced or optimized for another purpose, a dedicated adrenal-protocol CT with thin slices, oral contrast, and careful timing of intravenous contrast should be obtained for lesions that are homogeneous on the initial scan.⁶² Absolute percentage enhancement washout above a threshold of 60% (or relative washout above 40%) at 15 minutes has high sensitivity and specificity for lipid-poor ACA (Fig. 84.3).⁷⁹⁻⁸² Compared with CT, contrast-enhanced MRI is more sensitive for vascular invasion and is occasionally obtained as a complementary study in patients with larger tumors.⁷¹ Contrast-enhanced CT of the chest, abdomen, and pelvis is appropriate to evaluate for metastases and hence complete staging.⁷¹ Imaging of the head should only be obtained if neurologic symptoms are present, and bone scintigraphy can be obtained for those presenting with skeletal pain. Neither test is required in the initial evaluation of the asymptomatic patient.

Functional imaging can be useful in evaluating both cortical and medullary tumors of the adrenal gland. Deoxy-2[¹⁸F]fluoro-D-glucose positron emission tomography (¹⁸F-FDG-PET) (Fig. 84.2F) is a useful, complementary modality that can sometimes alter

Absolute percentage washout ≈ 18%.

management of an indeterminate lesion (i.e., one that is unable to be characterized with a high degree of certainty as benign or malignant). However, no validated quantitative criteria exist for reliably predicting whether a lesion that is indeterminate by anatomic imaging in a patient without a known primary cancer will be benign or malignant.^{78,83–88} Furthermore, metastatic disease from nonadrenal primary, PC (benign or malignant), and up to 10% of ACA can be positive on ¹⁸F-FDG-PET scan.^{79,89–93} ¹²³I-metaiodobenzylguanidine (¹²³I-MIBG) scans have high positive-predictive value for PCPGL and can be used for the identification of additional foci of disease, including multicentric tumors or metastasis, especially in patients with inherited syndromes.^{26,94} However, the use of ¹²³I-MIBG for diagnostic purposes is of rather limited utility as the diagnosis of PCPGL is often made through simple biochemistry and cross-sectional imaging. Moreover, for PGL of the head and neck ¹¹¹In-pentetreotide scintigraphy has better sensitivity.⁹⁵ It is worth mentioning that functional imaging will rarely discover any tumor that is not evident on cross-sectional imaging. In such cases where biochemical testing suggests PCPGL but imaging is negative, there are often other causes for clinical symptoms and/or elevated metanephrines (e.g., use of tricyclic antidepressants, congestive heart failure).

Percutaneous biopsy of adrenal tumors is almost never indicated because cytology is unhelpful in characterizing adrenal neoplasia, and biopsy has significant risk of complications including hemorrhage and pneumothorax.^{6,7,96–98} Careful consideration should be given to how the test will influence management and whether alternative approaches, such as PET/CT, can suffice, as most single adrenal masses can be diagnosed by imaging and endocrine evaluation.^{71,89} Only in the setting of a patient with a nonadrenal primary cancer should an adrenal biopsy be considered if it remains unclear whether the adrenal mass is a primary adrenal tumor versus a metastasis of the nonadrenal primary tumor. PCPGL should always be excluded prior to an attempted biopsy due to the high morbidity and mortality of biopsy-associated catecholamine surges.^{97,98}

GRADING AND STAGING OF MALIGNANCY

Establishing malignancy of adrenal neoplasms can be challenging. Histopathologic criteria established by Weiss predict malignancy in adrenocortical neoplasms when three or more of nine criteria are present.^{71,99} Mitotic rate is a particularly important criterion and indicates malignancy when greater than five mitoses are observed in 50 high-powered fields. Mitotic activity >20/50 high-powered fields defines a high-grade ACC.^{71,100,101} Several staging systems have been proposed for ACC, but the European Network for the Study of Adrenal Tumors staging system (Table 84.2) has become widely adopted as it best reflects outcome.^{102–105}

Differentiation between benign and malignant PCPGL is a challenging clinical problem as well. Indeed, because even extensive invasion does not accurately predict malignancy, the only criterion adopted by the World Health Organization for defining malignant PCPGL is metastasis.⁷³ No single histologic criterion predicts malignant PCPGL. The Pheochromocytoma of the Adrenal Gland Scaled Score system has been proposed for assessing malignant potential by using 12 histopathologic criteria,¹⁰⁶ but validation studies have produced conflicting results.^{107–109} At present, there is no staging system for PCPGL. Tumors are categorized as local, regional, or metastatic.⁶²

IMPORTANT CONSIDERATIONS IN PERIOPERATIVE MANAGEMENT OF ADRENAL TUMORS

Patients with adrenal neoplasms present unique perioperative challenges. In addition to hemodynamic and metabolic instability due to intraoperative catecholamine fluctuation, patients with PCPGL may have established cardiovascular sequelae related to chronic catecholamine excess.¹¹⁰ Those with cortisol-secreting tumors are at higher risk for infectious, metabolic, and wound-healing complications,

TABLE 84.2

Staging for Adrenocortical Carcinoma and Five-Year Cause-Specific Mortality

Stage	ENSAT 2008 ⁷⁴	Five-Year CSM (Eu) ¹⁰³	Five-Year CSM (NA) ¹⁰⁴
Stage I	T1N0M0	82%	74%
Stage II	T2N0M0	61%	64%
Stage III	T1-2,N1,M0 T3-4,N0-1,M0	50%	44%
Stage IV	T1-4,N0-1,M1	13%	6.9%

ENSAT, European Network for the Study of Adrenal Tumors; CSM, cause-specific mortality; Eu, Europe; NA, North America; T1 \leq 5 cm; T2 $>$ 5 cm; T3, infiltrating surrounding tissue; T4, invading organs, tumor thrombus in renal vein or vena cava; N0, no positive lymph nodes; N1, positive lymph node(s); M1, distant metastasis.¹⁰³

and will require careful glucocorticoid replacement following complete surgical resection due to suppression of the HPA.⁷⁰

Historically, perioperative mortality related to resection of PCPGL was as high as 45%. The introduction of α -blockade and volume repletion has reduced mortality to 0% to 3% in contemporary series.^{69,111} It is important to recognize that even patients with asymptomatic PCPGL are at risk for cardiovascular complications without preoperative α -blockade and that significant elevations in blood pressure may still occur intraoperatively despite adequate α -blockade.^{29,112} Either selective or nonselective α antagonists can be used to establish α -blockade. Selective α_1 -blockade has been used to avoid some undesirable α_2 -mediated side effects including reflex tachycardia, hypoglycemia, and somnolence, but these agents are less well studied compared with nonselective agents. Traditionally, phenoxybenzamine is the preferred nonselective α -blocker for PCPGL. Dosage can be titrated on an outpatient basis for adequate blockade, which often takes 2 weeks or longer. During this time, salt- and fluid-loading are recommended for volume optimization to minimize postoperative hypotension.⁶⁹ Other α -blocking agents can serve as an alternative to phenoxybenzamine and are preferred by some institutions.¹¹³ Initiation of a β -blocker for reflex tachycardia may be considered, but not before α -blockade is established. Data regarding the use of calcium channel blockers and angiotensin-converting enzyme inhibitors preoperatively in patients with PC are limited.¹¹⁴⁻¹¹⁶ It is important to recognize that α -adrenergic vasopressors may not be helpful in treating hypotension resulting from α -blockade and that volume expansion should be the treatment of choice.⁶⁹

Resection of cortisol-producing tumors may present unique perioperative challenges as well. Aggressive preoperative control of hypercortisolism is advocated but should not delay surgery.⁷⁰ Postoperative adrenal insufficiency should be anticipated in all patients with preoperative hypercortisolism and replacement should be initiated preemptively postoperatively, with surveillance of the HPA and treatment adjustment as necessary. Recovery of the HPA might take up to 6 to 24 months, and additional steroid replacement during times of stress to prevent Addisonian crisis is necessary.^{71,117,118}

MANAGEMENT OF BENIGN-APPEARING ADRENOCORTICAL TUMORS AND PHEOCHROMOCYTOMA

Before pursuing surgical management, an assessment of the likelihood of malignancy based on size, imaging, and clinical presentation must be made.¹¹⁹ The surgeon should strictly adhere to oncologic principles when resecting tumors not meeting criteria for being benign.⁷⁰

Although its role in potentially malignant lesions is controversial, minimally invasive adrenalectomy has lower morbidity, decreased pain, and shorter hospital stay, and is the procedure of

choice for benign-appearing adrenocortical tumors or PCPGL if technically feasible.¹²⁰⁻¹²² Minimally invasive approaches for adrenalectomy may be performed laparoscopically by an anterior abdominal approach or by a posterior retroperitoneal approach.^{120,123} The posterior retroperitoneal approach is advantageous in patients with prior abdominal operations because the potential need for adhesiolysis is obviated; however, the posterior retroperitoneal approach is not advised in patients with significant subcutaneous or perinephric fat, unfavorable anatomy, or tumors $>$ 8 cm.^{124,125} Partial (i.e., cortical-sparing) adrenalectomy is the preferred approach for patients with familial bilateral benign diseases, such as bilateral PCPGL in patients with von Hippel-Lindau disease or multiple endocrine neoplasia type 2.^{29,126,127}

SURVEILLANCE AFTER RESECTION OF PHEOCHROMOCYTOMA

There are no standard recommendations for surveillance for malignant PCPGL after resection of apparently benign disease. However, most endocrine neoplasia groups suggest that all patients receive some form of long-term follow-up.^{29,69} Surveillance strategies must be individualized and may depend on overall impression of risk for malignancy (e.g., *SDHB*), operative findings, and genetic predisposition to additional primary tumors.¹²⁸ Initially, all patients should undergo surveillance reevaluation with history, physical exam, laboratories, and imaging. Postoperative biochemical testing at 2 to 6 weeks and 6 months is appropriate, and chromogranin A may be useful if elevated preoperatively.^{29,69,94} The preferred imaging modality for surveillance is CT or MRI of the site of the initial tumor, as local recurrence is the most common form of relapse. Particularly in patients with hereditary syndromes, MRI should be preferred as the number of scans might otherwise lead to excessive radiation doses.⁹⁴

MANAGEMENT OF RECURRENT OR METASTATIC MALIGNANT PHEOCHROMOCYTOMA

Diagnosis of malignant PCPGL is made based on recurrence or identification of metastasis on initial presentation.¹²⁹ In a retrospective review of 176 patients with PCPGL initially presenting without evidence of malignancy, up to 17% of patients developed recurrence at either the primary site or another location. Recurrences were malignant in half of all cases and more commonly occurred in patients with familial syndromes or larger tumors.¹³⁰ The most common sites of metastasis of PCPGL are to bones, lungs, liver, and lymph nodes.^{69,94} Five-year survival is 34% to 60%, although this is dependent on location of metastasis, as those with

lung and liver lesions have shorter survival compared with those who have osseous metastasis only.²⁹

Treatment options for malignant PCPGL are limited and the goal of therapy is palliative, with a focus on controlling catecholamine secretion, pain, and tumor burden.^{72,131,132} Options include supportive medications, modalities for locoregional control, external-beam radiation, radiopharmaceuticals, and chemotherapy. Quality of life must be considered because in some cases observation and supportive medication alone is the best option.^{72,131} Debulking and metastasectomy can be considered in patients who have significant resectable tumor burden in the context of slowly progressive disease.^{26,72,131,132} Radiofrequency ablation (RFA) and transarterial chemoembolization (TACE) have been described for unresectable metastases. Similar to any surgery, these procedures require sufficient preoperative α -blockade.²⁶ External-beam radiation has been particularly useful in treating osseous metastases but can provoke hypertensive crises.²⁶ In patients with disease not amenable to surgery but with acceptable overall clinical status, ¹³¹I-MIBG can be used for locoregional control, provided ¹²³I-MIBG imaging demonstrates good avidity.^{26,131,132}

In patients with symptomatic unresectable disease for which other modalities have failed or are not indicated, cytotoxic chemotherapy can be considered.^{26,132} Cyclophosphamide-dacarbazine-based regimens are the most thoroughly evaluated.⁷² Three nonrandomized studies have shown radiographic and symptomatic responses in 40% to 50% of patients treated with these regimens, and 22-year follow-up of one nonrandomized prospective study published similar results with cyclophosphamide, vincristine, and dacarbazine.¹³¹ After therapy is discontinued, however, refractory disease tends to recur.²⁶ Cytotoxic chemotherapy has also been used in borderline resectable cases, with sufficient response allowing patients to proceed with surgery.⁷² During treatment surveillance, imaging with CT, MRI, and bone scan as indicated every 3 months to evaluate response is recommended.¹³¹

MANAGEMENT OF LOCAL AND LOCOREGIONALLY ADVANCED ADRENOCORTICAL CARCINOMA

Surgery is the cornerstone of management for ACC in stages I to III and should always follow the principles of an oncologic resection, which requires careful preoperative planning with an appreciation for the rapid growth potential of aggressive ACCs.^{70,71,133} Preoperative imaging can underestimate tumor size by as much as 40%, and relationships to surrounding structures are subject to change during the interval between imaging and operation.^{70,133} The surgeon should be prepared for concomitant resection of liver, kidney, spleen, pancreas, stomach, colon, diaphragm, or vena cava, as suggested by imaging. Although there is no evidence that prophylactic nephrectomy of an uninvolved ipsilateral kidney improves survival, threshold for *en bloc* resection should be low, and nephrectomy is indicated for involvement of renal capsule or vein.^{71,72} The celiac axis and root of the superior mesenteric artery may be partially encased by tumor, which may be a contraindication to surgery if resection and reconstruction is not feasible.¹³³

Locally advanced tumors of questionable resectability or behavior can be considered for systemic preoperative therapy with close monitoring. Patients with rapidly progressive disease may not derive sufficient benefit to justify a large resection, whereas tumors that respond to therapy may subsequently be deemed resectable.^{72,133}

Adrenalectomy is traditionally performed through a midline or subcostal incision, depending on preoperative assessment of need for multivisceral resection.⁷⁰ A thoracoabdominal incision may provide better exposure for diaphragmatic resection and repair or in those with prior abdominal surgery.^{133,134} Access to the retrohepatic inferior vena cava is necessary if it is infiltrated by tumor

directly or harbors tumor thrombus requiring venotomy or resection.¹³⁵ On rare occasions, median sternotomy and cardiopulmonary bypass are necessary for extracting tumor thrombus extending into the right atrium.¹³⁵

The role of locoregional lymphadenectomy is not established, but one study suggests improvements in staging and possibly survival.^{9,72,136} Lymph node metastasis is not uncommon in ACC, and *en bloc* lymphadenectomy, when feasible, to clear nodes of the celiac axis, superior mesenteric artery, and renal hilum has been advocated.^{70,137}

Consideration of laparoscopy for resection of potentially malignant low-stage ACC <8 cm is advocated by some, provided an R0 resection can be achieved and the operation is conducted by an expert surgeon.⁷² This issue is highly controversial, and failure to achieve an R0 resection can rarely be overcome by additional operations or adjuvant treatments.^{70,72,133} Independent of approach, strict adherence to oncologic principles is necessary for optimal outcome, including a complete and systematic evaluation of the entire peritoneal cavity, full mobilization of overlying uninvolved organs, and *en bloc* resection including the entire retroperitoneal fat pad surrounding the tumor without directly manipulating the tumor to prevent rupture of the fragile capsule and consequential peritoneal seeding.^{70,71,133,138} Surgical specimens should be submitted to pathology carefully marked and intact, and clips should be placed in the tumor bed for targeting of adjuvant radiotherapy if necessary.⁷⁰

Patients undergoing adrenalectomy at high-volume centers have better oncologic outcome; therefore, referral to an experienced facility is advised.^{20,70,102,139}

SURVEILLANCE AND ADJUVANT THERAPY FOR ADRENOCORTICAL CARCINOMA

Recommendations for surveillance and adjuvant therapy depend on behavior and appearance of the tumor, stage at presentation, and operative findings. Pathologic findings should be carefully reviewed as it has been reported that 25% of patients diagnosed with stage III disease by pathologic evaluation after resection were thought pre- and intraoperatively to have a lower-stage tumor.¹³³

Data from the National Cancer Database show that 19% of patients undergoing surgery do not receive an R0 resection.¹³⁷ In patients who remain good operative candidates, repeat resection by an expert surgeon should be considered, especially after an R2 resection.¹⁴⁰ Those who are not candidates for reoperation can be considered for radiotherapy.⁷¹

In those who do undergo R0 resection, rates of local recurrence remain high at 19% to 34%, with the overwhelming majority of recurrences occurring in the first 5 years.^{20,70,141} Close surveillance is mandatory, and a complete evaluation every 3 months for 2 to 3 years has been advocated. Subsequently, this can be reduced to biannually until 5 years and annually thereafter. Evaluation in this setting should include a history and physical exam, a complete blood count and metabolic profile, including liver enzymes, as well as steroid profile, and cross-sectional imaging of the chest, abdomen, and pelvis.^{71,72} Steroid profiles should be carefully evaluated as recurrence of preoperative patterns of elevation raise concern for recurrence.²¹ Additional laboratories are necessary for monitoring mitotane therapy in patients receiving this treatment.¹⁴² ¹⁸FDG-PET scan is not a standard modality for surveillance but is useful in characterizing newly discovered lesions on surveillance imaging as ACCs are almost invariably PET-positive.^{71,72,88}

Evidence-based guidelines for adjuvant therapy after completely resected disease are lacking. Radiotherapy has historically been avoided because of a pervasive impression that ACC is radioresistant.⁷⁰ Although there is no convincing evidence corroborating this notion, <10% of patients with ACC receive radiotherapy.²⁰ Modern series have reported conflicting results on adjuvant radiotherapy, raising the possibility that radiotherapy may be a useful modality.¹⁴³⁻¹⁴⁵ In general, radiotherapy has been shown to provide

good local control and decrease the risk of local recurrence following primary resection, but its effect on survival parameters is not well researched. Current expert consensus opinion and practice guidelines recommend radiotherapy in the adjuvant setting, especially in those who have previously undergone R1 or R2 resection.^{71,72,146}

Similarly, there are conflicting data regarding the benefits of mitotane as adjuvant therapy, with an ongoing prospective, randomized clinical trial designed to address this issue (ADIUVO trial). In patients undergoing R0 resection, immunohistochemistry for Ki67 can be used to inform decision making. A large retrospective study showed significant improvement in median tumor-free survival with adjuvant mitotane therapy in patients with Ki67 >10%, and therefore mitotane therapy should be offered to all of these patients.^{72,147-150} Although there is no robust evidence for the use of combination radiotherapy and mitotane as adjuvant treatment, this should be considered in patients with stage III disease or those who have undergone repeated resection. Mitotane is routinely started within 3 months of resection and continued for at least 2 years in lower-risk patients, and if tolerated up to 5 years or longer, especially for higher-risk patients. Mitotane requires careful monitoring as the therapeutic window is tight and complications may be dose limiting.^{70-72,142,150}

MANAGEMENT OF LOCOREGIONAL RECURRENCE OF ADRENOCORTICAL CARCINOMA

Failure of primary treatment may manifest as locoregional recurrence detected during surveillance. The extent and timing of recurrence, as well as the histologic appearance of the tumor from surgical specimens, are important predictors for survival.^{70,71,101,105,151} Repeat resection is not a curative modality but may prolong survival and should be considered in patients with excellent performance status who have recurrence confined to a minimal number of sites and can undergo resection of all remaining tumor.^{71,101,151,152} Other situations in which repeat resection can be considered include patients with long disease-free intervals and low-grade appearance, as patients with high-grade tumors or rapidly progressive disease may benefit less than those with more indolent disease. For questionably resectable lesions, systemic therapy including mitotane followed by repeated evaluation after 3 months can be considered. Although complete remission is rare, up to 30% of patients show stable disease or partial remission with mitotane therapy.^{70,71,133,141} In situations where local recurrence is symptomatic and not amenable to surgical management, definitive radiotherapy can be considered. In patients with asymptomatic recurrence, this modality is controversial.⁷⁰⁻⁷²

MANAGEMENT OF ISOLATED METASTASES OF ADRENOCORTICAL CARCINOMA

All therapy for metastatic ACC is palliative, and appropriate counseling of patients regarding expectations of additional therapies is paramount.⁷⁰ When recurrence presents as an isolated metastasis, surgery can be considered in highly selected patients when complete resection is possible without undue morbidity.^{71,72} Metastectomy has shown promise particularly with limited pulmonary disease, and can be repeated in selected patients when technically feasible.¹⁵³⁻¹⁵⁵ In other circumstances, additional palliative modalities are available, including RFA, TACE, and external-beam radiation.⁷⁰⁻⁷² Radiotherapy has been particularly useful in treating osseous metastasis and has also been utilized in treating metastases to the brain and other locations. Although there are no robust clinical trial data available to support the use of RFA or TACE, these options can be used in combination with surgery

for isolated metastases that are difficult to access or for situations when surgery is not indicated or desired. RFA has demonstrated success in liver metastasis and has also shown promise in other locations, with better outcomes in lesions <5 cm that are not near large blood vessels to avoid a heat-sink effect, which can inhibit efficacy.^{71,156-158} TACE, which involves selective embolization and intratumoral infusion of high concentrations of cytotoxic chemotherapy, is used often to treat isolated metastases with few reported complications, although published experience is limited and treatment of primary tumors has been reported to cause hemorrhage.¹⁵⁹⁻¹⁶¹ More information regarding both modalities is needed before definitive recommendations can be made.

MANAGEMENT OF METASTATIC OR UNRESECTABLE ADRENOCORTICAL CARCINOMA

Goals of palliative care for metastatic ACC are control of pain, symptoms of hormone excess, side effects of treatments, and prevention of fractures.⁷⁰ Patients presenting with widespread metastasis in multiple organs or unresectable deposits in a single organ system do not typically undergo surgery and all therapy is palliative. Debulking for control of symptomatic hormone excess can be performed in patients with excellent functional status but is not expected to provide a durable response and may not be advisable in situations where only limited debulking is feasible (e.g., patients with rapidly growing tumors or expected debulked load of <80% to 90%).^{70,71} Furthermore, steroidogenic inhibitors are replacing surgical debulking as a growing means of lowering steroid levels (see the following).¹⁶²⁻¹⁶⁴

The mainstay of therapy for widely metastatic disease is cytotoxic chemotherapy.⁷⁰ Initial studies of single agents led to most common contemporary regimens. In the past few decades, the two most promising cytotoxic chemotherapeutic regimens used in combination with mitotane have been etoposide, doxorubicin, and cisplatin, or streptozotocin.¹⁶⁵⁻¹⁷¹ Recently, these regimens (etoposide, doxorubicin, and cisplatin with mitotane, and streptozotocin with mitotane, respectively) were compared in a randomized controlled trial (FIRM-ACT) that demonstrated a modest but significant increase in progression-free survival of 5 months in the etoposide, doxorubicin, and cisplatin with mitotane compared with 2 months in the streptozotocin with mitotane group. Although significant comparative improvements were demonstrated, objective response and median duration of survival remained dismal.¹⁷²

Although cytotoxic chemotherapy is often administered concurrently with mitotane, the latter causes CYP3A4 induction with attendant catabolism of many drugs. This has led some to question whether mitotane therapy has confounded earlier studies of chemotherapeutics (as well as recent trials of targeted therapy), but prospective studies of regimens with and without mitotane are heterogeneous and have not convincingly resolved this issue.⁷⁰

Patients suffering from metastatic ACC experience debilitating hormonal symptoms, necessitating effective control. The adrenolytic and steroidogenic inhibitory effects of mitotane are often successful in mitigating these symptoms in patients who have achieved therapeutic levels. In others, however, steroidogenic inhibitors such as ketoconazole or metyrapone are commonly required.¹⁴² Typically, 24-hour urine cortisol is used to guide therapy, but titration is challenging because cortisol levels are often unreliable in this setting. Furthermore, patients undergoing systemic therapy or treatment with inhibitors of steroidogenesis may require supplementary glucocorticoid treatment during times of stress. Alternatively, hypercortisolism can be controlled by using mifepristone, a direct glucocorticoid receptor antagonist. However, under mifepristone therapy, cortisol and ACTH levels rise and cannot be used to guide therapy; therefore, doses are usually titrated clinically. Patients with mineralocorticoid excess can be treated with spironolactone, which may also benefit females

with virilizing symptoms due to its antiandrogenic effect. Males suffering from feminization may benefit from aromatase inhibitors or estrogen receptor antagonists.⁷⁰

EMERGING DIAGNOSTIC TECHNIQUES AND TREATMENT STRATEGIES FOR ADRENAL TUMORS

Ongoing effort in basic science, translational, and clinical research is expected to yield improved diagnostic tools and therapies. Rigorous evaluation of currently available therapeutics is necessary to identify optimal treatment regimens. With regard to surgical management, this includes addressing the controversy surrounding operative approach (open versus laparoscopic) for presumed low-grade ACC, necessity for lymphadenectomy, and utility of debulking procedures. The role of radiotherapy both in the adjuvant setting and for unresectable disease needs further clarification.¹⁷³ Novel strategies for optimal delivery of radionuclide treatment including non-carrier-added techniques, new ligands, sensitizing agents, and combination delivery are undergoing evaluation.^{70,131,138,139,174} Many questions regarding mitotane treatment remain, including its utility in the adjuvant setting for low-intermediate-risk disease (ADIUVO trial) and implications of its profound, lasting induction of CYP3A4 on concomitantly delivered therapeutics. Although early trials of targeted therapeutics in both PCPGL and ACC have not been promising, further study has resulted in increased appreciation for the complexity of the pathways involved and offered some explanations for past failures. Additional innovations are also necessary in diagnostic techniques to address the challenge of accurately predicting malignant potential of adrenal neoplasms. A variety of promising molecular imaging agents need to be rigorously evaluated.¹⁷⁵ Urine steroid profiling is an intriguing tool that may be useful in diagnosis and surveillance but requires validation.^{21,78,107,173} Upcoming genome-wide expression studies and international collaboration may suggest additional biomarkers for diagnosis and surveillance or potential therapeutic targets.

SPECIAL CONSIDERATIONS IN PREGNANCY

Adrenal neoplasms considered in this chapter (PCPGL, ACA, ACC) have all been described in pregnancy, albeit rarely, and management is often complex.¹⁷⁶ Many typical physiologic changes or common complications of pregnancy can mask signs and symptoms of an underlying adrenal neoplasm, resulting in the potential for mortality as high as 29% without an antenatal diagnosis.¹⁷⁶ The preferred imaging study is MRI, because radioisotope studies, CT scans, and gadolinium are contraindicated in pregnancy.^{176,177} Biochemical diagnosis of PCPGL is established as for nonpregnant patients, and α -blockade is essential to prevent hypertensive crises. Adrenalectomy for patients diagnosed with PCPGL within the first two trimesters is advocated.¹⁷⁷ When diagnosed in the third trimester, caesarean section is recommended, with adrenalectomy immediately after, or at a later date.^{176,177}

Similarly, diagnosis of adrenocortical tumors may be more challenging due to significant physiologic elevations in adrenocortical steroid hormones with pregnancy.¹⁷⁸ Furthermore, in the case of hypercortisolism, symptoms such as weight gain, striae, and fatigue may similarly be misattributed to normal pregnancy. Although hypercortisolism in pregnancy is rare, 50% of cases are caused by cortisol-producing ACA and 10% by ACC.¹⁷⁸ Surgical management is preferred due to significant fetal morbidity of untreated hypercortisolism.¹⁷⁸ Conversely, most reported cases of aldosterone-producing ACA are managed medically until delivery.^{179,180} Finally, poor outcomes are reported for pregnancies in

the setting of ACC or mitotane therapy; therefore, effective contraceptive in such patients is recommended.¹⁸¹

ADRENAL NEOPLASIA IN CHILDHOOD

Many diagnostic and management considerations for ACC and PCPGL in children parallel their adult counterparts, but several important distinctions deserve special attention. PCPGL is a rare diagnosis in children, estimated at 1 in 2 million overall.¹⁸² Several small series suggest a slight male preponderance and presentation in early adolescence on average.^{183–185} Genetic mutations (including *SDHB* and *VHL*, as described previously) are reported in up to 33%,^{183,185} though this may be an underestimate. Presentation appears variable but symptoms such as diaphoresis may be more prevalent and severe compared with adults.^{183,184} Reported complications of sustained hypertension in these patients include hypertensive retinopathy and hypertonic cardiomyopathy.¹⁸² As in adults, the biochemical diagnosis is established with plasma metanephrines and normetanephrines; however, careful consideration should be given to choice of imaging modality to limit radiation exposure if possible. Definitive treatment is surgical, with mandatory preoperative α -blockade and volume expansion. Laparoscopic and cortex-sparing procedures are commonly utilized, especially for patients with bilateral disease or hereditary syndromes.^{183,184,186} As a caution, PCPGL can be mistaken for the far more commonly encountered neuroblastoma preoperatively,^{182,186,187} this can have adverse consequences because preoperative α -blockade is not usually initiated for resection of neuroblastoma.^{185,188}

ACC is also a rare diagnosis in children, accounting for 0.2% of childhood cancers.¹⁸⁹ An early peak at ages 3 to 4 years is described, with another smaller increase in incidence in adolescence.¹⁸⁹ Although there is a slight overall female predilection, gender distribution appears age dependent.^{189,190} In contrast to their adult counterparts, adrenocortical tumors in children are malignant in >60% of cases.¹⁸⁶ In general, a predisposing genetic mutation is identified in >50% of all childhood ACC, and most are mutations in *TP53*.¹⁸⁹ A cohort of patients in southern Brazil has been identified with 10 to 50 times higher rate of ACC, of whom 95% have a specific germline mutation in *TP53*.¹⁸⁹ Many other genomic changes have been described that appear distinct from the adult population.¹⁸⁹ Intriguingly, histopathologic features, molecular signature, clinical presentation, and prognosis of ACC appear distinct in tumors from young children compared with those from adolescents. Features characteristic of the fetal adrenal cortex have been demonstrated in specimens of early childhood ACC by microscopy and microarray analysis.^{189,190} Moreover, the overwhelming majority of early childhood ACC present with virilization, compared with those presenting in adolescence, when hypercortisolism is more common.¹⁹⁰ Either way, 90% of childhood ACC are functional and virilization alone or in combination with hypercortisolism has been described in 80%.¹⁸⁹ In some cases, subtle signs or laboratory evidence of hormone excess have been documented years before diagnosis.¹⁹¹ Approximately one-third of patients with childhood ACC present with unresectable disease, and overall 5-year survival is reported at 54% to 74%,^{189,190,192,193} although prognosis for younger children is better, especially in those with smaller tumors after complete resection.¹⁹⁰ As in adults, surgery is the primary treatment modality with multimodal therapy for more advanced disease including mitotane and cytotoxic chemotherapy.¹⁸⁹

85 Pancreatic Neuroendocrine Tumors

James C. Yao and Douglas B. Evans

INTRODUCTION

Pancreatic neuroendocrine tumors (pNET), also known as pancreatic endocrine tumors, islet cell carcinoma, or pancreatic carcinoid, are low- to intermediate-grade neoplasms and have a more indolent course compared to pancreatic adenocarcinoma. pNETs can secrete hormones and be functional or nonfunctional. Functional status is generally influenced by several factors, including disease bulk, stage, secretory status, and whether the peptide secreted is intact and causes distinct clinical symptoms. pNETs are generally considered functional if they are associated with a hormonal syndrome. Regardless of tumor staining for hormones by immunohistochemistry (IHC) or serum levels of measured peptides in blood, those pNETs not causing a clinical hormonal syndrome are considered nonfunctional. It is also recognized that the functional status of these tumors may change over time or with treatment. Moreover, some of these tumors can produce multiple hormones simultaneously, although symptoms related to one of these hormones often will dominate.

Management of pNETs generally can be categorized into management of the problems caused by secreted hormone(s) and oncologic issues related to tumor growth and metastasis. The organization of this chapter parallels this paradigm. Following discussions of the epidemiology, pathology, and molecular genetics of these tumors, the oncologic issues common to the diagnosis and management of pNETs are discussed in the section on nonfunctional tumors. This is followed by discussions of issues unique to each functional “endocrinoma.” Next is a section on additional clinical considerations, which includes hereditary cancer syndromes, pathology pitfalls, surgical pitfalls, and high-grade NETs. Our goal for this chapter is to provide a systematic, up-to-date, and practical approach to pNETs.

EPIDEMIOLOGY

pNETs are reputed to be relatively rare neoplasms, but their exact incidence and prevalence are somewhat elusive. This is in part because most registries, including the Surveillance, Epidemiology, and End Results (SEER) program, only include neoplasms that are deemed malignant. For pNETs, the definition of malignant behavior is complex. In the absence of malignant behavior such as direct invasion of adjacent organs or metastases to regional lymph nodes or distant sites, size is typically used to classify the malignant potential of pNETs. The age-adjusted incidence of pNETs has risen significantly over the last three decades (Fig. 85.1). The diagnosed incidence of pNETs in the United States was estimated to be 5.6 (95% confidence interval [CI], 5.1 to 6.2) per million in 2010.^{1,2} The incidence of smaller pNETs in the general population, however, is likely to be much higher. In an analysis of 11,472 autopsies performed at a Hong Kong hospital, pNETs were found in 0.1% of all cases.³ This suggests that the prevalence of small asymptomatic islet cell tumors, many of which are never diagnosed, may be 100-fold more common than the data suggested by SEER registries. It is yet unclear whether the observed increase in is purely due to better diagnosis and classification

or environmental factors including the use of certain medications, which may have led to a real increase in incidence.⁴

pNETs were slightly more common among men (53%) than women (47%), and the median age at diagnosis was 60 years.^{1,5} At diagnosis, 14% had localized disease, 22% had regional disease, and 64% had distant disease. The survival of patients with pNETs has improved over time.^{5,6} Among patients diagnosed from 1988 through 2004, the 5-year survival rates among patients with localized, regional, and distant pNETs were 79%, 62%, and 27%, respectively (Fig. 85.2).¹

CLASSIFICATION, HISTOPATHOLOGY, MOLECULAR GENETICS

Criteria for Pathologic Diagnosis

A larger fraction of endocrine cells in the pancreas are insulin-producing (B) and glucagon-producing (A) cells. Relatively minor populations of cells produce somatostatin (D) and pancreatic polypeptide (PP). Rare cells also produce serotonin (EC) and ghrelin (P/D₁).⁷ These endocrine cells are believed to be the source of pNETs. It is a matter of debate if tumors arise from islets or ducts. Transgenic mice expressing potent oncogenes in endocrine cells⁸ and multiple endocrine neoplasia (MEN)1 knockout mice^{9,10} point to an islet origin of tumors consistent with the auto-renewal properties of islet cells¹¹ and clinical observations in patients with MEN1.¹² Conversely, molecular evidence from islet microdissection in patients with MEN1 indicate a duct cell origin.¹³ No matter where the truth lies, endocrine tumor cells largely display the same phenotype as their normal endocrine counterpart.

Aggressiveness of pNETs can be classified according to differentiation or proliferative rate. In the 2010 World Health Organization (WHO) classification, well-differentiated pancreatic neuroendocrine neoplasm is termed neuroendocrine tumor, whereas poorly differentiated neuroendocrine neoplasm is termed neuroendocrine carcinoma.¹⁴ Histologically, well-differentiated tumors are characterized by bland features: trabecular, glandular, acinar, or mixed structures; the stroma is generally fine and rich in well-developed blood vessels, sometimes with hyalinised deposits of amyloid; tumor cells are monomorphic with abundant, variably eosinophilic cytoplasm, low cytological atypia and low mitotic index. Necrosis is usually absent or may be seen as spotty, limited areas in histologically more aggressive neoplasms. On the contrary, poorly differentiated neuroendocrine carcinomas are characterized by prevalent solid structure with abundant necrosis, often central, round tumor cell of small to medium size with severe cellular atypia and high mitotic index.

Fine Needle Aspiration Versus Core Needle Biopsy

The diagnosis of pNET is necessary (1) to meet the previously defined histologic and cytologic criteria, (2) to assess the status of endocrine differentiation, and (3) to evaluate prognostic markers (proliferative index). Fine needle aspiration (FNA) biopsy is

Figure 85.1 Age adjusted incidence rate per 1 million population.²

an effective technique in expert hands, allowing confirmation of the cytologic diagnosis on isolated or grouped cells with little information on tumor structure. The advantages of FNA are several, including its simplicity, low invasiveness, and cost. The disadvantages are mainly its operator-dependent efficacy and limited option for further study (small sample size) to include prognostic variables.

Conversely, the core needle biopsy (ideally 2 mm in diameter) produces a larger sized tumor sample, potentially allowing a cyto/histologic diagnosis complete with all known prognostic parameters. Besides the easier diagnostic approach intrinsic to histology, its major advantage is certainly the potential for further studies to include all IHC studies and assessment of proliferative index.

Disadvantages are the invasiveness of the procedure(s) and the relatively higher costs.

We typically recommend core needle when considering biopsy of liver metastases and FNA for biopsy of the pancreas.

Minimum Immunohistochemistry Markers

A large number of antigens, commonly defined as “neuroendocrine markers,” are expressed in tumor cells.⁷ They comprise markers dispersed in the cytosol including neuron-specific enolase (NSE) and protein gene product 9.5, and markers of the secretory compartment, either associated with electron-dense granules, large-dense-core vesicles such as chromogranins and related fragments (the most popular being chromogranin A [CgA]), or associated with small synaptic-like vesicles such as synaptophysin. These antigens are defined as “general markers,” since they are widely expressed in cells of the diffuse endocrine system. Hormones and/or amines are produced by specific cell types and thus defined as “specific markers.” The positive identification of the endocrine cell product(s) in tissue sections is obtained by IHC.

A minimal IHC histology panel is designed to (1) positively identify the degree of endocrine differentiation in tumor cells, and (2) determining the proliferation activity status. Determining the proliferation status is achieved by Ki67 IHC using the MIB1 antibody or it can be expressed as mitoses per 10 high power microscopic fields (or 2 mm²).

Grade—World Health Organization 2010, American Joint Committee on Cancer, Union for International Cancer Control

Proliferative rate has been widely acknowledged as an important prognostic factor in pNETs. Though some controversies remain, the grading system based on mitotic rate and Ki 67 labeling

Figure 85.2 Survival by stage. Median survival for patients with localized, regional and distant metastatic disease were >10 years, 9.3 years, and 2.3 years, respectively.¹

^b MIB1 antibody; % of 2,000 tumor cells in areas of highest nuclear labeling.

has been widely adopted by the American Joint Committee on Cancer (AJCC), International Union Against Cancer (UICC), and WHO (Table 85.1).^{15,16} Low (G1) and intermediate (G2) grade neoplasms are termed pNETs, whereas aggressive high-grade (G3) neoplasm are termed pancreatic neuroendocrine carcinoma.

The general utility of such a grading scheme has been validated in a number of studies.^{17–21} However, the optimal Ki-67 cut-off between G1 and G2 remains debated in the literature. Some authors have proposed 5% (instead of 2%) as a more discriminatory cut-point for important outcomes including overall survival (OS).²² In one multivariate analysis that included lymph node ratio, a Ki-67 >5% was identified as the strongest predictor of recurrence after resection of malignant pNETs.²³ At the current time, G1 and G2 tumors are managed in a similar way. Therefore, the distinction between G1 and G2, while prognostic, does not have major therapeutic implications. A more important issue is the distinction between G2 and G3 as platinum-based chemotherapy is generally recommended for G3 tumors. In a recent review of a large Nordic series, response rate to platinum-based chemotherapy was low for the subgroup of G3 patients with Ki-67 between 20% and 55%. Tumors with a Ki-67 >55% appear more responsive to platinum-based chemotherapy.²⁴

Tumor, Node, Metastases (TNM)

The recent European Neuroendocrine Tumor Society proposal of tumor node, metastases (TNM) for non functional pNETs is based on criteria previously identified by the WHO 2004 classification and implies a malignant potential for any tumor type.¹⁵ The practical utility of this system was demonstrated in six independent studies.^{17–21,25} In 2010, a TNM system was officially provided by AJCC and the UICC.¹⁶ Their recommendation was to apply the same TNM system devised for exocrine pancreatic cancer to pNETs (see Table 85.1). The AJCC-UICC TNM scheme is based on a publication investigating a large tumor registry database.²⁶ As there is currently no adjuvant therapy available for pNETs, the distinction between the two staging system carries no practical therapeutic implications.

Molecular Genetics of Pancreatic Neuroendocrine Tumors

Advances in technology over the past 5 years have led to an explosion of new data emerging from high throughput molecular analyses. Recent exome sequencing studies have simultaneously

confirmed the importance of genes associated with inherited cancer syndromes and discovered important novel genetic aberrations among patients with sporadic pNETs.²⁷

The importance of the *MEN1* gene in the carcinogenesis of pNETs has long been implicated by the genetic cancer syndrome bearing its name as well as studies showing frequent loss of 11q13 where the *MEN1* gene locus is found.^{28–35} Studies using comparative genomic hybridization and high-resolution allelotyping have demonstrated frequent amplification and deletions across a large number of chromosomes compatible with karyotypic instability.^{29–33} Exome sequencing studies identified three main groups (pathways) of mutations in sporadic pNETs. These include *MEN1*, *DAXX* or *ATRX*, and mammalian target of rapamycin (mTOR).²⁷ *MEN1* is thought to be involved in epigenetic regulation and is implicated in the regulation of endocrine mass during pregnancy through a p27-dependent pathway.³⁴ *DAXX* and *ATRX* mutations are associated with alternative lengthening of telomeres and may offer escape from senescence.³⁵ mTOR pathway mutations suggest an attractive therapeutic target that has now been validated in a pivotal phase III study.³⁶

DIAGNOSIS AND MANAGEMENT OF PANCREATIC NEUROENDOCRINE TUMORS

Nonfunctional Tumors

Symptoms and Diagnosis

Nonfunctioning pNETs and PP-secreting tumors do not cause a clinical syndrome. Rarely, case reports of PP-secreting tumors have been associated with watery diarrhea,^{37–39} diabetes mellitus, ulcer diathesis,⁴⁰ or an erythematous pruritic skin rash different from that seen in patients with glucagonomas.⁴¹ Until the tumor causes obstruction of the biliary tree or gastric outlet, the patients are usually asymptomatic unless the tumor bulk results in pain; this is in sharp contrast to pancreatic adenocarcinoma where very low tumor burden may be associated with profound symptoms and death. Jaundice may be the presenting symptom in patients with tumors to the right of the superior mesenteric artery (SMA) and superior mesenteric vein; these tumors originate in the pancreatic head or uncinate process, which may cause obstruction of the intrapancreatic portion of the common bile duct.^{42,43} Tumors in this location may also cause gastric outlet obstruction and/or pain owing to invasion of the autonomic mesenteric plexus. Pain may also be secondary to tumor extension into the celiac ganglion (most commonly seen with tumors arising in the body of the pancreas) or to liver metastases that invade the liver capsule or extend to the parietal peritoneum. Occasional patients may experience gastrointestinal hemorrhage secondary to tumor erosion into the duodenum or secondary to splenic vein occlusion causing gastroesophageal varices (sinistral portal hypertension). Nonfunctioning pNETs can sometimes grow to an enormous size without producing jaundice or other symptoms. pNETs arising to the left of the SMA and superior mesenteric vein may cause vague, poorly localized upper abdominal pain or dyspepsia, but such tumors are usually asymptomatic until they reach a considerable size. In contrast to patients with adenocarcinoma of the pancreas, patients with pNETs may not experience significant weight loss, cachexia, or back pain, or show other signs of advanced disease.^{42,43} In the absence of a large tumor or metastatic disease (of significant volume), pNETs are often detected incidentally on abdominal imaging studies.

On contrast-enhanced multidetector computed tomography (CT), pNETs characteristically appear hyperdense, as they are hypervascular. Therefore, imaging of the pancreas during the arterial phase is critically important to detect these lesions and their hypervascular liver metastases. However, similar to pancreatic adenocarcinomas, pNETs may occasionally appear hypodense

compared with adjacent pancreatic parenchyma, and they may contain cystic components or microcalcifications. Importantly, intrapancreatic accessory splenic tissue can present as an asymptomatic, hypervascular mass involving the distal pancreatic tail, thus mimicking a pNET.

The current practice at our institutions is to obtain high-quality multidetector (multislice) CT images of the pancreatic tumor. We use objective CT criteria to determine a tumor's resectability based upon the relationship of the pancreatic tumor to the SMA and celiac axis.^{44,45} Encasement (defined as >180-degree involvement of the vessel by tumor) of the SMA or occlusion of the superior mesenteric-portal venous confluence without the technical option of venous reconstruction are considered criteria for a tumor's unresectability. Similar to our philosophy on local-regional management of pancreatic adenocarcinomas,⁴⁶ we do not perform incomplete resection (debulking) of nonfunctioning pNETs. Some investigators have suggested that incomplete resection of the pancreatic tumor may provide relief of local tumor-related symptoms and improve survival, but most of these reports included patients with syndromes of hormone excess; no accurately reported data are available to support debulking in patients with unresectable nonfunctioning pNETs. However, in patients without distant metastases (or minimal liver metastases) extended resections to include complex vascular resection and reconstruction may be considered at those centers with experience in such complex operations.^{47,48} Magnetic resonance imaging (MRI) is preferred over CT for patients with a history of allergy to iodine contrast material or for those with renal insufficiency. Moreover, MRI may be more sensitive than CT for the detection of small liver metastases. Endoscopic ultrasound (EUS) is currently considered the most sensitive modality for identifying small pNETs and is thus used for preoperative tumor localization in patients with *MEN1*, in which multifocal disease is common. In the absence of an inherited endocrine syndrome associated with multifocal disease, the role of EUS is limited to FNA biopsy of the tumor. In the current era of invasive gastroenterology, EUS is safe and is becoming more widely available.

Accurate preoperative diagnosis and staging of the primary tumor is necessary to ensure correct treatment. The oncologic (surgical and medical) approach to a pNET is different from that for pancreatic adenocarcinoma. Because of the poor prognosis associated with pancreatic adenocarcinoma, patients with pNETs who are incorrectly thought to have large, locally invasive or metastatic adenocarcinomas may not undergo surgery when it is indicated and also may receive incorrect chemotherapy. Unless a surgery first strategy is considered (in which preoperative biopsy may not be necessary) pretreatment FNA biopsy should always be performed to prevent an error in diagnosis; this is especially true when the clinical history, physical examination, and radiographic images are confusing and not consistent with the presumed clinical diagnosis.

Serum Tumor Markers

Several circulating tumor markers have been evaluated for the diagnosis and follow-up management of pNETs. While these can be very useful for follow-up, isolated elevation of marker levels is generally not sufficient for diagnosis. These markers usually can be divided into those associated with specific endocrine syndromes and those more general markers that may be present in functional as well as nonfunctional tumors. The most important of these markers, CgA, is a 49-kDa acidic polypeptide that is widely present in the secretory granules of neuroendocrine cells. CgA is elevated in the majority of patients with either functioning or nonfunctioning pNETs.^{49–52} In a study where patients with advanced pNETs were treated with streptozocin-based chemotherapy, 79% of patients had elevation of CgA at the time of diagnosis.⁵³ In addition, response to therapy was associated with a 30% decrease in serum CgA.⁵³ This concept was also tested in the RADIANT-1 study, which treated patients with progressive pNETs after cytotoxic chemotherapy with the mTOR inhibitor everolimus. In this study, a 30% decrease in

CgA, 4 weeks after initiation of therapy, was associated with significantly longer progression-free survival (PFS).⁵⁴ However, care should be taken in measuring CgA and interpreting the results. For example, as somatostatin analogues are known to affect blood levels of CgA, serial CgA levels should be measured at approximately the same interval from injection in patients receiving long-acting somatostatin analogues. Spuriously elevated levels of CgA have also been reported in patients using proton pump inhibitors, in patients with renal or liver failure, or in those with chronic gastritis.

Another general neuroendocrine marker, NSE, is a dimmer of the glycolytic enzyme enolase. NSE is present in the cytoplasmic compartment of the cell, and its serum level is thought to be unrelated to the secretory activity of the tumor.⁵² While less specific as a diagnostic marker, it may be helpful in the follow-up of patients with unresectable disease. In the RADIANT-1 study, a 30% decrease in NSE at week 4 was associated with significantly longer PFS.⁵⁴

PP levels also are frequently elevated in patients with pNETs. Elevation of PP is not associated with a distinct hormonal syndrome and is only considered significant when PP level is at least three times the age-matched normal basal level obtained in a fasting state.⁵⁵ A variety of other secreted amines can also be measured. These include other chromogranins such as chromogranin B and C, pancreastatin, substance P, neurotensin, neurokinin A, gastrin, glucagon, vasoactive intestinal peptide, insulin, proinsulin, and c-peptide. In general, blood markers should be drawn in the fasting state.

It is recognized that NETs sometimes can change what (if any) hormones and biomarkers are produced. The general principle of biomarker measurement is to evaluate a large panel of markers at key points in time (diagnosis or relapse) in order to identify the biomarkers that are elevated and then follow these over time. It is generally not necessary to check every biomarker at every visit.

Surgical Treatment

The majority of pNETs are malignant, with the exception of insulinomas, which are benign in 95% of patients. It is probably best to assume that if left untreated, all non-insulin-secreting pNETs have the biologic ability for uncontrolled local growth and metastasis to distant organs. pNETs frequently metastasize to regional lymph nodes, and the frequency of lymph node metastases depends on the extent of surgery and on the degree and accuracy of the pathologist's examination of the surgical specimen.⁵⁶

Based on our experience and the reports from others, we have developed general guidelines for the surgical management of patients with nonfunctioning pNETs:

1. We establish the diagnosis with needle biopsy (EUS-guided FNA of the pancreas or image-guided core needle biopsy of the liver metastases is preferred) and decompress the biliary tree with an endobiliary stent if a distal bile duct obstruction is present. Once biliary obstruction is recognized and a stent is placed in the bile duct, an operation to remove the primary tumor or bypass the site of obstruction will likely be needed; in the absence of large volume distant metastases, the patient will most likely outlive the biliary stent and experience significant stent-related morbidity.
2. We resect localized, nonmetastatic disease confined to the pancreas if a gross complete resection can be performed. If radiographically occult liver metastases are found at the time of the operation, they are removed if possible. If the liver metastases are of small volume but diffuse, the primary tumor is usually removed due to the potential for major morbidity from the primary, which is a possibility because of the relatively long-anticipated survival of the patient.
3. There is an emerging body of literature to suggest that nonfunctioning pNETs < (approximately) 2 cm in diameter are of limited metastatic potential. This is especially important when dealing with patients of advanced age or clinically significant comorbidities (which increase operative risk even if the procedure

- is performed laparoscopically). In this setting, if the pNET represents an incidental finding on CT/MRI obtained for an unrelated reason, observation may be the best approach.⁵⁷⁻⁵⁹ Repeat imaging in 6 to 12 months will provide a window of opportunity to assess tumor biology. If observation is chosen and the diagnosis is confirmed on imaging, to include a functional study such as somatostatin receptor scintigraphy, biopsy may not be necessary.
4. In the setting of known metastatic disease or a large, borderline resectable primary tumor, we would first initiate systemic therapy as a bridge to eventual operation. Significant downstaging of the overall tumor burden can improve the safety of surgery in some patients.
 5. The decision to operate on the primary pancreatic tumor is based upon the presence and/or extent of distant disease and the presence or absence of symptoms (bleeding, obstruction) from the primary tumor. For example, resection of an asymptomatic primary in the distal pancreas has a limited role, if any, in the presence of unresectable, moderate- to large-volume extrapancreatic metastatic disease. As treatments for metastatic disease become more effective, the rationale for aggressive management of the primary tumor despite the presence of extrapancreatic disease may become more compelling. However, treatment sequencing will likely emphasize a surgery-last strategy (after induction systemic therapy) to identify those patients most likely to benefit from large, multiorgan resections.
 6. When dealing with a resectable primary tumor and resectable liver metastases, we usually remove the pancreatic tumor first; if that procedure goes well, we then consider resecting the liver under the same anesthesia induction.⁶⁰ However, we often use a two-stage procedure if all needed surgery cannot safely be performed at one operation.

The goals of surgery are to maximize local disease control and to increase the quality and length of patient survival. These goals must be tempered by the potential operative morbidity and the long-term complications of insulin dependence and gastrointestinal dysfunction. We previously reported survival data for 163 patients with nonfunctioning pNETs treated at our institution.⁶¹ As expected, patients with localized or regional disease at diagnosis had a significantly superior median survival compared with those who had metastatic disease (7.1 years versus 2.2 years; $p < 0.0001$). Among patients with localized disease, those who underwent complete resection of the primary tumor demonstrated an additional survival advantage over those with locally advanced, unresectable tumors (median survivals of 7.1 years for patients with localized, resectable disease versus 5.2 years for patients with locally advanced, unresectable tumors).⁶¹ However, only 48% of the 42 patients with localized, nonmetastatic disease who underwent resection of the primary tumor were alive and without evidence of recurrent disease at a median follow-up of 2.7 years (range, 1 to 8 years) from diagnosis. It is thus inappropriate to assume that complete resection of the primary tumor in the absence of metastatic disease corresponds to long-term cure.

Occasionally, an extended operation is required to achieve complete tumor resection of nonfunctioning pNETs. A high-risk operation (to include most that require complex vascular resection and reconstruction) should not be performed in a high-risk patient who because of age and medical comorbidities has a significant risk of perioperative mortality (=10%) or morbidity (=30%). In the absence of surgery, survival duration is often measured in years even in the presence of distant metastases and therefore surgery-related complications are to be avoided.⁶² At present, we are highly selective in our use of extended pancreaticoduodenectomy or left-sided resections to include the celiac axis (Appleby procedure). Patients who undergo such high-risk operations must have limited to no medical comorbidities and have an excellent performance status. Decisions for or against surgical treatment are particularly difficult when dealing with large primary tumors, which require an extend resection, in the absence of distant metastases. The median

survival duration for patients with unresectable, nonmetastatic, nonfunctioning pNETs is approximately 5 years. As survival time without operation increases and as potential operative morbidity and mortality increase, we are less accepting of the upfront risks of surgery. However, as mentioned previously, occasionally, locally advanced tumors of the pancreatic head or uncinate process are associated with significant patient morbidity due to complications such as biliary obstruction, gastric outlet obstruction, or gastrointestinal hemorrhage.⁶¹ In contrast to the management of patients with pancreatic adenocarcinoma (where endoscopic stenting of the bile duct and occasionally the duodenum are fairly routine in the setting of locally advanced or metastatic disease), we would rarely use a duodenal stent in a patient with neuroendocrine carcinoma and would utilize endobiliary stents only for short-term (months, not years) biliary decompression. Because of the longer survival times of patients with pNETs (even advanced disease), we favor operative bypass of the bile duct and duodenum in most cases.

Oncologic Management of Advanced Pancreatic Neuroendocrine Tumors

Advanced, unresectable pNETs generally are not curable. The goals of oncologic management include palliation or prevention of symptoms and cytoreduction of bulky tumors in an effort to prolong survival. Although low- to intermediate-grade pNETs have a reputation of being indolent, most patients with advanced pNETs will not survive the disease.

Management of patients with advanced pNETs requires an understanding of the disease process and the importance of a multimodality approach. Treatment options include cytotoxic chemotherapy, everolimus, sunitinib, somatostatin analogues, peptide-receptor radiotherapy, as well as ablative approaches such as hepatic artery embolization and radiofrequency ablation (RFA). Occasionally, systemic therapy may also convert cases of unresectable tumors into cases wherein surgery may render the patients disease free. In such cases, we recommend that surgical options be considered in a multidisciplinary setting. Much of what is discussed here for non functional pNETs also holds true for managing the growth of functional tumors.

Systemic Therapy

Somatostatin Analogues

Somatostatin is a hormone that binds to specific high-affinity membrane receptors on target tissues. To date, five subtypes of somatostatin receptors (SSTR) have been identified. When

activated, these receptors trigger differing biologic activity. The somatostatin analogues octreotide and lanreotide both bind with high affinity to SSTR 2 and with slightly lower affinity to SSTR 5. Pasireotide is a novel cyclohexapeptide in development that binds to SSTR 1, 2, 3, and 5.⁶⁵

The somatostatin analogue octreotide is approved for the control of symptoms related to hormonal hypersecretion in NETs. More recently, randomized controlled studies have also demonstrated that somatostatin analogues can delay tumor growth. The PROMID study compared octreotide LAR 30 mg every 4 weeks to placebo among treatment-naïve patients with midgut NETs (carcinoid tumors). The study demonstrated significant benefit in time to progression (hazard ratio [HR] = 0.34; 95% CI, 0.20 to 0.59; $p < 0.0001$).⁶⁴ In a larger study that included a substantial number of pNETs, lanreotide 120 mg was compared to placebo in a population of patients with mostly stable disease (Table 85.2). Treatment with lanreotide was also associated with significant benefit in PFS (HR = 0.47; 95% CI, 0.30 to 0.73; $p = 0.0002$).⁶⁵ The long median PFS of 12 (95% CI, 9.4 to 18.3) months among patients with pNET receiving placebo suggests that many patients with known stable disease may not need immediate treatment.

Everolimus

mTOR is an intracellular protein that has a central role in cellular function. It acts as a nutrient sensor and mediates signaling downstream of receptor tyrosine kinases controlling cell growth, protein synthesis, autophagy, and angiogenesis. The association between aberrant mTOR pathway signaling and the pathogenesis of pNETs is suggested by the development of pNETs in patients with inherited genetic mutations in TSC2 and NF1. Loss of TSC2 and NF1 are both associated with mTOR activation. In an exome sequencing study, mTOR pathway mutations were also found in sporadic pNETs.²⁷ Finally on a protein level, low expression of PTEN and TSC2 were associated with poor prognosis.⁶⁶

Phase 2 studies of the mTOR inhibitor everolimus have reported evidence of clinical activity.^{54,67} In the initial report, the combination of octreotide LAR and everolimus was studied in 60 patients with NETs.⁶⁷ The response rate among 30 patients with pNET was 27%. In a subsequent multinational phase 2 study (RADIANT-1) in advanced pNETs with progression following chemotherapy, 160 patients were treated in two strata, with everolimus ($n = 115$) or everolimus plus octreotide ($n = 45$) based on whether patients were on octreotide at study entry.⁵⁴ By central radiology review, the response rate was lower at 9.6%. Durable disease stabilizations were, however, observed among patients with progression at study entry. The median PFS for patients receiving everolimus or

TABLE 85.2

Selected Phase 3 Studies in Pancreatic Neuroendocrine Tumors

Regimen	Number of Patients	Median PFS (Months)	Hazard Ratio (95% CI)	P
Study in patients with predominantly stable disease				
Lanreotide 120 mg q 4 weeks (overall) ⁶⁵	101	Not reached	0.47 (0.30–0.73)	0.0002
Placebo (overall)	103	18		
Lanreotide 120 mg q 4 weeks (pNET)	42	Not reached	0.58 (0.32–1.04)	0.06 ^a
Placebo (pNET)	49	12.1		
Studies in patients with progressive disease				
Everolimus 10 mg daily ⁶⁸	204	11	0.35 (0.27–0.45)	<0.0001
Placebo	203	4.6		
Sunitinib 37.5 mg daily ⁷⁰	86	11.4	0.42 (0.26–0.66)	0.0001
Placebo	85	5.5		

PFS, progression-free survival; CI, confidence interval; pNET, pancreatic neuroendocrine tumor.

^a Study not designed to test the treatment effect in pNET subgroup.

everolimus plus octreotide were 9.7 months and 16.7 months, respectively. In the largest phase 3 study to have been conducted in pNETs (RADIANT-3), 410 patients with progressive pNETs were randomly assigned to receive everolimus or placebo. The study demonstrated clinically and statistically significant benefit in PFS for patients receiving everolimus (see Table 85.2).⁶⁸ Everolimus prolonged median PFS from 4.6 months to 11 months leading to a 65% risk reduction for progression compared to placebo (HR = 0.35; 95% CI, 0.27 to 0.45; $p < 0.0001$). Treatment also reduced the level of tumor-secreted hormones.

Sunitinib

pNETs are vascular tumors known to express vascular endothelial growth factor (VEGF). Recent studies have demonstrated the expression of VEGFR-FLK and VEGFR-FLT1 on tumor cells. Sunitinib is a novel tyrosine kinase inhibitor with activity against VEGF receptors, c-Kit, and platelet-derived growth factor receptor. In a multicenter phase 2 study, investigators treated patients with carcinoids and pNETs in separate strata and also observed evidence of clinical activity. Interestingly, in this study, the tumor response rate appeared to be higher among patients with pNETs than in patients with carcinoids (17% versus 2%).⁶⁹ A subsequent phase 3 study compared sunitinib to placebo in pNETs (see Table 85.2). Results of an early unplanned analysis showed improved PFS (5.5 months versus 11.4 months).⁷⁰ Although the study showed clinically meaningful benefit (HR = 0.42, 95% CI, 0.26 to 0.66), the type 1 error was uncontrolled. Due to the small number of events and unplanned nature of the analyses, the results failed to cross the O'Brien Fleming efficacy threshold for statistical significance.

Cytotoxic Chemotherapy

Systemic chemotherapy for advanced pNETs has been studied in many clinical trials over the last three decades. Despite the multitude of publications, the role of cytotoxic chemotherapy continues to be debated. Older studies often used criteria to measure outcome that are not accepted today. Older studies using cytotoxic agents have not documented improvements in PFS or OS versus best supportive care.^{71,72}

Streptozocin-Based Chemotherapy. Streptozocin was originally isolated from *Streptomyces achromogenes* in the 1950s. Its antitumor activity in pNETs was first reported in 1973; in a study that included 52 patients, a response rate of 50% was reported.⁷³ Streptozocin's single-agent activity in pNETs was subsequently confirmed in a study comparing that agent alone with streptozocin plus fluorouracil.⁷¹ In this study, a higher response rate was reported for the combination of streptozocin and fluorouracil. The Eastern Cooperative Oncology Group subsequently compared this combination to streptozocin plus doxorubicin⁷² and reported a significantly higher response rate (69% versus 45%), time to progression (median, 20 months versus 7 months), and OS (median, 2.2 years versus 1.4 years) for streptozocin plus doxorubicin than for streptozocin plus 5-FU. Based on these data, combination chemotherapy with streptozocin-based regimens is considered the standard treatment option by many.

However, two small retrospective series have recently cast doubt on the value of streptozocin-based chemotherapy. Each of these studies examined only 16 patients. Both reported a disappointing radiologic response rate of only 6%.^{74,75} This 10-fold difference in response rates has aroused considerable controversy as to the role of chemotherapy in treating pNETs. Some of the disparity in response rate may be accounted for by differences in response criteria. For example, in a study reported by Eriksson et al.,⁷⁶ the response rates based on either decreased biochemical parameters or decreased tumor measurement were 36% for streptozocin plus doxorubicin and 58% for streptozocin plus 5-FU. When only radiologic response was counted, the respective response rates were 8% and 32%.⁷⁶

A chemotherapeutic combination of 5-FU, streptozocin, and doxorubicin was studied in two small trials with 10 and 12 patients, and response rates were 40% and 55%, respectively.⁵³ In light of the continuing controversy regarding the role of chemotherapy in the management of pNETs, a larger retrospective study examined the outcome of 84 consecutive patients treated with the 5-FU-doxorubicin-streptozocin combination and observed a response rate of 39%.⁵³ The median PFS in that series was 18 months, and median OS was 37 months.

Dacarbazine- and Temozolomide-Based Chemotherapy.

Dacarbazine was initially studied in a phase 2 study that included 42 patients with pNETs. A response rate of 33% was observed.⁷⁷ Temozolomide is an oral alkylating agent that metabolizes to the same active metabolite as dacarbazine, 5-(3-methyl-triazeno)imidazole-4-carboxamide. While a number of temozolomide-based doublets have been reported in clinical trials or retrospective series, the activity of single-agent temozolomide has not been prospectively evaluated.¹⁸⁻²⁰ In one large series, 18 (34%) of 53 patients with pNETs had objective response following temozolomide-based chemotherapy.⁷⁸ Although temozolomide-based therapy is generally well tolerated, absolute lymphopenia may occur and has been associated with opportunistic infections.⁷⁹ These studies suggest that temozolomide may have activity in pNETs. A randomized study comparing temozolomide versus temozolomide plus capecitabine is ongoing.

Cytotoxic chemotherapy continues to play an important role in the management of pNETs.

Peptide Receptor Radiotherapy

The presence of somatostatin receptors in high density on tumor cells has led to the development of peptide receptor radiotherapy for NETs. Early studies with ¹¹¹In-, ⁹⁰Y-, or ¹⁷⁷Lu-labeled somatostatin analogues have reported promising results in the control of hormone-associated symptoms.⁸⁰ The earliest studies were carried out with [¹¹¹In-DTPA⁰] octreotide. Although symptomatic improvements were reported, objective tumor responses were rarely observed. Subsequently, ⁹⁰Yttrium was linked to octreotide to create [⁹⁰Y-DOTA⁰,Tyr³] octreotide. Several studies were carried out in patients with NETs and produced response rates of 10% to 30%.⁸⁰ In the largest prospective study of 90 patients with NETs, only a modest response rate of 4% was observed.⁸¹

Finally, a number of European centers are now using octreotate that substitutes the C-terminal threoninol with threonine. Octreotate is linked to ¹⁷⁷Lutetium to create ¹⁷⁷Lu-DOTA⁰,Tyr³ octreotate. In the largest reported series, a response rate of 30% was found among a subset of 310 patients. However, if intent-to-treat analysis were performed, the objective response would be approximately 18%.⁸² In general, expected toxicities with peptide receptor radiotherapy included nausea, vomiting, abdominal pain, cytopenia, and hair loss. More serious side effects, including renal failure, leukemia, and myelodysplastic syndrome, have also been reported. Large-scale random assignment trials are needed to define its role in the management of pNETs.

Liver-Directed Regional Therapy

Because the liver is the most common and sometimes the only site of metastasis, the development of liver-directed therapeutic approaches for pNETs is of obvious interest. These treatment approaches are generally palliative. In the absence of a hormonal syndrome, typical indications for liver-directed therapy include right upper quadrant pain, early satiety due to gastric compression by an enlarged left hepatic lobe, and the need to control slowly progressive but bulky disease.

Hepatic Artery Embolization and Chemoembolization.

Hepatic artery embolization takes advantage of the liver's dual blood supply. The normal liver derives most of its blood supply

from the portal circulation. pNET metastases, however, receive most of their blood supply from the hepatic artery. Thus, interruption of the blood supply from the hepatic artery preferentially causes ischemic necrosis of the metastases while sparing most of the normal liver. Currently, most procedures for occlusion of the hepatic artery involve the percutaneous intra-arterial infusion of small particles. The choice of embolic material varies by center and may include lipiodol or ethiodized oil, small plastic particles, or gelatin foam particles. Comparative studies of various embolic materials are lacking. In performing hepatic artery chemoembolization, cytotoxic agents are administered intra-arterially before the vessels are embolized, as this approach has the potential to enable delivery of a higher chemotherapy dose to liver metastases.

Most published studies of hepatic artery embolization or chemoembolization have included a mix of patients with carcinoids and pNETs. Studies have reported a wide range of response rates ranging from 8% to >60% using heterogeneous response criteria.^{83,84} In a retrospective study from MD Anderson, where the outcome of patients with pNET were separately examined, the objective tumor response rate was 35%. When the bland embolization group was compared with the chemoembolization group, a trend was observed for improved response rate with the addition of chemotherapy (50% versus 25%; $p = 0.06$).⁸³ In a similar retrospective study of 67 patients with NETs (19 with pNETs) who underwent chemoembolization in France, investigators compared doxorubicin with streptozocin during embolization and reported a higher response rate with streptozocin-based chemoembolization after multivariate analyses.⁸⁵

Based on these findings, we recommend hepatic artery chemoembolization in select patients with pNET with liver metastases. The procedure should be carried out in a hospital setting because treatment-related toxic effects are common and may be severe. A constellation of transient symptoms and laboratory abnormalities, sometimes referred to as "postembolization syndrome," occurs in most patients. These findings include abdominal pain, nausea, fever, fatigue, and elevated liver enzymes. Crises related to massive release of hormone(s) may occur in the presence of functional tumors; prophylactic administration of somatostatin analogues should always be considered. Major complications (even deaths) have been reported in clinical trials. To minimize the risk of hepatic insufficiency, embolization should be carried out in one liver lobe at a time. In patients with bulky disease or poor liver function, more limited embolization of liver segments should be considered; experience is clearly very important in the use of this treatment modality.

More recently, radioactive microsphere embolization is emerging as a well-tolerated outpatient procedure providing symptom relief and varying response rates.⁸⁶⁻⁸⁸ However, prospective studies are lacking in patients with NETs and specifically those with pNETs.

Hepatic Metastasectomy and Transplantation. Because of the relatively indolent behavior of the disease, aggressive surgical resection has a role in the management of metastatic islet cell carcinoma. The largest published experience with pNETs involving liver resection was included in a series of 170 patients with NET at Mayo Clinic.⁸⁹ A total of 52 pNETs were included in this study. A separate analysis of pNETs was not performed, but the OS rate for all 170 patients was reported to be 61% and 35% at 5 and 10 years, respectively. It is, however, also clear from this study that liver resection is not curative in most patients; the disease recurrence rate was 85% at 5 years.⁸⁹

We encourage resection for patients with a solitary metastasis. For patients with more extensive but still resectable disease, we advocate resection for those tumors with favorable biologic characteristics. Liver resection should be avoided in patients with a high-grade histologic subtype. A period of systemic chemotherapy may be used as part of a test-of-time approach to select patients whose disease is less likely to progress and who are therefore more likely to benefit from aggressive surgical intervention.

For those with clearly unresectable liver metastases, there has been some experience, although limited, with hepatic transplantation. However, following liver transplantation, survival of patients with pNETs was found to be inferior to that of patients who had carcinoid tumors (3-year survivals of 8% versus 80%).⁹⁰ Given the upfront operative risk and, as yet, the lack of data supporting a survival benefit, hepatic transplantation for the management of pNETs should be considered investigational. Further, the challenge of limited organ availability (at least in the United States) makes liver transplantation for pNET an unrealistic option in the absence of a living-related donor.

Radiofrequency Ablation. Given the natural history of non-functional pNETs, most patients are diagnosed with extensive disease. Those with unresectable disease often have diffuse liver involvement and/or have the primary tumor intact. The majority of these patients should receive systemic therapy or chemoembolization. Occasionally, patients may have liver metastases that are unresectable but still small and few enough to allow for an ablative approach. RFA can be carried out during laparoscopy, laparotomy, or via a percutaneous approach. Although RFA has not been systematically compared with other treatment modalities, an anecdotal description of the clinical benefit of RFA has been reported. In one series of 34 patients, including 9 with pNETs who underwent laparoscopic RFA, 79% of patients with symptoms at baseline reported either complete resolution or a significant reduction of tumor-related symptoms.⁹¹

Therapeutic Strategy for Advanced Unresectable Pancreatic Neuroendocrine Tumors

The past decade has seen rapid advances in the therapeutic options for pNETs. Agents approved by the US Food and Drug Administration include streptozocin, everolimus, and sunitinib. Recently, the somatostatin analogue lanreotide has also demonstrated significant antiproliferative activity in a phase 3 study. Surgical resection, regional therapy, and therapies not yet approved, including peptide receptor radiotherapy, selective internal radiotherapy, and temozolomide, offer additional options. Studies have also been completed in heterogeneous populations with the lanreotide study being conducted in an indolent (stable disease) population while the everolimus and sunitinib were studied among patients with progressive disease. None of these options have been compared in head-to-head clinical trials.

While the rarity of the pNETs precludes the large studies necessary to answer treatment sequencing questions, the relatively longer survival means patients will likely go through many of these options in varying sequence. A conceptual framework for choosing therapy at each stage should take into account the aggressiveness of the tumor, the burden (volume) of disease, and any symptoms due to tumor burden or hormonal secretion (Fig. 85.3). Depending on these variables, decisions can be made to prioritize the goals of therapy. For example, for a patient with low-volume, stable, and asymptomatic disease, quality of life can be prioritized by expectant observation or treatment with somatostatin analogues. Cytotoxic chemotherapy, on the other hand, may offer relief to a patient with bulky, progressive, and symptomatic disease. Everolimus or sunitinib can be suitable options for most patients in between the two extremes. The choice between everolimus and sunitinib can be considered based on the strength of published evidence, secretory status, and the matching of patient comorbidities to the adverse event profile of the drug. For example, everolimus has been more extensively studied among treatment-naïve patients and patients who have failed prior chemotherapy. It may also be preferred among patients with secretory (functional) tumors. Based on its safety profile, sunitinib would be a better choice for patients with uncontrolled diabetes or poor pulmonary function.

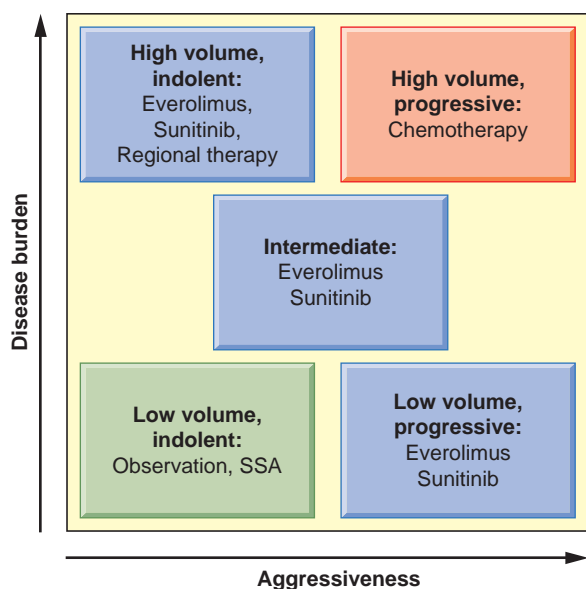

Figure 85.3 Management of patient with unresectable pancreatic neuroendocrine tumors. SSA, somatostatin analogue.

Conversely, everolimus may be safer in patients with hypertension or a history of heart disease.

Functional Tumors

Gastrinoma

Diagnosis and Management of Localized Disease. Gastrinoma, or Zollinger-Ellison syndrome (ZES), is a rare disease caused by a NET (gastrinoma) in the pancreas or duodenum. The hypersecretion of gastrin results in uncontrolled stimulation of parietal cells and production of gastric acid causing refractory peptic ulcer disease. Consequently, most patients have a long history of ulcers, abdominal pain, diarrhea, severe gastroesophageal reflux, and prolonged use of acid-suppressive medication and/or a history of gastric or duodenal surgery. However, the diagnosis of ZES is becoming more difficult owing to the frequent use of proton pump inhibitors (PPI), which usually control the symptoms of excess acid while the medication is taken.⁹² Importantly, the vast majority of patients who are found to have an elevated level of serum gastrin do not have a gastrinoma. Hypergastrinemia is most commonly caused by acid-suppressive medications, especially PPIs. If the serum gastrin level is still elevated 1 week after the patient has stopped acid-suppressive therapy, it is then important to measure gastric pH. Basal gastric acid output analysis is not available in most centers, and gastric pH is rarely measured at the time of upper endoscopy (although at that time, the patient is usually tested for infection with *Helicobacter pylori*, which can also cause hypergastrinemia). Thus, the easiest way to measure gastric pH is to simply place a nasogastric tube and aspirate the gastric contents. These contents can be placed on litmus paper and the pH estimated; patients with ZES should have a gastric pH of <2. Elevated serum gastrin level and elevated gastric pH suggest a normal response of the gastric G cells (which produce gastrin) to parietal cell dysfunction associated with achlorhydria, atrophic gastritis, and pernicious anemia.

Patients with sporadic ZES usually have a fasting gastrin level of >600 pg/ml, and virtually all patients have a gastrin level of =100 pg/ml.⁹³ A serum gastrin \geq 1,000 pg/ml or 10-fold above the normal range, and a gastric pH \leq 2 secures the diagnosis of ZES. In patients with gastrin levels between 100 pg/ml and 1,000 pg/ml

and a gastric pH \leq 2, a secretin or calcium stimulation test should be considered. A positive secretin test is associated with a postinjection serum gastrin level increase of >200 pg/ml, and a positive calcium stimulation test with a postinjection serum gastrin level increase of >395 pg/ml.⁹³

Gastrinomas may reside in the duodenum (most often in the proximal duodenum) or pancreas, with duodenal location being the most common. Duodenal tumors are usually small (often <1 cm in diameter) and rarely associated with liver metastases. When located in the pancreas, gastrinomas are usually found in the pancreatic head or uncinate process; in the pancreas, that is to the right of the superior mesenteric vessels. Serum gastrin levels correlate with the extent of disease and are highest in those patients with locally advanced or metastatic disease.

Patients suspected to have ZES should be managed at a referral center experienced in the diagnosis and management of this disease. Once the diagnosis is established biochemically, tumor localization studies should be performed as part of the preoperative evaluation; these include upper endoscopy with EUS of the pancreatic head and duodenum, multidetector CT, and somatostatin receptor scintigraphy.^{92,94} Because of the delay in diagnosing ZES in most patients combined with the improvements in imaging studies and EUS, gastrinomas seen today are usually successfully localized. When all localization studies are negative, the gastrinoma is most likely in the duodenum, which must be opened surgically (duodenotomy) to successfully locate and remove the tumor. For pancreatic gastrinomas, the operation is based on the anatomy of the tumor and may consist of enucleation or pancreaticoduodenectomy. Consistent with the operative management of most neuroendocrine carcinomas, regional lymphadenectomy is critically important. If the entire pancreatic head and duodenum are removed, regional lymphadenectomy is fairly easy to accomplish. If a less radical resection is performed, the lymph nodes located in the peripancreatic region, adjacent to the hepatic artery, and within the porta hepatis should be removed.

Management of Advanced Gastrinoma. As with other functional pNETs, the management of malignant gastrinoma has two goals: management of gastrin hypersecretion and its potential complications, and management of metastatic disease similar to the concern with advanced nonfunctional pNETs. Here, we will focus on issues unique to gastrinomas.

Prior to effective therapy for the control of gastric acid secretion, the principal therapy for ZES was gastrectomy to prevent gastric ulceration. Left unchecked, excessive acid secretion would frequently lead to massive gastrointestinal hemorrhage or gastric perforation. Early medical therapy for ZES included the use of histamine 2 receptor blockers such as cimetidine, ranitidine, and famotidine. The introduction of PPIs brought significant advances in the management of ZES, allowing for once or twice daily dosing. The dose of PPIs required to manage ZES is significantly higher than typically used in idiopathic peptic ulcer disease. In addition to careful monitoring for the absence of symptoms of acid hypersecretion, we have a low threshold for checking gastric pH prior to the next dose of PPI.

Another aspect that deserves special attention in patients with advanced gastrinoma is the development of type II gastric carcinoids in the setting of MEN1-associated ZES. These gastric carcinoids are often small, multifocal, and of low malignant potential. Occasionally, they can also become large, involve the stomach diffusely, and cause symptoms. When few in number, they can often be excised endoscopically. Regression of gastric carcinoids has been described in cases where somatostatin analogues or other treatment targeting the gastrinoma successfully reduced gastrin levels in a sustained manner.⁹⁵ Because gastric carcinoids are rarely seen in patients with sporadic ZES, the development of gastric carcinoids requires more than just hypergastrinemia (such as pernicious anemia or an additional genetic defect as is present in MEN1) and is likely unrelated to chronic administration of PPIs.

Insulinoma

Diagnosis and Management of Localized Disease. Insulinomas are seldom malignant and represent the most common functioning pNET. If metastatic disease is not found at the time of initial diagnosis, it is unlikely to develop in the future.⁹⁶ It is unknown whether this unique feature of insulinomas results from underlying tumor biology or simply because, owing to their profound symptom complex, these tumors are virtually always surgically excised early, when they are small. As with all functioning and nonfunctioning tumors of the pancreas, insulinoma may occur either as a unifocal sporadic event or as part of MEN1.⁹⁷ The uncontrolled secretion of insulin results in hyperglycemia, manifested by neuroglycopenic symptoms such as blurred vision, confusion, and abnormal behavior, which may progress to loss of consciousness and seizure. In response to hypoglycemia, the body releases catecholamines, which elicit perspiration, anxiety, palpitations, and hunger. Most patients with insulinoma associate the intake of food with the resolution of such symptoms very early in the disease process; this likely accounts for the weight gain experienced by most patients with insulinoma.

The diagnosis of insulinoma syndrome is established by supervised fasting of the patient, including laboratory evaluation and clinical observation. Serum levels of plasma glucose, C-peptide, proinsulin, insulin, and sulfonylurea are measured at intervals of 6 to 8 hours and when symptoms develop, patients with insulinoma have an insulin level $>3 \mu\text{IU/ml}$ (usually $>6 \mu\text{IU/ml}$) when their blood glucose is <40 to 45 mg/dL . The insulin-to-glucose ratio is ≥ 0.3 reflecting the inappropriate secretion of insulin at the time of hypoglycemia. During the production of insulin, C-peptide is cleaved from proinsulin and thus, both are elevated in patients with insulinoma. In contrast, exogenous insulin does not contain C-peptide; therefore, an elevated insulin level combined with no detectable C-peptide would indicate exogenous administration of insulin. Detectable levels of sulfonylurea would indicate the administration of oral medications to induce hypoglycemia. When the patient is under observation as part of a supervised fast, symptomatic hypoglycemia and a serum glucose level $<45 \text{ mg/dL}$ should be treated with 1 mg of intravenous glucagon. If the hypoglycemia is insulin mediated, this will cause the release of glucose from the liver, resulting in an elevation of serum glucose (usually by 20 mg/dL) and the rapid resolution of symptoms.

In contrast to gastrinomas, which usually occur in the duodenum, pancreatic head, or uncinate process, insulinomas do not develop in the duodenum and may occur anywhere throughout the pancreas. In the absence of MEN1, insulinomas, similar to gastrinomas, are usually unifocal. Once the biochemical diagnosis is established, localization studies performed as part of the preoperative evaluation include contrast-enhanced, multidetector CT and usually upper endoscopy with EUS of the pancreas. In our practice, these studies will localize the overwhelming majority of sporadic insulinomas. For the very rare patient in whom tumor localization is not successful, we proceed with a regionalization study to determine whether the tumor is located to the right or left of the mesenteric vessels. Regionalization of an insulinoma is performed with selective arterial calcium stimulation and hepatic vein sampling.⁹⁸ Calcium is used as a secretagogue for insulin and is injected into the gastroduodenal artery, SMA, and splenic artery; a serum sample for insulin measurement is obtained from the right hepatic vein. An elevation of insulin in the hepatic vein following selective arterial injection regionalizes the insulinoma to that portion of the pancreas injected with calcium. It is therefore possible to determine whether the insulinoma is in the pancreatic head or uncinate process (elevation of hepatic vein insulin following calcium infusion of the gastroduodenal artery and/or SMA) or in the body or tail of the pancreas (elevation of insulin following calcium infusion into the splenic artery). Because tumor localization with a combination of multidetector CT and EUS is so successful, when these methods fail to localize the tumor in a patient

presumed to have insulinoma syndrome, we first carefully double check the diagnostic evaluation and if confirmed, we then proceed with selective arterial calcium stimulation and hepatic vein sampling to minimize the potential for an unsuccessful operation.

Because nonmetastatic insulinomas are thought to be benign (or at least to have a very low malignant potential), the standard treatment is enucleation. It is important to remove the tumor with the tumor capsule and not to leave a portion of the tumor behind, as local recurrence can occur.⁹⁹ If enucleation is not possible due to the location of the tumor within the pancreas, segmental resection of the pancreas, distal pancreatectomy, or pancreaticoduodenectomy may be necessary. In our experience over the past 20 years, we have only performed a handful of pancreaticoduodenectomies for sporadic insulinoma due to large size and proximity to the intrapancreatic bile duct. Large defects in the pancreas resulting from enucleation are usually treated with a Roux-en-Y pancreaticojejunostomy to prevent a pancreatic leak at the enucleation site. Metachronous distant metastases are very rare but have been reported.¹⁰⁰ It is interesting to hypothesize that the biology of the disease may change to a more aggressive phenotype in the setting of incomplete surgical excision and local recurrence. In contrast to the findings of a few reports in the literature,¹⁰⁰ we have not seen a patient with a surgically excised, nonmetastatic, isolated insulinoma develop metachronous tumor recurrence in a distant organ. The patients with metastatic insulinoma seen by these authors had liver metastases with or without bone metastases at the time of diagnosis.

Management of Advanced Insulinoma. In rare cases, insulinomas can be metastatic at diagnosis. These cases are challenging to manage often because of refractory hypoglycemia. There is no data to suggest that insulinomas respond differently to systemic or liver-directed therapy. Thus, the previously discussed strategies outlined for nonfunctional tumors can be applied. We will focus here on the aspects of malignant insulinoma that require special attention.

Glycemic control is a key aspect of managing malignant insulinomas. Mild symptoms sometimes can be controlled by diet. Patients may need to eat frequently; family members or caregivers may need to wake the patient at night for a snack to avoid early morning hypoglycemia. In selected cases, enteral feeding tubes may be required to provide continuous nocturnal caloric support. Medical therapy may include diazoxide, an antihypertensive agent known to increase blood sugar. It is typically administered in doses of 50 to 300 mg per day. Side effects include edema, weight gain, renal impairment, and hirsutism. Glucagon may also have a role in the management of insulinomas. A glucagon pen may be given to the patient's family and caregiver to be used in emergent cases. Not all insulinomas respond well to glucagon. We suggest that a test dose be given under supervision during a hypoglycemic episode before the drug is prescribed. While all of the aforementioned drugs may help control symptoms, eventual resistance may develop. These drugs are perhaps best used to maintain glycemic control while other therapeutic strategies are being applied.

Somatostatin analogues such as octreotide may be helpful for the control of insulin release, but they can also suppress counterregulatory hormones such as growth hormones, glucagon, and catecholamines. In this situation, somatostatin analogues can lead to worsening of hypoglycemia.¹⁰¹ Therefore, we recommend that short-acting somatostatin analogues be initiated under direct medical supervision. Glucose and insulin levels should be checked before and after injection to assess the analogue's effect on hormonal production before committing the patient to long-term outpatient therapy.

Despite these measures, refractory hypoglycemia frequently occurs and can be difficult to manage. It has been recently observed that such patients often respond to the mTOR inhibitor everolimus. Data suggest that insulin triggers its own production and release via the insulin receptor.^{102,103} The mTOR pathway mediates

signal transduction downstream of the insulin receptor and mTOR inhibitors block insulin stimulated insulin synthesis, release, and proliferation.^{102,103} In a series of four consecutive patients with malignant hypoglycemia treated with everolimus, all four patients experienced dramatic improvements in glycemic control.¹⁰⁴ Since this initial report, the efficacy of everolimus for the treatment of insulinoma has been confirmed in several case series.^{105,106}

Finally, aggressive therapy targeting the tumor is needed. As malignant insulinomas can often be indolent in terms of tumor growth, surgical resection, hepatic artery chemoembolization, and RFA can all be considered. Streptozocin-based chemotherapy should also be considered based on tumor location and extent as data suggest that streptozocin is toxic to insulin-producing cells. In addition to its cytotoxic effect, streptozocin can decrease insulin production in beta cells. Indeed, our experience with some patients indicates that streptozocin may “turn off” the production of insulin for years, even in the absence of tumor response. Chemotherapy, however, may require intensive supportive care because the nausea, vomiting, and anorexia associated with treatment may transiently worsen hypoglycemia.

Rare Functional Endocrine Tumors

In addition to gastrinomas and insulinomas, several other less common functional tumors deserve special consideration. These include VIPomas, glucagonomas, somatostatinomas, adrenocorticotropic-secreting tumors, and parathyroid hormone-related peptide-secreting tumors. Similar to other functional pNETs, the bulk of these rare tumors are well differentiated (low Ki67 index). For the most part, the workup and management of these tumors are similar to those of nonfunctional pNETs. Thus, only the unique aspects of these tumors will be briefly discussed here.

VIPoma

VIPomas are the cause of the classic Verner-Morrison syndrome.¹⁰⁷ These endocrine tumors secrete vasoactive intestinal peptide, which can cause watery diarrhea, hypokalemia, and achlorhydria. Diarrhea in patients with VIPomas is often insidious at onset but extreme by the time the patient comes to diagnosis. Patients can have more than 20 bowel movements a day, with a daily stool volume exceeding 3 L. Thus, fluid and electrolyte replacement is often needed at the time of diagnosis. In adults, most VIPomas arise from the pancreas. In children, however, most vasoactive intestinal peptide-secreting tumors arise from an extrapancreatic location.

Control of diarrhea is an important part of management. These tumors are often quite sensitive, at least initially, to somatostatin analogues¹⁰⁸; octreotide can promptly control diarrhea in 80% to 90% of patients. However, over time many patients will escape pharmacologic control. Dose escalation can be helpful in some cases. With short-acting octreotide, a dose of 50 to 400 mcg per day is typically used. With depot formulation, octreotide LAR doses exceeding 30 mg every 3 weeks have been advocated by some. Somatostatin analogues often cause exocrine pancreatic insufficiency, which can lead to malabsorptive diarrhea; pancrelipase and gastric acid suppression should be used in all patients who are receiving somatostatin analogues. Because of its toxicity, interferon is rarely used in the frontline setting, but it may have a role in cases refractory to somatostatin analogues. In general, measures aimed at cytoreduction should be initiated whenever possible.

Glucagonoma

Glucagon is a 29-amino acid peptide that causes glycogenolysis, gluconeogenesis, ketogenesis, lipolysis, and catecholamine secretion. Patients typically present with a syndrome that includes diabetes and a characteristic rash known as necrolytic migratory erythema. Weight loss, diarrhea, glossitis, and angular stomatitis

have also been reported.⁴³ These patients typically also have amino acid depletion due to the high level of glucagon. Somatostatin analogues may have a role in the management of the hormonal syndrome in patients with unresectable tumors.¹⁰⁹ Oral hypoglycemic agents and insulin can be used to control the diabetes. Necrolytic migratory erythema is thought to be related at least in part to amino acid depletion.¹¹⁰ Thus, amino acid and zinc supplementation may also be helpful.¹¹¹

Somatostatinoma

Somatostatinomas are very rare functional endocrine tumors that can arise from the pancreas or the duodenum. Because of the insidious and nonspecific nature of the symptoms, most somatostatinomas are diagnosed at an advanced stage. Patients typically present with symptoms including diabetes, diarrhea, and jaundice due to biliary obstruction. Somatostatinomas may be associated with von Recklinghausen disease (neurofibromatosis); these tumors are usually duodenal or ampullary in origin, are less likely to be associated with a hormonal syndrome, and are usually small and localized (nonmetastatic) at the time of diagnosis.¹¹² The principles of management for somatostatinomas parallel those of nonfunctional pNETs.

Adrenocorticotropic-Secreting Tumors

Adrenocorticotropic hormone-secreting tumors are also among the rare functional tumors of the pancreas. Patients with adrenocorticotropic-secreting tumors often present with florid Cushing syndrome due to ectopic production of adrenocorticotropic hormone. Induction chemotherapy in these patients is fraught with difficulties owing to the patient's hypercortisolism causing immunosuppression and a debilitated state. Initial management should be aimed at controlling corticosteroid production. Metyrapone, ketoconazole, and mitotane tend to be more effective in this setting than for adrenal cortical carcinoma and can be used to suppress excess cortisol production. In rare cases, bilateral adrenalectomy may be needed.

ADDITIONAL CLINICAL CONSIDERATIONS

Hereditary Syndromes

It is known that pNETs can occur in the setting of several genetic syndromes. These include MEN1, tuberous sclerosis, neurofibromatosis, and von Hippel-Lindau disease (VHL). MEN1 is discussed in greater detail elsewhere in this book. Here, we will limit our discussion to special considerations involved in the surgical management of MEN1-related pNETs and selected aspects of tuberous sclerosis, neurofibromatosis, and VHL as they relate to pNETs. As in all genetic cancer syndromes, genetic counseling and cancer screening are necessary aspects of optimal patient management.

Multiple Endocrine Neoplasia Type 1

With regard to patients with MEN1 who have nonfunctioning pNETs, their surgical management remains controversial. Due to the characteristic multifocality of MEN1-associated pNETs and the desire to avoid total pancreatectomy, some investigators have discouraged early surgery in patients with MEN1.¹¹³ It has been suggested that surgery for nonfunctioning pNETs should be limited to those tumors >2 to 3 cm in diameter.^{98,113–118} In a single institution series, a trend was shown for larger tumors to be associated with the presence of synchronous distant metastases at the time of diagnosis.¹¹⁹ None of the 19 pNETs that were 2.5 cm or less, in maximum dimension, had distant metastases at the time of diagnosis compared with 5 (23%) of the 22 pNETs >2.5 cm ($p = 0.05$).

However, tumor size may not be a completely reliable predictor of malignant behavior, as metastatic disease may be present in patients with MEN1 even when the primary tumors are small.¹²⁰

Thompson^{121,122} was the first to advocate a specific surgical procedure in patients with MEN1 with nonfunctioning pNETs >1 cm in diameter to include distal subtotal pancreatectomy, enucleation of any identified lesions in the pancreatic head or uncinate process, and regional lymphadenectomy.^{121,122} Enthusiasm for this approach has waned largely due to an improved understanding of both the complex biology and often unpredictable natural history of MEN1-associated pNETs.

We currently operate on all patients with MEN1 who have evidence of a pNET(s) on CT imaging that are in the range of 1.5 to 2 cm in size or larger, or have demonstrated an increase in size on serial imaging. We agree that preservation of islet cell mass is important, especially in young patients, to hopefully prevent the complications of insulin-dependent diabetes associated with total pancreatectomy. The goal of the first operation is to delay the need for total pancreatectomy assuming that some patients may develop metachronous neoplasms in the remaining pancreas and require completion total pancreatectomy. In patients with large tumors within the head of the pancreas that are not amenable to enucleation, pancreaticoduodenectomy (with preservation of a portion of the pancreatic body and tail when possible) is an appropriate alternative. The extent to which removal of the duodenum and perhaps distal stomach reduce the level of trophic gastrointestinal hormones and prevent/retard tumor growth (in the remaining pancreas and in distant sites) is at present an unsupported theory based on anecdotal clinical observation. It is interesting to speculate if the historical emphasis on avoiding pancreaticoduodenectomy in MEN1-associated pNET may be misguided.

von Hippel-Lindau Syndrome

VHL is an autosomal dominant inherited familial cancer syndrome that was initially discovered in 1927.¹²³ It is associated with a variety of neoplasms, frequently including retinal, cerebellar, and spinal hemangioblastoma, as well as renal cell carcinoma, pheochromocytoma, and pNETs. The vHL gene is located on chromosome 3p26-p25. Tumors arising in the setting of VHL are often vascular likely due to the role of the vHL gene in regulating angiogenesis.

pNETs occur in approximately 15% of patients with VHL.¹²⁴ However, the vHL gene may be involved in sporadic cases of pNETs. Allelic deletion at chromosome 3p, the site of the vHL gene has also been described to occur frequently in sporadic pNETs.^{30,125}

Tuberous Sclerosis and Neurofibromatosis

Tuberous sclerosis and neurofibromatosis are two other hereditary cancer syndromes associated with the development of pNETs. The genes responsible for tuberous sclerosis, TSC-1 and TSC-2, are located on chromosomes 9q34 and 16p13.3, respectively, and code for the proteins hamartin and tuberin. TSC1/2 complex is an inhibitor of mTOR, which is a key regulator of cellular proliferation and survival. TSC1/2 are normally expressed in neuroendocrine cells.¹²⁶ Although benign hamartomas are the most common manifestation of mutations in TSC1/2, patients with defects in the TSC2 gene have tuberous sclerosis and are known to develop islet cell carcinoma.¹²⁷

Neurofibromatosis type 1 (NF1), also known as Von Recklinghausen disease, is an autosomal dominant disease associated with the development of cutaneous neurofibromas and skin lesions known as café au lait spots. The gene responsible for NF1 codes for the protein neurofibromin 1 and is located on chromosome 17. It has recently been discovered that NF1 regulates the activity of TSC2. The loss of NF1 in neurofibromatosis leads to constitutive mTOR activation and tumor formation.¹²⁸ NF1 is associated with the development of NETs in the region of the duodenum and

ampulla of Vater.¹²⁷ Many of the endocrine tumors that arise from Von Recklinghausen disease (NF1) are somatostatinomas.

High-Grade Neuroendocrine Carcinoma

High-grade neuroendocrine carcinomas (also known as poorly differentiated neuroendocrine carcinomas)¹²⁹ rarely arise from the pancreas. These aggressive tumors are characterized by early systemic dissemination and rapid growth. Sometimes also described as small-cell carcinoma or large cell NET, high-grade neuroendocrine carcinomas share a similar pattern of clinical behavior with small-cell carcinomas of the lung. Although the diagnosis of poorly differentiated carcinoma is usually straightforward, when the diagnosis is made by FNA, the grade of the tumor may not be specified.

Owing to the rarity of these tumors, little prospective data is available to guide management. Much of the current practice has been based on experience with small-cell lung carcinoma. High-grade NETs of the pancreas are often diagnosed at advanced stages. We recommend induction chemotherapy even for localized potentially resectable cases due to the aggressive nature of this disease and the high rate of relapse.

These rare but aggressive tumors are initially chemosensitive. Treatment generally parallels the therapy developed for small-cell lung cancer. Platinum-based chemotherapy is recommended in the front-line setting; two-drug combinations such as etoposide plus cisplatin or irinotecan plus cisplatin have shown activity.^{130,131}

SURGERY PITFALLS

For functioning tumors, it remains critically important to separate the diagnostic and the tumor localization phases of the evaluation. It is tempting to proceed with localization studies before the diagnosis of ZES or insulinoma is firmly established. In such cases, an incidental finding on cross-sectional imaging (now quite common due to the sensitivity of CT/MRI and their overuse) may prompt an ill-advised surgical procedure. If the diagnosis is biochemically confirmed but localization studies are negative, one should consider referring the patient to a specialty center and an experienced endocrine surgeon.

When dealing with a large, borderline resectable/locally advanced primary tumor (pNET) where there is a technical option for tumor removal, we frequently consider preoperative induction chemotherapy. In such patients, as well as those with both a pNET and liver metastases, determining the patient's candidacy for surgery has become very complex. For example, in the patient who has both local disease and liver metastases, we may follow induction chemotherapy with a two-staged surgical approach if imaging studies suggest that an adequate portion of the liver is uninvolved (or minimally involved) with disease. At the first operation, the primary tumor is removed, and the liver bisegment (or lobe) that is to remain in place is cleared of disease. This may then be followed by portal vein embolization of the hepatic lobe to be removed, with a second operation planned for liver resection.¹³² Such multidisciplinary management requires a dedicated group of physicians and an infrastructure that can assist patients with treatment-related complications such as biliary stent occlusion, nutritional depletion, gastrointestinal and hematologic toxicity, and surgery-related morbidity.

Finally, all physicians must remember that pNETs usually grow slowly and, therefore, if patients have a good performance status, they will usually survive longer than we anticipate despite the presence of locally advanced or metastatic disease. Because of this, treatment-related mortality (especially surgery induced) should be avoided. An ill-advised operation with a bad outcome in an otherwise healthy patient (of any age and especially those of young age where the temptation/pressure to operate is often great) should be considered an act of poor judgment rather than heroism.

86 Carcinoid Tumors and the Carcinoid Syndrome

Jeffrey A. Norton and Pamela L. Kunz

INCIDENCE AND ETIOLOGY

Neuroendocrine tumors (NET) of the gastrointestinal tract (carcinoid tumors) are uncommon but are more common than other primary sites, followed by NETs of the lungs, thymus, and other less common sites like ovaries, testes, and hepatobiliary system.¹ The incidence of gastrointestinal (GI) NETs is 6.2 per 100,000 population and has been steadily increasing. The increasing incidence of NETs reported in many studies is likely multifactorial and includes increased awareness and improved endoscopic methods of detection.

Small bowel NETs (midgut carcinoids) are much more common than both foregut and hindgut.² The incidence is approximately 2 per 100,000 per year. In one study of 254 patients from Germany with GI NETs, the primary tumor was foregut, midgut, or hindgut in 44.1%, 43.7%, and 4.3%, respectively.³ Midgut NETs can remain small (<1 cm) and still metastasize to regional lymph nodes and liver. Midgut carcinoids are the only primary site in which size does not directly correlate with metastatic disease, because these tumors may still spread despite a small size. Risk factors for the development of midgut carcinoid tumors include age, male sex, increased body mass index, and menopausal hormone therapy.⁴

As these tumors are indolent and patients survive a long time, the prevalence is quite high, making them the second most prevalent GI tract tumor, second only to colon cancer. Some are clinically silent and have been detected only at autopsy (incidence 8%). Further, patients with GI NETs have a higher risk of other noncarcinoid primary tumors.⁵ The overall 5-year survival rate of all patients with GI NETs is 28.5%.

ANATOMY AND PATHOLOGY

In 1907, Oberndorfer first coined the term carcinoid, meaning “cancer-like,” to describe a rare ileal tumor with less malignant behavior than the more commonly identified large bowel carcinomas. Now, it is clear that carcinoids are, indeed, malignant. They are derived from the diffuse neuroendocrine system that is composed of peptide- and amine-producing cells that may secrete different hormones depending on the site of origin.⁶ The World Health Organization recently dropped the term carcinoid and now classifies these tumors as NETs, although carcinoid may likely remain in the vernacular.⁷ NETs are composed of monotonous sheets of small round blue cells with uniform nuclei and cytoplasm.

The nomenclature, classification, and grading systems for NETs have historically been inconsistent, and there is currently no single system for NETs at all anatomic sites. Through critical evaluations of these systems, common principles have emerged.^{8,9} Critical factors in NET pathology include key features that have been classified by various schema over the years. These are embryologic site of origin (foregut, midgut, hindgut), functional status (defined as hormone secretion associated with symptoms

of hormone excess), and grade. The recent 2010 World Health Organization pathology classification relies mainly on proliferation rates as measured by Ki67 antibody staining or mitotic index.⁷ Low-grade tumors (grade 1) are the most common and have a mitotic index of fewer than two mitoses/10 high power field (hpf) and a Ki67 <3%. Intermediate-grade tumors (grade 2) have a mitotic index of 2 to 20 mitoses/10 hpf and a Ki67 3% to 20%. High-grade tumors (grade 3) have a mitotic index >20 mitoses/10 hpf and a Ki67 >20%. These numbers have clinical importance because extensive surgery including resection of locally advanced tumor and/or distant metastases is the treatment strategy of choice for low-grade tumors, whereas high-grade tumors are treated primarily with chemotherapy. Chromogranin A and synaptophysin immunostains identify proteins of neurosecretory granules and are specific immunologic markers for NETs. Other immunostains like gastrin and glucagon are sometimes performed but do not indicate whether a tumor is “functional” as defined by clinical symptoms of hormone excess. NET pathology guidelines have recently been updated and now recommend a set of minimum data elements to be included in all pathology reports for NETs^{8,9} (Table 86.1).

Until recently, an understanding of the molecular basis of NETs has been elusive. Banck et al.¹⁰ performed exome sequencing on 48 small intestine NETs. They reported an average of 0.1 somatic single nucleotide variants per 106 nucleotides (range, 0 to 0.59), mostly transitions (C>T and A>G). They discovered 197 protein-altering somatic single nucleotide variants affected mostly cancer genes, including FGFR2, MEN1, HOOK3, EZH2, MLF1, CARD11, VHL, NONO, and SMAD1. Alterations with potential therapeutic application were found in 35 patients, including SRC, SMAD family genes, AURKA, EGFR, HSP90, and PDGFR. Mutually exclusive amplification of AKT1 or AKT2 was the most common event in the 16 patients with alterations of phosphatidylinositol-3 kinase/protein kinase B/mammalian target of rapamycin (mTOR) signaling.¹⁰

Screening

The low NET incidence rates do not warrant population screening. For certain patients with an inherited predisposition for NETs (like in multiple endocrine neoplasia [MEN] syndromes), screening programs are often instituted. See Chapter 87 on MEN.

GENERAL PRINCIPLES OF NEUROENDOCRINE TUMOR DIAGNOSIS, STAGING, AND MANAGEMENT

General Diagnostic Principles

The diagnosis of GI and pulmonary NETs is often incidental, though patients with functional tumors can present with symptoms of hormone excess. The diagnostic approach for a patient with NETs is summarized by the North American

TABLE 86.1

Staging Criteria for Neuroendocrine Tumors

Grade	Low Grade	Intermediate Grade	High Grade
Old Terminology	Typical Carcinoid	Atypical Carcinoid	Small-Cell/Large-Cell Carcinoma
Ki67	<3%	3% to 20%	>20%
Mitotic index	<2/10 hpf	2–20/10 hpf	>20/10 hpf
AJCC	T ₁ -T ₂ , N ₀ , M ₀	T ₃ , N ₁ , M ₀	T ₄ ± M ₁
SEER	Localized	Regional	Distant

hpf, high power field; AJCC, American Joint Committee on Cancer; SEER, Surveillance, Epidemiology, and End Results.
 AJCC definition: T₁ <2 cm, T₂ >2 cm, T₃ >4 cm, T₄ tumor extends outside structure. N₀ negative nodes, N₁ positive nodes, M₀ no distant metastases, M₁ distant metastases.

Neuroendocrine Tumor Society¹¹ and the National Comprehensive Cancer Network NET guidelines.¹²

Serum hormone markers are often elevated in NETs and can be a surrogate marker of symptoms of hormone excess or tumor growth, though none are sensitive enough to be used as a screening test. Chromogranin A levels are elevated in approximately 80% of patients with GI NETs; sensitivity is 75% and specificity is approximately 85%. Falsely positive elevated serum levels of chromogranin A may occur when patients take a commonly prescribed proton pump inhibitor (PPI) or H₂ receptor antagonist, so these medications should be discontinued for several days prior to testing and testing should be done fasting. Urine 5-hydroxyindoleacetic acid (5-HIAA), the primary metabolite of serotonin, is elevated in carcinoid syndrome. Test characteristics of this assay are sensitivity of 35% and specificity of 100%. Abnormal levels (>5 mg/24 hours) of 5-HIAA are diagnostic of carcinoid syndrome. Elevated levels of serum serotonin are also confirmatory and consistent with carcinoid syndrome, though more difficult to measure reproducibly. Patients need to be on a special diet in order to avoid false positive results. Bananas, pineapple, tomatoes, plums, eggplant, avocado, kiwi, fruits, and nuts must be avoided for 3 days. Medications such as PPIs, cough and antihistamine medications, thorazine and compazine, nasal drops and sprays, hypertension medications, acetaminophen, and muscle relaxants especially roboxin, valium, and flexeril can also lead to false positives and should be avoided.

Less common NETs may also be identified by the specific hormone and syndrome that is produced. For example, thymic carcinoid tumors may produce adrenocorticotropic hormone (ACTH) and corticotropin-releasing factor and result in ectopic Cushing syndrome.⁵ Thirty percent of these tumors can also secrete catecholamines; therefore, 24-hour urinary catecholamine excretion should be measured as clinically indicated.

The diagnostic evaluation for GI and pulmonary NETs often begins with high-resolution cross-sectional imaging with either multiphase computed tomography (CT) or magnetic resonance imaging (MRI). Small intestine NETs are often characterized by mesenteric masses that represent abnormal lymph nodes associated with cicatrization or desmoplastic changes and scarring (Fig. 86.1). Additionally, most NETs express somatostatin receptors that can bind and internalize the currently available octapeptide somatostatin analogues octreotide and lanreotide. This feature can be exploited both in terms of somatostatin receptor-based treatments and scintigraphy (SRS). ¹¹¹In-pentetreotide scintigraphy (Octreoscan; Mallinckrodt, Dublin, Ireland) can image approximately 80% to 90% of patients and can unmask the primary tumor, regional lymph node metastases, and distant metastases. Positron emission tomography (PET) scanning with Ga-68 DOTATATE

Figure 86.1 Coronal computed tomography of bulky mesenteric lymph node metastases from an ileal carcinoid (neuroendocrine) tumor. Nodes are centrally located near the superior mesenteric vein and are causing cicatrization and scarring. Patient needed an extended right hemicolectomy and distal ileal resection to completely remove the small primary (not shown) and bulky lymph node metastases.

is a newer somatostatin-based scintigraphy that is thought to be more sensitive than ¹¹¹In scans. At present, this imaging modality is available primarily in Europe and select centers in the United States such that it is still considered experimental. Standard PET scanning with ¹⁸F-deoxyglucose is disappointing in patients with well-differentiated GI and pulmonary NETs, although poorly differentiated NETs are often ¹⁸F-deoxyglucose avid. ¹²³I- or ¹³¹I-meta-iodobenzylguanidine is taken up and accumulated in some NET cells. Sensitivity of ¹³¹I-meta-iodobenzylguanidine scan in patients with small intestine NETs is between 60% and 85%, and is especially useful in patients whose tumors secrete catecholamines. CT-enteroclysis is a newer imaging modality designed to image tumors of the small bowel. It has a sensitivity of 86% and a specificity of 100% for small bowel NETs.¹³ Echocardiography is also included in the diagnostic workup to either confirm or exclude carcinoid heart disease.

General Staging Principles

The seventh edition of the American Joint Committee on Cancer (AJCC) *Staging Manual* is the first edition to include specific staging for GI NETs such as stomach, small bowel, appendix, colon, and rectum, and parallels staging for adenocarcinomas of those same sites.¹⁴ Multiple papers have been published recently which both validate this AJCC staging and propose some additional modifications to enhance future AJCC versions^{15,16} (see Table 86.1).

General Management Principles

Management of NETs falls under two main categories: therapies directed at tumor control and therapies directed at controlling symptoms of hormone excess. Additionally, therapies directed at tumor control are further divided based on biologic differences of

well- versus poorly differentiated NETs. Unless noted, antitumor therapies will all be for well-differentiated tumors. Carcinoid syndrome and medical management of hormone-related symptoms will be addressed in detail later in this chapter.

Therapies directed at tumor control include surgery. Surgical resection remains the mainstay of treatment for resectable NETs of the GI tract and lungs. The primary goal of surgical intervention is to prolong survival. Yet, in addition to prolonged survival, surgery can also palliate symptoms of obstruction, diarrhea, flushing, and/or pain with eating.¹⁷ In the setting of unresectable disease, antitumor therapy is only indicated in the setting of symptoms, tumor bulk, and/or disease progression. In newly diagnosed asymptomatic patients with unresectable or metastatic disease, it is often reasonable to monitor closely without any active treatment.

DIAGNOSIS, STAGING, AND MANAGEMENT BY PRIMARY TUMOR SITE

The previously mentioned general principles apply to most NETs of the GI tract and lungs. Following are some unique aspects of the diagnosis, staging, and management by primary tumor site. Management here focuses on surgical management of localized disease and management of hormone symptoms. Management of metastatic disease will be addressed separately.

Thymic Neuroendocrine Tumors

NETs of the thymus are rare. Thymic NETs make up between 2% and 7% of anterior mediastinal masses. CT or MRI is commonly used for imaging and the diagnosis. Patients may present with severe Cushing syndrome secondary to ectopic ACTH production.¹⁸ Approximately 25% of patients with thymic carcinoids will have MEN-1. Patients typically present with either stage 1 well-differentiated neuroendocrine carcinoma previously termed typical carcinoid syndrome, or stage 2 moderately differentiated neuroendocrine carcinoma previously called atypical carcinoid tumor or stage 3 poorly differentiated or small cell neuroendocrine carcinoma. Surgery (radical thymectomy) is the primary treatment for stage 1 and 2 thymic NETs, whereas chemotherapy is best for stage 3. Five- and ten-year survival for resected thymic NETs is between 20% and 30%. Radiation may help with local control following incomplete resection.

Bronchial Neuroendocrine Tumors

Bronchial NETs appear histologically like intestinal NETs and are not related to cigarette smoking. These tumors are more common in patients with MEN-1. Poor prognostic factors include higher mitotic index, nuclear pleomorphism, vascular and lymphatic invasion, and poorly differentiated growth pattern. The bronchus is the site of a primary NET in approximately 2% of cases. These tumors occur close to the hilum on CT and MRI scan and may be confused with blood vessels. Bronchial NETs are divided into three categories: benign or low-grade malignant, which is the typical carcinoid form; low-grade malignant, which is the atypical carcinoid form; and poorly differentiated, either large cell or small cell. The grading system differs slightly when compared to GI NET grading. The three different categories of bronchial carcinoid tumors have different prognosis from excellent for typical well-differentiated carcinoids to poor for small cell neuroendocrine carcinomas. The well-differentiated tumors are surgically resected with a lobectomy while the small cell tumors are treated primarily with chemotherapy. SRS can be used to complement cross-sectional imaging with multiphasic CT or MRI. Atypical carcinoid tumors have more uptake of deoxyglucose on PET scan, while typical carcinoid tumors have more uptake of sandostatin (octreotide).¹⁹ On bronchoscopy, NETs

appear as a cherry red mass within the bronchus protruding into the lumen. It is recommended not to biopsy them as they can bleed excessively with biopsy. Bronchial carcinoids are the most common cause of ectopic ACTH syndrome, and Cushing syndrome is severe with usual clinical signs and symptoms plus severe weakness secondary to hypokalemia.²⁰

Esophageal Neuroendocrine Tumors

Esophageal NETs are very uncommon (<1% of GI NETs). They occur predominantly in men at an age >60 years. Symptoms are nonspecific and vary from asymptomatic to indigestion and burning pain. Most tumors are seen in the distal esophagus just proximal to the esophageal-gastric junction. They are seen on endoscopy as a submucosal mass, and they usually dimple the mucosa. Endoscopic ultrasonography and SRS are indicated for staging because lymph node metastases occur in 50% of patients. Endoscopic mucosal resection (EMR) is done if there is no evidence of lymph node metastases and the tumor is amenable to complete excision. Open resection is done for patients with lymph node metastases. The operative procedure is most commonly an Ivor Lewis esophagogastrectomy that requires an upper midline incision and a right thoracotomy. Survival is dependent on stage of disease and adequacy of resection.

Gastric Neuroendocrine Tumors

Gastric NETs are rare tumors and constitute <1% of gastric tumors and 9% of GI NETs (Table 86.2). These tumors arise from the enterochromaffin-like (ECL) cells of the stomach that occur in the gastric fundus and body. Gastric NETs are immunoreactive to histamine, chromogranin A, and synaptophysin. Gastric NETs have three different forms: type 1, type 2, and type 3. Type 1 gastric carcinoids typically occur in a state of chronic atrophic gastritis that results in achlorhydria and hypergastrinemia.²¹ They occur in 80% of gastric NETs. These tumors are typically multicentric consisting of multiple small gastric polyps and invariably develop from ECL cell hyperplasia and become small polypoid tumors.²² Tumors vary in size from a few millimeters to 1.5 cm. These tumors are almost always benign with minimal risk of invasion or metastases. These are usually treated with repeat endoscopic examination, excision, and EMR of larger tumors. There is a very low risk of lymph node metastases (5%) or distant metastases (2%). Larger tumors (approximately >2 cm) require resection, either endoscopic or open surgery. If gastric surgery is performed, antrectomy is indicated as this will remove the source of the hypergastrinemia and the stimulus for ECL cell growth.

TABLE 86.2

Incidence and Prognosis of Different Stage Gastrointestinal Neuroendocrine Tumors

Site	Incidence (% GI NETs)	Five-Year Survival T ₁₋₂ , N ₀	Five-Year Survival T ₃ , N ₁	Five-Year Survival T ₄ ±M ₁
Stomach	9	93	65	25
Duodenum	4	68	55	46
Ileum/jejunum	42	78	71	54
Appendix	8	98	78	25
Colon	4	85	46	14
Rectum	27	93	62–75	33

GI, gastrointestinal; NET, neuroendocrine tumor.

Type 2 gastric carcinoid tumors are rare and occur in only 6% to 8% of patients with gastric NETs. They are much less common than those seen in atrophic gastritis. Type 2 tumors occur in patients with MEN-1 with Zollinger-Ellison syndrome (ZES) who have been treated with PPIs for a long time period. They occur equally in both men and women with an age distribution of 45 to 50 years. The hypergastrinemia of ZES is exacerbated by the prolonged use of the PPI (approximately 10 years) to control symptoms related to excessive acid secretion. These NETs develop in a hyperplasia-dysplasia-neoplasia sequence. Moreover, there must be an effect of the *menin* gene defect, because non-MEN-1 patients with (sporadic) ZES have also been treated with prolonged use of PPI and have not developed similar tumors. Type 2 NETs of the stomach are often multiple and small (73% <1.5 cm), but are larger than the type 1 tumors. Lymph node metastases are present in 30% of patients with type 2 gastric carcinoid tumors, and distant metastases occur in 10% to 20%. Patients with MEN-1 may develop distant metastases from pancreatic NETs, so it is sometimes difficult to tell which primary NET led to the development of a liver NET. However, rare cases of highly malignant gastric NETs with a poor prognosis have been described in some patients with MEN-1/ZES. These patients have diffuse involvement of the entire stomach with NETs, and total gastrectomy with adjacent lymph node dissection is recommended.

Type 3 gastric NETs are those that occur sporadically with no association of hypergastrinemia. They represent 15% to 20% of gastric NETs and are markedly different from type 1 and 2 NETs. They occur sporadically, are solitary, and grow much more rapidly. Most have distant metastases at the time of diagnosis. These tumors have a male predominance and occur 3:1 in men. Mean age at presentation is 50 years. These tumors are large (mean size 3 cm). Most lesions invade the full thickness wall of the stomach. They are usually located in the body or fundus. Regional lymph node and liver metastases are present in 70% of patients. A total of 73% of patients with this disease are alive at 5 years, but those with liver metastasis have a 5-year survival of 10%. Sporadic type 3 gastric NETs usually have a Ki67 index of >2%. According to older classifications, these tumors may have typical or atypical histology. Atypical implies nuclear pleomorphism, more mitosis, and necrosis. Atypical tumors are larger (>5 cm) and have a more unfavorable prognosis. The atypical carcinoid syndrome occurs in these patients and is associated with tumor release of histamine. The atypical carcinoid syndrome has bright red cutaneous flushing, edema, itching, wheezing, and lacrimation. In patients with type 3 gastric NETs, tumor debulking of the primary and lymph node metastases may relieve symptoms. Hepatic metastases are treated with resection, hepatic artery embolization or chemoembolization, radiofrequency ablation, and sandostatin long-acting repeatable (LAR) that may ameliorate the symptoms of the atypical carcinoid syndrome. Chemotherapy is likely to be useful when the proliferation rate exceeds 5%. Response rates are between 20% to 40%.

Small Bowel Neuroendocrine Tumors

NETs of the duodenum are rare and comprise <4% of all GINETs. Gastrinomas are the most common functional duodenal NET and represent 60% of duodenal NETs. These tumors are more common in the proximal duodenum and are less likely to arise in the distal duodenum. They are usually small <5 mm and multiple in MEN-1. They frequently (30% to 70%) spread to regional lymph nodes such that adjacent lymph node sampling is recommended but do not commonly spread to distant sites. Overall, the 10-year survival of duodenal NETs is 64%.²³ The 10-year survival rate for patients with duodenal gastrin-secreting NETs is 90%. Duodenotomy (opening the duodenum) at the time of surgery is the most effective method to identify these tumors. When found, complete excision of the duodenal wall around the tumor with lymph node

sampling is recommended. Some advocate Whipple procedure, but the prognosis is excellent with local tumor resection and the cure rate is 60%, so many think that Whipple resection is not indicated.

Periampullary duodenal NETs do not usually produce a hormonal syndrome.²³ Given their location, these tumors may cause obstructive jaundice or bleeding. The size of these tumors is small (between 1 to 2 cm in diameter). They are typically nodular, polypoid, and ulcerated. Periampullary NETs are associated with von Recklinghausen neurofibromatosis. A total of 50% of the patients have either lymph node or liver metastases. They require either local excision or Whipple pancreaticoduodenectomy, dependent on the size of the tumor, the age of the patient, and the relationship to the ampulla. Nonampullary duodenal NETs that are found during endoscopy have an excellent prognosis and can be removed by EMR if <1 cm. They are removed by surgical excision if the tumor is >2 cm. Lymph node metastases can occur in approximately 40% of patients, so lymph node sampling is recommended. For treatment of NETs >3 cm, Whipple pancreaticoduodenectomy is recommended. Small bowel NETs are most common GI NET, and they are most prevalent within the ileum. They account for 42% of all GI NETs. They usually occur within 20 cm of the ileal-cecal valve. They feel like a firm mobile nodule within the wall of the bowel. Patients typically have a long history of vague nonlocalizing abdominal pain before the tumor is detected. These symptoms may be borborygmi, episodic abdominal pain or cramping, and episodic diarrhea and constipation. Others may develop clinical signs of the typical carcinoid syndrome that include diarrhea, flushing, palpitations, intolerance of certain specific foods like cheese or red wine, intestinal venous congestion, and infarction, and these can occur as the tumor lymph node metastases enlarge and block the venous outflow. Intermittent severe episodes of abdominal pain or even intestinal obstruction can occur as the tumor progresses. Ileal NETs are commonly very small (2 to 4 mm) and multiple within the wall of the ileum, with adjacent large lymph node metastases that cause cicatrization and venous congestion that can result in small bowel obstruction (see Fig. 86.1). Approximately 50% of patients will have liver metastases or peritoneal carcinomatosis at the time of diagnosis. The 10-year survival for jejunal and ileal NETs is 53% and 50%, respectively. Surgery includes wide resection of the small bowel with the primary tumors, its mesentery, and lymph node metastases. This usually requires an extended right hemicolectomy and may result in a relative short gut syndrome because the lymph node metastases can be very centrally located and require resection of proximal branches of the superior mesenteric artery and vein. Recent studies also suggest that surgery can be effectively done laparoscopically,²⁴ but commonly extensive nodal disease is present such that the superior mesenteric artery and vein must be skeletonized that usually requires open surgical techniques. Surgery for ileal NETs is the mainstay of treatment and surgical resection of the primary tumor even in the setting of numerous distant metastases has been recommended in order to avoid the cramping and bowel obstruction associated with primary NETs that are left to progress.²⁵ Patients with unknown primary metastatic NETs can often harbor occult primary ileal NETs. This is quite common, and careful exploration and palpation of the ileum allows detection of small submucosal primaries that feel like little peas within the bowel wall.²⁶ Cholecystectomy is also indicated because most of these patients with either lymph node or liver metastases will require the long-term use of somatostatin analogues that can cause gallstones when administered long-term.

Appendiceal Neuroendocrine Tumors

Appendiceal NETs represent between 5% to 8% of GINETs. They occur in approximately 1 in 200 to 300 appendectomies.^{27,28} Most are located in the tip of the appendix. They commonly present

in younger patients who have a mean age of <50 years. They seldom metastasize; lymph node metastases occur in 3.8% and distant metastases in only 0.7%. The long-term survival is nearly 95% for all patients with appendiceal carcinoid tumors, 84% for those with lymph node metastases, and 28% for those with liver metastases. Appendectomy is adequate for tumors <2 cm and those that do not invade through the wall of the appendix or are present at the base. For patients with tumors >2 cm, invasion through the appendiceal wall, presence at the base, or lymph node metastases, a right hemicolectomy is indicated.

Colorectal Neuroendocrine Tumors

NETs of the colon are rare and account for only approximately 4% of GI NETs and 1% to 5% of colorectal tumors.²⁹ These tumors occur more commonly in older individuals >65 years. Tumors in the right colon are more common and can cause symptoms of carcinoid syndrome. The majority of colon NETs are well differentiated but some are large, less differentiated, and exophytic. These larger, less-differentiated tumors grow more rapidly and have a higher incidence of lymph node and liver metastases. The 5-year survival for colon NETs is 37%, which is only slightly better than all patients with colon cancer. In general, colon NETs should be treated with a hemicolectomy including adequate lymph node retrieval.

The incidence of rectal NETs is increasing.³⁰ They are among the most common NETs reported in recent series. They constitute 27% of GI NETs and 1% to 2% of all rectal tumors. These tumors are more common in Asian and Black populations. Most are small and discovered incidentally during endoscopy. The overall prognosis is favorable, and the 5-year survival for patients with stage 1 to 4 is 93%, 75%, 43%, and 33%, respectively.³⁰ Smaller tumors (<1 cm) can be treated by either EMR³¹ or local excision. Larger tumors >1 cm may require a low anterior resection or an abdominoperineal resection depending on the relationship to the distal rectum and anus.

DIAGNOSIS AND MANAGEMENT OF CARCINOID SYNDROME

Biogenic amines and vasoactive peptides in the systemic circulation cause symptoms of the carcinoid syndrome (Fig. 86.2). Serotonin, tachykinins, bradykinin, and histamine have each been measured in the systemic circulation of these patients. Enterochromaffin cells, precursors to NETs, have the ability to produce 5-hydroxytryptamine (serotonin). In the liver, serotonin is metabolized to 5-HIAA that eliminates the development of the signs and symptoms of the carcinoid syndrome. However, in patients with liver metastases or extrahepatic tumor in sites such as the ovary or the retroperitoneum, an excessive amount of serotonin enters the systemic circulation and causes carcinoid syndrome. Small bowel NETs are most often associated with carcinoid syndrome.

Symptoms of carcinoid syndrome include diarrhea, flushing, wheezing caused by bronchial obstruction, and carcinoid heart disease. Most patients complain of intermittent crampy abdominal pain. Flushing is the most common symptom, occurring in 94% of patients, and has been linked to secretion of tachykinins, serotonin, and histamine. Flushing has a uniform distribution and most commonly involves the upper chest, neck, and face. It may be provoked by certain foods like nuts, cheese, drugs, and alcohol, and during times of stress. Patients will develop skin thickening and redness in this distribution secondary to chronic flushing. Diarrhea occurs in 80% of patients with carcinoid syndrome. Serotonin is thought to be the most common cause of diarrhea, but other active amines like histamine, kallikrein, prostaglandin, substance P, and motilin may play a role. Further, a relative short gut

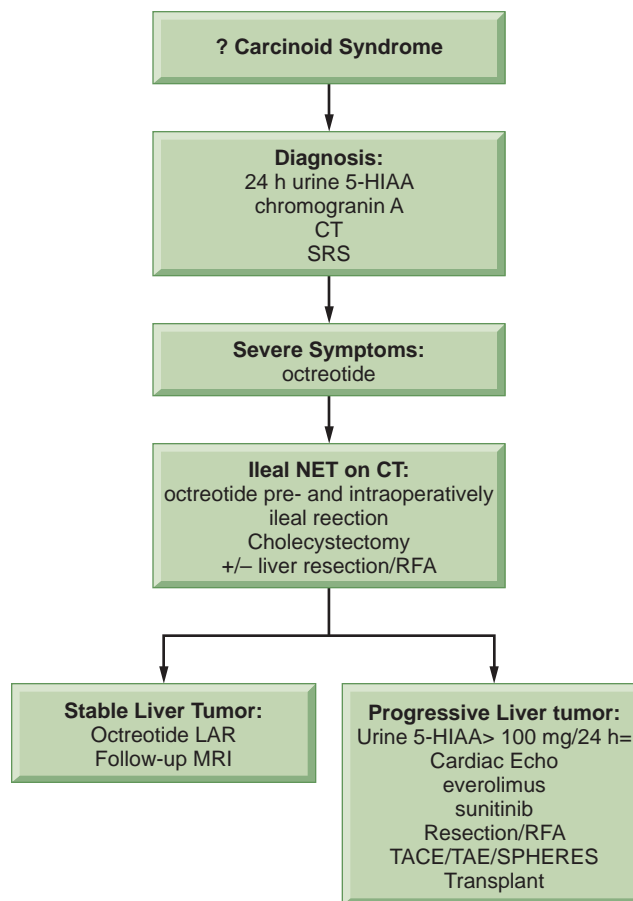

Figure 86.2 Flow diagram for the diagnosis and management of carcinoid syndrome. Diagram includes diagnosis and management of a primary ileal carcinoid tumor and liver metastases. HIAA, hydroxyindoleacetic acid; CT, computed tomography; SRS, somatostatin receptor-based treatments and scintigraphy; NET, neuroendocrine tumor; RFA, radiofrequency ablation; MRI, magnetic resonance imaging; TACE, chemoembolization; TAE, transarterial embolization; SPHERES, Radioactive SPHERES.

syndrome may occur following removal of the primary tumor and malabsorption of bile salts and fat, as well as bacterial overgrowth, may also contribute to diarrhea.

Carcinoid heart disease develops in approximately 40% of patients with carcinoid syndrome. It is characterized by carcinoid plaques on the right side of the heart with involvement of the tricuspid and pulmonary valves and the endocardium.³² The pathogenesis of these plaques and fibrosis is increased synthesis of collagen secondary to serotonin-induced transforming growth factor-beta secretion. The most common clinical manifestation is tricuspid and pulmonic valve insufficiency and stenosis. These valvular lesions can be significant and lead to right-sided heart failure. Several studies have shown that patients with carcinoid syndrome with valve disease have much greater levels of urinary 5-HIAA excretion. Cardiac surgery is indicated for valve replacement. Patients with urinary 5-HIAA excretion rates >100 mg/day should be screened by transthoracic echocardiography on a regular basis. Similarly, serotonin, histamine, and bradykinin also induce transforming growth factor-beta, collagen synthesis, and scarring in the mesentery of the bowel. This can lead to adhesions and bowel obstruction or venous obstruction that leads to inadequate venous outflow and bowel ischemia.

Intermittent bronchial obstruction and wheezing is present in 10% of patients with carcinoid syndrome. It usually occurs during episodes of flushing. It cannot be treated like asthma because

β_2 -agonists that are used to treat asthma lead to additional release of biogenic amines and peptides.

Pellagra is also associated with carcinoid syndrome, though in a minority of patients (5%). The triad of dermatitis, diarrhea, and dementia characterizes pellagra. Pellagra is a direct result of niacin deficiency. Niacin is directly obtained from the diet or synthesized from tryptophan, a precursor of serotonin. Carcinoid tumors use a large proportion of the body tryptophan stores for overproduction of serotonin. Increased tryptophan consumption leads to impaired niacin synthesis and pellagra. Pellagra should be treated with niacin supplementation.

Finally, carcinoid crisis can occur in patients with carcinoid syndrome who undergo anesthesia or surgery and are not sufficiently blocked with somatostatin analogues. The clinical picture includes flushing, hypotension, bronchial obstruction, and cardiac arrhythmias. Of note, all patients with small bowel NET undergoing surgical intervention should be given perioperative octreotide to prevent carcinoid crisis. This may occur with anesthesia, surgery, and interventional radiology procedures like embolization, chemoembolization, dental procedures, and radiofrequency ablation. Basically, whenever an invasive procedure is planned on a patient with carcinoid syndrome, it is prudent to pretreat with a large dose of somatostatin analogue to avoid the development of carcinoid crisis. The recommended dose of octreotide is 25 to 500 mcg subcutaneously or intravenously 1 to 2 hours prior to the procedure.³³ For the same reason, adrenergic drugs should be avoided in patients with carcinoid syndrome. In a case of carcinoid crisis, the surgical or nonsurgical manipulation should be temporarily interrupted, intravenous volume administered under the guidance of hemodynamic monitoring, and additional doses of octreotide and steroids administered intravenously. Patients who develop intraoperative symptoms (hypotension or rash) should receive 500 to 1,000 mcg of octreotide intravenously until symptoms resolve and a continuous infusion of 50 to 200 mcg/hour.

Medical management of carcinoid syndrome centers around the use of somatostatin analogues.^{6,34} Somatostatin analogs are the foundation of symptom management for patients with functional NETs and can both decrease the secretion of such hormones and inhibit their end-organ effects. Somatostatin is a naturally occurring polypeptide produced by paracrine cells that are scattered throughout the GI tract; it inhibits GI endocrine and exocrine function. Its effects are mediated through G-coupled protein somatostatin receptors (1 to 5). Short- and long-acting octreotide (with high affinity for somatostatin receptor 2) is available in the United States. Lanreotide, available in Europe, is a long-acting analog with similar binding affinity to octreotide. Pasireotide, a novel somatostatin analog with a different binding affinity profile compared to octreotide or lanreotide, is currently in development. Side effects are usually mild but include nausea, bloating, biliary sludge, and steatorrhea. Blockade of serotonin receptors via somatostatin analogues can greatly ameliorate the diarrhea of carcinoid syndrome in 40% to 80% of patients. Similarly, a reduction or normalization of biochemical markers can be seen in 40% to 70% of patients. Most patients can be managed with octreotide LAR, but 30% require either an increase in dose or frequency of administration to continue to control symptoms of hormone excess. Standard doses of octreotide LAR 20 to 30 mg every month intramuscularly³⁵ and depot-lanreotide 60 to 120 mg via deep subcutaneous injection.³⁶ Patients who experience recurrence of their symptoms toward the end of the treatment cycle may benefit from increased frequency of administration (every 3 weeks). Supplemental doses of standard subcutaneous octreotide can be given if patients develop breakthrough symptoms. Tachyphylaxis to somatostatin analogues often occurs between 8 and 12 months but can usually be overcome by increasing the dose.

Inhibitors of serotonin synthesis are emerging as a new class of agents to treat carcinoid syndrome. Telotristat etiprate is an oral inhibitor of tryptophan hydroxylase, a key enzyme in the synthesis of peripheral serotonin. A recent study randomized carcinoid

patients with four or more bowel movements a day to receive telotristat etiprate or placebo as double-blind treatment. Treatment was associated with decreases in urine 5-HIAA and bowel movement frequency, and self-reported relief of bowel-related symptoms.³⁷ Phase 3 studies with telotristat etiprate for diarrhea and flushing are ongoing (NCT01677910).

Other methods for reducing diarrhea associated with carcinoid syndrome include drugs like cholestyramine that bind bile salts and increase bile absorption. Pancreatic enzymes are used to aid with fat absorption and reduce diarrhea. Antibacterial therapy can be used if there is evidence of bacterial overgrowth. Loperamide and tincture of opium are used to decrease transit time.

ANTITUMOR MANAGEMENT

Somatostatin Analogues

Clinical studies suggest that long-acting octreotide can also inhibit tumor growth. A total of 50% of patients with metastatic carcinoid who have had objective evidence of tumor progression had stabilization of tumor size when treated with long-acting octreotide. In vitro evidence suggests that octreotide interacts with somatostatin receptors that stimulate phosphotyrosine phosphatases that inhibit growth factors like insulin-like growth factor and vascular endothelial growth factor (VEGF) and thus inhibit tumor growth. The best clinical evidence came from the PROMID trial, which was a phase 3 study that randomized 85 patients with metastatic midgut carcinoids to octreotide LAR 30 mg versus placebo. The study demonstrated a significant improvement of median time to progression from 6 months in the placebo arm to 14.3 months in the treatment arm (hazard ratio = 0.34; $p < 0.01$). On multivariate analysis, patients with low hepatic tumor burden (<10%) and resected primary tumor appeared to benefit most from octreotide treatment. Because the study had a crossover design and thus a small number of deaths, overall survival was not analyzed. The study has also been criticized for not requiring disease progression at the time of study entry. Despite these limitations, octreotide LAR is now considered an appropriate first-line therapy for patients with progressive metastatic midgut NETs regardless of the presence or absence of carcinoid syndrome.³⁸

Interferon-Alpha

Interferons (IFN) exert antitumor effects through a variety of mechanisms including stimulation of T cells, inhibition of angiogenesis, and induction of cell cycle arrest in the G_1 and G_0 phases. IFN also induces somatostatin receptors. IFN was used in early trials prior to somatostatin analogues. Improvement of symptoms including palliation of diarrhea and flushing occurs in 50% of patients. However, objective antitumor responses occur in only 10% of patients. In vitro studies have suggested synergism between IFN and octreotide, prompting clinical trials to evaluate the combination. Three randomized trials have investigated octreotide alone versus the combination of octreotide with IFN. In one multicenter trial of 68 patients with metastatic midgut carcinoids, there was a strong suggestion of improvement with octreotide + IFN versus octreotide alone. The 5-year survival rate was 57% versus 37% but the difference was not significant ($p = 0.13$).³⁹ A three-arm trial compared subcutaneous lanreotide to IFN alone or the combination of both with a very small response rate (<7%) and no difference among the three groups.⁴⁰ A third randomized study of octreotide alone versus octreotide plus IFN demonstrated an increase in median survival with the combination (54 months versus 32 months), but the difference was not significant.⁴⁰ Response rates were low in both arms (<6%). The small number of patients accrued in these randomized trials preclude any meaningful

conclusions on the role of IFN. Doses of IFN used were small and toxicity was minimal. A pivotal phase 3 study of octreotide and IFN versus octreotide and bevacizumab in advanced, high-risk NETs has recently been completed; results are anticipated in 2014 (NCT00569127). IFNs are commonly associated with flu-like symptoms, chronic fatigue, depression, thyroid dysfunction, mild hepatotoxicity, and cytopenias.

Mammalian Target of Rapamycin Inhibitors

The mTOR is a conserved serine/threonine kinase that regulates cell growth, metabolism, and proliferation. The mTOR enzyme lies downstream of the phosphatidylinositol-3 kinase/protein kinase B pathway and is activated in response to growth factors and cytokines. Pancreatic NETs have mutations in mTOR-associated genes (phosphatase and tensin homolog and phosphatidylinositol-3 kinase) in approximately 15% of cases, while it is not known if mid-gut NETs have similar mutations.⁴¹

Everolimus is an oral mTOR inhibitor that has been studied extensively in NETs.⁴² Everolimus was approved by the US Food and Drug Administration for the treatment of metastatic pancreatic NETs based on improvement in progression-free survival from 4.6 months to 11 months in a randomized study of metastatic pancreatic NETs (RADIANT-3).⁴³ The phase 3 RADIANT-2 trial randomized 429 patients with metastatic NETs and evidence of carcinoid syndrome to treatment with everolimus plus octreotide LAR versus placebo plus octreotide LAR.⁴⁴ The majority of patients in each arm had primary small bowel NETs. Median progression-free survival was improved from 11.3 months in the placebo arm to 16.4 months in the everolimus arm (hazard ratio = 0.77; $p = 0.026$), though the result was not statistically significant because it failed to meet its prespecified p value. Overall survival was not improved in the treatment arm because of a crossover design. A major limitation of this study, contributing to its overall lack of statistical significance, was the issue of informative censoring and differences between central and investigator Response Evaluation Criteria In Solid Tumors reviews. Side effects of everolimus include oral aphthous ulcers, rash, hyperglycemia, cytopenias, and pneumonitis. Major guideline groups, like the National Comprehensive Cancer Network, do not currently recommend everolimus for management of small bowel NETs. Ongoing studies may expand the role of everolimus in other nonpancreatic NETs, particularly the RADIANT-4 study that is a non-crossover, randomized study of everolimus versus placebo in patients with NETs of lung or GI origin.

Angiogenesis Inhibitors

NETs are highly vascular tumors that frequently overexpress the VEGF receptor and its ligand. Consequently, inhibition of the VEGF pathway has been considered a promising target. In a randomized phase 2 trial, 44 patients with metastatic carcinoid tumors were randomly assigned to bevacizumab (a monoclonal antibody to circulating VEGF) versus pegylated IFN for 18 weeks, after which they received both agents in combination.⁴⁵ After 18 weeks of treatment, the progression-free survival was 95% in the bevacizumab arm versus 68% in the IFN arm. Moreover, the objective response rate was 18% in the bevacizumab arm, suggesting that the drug had significant clinical activity. This trial led to the development of a randomized phase 3 trial of octreotide and IFN versus octreotide and bevacizumab in advanced, high-risk NETs; it has recently completed accrual and results are anticipated in 2014 (NCT00569127).

Several other angiogenesis inhibitors have been evaluated in NETs, including tyrosine kinase inhibitors (TKI) of VEGF receptors. Sunitinib, an oral TKI, inhibits VEGF receptors 1, 2, and 3 as well as platelet-derived growth factor, cKIT, and Flt3. In

a single-arm phase 2 study of patients with advanced NETs, only 1 of 41 (2%) patients with carcinoid had evidence of an objective radiographic response to sunitinib; however, the median time to progression was 10.2 months.⁴⁶ Sunitinib has since demonstrated improved progression-free survival compared to placebo in a randomized phase 3 study of advanced pancreatic NETs, which led to its approval by the US Food and Drug Administration for this indication in 2010.⁴⁷ A phase 3 study of pazopanib versus placebo in GI NETs is ongoing and is poised to definitely answer the question about effectiveness of oral TKIs in nonpancreatic NETs.

Cytotoxic Chemotherapy

Studies of cytotoxic chemotherapy in small bowel NETs have been disappointing. This is documented in modern clinical trials using radiographic response criteria. The combination of temozolomide and thalidomide has a response rate of 45% in pancreatic NETs but only 7% in carcinoid tumors.⁴⁸ Similarly, temozolomide plus bevacizumab have a response rate of 0/18 in carcinoid tumors but 33% in pancreatic NETs.⁴⁹ Cytotoxic agents are not recommended for the treatment of metastatic well-differentiated small bowel carcinoid tumors, except in the context of a clinical trial. Poorly differentiated NETs, regardless of primary site, are typically treated like small-cell lung cancer with a platinum/etoposide-based regimen.

Peptide Receptor Radionuclide Therapy

Nearly 80% of well-differentiated NETs express high levels of somatostatin receptors. This is the basis for the development of therapy using the somatostatin receptor as a radioligand, so called peptide receptor radionuclide therapy.⁵⁰ Selection criteria for peptide receptor radionuclide therapy include evidence of strong radiotracer uptake on SRS. Early trials used the same isotope that is used for SRS imaging, ¹¹¹In-pentetreotide. With this agent, clinical responses were rare. Next generation used ⁹⁰Y, a high-energy beta-particle emitter. A single-arm phase 2 trial of ⁹⁰Y-Edotreotide in 90 patients with metastatic carcinoid tumors reported an objective response rate of 4%, stable disease in 70%, and a high rate of symptom control. Adverse events include nausea and vomiting attributed to the amino acid infusions that were given to prevent nephrotoxicity.⁵¹ The latest generation of radiolabelled somatostatin analogues utilizes ¹⁷⁷Lu-octreotate (¹⁷⁷Lu-DOTA-Tyr-[3]-octreotate), which is an alpha, beta, and gamma particle-emitting compound that has enhanced affinity for the somatostatin receptor 2. This compound provided an objective response rate of 23% in 188 patients with carcinoid tumors as reported in a large retrospective review.⁵⁰ Adverse effects were mild. Though this treatment is used routinely in Europe, it is not approved by the US Food and Drug Administration due to lack of prospective randomized data. The NETTER-1 study will hopefully provide a definitive answer to this question. In this randomized, multinational trial, patients with inoperable, progressive, somatostatin receptor-positive midgut carcinoid tumors are randomly assigned to receive high-dose octreotide (60 mg LAR monthly) versus ¹⁷⁷Lu-DOTA0-Tyr3-Octreotate (NCT01578239).

MANAGEMENT OF LIVER METASTASES

The liver is the predominant site of metastases in patients with GI NETs (Fig. 86.3). These patients typically have carcinoid syndrome, but they may also develop symptoms secondary to enlarging liver tumor burden including anorexia, weight loss, and pain. Liver-directed therapies include liver resection and/or ablation, transarterial embolization (TAE), chemoembolization (TACE), and liver transplantation. These therapies are reserved

Figure 86.3 T2-weighted axial magnetic resonance image of a right lobe carcinoid tumor liver metastasis from an ileal carcinoid tumor. This patient had carcinoid syndrome. Surgical resection required preoperative and intraoperative treatment with octreotide. Patient underwent a cholecystectomy and right hepatic lobectomy. He has done well with long-term maintenance sandostatin-LAR intramuscularly on a monthly basis.

for patients whose sole or major tumor burden is confined to the liver.

Liver resection has been used in patients with limited liver disease if >90% of the tumor can be either resected or ablated⁵²⁻⁵⁴ (see Fig. 86.2). Typically, resection is done with multiple wedge or segmental resections rather than anatomic resection so that reoperations remain feasible, if necessary. There are numerous single institution studies that suggest excellent palliation of carcinoid symptoms and prolonged survival of patients undergoing complete tumor resection; that is, surgery with curative or near-curative intent.^{52,53,55} These studies clearly demonstrate that the surgery is feasible and can be done with minimal morbidity and mortality. However, none of these studies are randomized and none have a control group of similar patients who have not had surgery, thus the survival benefit conferred by surgical therapy remains speculative and controversial. The most common ablation technique is radiofrequency ablation that is used for centrally located tumors that are not near major blood vessels or ducts and are ≤ 3 cm.⁵⁶ Radiofrequency ablation involves conversion of radiofrequency waves to heat using an alternating current that generates ionic vibration.

TAE or TACE is usually performed in patients with diffuse or widely scattered diffuse bilateral liver metastases. The theoretical basis for this type of treatment is that the hepatic artery preferentially perfuses liver tumors, whereas normal hepatocytes are perfused primarily through the portal vein. In patients with bilobar liver metastases, staged lobar embolizations are typically performed at 4- to 6-week intervals. TACE is also done by combining cytotoxic drugs like cisplatin or doxorubicin with iodized oil and injecting it into the hepatic arterial branches until there is obliteration of blood flow. There is no clear advantage of TAE versus TACE. Response rates are similar. Major biomarker response is between 40% and 100%,

symptom response between 67% and 100%, and radiographic response between 33% and 67%. Median survival is 31 months. Side effects of TAE/TACE include abdominal pain, fever, and fatigue. Liver function studies typically demonstrate an increase in transaminase 2 to 3 days postembolization. One prospective study on small bowel NETs used TAE followed by sunitinib. Of 39 patients enrolled, 26 had primary intestinal NETs, 72% of patients had a partial radiographic response and the progression-free survival was 15 months.⁵⁷ Other trials combining liver-directed therapies and systemic therapies are in development. Carcinoid syndrome can also be palliated through TAE and TACE. Of 19 patients with carcinoid syndrome and elevated urinary 5-HIAA levels, 16 (84%) had a >50% decrease in levels and excellent palliation of carcinoid syndrome. Of note, liver-directed therapies following extensive liver resection should be approached with caution given increased risk of hepatic abscesses.

A novel approach to hepatic metastases involves radioembolization with ⁹⁰Yttrium embedded either as a resin microsphere (SIR-Sphere) or a glass microsphere (TheraSphere).^{58,59} These techniques are also called selective intrahepatic radiotherapy. They provide delivery of radionuclide particles to hepatic metastases. Acute toxicities with this procedure appear to be less than the other procedures primarily because selective intrahepatic radiotherapy does not induce ischemic hepatitis. Therefore, it can be done on an outpatient basis. A rare, but significant, complication is radiation enteritis if the particles are accidentally infused into the enteric circulation. Chronic radiation hepatitis is another significant complication. Response rates are encouraging. This is becoming the procedure of choice for metastatic NETs to the liver. In several nonrandomized studies, the radiographic response rate with SIR-Spheres (Sirtex Medical Inc., North Ryde, Australia) and TheraSpheres (Nordion, Inc., Ottawa, Canada) is 51% and 63%, respectively, and the median survival is 70 months.

The role of liver transplantation in patients with metastatic NETs remains poorly defined and controversial. Data are retrospective. It is difficult to get live organs for these patients as they typically have a low priority on the transplantation list.⁶⁰ In the largest meta-analysis of 103 patients, the 5-year survival rate was 47% with only 24% free of disease recurrence.⁶¹ Another study of 85 cases reported a 47% 5-year survival and a recurrence-free survival of 20% at 5 years. As recurrence-free survival results have not plateaued, it is unclear if liver transplantation can be curative. Negative prognostic factors for liver transplantation are high burden of hepatic tumor, pancreatic primary (not intestinal), and elevated Ki-67 index.

CONCLUSIONS

NETs of the lungs and GI tract (carcinoid tumors) are rare but given their indolent nature are quite prevalent. Some studies suggest that certain primary sites are increasing in incidence. Some of these tumors produce hormones that lead to symptoms, such as diarrhea and flushing of carcinoid syndrome. These tumors are, indeed, malignant and are often diagnosed in advanced stages. Somatostatin analogues have a profound impact on the management of small intestinal NETs. They are efficacious from both symptom management and tumor inhibition. Other systemic drugs with potential benefit include interferon-alpha and everolimus. Liver-directed therapies such as cytoreductive surgery and transarterial embolization are important options for liver-dominant disease. Other novel therapies, including VEGF tyrosine kinase inhibitors, are currently being investigated in clinical trials. The landscape of diagnostic and treatment options for NETs is rapidly changing which is cause for great optimism in this field.

87 Multiple Endocrine Neoplasias

Jeffrey A. Norton and Pamela L. Kunz

INTRODUCTION

There are four multiple endocrine neoplasia (MEN) syndromes: MEN-1, MEN-2 (2a), MEN-3 (2b), familial medullary thyroid cancer (FMTC), and MEN-4 (Table 87.1). MEN-1 is inherited as an autosomal dominant syndrome caused by mutations of the *menin* gene. It is composed of multiple endocrine tumors classically affecting the parathyroid glands, anterior pituitary gland, and endocrine pancreas. It also may affect the adrenal cortex and thyroid gland. Neuroendocrine tumors (NET) of the bronchus, thymus, stomach, and small intestine (carcinoid tumors) are more common in patients with MEN-1. It also has some nonhormonal manifestations including facial angiofibromas, meningiomas, smooth muscle tumors, collagenomas, and lipomas.^{1,2}

FMTC, MEN-2, and MEN-3 are caused by specific mutations of the *RET* proto-oncogene.^{3,4} They are also inherited as an autosomal dominant condition. Patients with FMTC develop MTC usually late in adulthood with no other endocrine tumors. The MTC in this condition is indolent and nonmetastatic such that patients typically die from other causes. MEN-2 (also called MEN-2a) is characterized by medullary thyroid cancer (MTC), pheochromocytoma, and parathyroid hyperplasia. Cutaneous lichen amyloidosis has been described in several kindreds. MEN-3 (also called MEN-2b) is also associated with a *RET* mutation, but it is in the intracellular tyrosine kinase domain of the molecule. These patients develop a more aggressive form of MTC at a young age, and they have characteristic eye and bony changes. They also have bilateral pheochromocytomas usually in adulthood, but they do not have primary hyperparathyroidism (HPT). Finally, MEN-4 (also called MENX) is caused by a mutation in *CDKN1B* that encodes p27Kip1, a tumor suppressor gene that inhibits cell cycle progression.⁵ These patients may be confused with MEN-1 because they develop pituitary and parathyroid adenomas.⁶ This chapter will further characterize and describe these syndromes including specific molecular and genetic changes, epidemiology, screening, malignant potential, causes of death, and treatment.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

Incidence and Etiology in Multiple Endocrine Neoplasia Type 1

Patients with MEN-1 develop parathyroid hyperplasia and primary HPT typically as the first manifestation of the syndrome (90% to 100%),^{1,2} followed by pancreatic neuroendocrine tumors (pNET) either functional (20% to 70%) or nonfunctional (80% to 100%), pituitary adenomas (20% to 65%), adrenal tumors (10% to 73%), and thyroid adenomas (0% to 10%). Patients with MEN-1 also have a high occurrence of other endocrine and nonendocrine tumors including carcinoid tumors (thymic 0% to 8%, gastric 7% to 35%, bronchial 0% to 8%, and infrequently intestinal), skin and subcutaneous tumors (angiofibromas 88%, collagenomas 72%, lipomas

34%, and melanoma), central nervous system tumors (meningiomas, ependymomas, schwannomas 0% to 8%), and smooth muscle tumors (leiomyomas and leiomyosarcomas 1% to 7%). The main causes of death in these patients are the malignant potential of the pNET followed by the thymic carcinoid tumors² (Table 87.2).

Molecular and Genetic Basis in Multiple Endocrine Neoplasia Type 1

MEN-1 is inherited as an autosomal dominant disorder and has an incidence between 0.22% and 0.25% in autopsy studies. The gene causing MEN-1 is located on the long arm of chromosome 11 (11q13).⁷ It encodes a 610 amino acid nuclear protein called *menin* that controls cell division, genomic stability, and transcriptional regulation. It is a tumor suppressor gene. Abnormalities of the gene can result in mutations, deletions, and truncations of *menin* protein. *Menin* acts as a scaffold protein and increases or decreases gene expression by epigenetic regulation via histone methylation. It complexes with trimethylated histone H3 at lysine, which subsequently facilitates activation of transcription in cyclin-dependent kinase inhibitors and silences transcriptional activity in other target genes. MEN-1-associated tumors harbor germline and somatic mutations.

Screening in Multiple Endocrine Neoplasia Type 1

Genetic screening for MEN-1 is recommended when an individual has two or more MEN-1-related tumors, multiple abnormal parathyroid glands before age 30 years, recurrent HPT at a young age, gastrinoma and HPT or multiple pNETs at any age, plus a family history of kidney stones or endocrine tumors that are part of the syndrome.⁸ Genetic testing includes sequencing of the entire coding region of the *MEN-1* gene (exons 2 to 10) and identifies mutations in about 80% of patients with familial MEN-1.

Primary Hyperparathyroidism in Multiple Endocrine Neoplasia Type 1

Primary HPT is the most common endocrine abnormality in MEN-1. It reaches nearly 100% penetrance by the age of 50 years. HPT is usually the first manifestation of MEN-1 with a typical age of onset of 20 to 25 years. Decreased bone density and kidney stones are common. HPT often occurs at the same time as Zollinger-Ellison syndrome (ZES) and surgery to correct the HPT greatly ameliorates the clinical findings of ZES.⁹ As in sporadic cases, biochemical testing for HPT is critical to the diagnosis. Total or ionized serum level of calcium and intact serum parathyroid hormone levels are measured and both should be elevated. Twenty-four-hour urinary calcium should also be measured and will be elevated. Patients with MEN-1 and HPT typically have multiple abnormal glands. The tumors are asymmetric in size and should be considered as independent clonal adenomas.⁸ Imaging studies are not useful for initial

operations because all four parathyroid glands must be identified. The current operation of choice is a subtotal parathyroidectomy (3.5 gland resection) with removal of the thymus. Intraoperative parathyroid hormone level monitoring is recommended to be certain that sufficient abnormal parathyroid tissue has been removed. A viable 50 mg amount of normal parathyroid tissue should be left in the neck and marked with a hemoclip. Because of the multiple abnormal parathyroid gland nature of this disease, there is a high probability of recurrent HPT years after surgery if <3.5 resections are performed. Calcium-sensing receptor agonists (calcimimetics) are a new class of drugs that can act directly on the parathyroid gland, decrease parathyroid hormone release, and may even decrease parathyroid tissue growth. These agents may play an important role in the management of these patients in the future.⁸

Enteropancreatic Neuroendocrine Tumors in Multiple Endocrine Neoplasia Type 1

The prevalence of enteropancreatic NETs in MEN-1 is between 30% to 75%.^{1,2} The enteropancreatic pathology in MEN-1 is typically multicentric and multifocal with multiple endocrine tumors throughout the pancreas and the intestine. Tumors vary from microadenomas to carcinomas with lymph node and liver metastases. Duodenal gastrinomas in MEN-1 are usually small (<1 cm), submucosal, and multifocal. pNETs contain in decreasing frequency chromogranin, pancreatic polypeptide, glucagon, insulin, proinsulin, somatostatin, gastrin, vasoactive intestinal polypeptide, serotonin, calcitonin, growth hormone releasing factor, and neurotensin. Malignant enteropancreatic NETs are rare prior to the age of 30 years; however, 50% of middle-aged patients with MEN-1 have evidence for malignant pNETs. Recent studies identified the following factors as suggestive of poor prognosis: higher fasting serum levels of gastrin, presence of more than one functional hormonal syndrome, need for more than three parathyroid surgical procedures, presence of either liver metastases, aggressive primary tumor growth, large pNETs (>4 cm), pNETs with areas of poor vascular enhancement on computed tomography (CT), and serial imaging with evidence for progression.²

Gastrinomas (ZES) are the most common functional NET in MEN-1.¹⁰ Approximately 40% of patients with MEN-1 will have ZES, and 25% of all ZES cases occur in patients with MEN-1. ZES is diagnosed by elevated fasting serum level of gastrin (>100 pg/ml,

off proton pump inhibitors) and concomitant increased gastric acid output (>10 meq/hr). Approximately one-third of patients with ZES will die from the malignant progression of the tumor. Correlates for a poor prognosis with MEN-1/ZES are pancreatic primary tumors, metastases, Cushing syndrome, and severe hypergastrinemia (defined as >3,000 pg/ml).² Surgery has been done to try to cure patients with MEN-1 of ZES. Local removal of tumors without duodenal/pancreatic resection are associated with persistent ZES; however, Whipple pancreaticoduodenectomy is more consistently associated with biochemical cure.¹¹ This approach is still controversial because those who favor less than Whipple argue that the symptoms of ZES are well controlled with proton pump inhibitors and the morbidity/mortality of Whipple procedure is too significant.

Insulinoma is the second most common functional pNET in MEN-1.¹² Approximately 10% of patients with MEN-1 will develop insulinoma, and 10% of insulinomas occur in the setting of

MEN-1. Patients have hypoglycemia and neuroglycopenic symptoms (altered mental status and seizures). This occurs at a young age (<35 years). Fasting hypoglycemia (glucose <45 mg/dl) and concomitant hyperinsulinemia (levels >5 uU/ml) are diagnostic. Tumors are generally small (<2 cm) and distributed uniformly throughout the pancreas.^{1,8} Since patients with MEN-1 have multiple pNETs, it may not be clear which tumor is secreting the excessive insulin. However, one study reported that the insulinoma is most commonly a dominant pNET that is easily identified by conventional imaging studies like CT or magnetic resonance imaging (MRI)¹² (Fig. 87.1).

For nonfunctional enteropancreatic NETs in asymptomatic patients with MEN-1, there is controversy over the role of surgery. Several groups advocate that surgery should be avoided unless the tumor is 2 cm or growing.¹³ Other groups recommend surgery for tumors that are 1 cm.¹⁴ The goal of surgery in MEN-1 appears to be control tumor to prevent cancerous progression. The standard operation is distal or subtotal (resection margin superior mesenteric vein) pancreatectomy with intraoperative ultrasound and enucleation of tumors from the pancreatic head and duodenum. Extensive pancreaticoduodenal procedures are associated with increased risk, thus the indication for the procedure, potential benefit, and surgeon experience must be considered.

Pituitary Tumors in Multiple Endocrine Neoplasia Type 1

Anterior pituitary adenomas are the initial clinical manifestation of MEN-1 in 25% of cases.^{2,8} Its prevalence in MEN-1 is between 10% and 60%. Most anterior pituitary tumors are microadenomas (<1 cm in diameter). Every type of anterior pituitary tumor has been reported to occur in MEN-1 with the most common type being a prolactinoma. Screening for anterior pituitary tumors requires measuring serum levels of prolactin, insulin-like growth

factor 1, and MRI of the pituitary. Patients should be questioned for loss of peripheral vision and visual fields assessed formally if any suspicion. Treatment of pituitary tumors in MEN-1 is the same as sporadic pituitary tumors.

Less Common Tumors in Multiple Endocrine Neoplasia Type 1

Other primary sites of MEN-1 tumors include thymus, bronchus, and stomach. The most worrisome are thymic carcinoids because they are the second most common cause of death in patients with MEN-1.² Thymic carcinoids are seen more commonly in men with MEN-1 and are usually asymptomatic. Bronchial carcinoids also occur at a higher frequency and are more common in women with MEN-1. In patients with MEN-1 with ZES who have been taking proton pump inhibitors for a long time period, type II gastric enterochromaffin-like cell carcinoid tumors have been identified on upper gastrointestinal endoscopy. The tumors are usually multiple and may involve the entire stomach. These tumors may spread to lymph nodes and liver and may require total gastrectomy.¹⁵ Each of these three foregut carcinoid tumors in MEN-1 has malignant potential, and physicians caring for these patients should be vigilant for early diagnosis in patients with known MEN-1.

Adrenal cortical tumors are common in MEN-1. The majority are bilateral, hyperplastic, and nonfunctional. Pathology may include cortical adenoma, diffuse hyperplasia, nodular hyperplasia, and carcinoma. Some patients may present with Cushing syndrome secondary to an adrenal tumor, but adrenocorticotropic hormone from a bronchial carcinoid or a pituitary adenoma may also cause hypercortisolism.¹⁶ The adrenal cortical tumors are usually nonfunctional and benign so that surgical resection is not indicated; however, hormone production should be excluded. Multiple lipomas, both cutaneous and visceral, occur in one-third of patients with MEN-1. Lipomas in MEN-1 are small but can be large.^{2,7,8} They are usually multicentric, cosmetically disturbing, and not malignant. If they are excised, they do not recur. Multiple facial angiofibromas occur in 40% to 80% of patients with MEN-1; collagenomas also are common.

Management of Metastatic Disease in Multiple Endocrine Neoplasia Type 1

Of the MEN-1-associated tumors, metastatic disease is common in pancreatic, small bowel, and bronchial NETs. For example, approximately 60% of patients with enteropancreatic NETs have metastatic disease at the time of diagnosis.¹⁷ Patient selection is a critical first step in the treatment algorithm of these patients and is addressed extensively in other chapters. Management of metastatic disease in patients with MEN-1 is comparable to the management of patients without the syndrome. However, for patients with multiple primary endocrine tumors, vigilance must be taken when evaluating new findings on cross-sectional imaging to be certain which tumor is metastatic and/or progressing. The oncologic management of metastatic NETs has seen a recent renaissance, which is reflected in other chapters on pancreatic and small bowel NETs and MTC. Such advances include US Food and Drug Administration approval of two agents for the treatment of metastatic pNETs: everolimus¹⁸ and sunitinib.¹⁹ Additionally, multiple ongoing clinical trials are poised to address important questions in this field around the roles of chemotherapy and adjuvant treatment.

Follow-Up

CT and MRI are recommended for early diagnosis, but somatostatin receptor scintigraphy (octreoscan) is more sensitive. Recently Ga-68 DOTATOC positron emission tomography/CT scan may be even more sensitive for imaging ectopic or metastatic NETs.²⁰ It is

a total body study, and these tumors have somatostatin receptors so there are few false positives. Further, once the diagnosis of MEN-1 is made, somatostatin receptor scintigraphy and DOTATOC positron emission tomography/CT may be useful to exclude unsuspected malignant tumors like bronchial and thymic carcinoids.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2, TYPE 3, AND FAMILIAL MEDULLARY THYROID CANCER

Incidence and Etiology in Multiple Endocrine Neoplasia Type 2, Type 3, and Familial Medullary Thyroid Cancer

MTC is a common feature of these three inherited syndromes. It is a rare type of thyroid cancer. It accounts for only 3% to 10% of all thyroid cancers. A total of 20% of all MTC is associated with one of these syndromes; 80% is sporadic. Familial forms of this disease present earlier in life. The mean age of sporadic MTC is 47 ± 17 ; for the familial forms, it is 25 ± 15 years. Patients who present with a thyroid nodule are seldom cured (Fig. 87.2). Thus in the familial form with 100% penetrance, screening for the inherited RET gene mutation is critical.

Molecular Genetic Basis of Multiple Endocrine Neoplasia Type 2, Type 3, and Familial Medullary Thyroid Cancer

RET is an oncogene composed of 21 exons located on the long-arm of chromosome 10 (10q11.2) encoding a transmembrane receptor tyrosine kinase. The RET protein is composed of three functional domains: an extracellular ligand-binding domain, a transmembrane domain, and a cytoplasmic tyrosine kinase domain. RET is involved in a number of cellular signaling pathways during development regulating the survival, proliferation, differentiation, and migration of the enteric nervous system progenitor cells, as well as the survival and regeneration of neural and kidney cells.

All MEN-2 cases have an identified mutation in the RET gene, and when tested no family with MEN-2 has failed to have a RET gene mutation.³ MEN-2-associated mutations in RET have been identified on exons 10, 11, 13, 14, 15, and 16. The likelihood of a RET mutation in a patient with sporadic MTC is 1% to 7%. Recently, it has been shown that HRAS, KRAS, and NRAS mutations occur in approximately 10% to 45% of sporadic MTC cases. How-

ever, all cases of sporadic MTC should still be tested for a germline RET mutation. This should be performed through a laboratory that analyzes exons 10, 11, 14, 14, 15, and 16. If these exons are negative, the remaining 15 RET exons should be sequenced.³

Approximately 95% of patients with MEN-2 have RET mutations at 609, 611, 618, and 620 in exon10, or at codon 634 in exon11. The presence of mutations at codon 634 is associated with the development of primary HPT and pheochromocytoma. Most patients with MEN-3 have mutations in exon 16 M918T and less often exon 15 A883F. Patients with MEN-3 with mutations at A883F have a better prognosis, and rarely long-term cures have been reported following thyroidectomy in these patients. The most common FMTC mutations affect extracellular cysteine codons in RET exon 10 or intracellular RET codons other than A883 or M918³ (Table 87.3).

Screening in Multiple Endocrine Neoplasia Type 2, Type 3, and Familial Medullary Thyroid Cancer

Screening for MTC in each of these syndromes is done by measuring the specific RET germline mutation. MTC arises from the calcitonin secreting cells or C-cells. C-cell hyperplasia is not itself malignant, but can transform to MTC; thyroidectomy during the hyperplasia stage can prevent development of MTC. Since C-cells make calcitonin, screening for MTC used to be done by measuring pentagastrin/calcium stimulated levels of calcitonin. However, since all of these patients have germline mutations in RET and all develop MTC, C-cell hyperplasia and MTC can be diagnosed in each affected individual by RET gene analysis. One cannot over-emphasize the importance of direct DNA sequencing to detect RET mutations in kindred members at risk for MTC. Further, approximately 3% to 7% of patients with presumed sporadic MTC have familial MTC.³

A major issue is the age to perform screening and prophylactic thyroidectomy. In patients from a family with MEN-2 and a RET mutation, most clinicians recommend that the individual should be screened at age 5 and the thyroid gland be removed if affected. In this setting, central compartment lymph node dissection is unnecessary as it can increase the occurrence of postoperative hypoparathyroidism. In patients with MEN-3, the surgery should be done at any age as soon as the diagnosis is established. Since these patients commonly have a more aggressive tumor, central lymph node dissection should always be done. In patients with FMTC, screening should be done at age 21 and, if positive, thyroidectomy without central lymph node dissection. Postoperatively at 6 months, physical examination and serum levels of calcitonin and

Figure 87.2 (A) Gross photograph of thyroid with central lymph nodes in a patient with multiple endocrine neoplasia type 2a who presented with palpable thyroid nodules bilaterally. Note that the medullary thyroid cancer is bilateral and that the central lymph nodes are involved. MEN, multiple endocrine neoplasia; MTC, medullary thyroid cancer; HPT, hyperparathyroidism. From Wells SA Jr, Pacini F, Robison BG, et al. Multiple endocrine neoplasia type 2 and familial medullary thyroid carcinoma: an update. *J Clin Endocrinol Metab* 2013;98:3149–3164.

carcinoembryonic antigen (CEA) are measured. If calcitonin and CEA levels are undetectable or normal for 5 years, no additional studies are necessary.

Multiple Endocrine Neoplasia Type 2

MEN-2 (also termed MEN-2a) accounts for 80% of the FMTC syndromes. In MEN-2, beside MTC, 50% of patients develop pheochromocytomas, and 30% develop primary HPT depending on the RET codon mutation.²¹ Patients with MEN-2 may also develop cutaneous lichen amyloidosis, Hirschsprung disease, and prominent corneal nerves. C-cells secrete calcitonin and CEA. Either calcitonin or CEA levels in the blood serve as an excellent marker for MTC. Pentagastrin or calcium stimulated serum calcitonin levels may serve as a more sensitive marker for MTC. Unlike sporadic MTC that is usually unilateral, familial forms of MTC are always bilateral (see Fig. 87.2). The tumor is multicentric and occupies the superior and central portion of each lobe. MTC initially remains confined to the thyroid gland but subsequently spreads to regional lymph nodes and then distant sites including the liver, lung, bone, and brain. The tumor is very firm and has a fibrous acellular stroma that has staining properties similar to amyloid, but it is immunohistochemically calcitonin.

Pheochromocytomas develop in 50% of patients with MEN-2 and -3.^{22,23} The clinical findings and behavior is the same in both syndromes. The mean age at presentation is 36 years, and the diagnosis is made after MTC in 40% of cases and before MTC in 10%. In this setting, the pheochromocytomas are benign and confined to the adrenal gland. Sixty-five percent of the time, these tumors are bilateral; with 10-year follow-up, patients with a unilateral pheochromocytoma will develop a contralateral tumor. It is critical to exclude the diagnosis of pheochromocytoma in these patients before doing any invasive procedure because sudden death may occur if a pheochromocytoma is not detected and the patient is not appropriately prepared with alpha-adrenergic blocking agent. Deaths have been reported during surgical procedures and childbirth. Patients suspected of having a pheochromocytoma should have measurement of plasma-free metanephrine and normetanephrine levels or a 24-hour urine for vanillylmandelic acid, metanephrines, and total catecholamines. CT and MRI are used to image pheochromocytomas. The sensitivity and specificity are similar for the two procedures, 90% to 100% and 70% to 80%, respectively.

The pheochromocytoma should be resected before the thyroid surgery. Preoperative preparation with an alpha-adrenergic blocking drug like phenoxybenzamine is done. If necessary after the patient is well blocked and just before surgery, a beta-adrenergic drug is added. Despite the fact that the pheochromocytomas are

usually bilateral, if on CT or MRI only one adrenal appears to contain tumor, unilateral adrenalectomy is recommended for the gland with the tumor.²² This is recommended because there has been reported a significant risk of Addisonian crisis with bilateral adrenalectomy. Some other surgeons have recommended bilateral subtotal adrenalectomy for these patients to preserve cortical function. Although this approach may have merit, there have been limited follow-up and report of long-term function or recurrent pheochromocytomas with this procedure. Adrenalectomy can usually be accomplished laparoscopically, and this approach greatly reduces morbidity. In patients who undergo bilateral adrenalectomy, corticosteroid coverage is necessary both preoperatively and postoperatively.

Primary HPT develops in 20% to 30% of patients with MEN-2.²⁴ The mean age of onset is 36 years. It can occur prior to any manifestation of MTC in 5%. The hypercalcemia is minimal and most patients do not have symptoms. The parathyroid glands are asymmetrically enlarged and contain hyperplastic nodules. Pathologically, it is called pseudonodular hyperplasia. The operation of choice is subtotal parathyroidectomy or 3.5 gland parathyroidectomy.

Multiple Endocrine Neoplasia Type 3

MEN-3, also called MEN-2b, accounts for 5% of hereditary MTC.²⁵ These patients all have MTC, bilateral pheochromocytomas, and characteristic phenotype, but they do not develop primary HPT. Patients with MEN-3 have a characteristic phenotype that includes marfanoid habitus, prolonged facies, muscular skeletal abnormalities (pectus, saber shins, bowing of the extremities), ocular abnormalities (inability to cry tears and corneal nerve hypertrophy),²⁶ mucosal neuromas usually on the tip of the tongue (Fig. 87.3), and ganglioneuromatosis. Most have gastrointestinal symptoms characterized by pain, diarrhea, constipation, bloating, and megacolon. These symptoms may occur in children and young adults with this syndrome.

The MTC is uniformly aggressive and spreads to distant sites early in these patients. It occurs during infancy and early diagnosis is critical.²⁵ In approximately 50% of MEN-3 cases, de novo germline RET mutations give rise to the disease. In patients with de novo MEN-3, the mutated allele generally comes from the father. Babies are at a high risk in this setting because the parents are asymptomatic and the disease is not expected. This is unfortunate because there is only a narrow window during which thyroidectomy may be curative. Even in the most advantageous setting where thyroidectomy was performed during the neonatal period, most babies are not cured. These patients also get pheochromocytoma (usually bilateral), but they do not develop parathyroid disease.

Figure 87.3 (A) Mucosal neuromas on the tip of the tongue in a patient with multiple endocrine neoplasia type 2a (MEN-3). (B) Patient had documented medullary thyroid cancer and needed a thyroidectomy, but the preoperative workup documented a pheochromocytoma that was localized to the left adrenal (arrows) by magnetic resonance imaging. A normal-appearing right adrenal (arrows) is also seen.

Familial Medullary Thyroid Carcinoma

FMTC accounts for 15% of hereditary MTC.³ These patients only have MTC that occurs at a late age and is less aggressive than the other familial forms. They do not get pheochromocytomas or parathyroid disease. The diagnosis is made when an individual can identify 10 affected individuals occurring in kindred over the age of 50 years with an adequate history and biochemical data to exclude pheochromocytoma and primary HPT in affected individuals.

The strongest predictor of survival for patients with MTC is the stage of disease at the time of thyroidectomy. The 10-year disease-specific survival of MTC is 90% with localized disease, 78% with lymph node metastases, and 40% with distant metastases. Only 10% of patients with metastases to cervical lymph nodes are cured with extensive lymph node dissection. The prognosis is excellent for patients with FMTC who have a preoperative calcitonin level <150 pg/ml, an MTC <1 cm, and no lymph node metastases.³ The 10-year survival approaches 100% if basal and stimulated calcitonin levels are undetectable after thyroidectomy. In patients with MTC confined to the thyroid gland, the standard operation is total thyroidectomy and resection of all lymph nodes in the central zone of the neck. The neck dissection is more extensive in patients with advanced nodal disease.

A reliable indicator of progression of MTC is the calcitonin or CEA doubling time. A calcitonin doubling time between 6 months and 2 years is associated with a 5-year survival of 92% and a 10-year survival of 37%, whereas a doubling rate of <6 months is associated with a 25% and 8% survival, respectively. In most patients, the calcitonin level is most predictive of prognosis, but in some patients the CEA level is more correlative so both should be measured. If the postoperative serum calcitonin level rises above 150 to 200 pg/ml, total body CT scan should be performed. In the absence of distant metastases and the presence of cervical lymph node disease, a neck dissection should be performed. Prior studies suggested that this strategy may cure approximately 30% of patients, but more recent long-term follow-up indicate that these patients will recur. Some studies suggest that external beam radiation should be administered after neck dissection; however, this treatment has not improved survival.

Management of Metastatic Disease in Multiple Endocrine Neoplasia Type 2, Type 3, and Familial Medullary Thyroid Cancer

Development of metastatic disease in patients not identified by screening is common in MTC. The survival of patients with distant metastases from MTC is 51% at 1 year, 26% at 5 years, and 10% at

10 years. When patients develop distant metastases from MTC and calcitonin levels increase, they may also develop secretory diarrhea that is difficult to control. Management of metastatic disease in patients with inherited forms of MTC is similar to management in sporadic MTC and is addressed extensively in the chapter on thyroid cancer (Chapter 82). Loperamide, codeine, or sandostatin may help control diarrhea in some cases. Tumor debulking or selective arterial embolization may provide symptomatic improvement in others. Two new compounds have recently been approved by the US Food and Drug Administration for the treatment of metastatic MTC and include vandetanib²⁷ and cabozantinib,²⁸ and were shown to prolong progression-free survival in phase 3 clinical trials.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 4

MEN-4 (also known as MENX) has been recently identified.^{5,29} It is characterized by the occurrence of parathyroid, anterior pituitary, and in possible association with tumors of the adrenal, kidneys, and reproductive organs (testicular cancer, neuroendocrine cervical carcinoma). It is caused by a heterozygous mutation of CDK1B that encodes the 196 amino acid CDK1 p27 Kip1 protein that is activated by H3K4 transmethylation.

There is a population of patients who are thought to have MEN-1, but they do not have mutations of menin and may have mutations of other genes. One of these other genes may be CDKN1B, which encodes a cyclin-dependent kinase inhibitor (CKI) p27^{Kip1}. It was identified as causing a MEN-like syndrome in rats referred to as MENX. Rats with MENX have parathyroid adenomas, pancreatic islet cell hyperplasia, thyroid C-cell hyperplasia, bilateral pheochromocytomas, paragangliomas, and cataracts. The disorder is inherited as an autosomal recessive trait. Genetic mapping localized MENX to the distal part of rat chromosome 4, a region that contained the putative tumor suppressor CKIP27^{Kip1}, which is also called p27. Mutation of this tumor suppressor gene resulted in a loss p27 protein in tumor cells. These findings prompted studies in patients with suspected MEN-1, who did not have MEN-1 mutations, for abnormalities of CDKN1B that in man is located on chromosome 12p13. These studies revealed that approximately 3% of patients with MEN-1 phenotype actually had CDKN1B mutations. These patients had parathyroid adenomas, pituitary adenomas, and pNETS, plus gonadal, adrenal, renal, and thyroid tumors. Currently, eight different heterozygous loss-of-function CDKN1B mutations have been identified in patients with MEN-1-like tumors. This indicates that MEN-4 in man is an autosomal dominant disorder, unlike MENX in rats. Further, germline mutations of CDKN1B have been identified in sporadic (nonfamilial) forms of primary HPT.

Genetic Testing in the Endocrine System

Robert Pilarski and Rebecca Nagy

INTRODUCTION

A number of hereditary syndromes, caused by mutations in an even larger number of tumor suppressor genes and oncogenes, can cause tumors in organs of the endocrine system. Table 88.1 summarizes the major syndromes, genes, and endocrine organs affected.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

Syndrome Description

Multiple endocrine neoplasia (MEN) type 1 is an autosomal dominant syndrome with an estimated incidence in the general population on the order of 1/100,000 to 10/100,000.^{1,2} The major endocrine features of MEN1 are parathyroid adenomas, enteropancreatic endocrine tumors, and pituitary tumors. A diagnosis of MEN1 is made in a person with two of the three major endocrine tumors, or in an individual with at least one of these tumors if another relative has a diagnosis of MEN1.³⁻⁵ The age-related penetrance of MEN1 is 45% at the age of 30 years, 82% at the age of 50 years, and 96% at the age of 70 years.⁵⁻⁷

The most common feature of MEN1 is parathyroid adenoma, which results in primary hyperparathyroidism (PHP). In approximately 50% to 85% of patients with MEN1, PHP will be the presenting manifestation. These tumors occur in 80% to 95% of patients by the age of 50 years,^{5,8-10} and are typically multiglandular and often hyperplastic.¹ The average age at onset of PHP in MEN1 is 20 to 25 years, in contrast to that in the general population, which is in the 50s. Parathyroid carcinoma in MEN1 is rare but has been described.¹¹⁻¹³

Pancreatic endocrine tumors are the second most common endocrine manifestation in MEN1, occurring in up to 30% to 80% of patients.^{5,8} Gastrinomas and insulinomas are most common, followed by VIPomas (vasoactive intestinal peptide), glucagonomas, and somatostatinomas. These tumors are usually multicentric and can arise in the pancreas or more commonly as small (<0.5 cm) foci throughout the duodenum.¹⁴ Gastrinomas represent 50% of the gastrointestinal neuroendocrine tumors in MEN1 and are the major cause of morbidity and mortality in patients with MEN1.^{5,15} Most result in peptic ulcer disease (Zollinger–Ellison syndrome), and half are malignant at the time of diagnosis.¹⁴⁻¹⁶ Nonfunctional tumors of the enteropancreas, some of which produce pancreatic polypeptide, are seen in 20% of patients.¹⁷⁻¹⁹

Approximately 15% to 50% of patients with MEN1 will develop a pituitary tumor.^{5,8} Two-thirds are microadenomas (<1 cm in diameter), and the majority are prolactin secreting.²⁰ Other manifestations of MEN1 include carcinoids of the foregut (typically bronchial or thymic), skin lipomas, facial angiomas, and collagenomas and adrenal cortical lesions, including cortical adenomas, diffuse or nodular hyperplasia, or rarely carcinoma.^{7,21} Thyroid adenomas, pheochromocytoma (PC) (usually unilateral), spinal ependymoma, and leiomyoma have also been reported.²²

Genetic Testing

MEN1 is caused by mutations in the *MEN1* gene, which is located on chromosome 11q13. It is inherited in an autosomal dominant manner. Germline mutations are typically found in 80% to 95% of families with two or more affected members and in up to 65% of simplex cases (single case of MEN1 with no family history).^{4,23} Menin, the protein encoded by the *MEN1* gene, functions as a tumor suppressor gene and is involved in multiple cellular functions including transcription regulation, genomic stability, cell division, and cell cycle control.²⁴

More than 1,100 mutations have been identified in the *MEN1* gene to date, and these are scattered across the entire coding region.²⁴ The majority of these are nonsense or frameshift mutations, and the remainder are missense or in-frame deletions that lead to expression of an altered protein. Splice-site mutations have also been described. There is currently no evidence of genotype–phenotype correlations, and interfamilial and intrafamilial variability is the rule.^{25,26}

Whereas the *MEN1* mutation detection rate is quite high in simplex and familial cases, the greater diagnostic challenge for the clinician is when to order genetic testing in an individual who does not meet diagnostic criteria, but has one of the three component tumors. The prevalence of MEN1 among patients with apparently sporadic component tumors varies widely by tumor type. Approximately one-third of patients with Zollinger–Ellison syndrome will carry an *MEN1* mutation.^{27,28} In individuals with apparently isolated hyperparathyroidism (HPT) or pituitary adenomas, the mutation prevalence is lower, on the order of 2% to 5% for each,^{20,29,30} but the prevalence is higher in individuals diagnosed with these tumors at younger ages (<30 years old). In a small series of patients with isolated foregut/midgut carcinoids, none of 68 were found to carry an *MEN1* mutation. Some authors suggest *MEN1* testing in those not meeting diagnostic criteria if one of the following is present: Gastrinoma at any age, multifocal pancreatic islet cell tumors at any age, parathyroid adenomas before the age of 30 years, multiglandular parathyroid adenomas, or recurrent HPT, or in individuals with one of the three main MEN1 tumors plus one of the less common tumors/findings.³¹

Management

Screening and surveillance for MEN1 should use a combination of biochemical screening and imaging as follows³:

- Annual serum prolactin and insulin-like growth factor 1 starting at the age of 5 years
- Annual fasting total serum calcium and/or ionized calcium and PTH starting at the age of 8 years
- Annual fasting serum gastrin starting at the age of 20 years; consider chromogranin A, glucagon, and proinsulin for other enteropancreatic tumors
- Annual fasting glucose starting at the age of 5 years

TABLE 88.1

Major Endocrine System Tumors and Associated Hereditary Syndromes

Tumor Site Type	<i>MEN1</i> (MEN 1)	<i>RET</i> (MEN 2)	Gene (Syndrome) <i>PTEN</i> (CS PHTS)	<i>SDHX</i> (HPCC/PGL)	<i>VHL</i> (VHL)
Adrenal (PC)		X		X	X
Carcinoid	X				X
Neuroendocrine	X			X	
Pancreas (islet cell)	X				X
Parathyroid	X	X			
Paraganglioma				X	X
Pituitary	X				
Thyroid		MTC	PTC, FTC		

MEN, multiple endocrine neoplasia; CS, Cowden syndrome; PHTS, *PTEN* hamartoma tumor syndrome; HPCC/PGL, hereditary pheochromocytoma/paraganglioma syndrome; VHL, von Hippel-Lindau disease; PC, pheochromocytoma; MTC, Medullary thyroid cancer; PTC, Papillary thyroid cancer; FTC, Follicular thyroid cancer.

- Brain magnetic resonance imaging (MRI) at the age of 5 years, repeat every 3 to 5 years based on biochemical test results
- Abdominal computed tomography or MRI starting at the age of 20 years, repeat every 3 to 5 years based on biochemical test results

Surgical management of MEN1 is complex and controversial given the multifocal and multiglandular nature of the disease and the high risk of tumor recurrence even after surgery. A full review of surgical options is outside the scope of this review, but this topic has been reviewed elsewhere.^{32,33} Establishing the diagnosis of MEN1 before making surgical decisions and referring affected individuals to a surgeon with experience in treating MEN1 can be critical in preventing unnecessary surgeries or inappropriate surgical approaches.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

Syndrome Description

MEN2, caused by germline mutations in the *RET* proto-oncogene, is an autosomal dominant syndrome characterized by medullary thyroid cancer (MTC), PC, and/or HPT. Historically, families were classified into one of the three clinical subtypes, MEN2A, MEN2B, and familial medullary thyroid carcinoma (FMTC) based on the presence or absence of certain endocrine tumors and other phenotypic features. However, there is debate about whether FMTC represents a separate entity or is a variation of MEN2A in which there is a lower lifetime risk and delay in the onset of the extrathyroidal manifestations.³⁴ Incorrect classification of families with MEN2A as having FMTC may result in delayed diagnosis of PC, a disease with significant morbidity and mortality. For this reason, current management recommendations include screening for all three tumors in individuals carrying a germline *RET* mutation, with the exception of parathyroid screening in MEN2B cases³⁵ (see section on management).

The endocrine tumors in MEN2 are often multifocal and bilateral/multiglandular and present at an early age. MTC is present in up to 95% of mutation carriers, and the age at presentation varies, somewhat depending on the specific mutation. Early diagnosis of MTC is critical, given the poor overall survival for individuals diagnosed with distant metastases.^{36–38} PCs are present in up to 50% of carriers, and the lifetime risk is also dependent on genotype. Although the PCs in MEN2 rarely metastasize, they can be clinically significant because of intractable hypertension or

anesthesia-induced hypertensive crises. Parathyroid abnormalities are the least common finding, occurring in up to 30% of patients. The parathyroid disease in MEN2 can include benign parathyroid adenomas or multiglandular hyperplasia, but is typically asymptomatic or associated with only mild elevations in calcium.^{39,40}

MEN2A is diagnosed clinically by the occurrence of two or more of the specific endocrine tumors in a single individual or in close relatives. MEN2A may also be suspected when MTC occurs at an early age (<50 years) or is bilateral or multifocal even in the absence of family history. Several large series indicate a mutation frequency of 1% to 7% in isolated cases of MTC.^{40,41} Based on these data, it is widely recommended that *RET* gene mutation testing be performed for all cases of MTC, regardless of age at diagnosis and family history.^{3,35,42}

MEN2B, which makes up 5% of MEN2 cases, is characterized by the early development of an aggressive form of MTC in all patients.⁴³ Patients with MEN2B who do not undergo thyroidectomy at an early age (~1 year) are likely to develop metastatic MTC at an early age. PCs occur in about 50% of MEN2B cases, and clinically significant parathyroid disease is very uncommon.⁴⁴ Individuals with MEN2B can also have distinctive facies with enlarged lips, mucosal neuromas of the lips and tongue, medullated corneal nerve fibers, and an asthenic marfanoid body habitus.⁴⁴ About 40% of patients have diffuse ganglioneuromatosis of the gastrointestinal tract.⁴⁵

Genetic Testing

MEN2 is the result of germline mutations in the *RET* gene, located on chromosome region 10q11.2.^{46,47} The *RET* gene is a proto-oncogene encoding a receptor tyrosine kinase with extracellular, transmembrane, and intracellular domains. *RET* mutations causing MEN2 are activating mutations, resulting in a constitutively activated tyrosine kinase receptor.⁴⁸

Genetic testing in MEN2 is considered an important part of the management of at-risk family members. As MTC and other tumors can develop in childhood, testing of children who have no symptoms is considered beneficial.³⁵ Timing of *RET* testing depends largely on the mutation present in the family. Several groups have developed mutation stratification systems to guide clinicians with regard to the appropriate timing of *RET* testing, prophylactic thyroidectomy, and biochemical screening.^{3,35} These are based mainly on age at onset, aggressiveness of thyroid disease, and clinical phenotype, but have not been validated as clinical decision-making tools. The original stratification system was developed by the International RET Consortium.³ A newer classification system by the American Thyroid Association³⁵ was published in 2009 (Table 88.2).

TABLE 88.2

Multiple Endocrine Neoplasia Type 2 Mutation Classification System and Management Guidelines of the American Thyroid Association

ATA Risk Level	Mutated Codon(s)	Age at RET Testing	Age at Prophylactic Thyroidectomy	Timing and Frequency of Other Surveillance
A	768, 790, 791, 804, 891	<age 3–5 y	May delay surgery after age 5 y if criteria are met ^a	Age 20 y, repeat periodically
B	609, 611, 618, 620, 630, compound heterozygote: V804M + V778I	<age 3–5 y	Consider surgery before age 5 y; may delay surgery after age 5 y if criteria are met ^a	Age 8 y for codon 630; age 20 y for all others; repeat periodically
C	634	<age 3–5 y	Before age 5 y	Age 8 y, annually
D	883 and 918 Compound heterozygotes V804M + S904C V804M + E805K V804M + Y806C	ASAP and within the first year of life	ASAP and within the first year of life	Age 8 y, annually for PC only

ATA, American Thyroid Association; ASAP, as soon as possible; PC, pheochromocytoma.

^a Criteria include a normal annual basal and/or stimulated serum count, normal annual neck ultrasound, less aggressive medullary thyroid cancer family history, and family preference.

From Kloos RT, Eng C, Evans DB, et al. Medullary thyroid cancer: Management guidelines of the American Thyroid Association. *Thyroid* 2009;19:565–612.

Approximately 95% of patients with MEN2A or MEN2B will have an identifiable germline *RET* mutation.⁴³ As mentioned previously, 1% to 7% of apparently sporadic cases of MTC will carry a germline *RET* mutation, underscoring the importance of testing all cases of MTC.^{3,35,42} A targeted exon approach is most commonly used in families with MEN2A. If the clinical suspicion is MEN2B, a targeted mutation analysis can be used. If targeted testing in a family with a high clinical suspicion for MEN2 is normal, sequencing of the remaining exons can then be performed. For families that do not have a detectable mutation, management recommendations can be based on the clinical features in the affected individual and in the family.

Management

Management of *RET* mutation carriers includes prophylactic thyroidectomy, as well as biochemical screening for PC and HPT.^{3,35} The timing of these interventions has been largely based on genotype, but this remains controversial. Prophylactic thyroidectomy and parathyroidectomy with reimplantation of one or more parathyroid glands into the neck or forearm are a preventive option for all subtypes of MEN2. For those with mutations associated with early-onset aggressive MTC, genetic testing alone is used to determine timing of surgery.^{3,35} For individuals carrying lower- or intermediate-risk mutations (see Table 88.2), some centers allow surgery to be delayed until biochemical screening becomes abnormal and/or the individual reaches a particular age.³⁵ This is still somewhat controversial, however, given the great intrafamilial variability and the fact that MTC can be present even in the absence of an elevated basal or stimulated calcitonin.

Biochemical screening for parathyroid disease and PC is recommended, and the timing and frequency depend on the genotype and, in some cases, presence/absence of these tumors in the family (see Table 88.2). Annual screening for HPT should include albumin-corrected calcium or ionized serum calcium with or without intact PTH measurement (American Thyroid Association, 2009). Screening for PC with plasma-free metanephrines and/or urinary fractionated metanephrines is recommended, given that these provide a higher diagnostic sensitivity than urinary catecholamines.^{49,50} When biochemical screening suggests PC, MRI or computed tomography can be performed.^{51,52} Confirmation of the diagnosis can be made using various anatomic and functional modalities.^{52–54} Several reviews provide a succinct summary of the

biochemical diagnosis, localization, and management of PC.^{52,55} If surgical removal is required, laparoscopic adrenalectomy is the recommended approach for the treatment of unilateral PC.⁵⁶ For individuals with bilateral PC, cortical-sparing adrenalectomy is an option to minimize the risk of adrenal insufficiency.^{56,57}

PHOSPHATASE AND TENSIN HOMOLOG ON CHROMOSOME 10

Clinical Features

Germline mutations in the *PTEN* (phosphatase and tensin homolog on chromosome 10) gene have been associated with a number of related clinical disorders, including Cowden syndrome (CS), Bannayan–Riley–Ruvalcaba syndrome, a Proteus-like syndrome, adult Lhermitte–Duclos disease, and autism-like disorders with macrocephaly. Although CS is the only one with a documented risk for endocrine (thyroid) cancer, it is possible that any person with a *PTEN* mutation is at increased risk.⁵⁸

The prevalence of CS, an autosomal dominant disorder, has been estimated to be between 1/200,000 and 1/250,000.⁵⁹ Diagnostic criteria for CS were initially developed in 1996,⁶⁰ and subsequent modifications have been proposed.^{61–63} A clinical diagnosis requires a requisite number of clinical features, which are divided into groups of “pathognomonic,” “major,” and “minor” criteria (Table 88.3).

Cancer rates in CS have historically been reported as 25% to 50% for breast cancer, 3% to 10% for thyroid cancer, and 5% to 10% for endometrial cancer, based on compilations of cases published in the early literature.^{64–66} Thyroid cancer in CS is exclusively of follicular or papillary histology. More recently, an increased risk for colon cancer has been reported.⁶⁷ Although recent reports from two large cohorts found cancer rates similar to these,^{67,68} a follow-up report on one of these cohorts projected lifetime cancer risks of 85% for breast cancer, 35% for thyroid cancer, 28% for endometrial cancer, 34% for kidney cancer, and 9% for colon cancer.⁶⁹ However, these high risks are subject to significant selection bias and should be considered with caution, given their discrepancy with clinical experience with patients with CS.

Benign lesions are also seen in CS and include mucocutaneous lesions (trichilemmomas, acral keratoses, and papillomatous papules, seen in most patients), thyroid abnormalities (goiter, adenoma in 50% to 67%), benign breast lesions (fibroadenomas,

TABLE 88.3

Cowden Syndrome Diagnostic Criteria

Pathognomonic criteria
<ul style="list-style-type: none"> ■ Lhermitte–Duclos disease—adult ■ Mucocutaneous lesions ■ Trichilemmomas, facial ■ Acral keratoses ■ Papillomatous lesions
Major criteria
<ul style="list-style-type: none"> ■ Breast cancer ■ Thyroid cancer (papillary or follicular) ■ Macrocephaly (≥ 97th percentile) ■ Endometrial cancer
Minor criteria
<ul style="list-style-type: none"> ■ Other structural thyroid lesions (e.g., adenoma, multinodular goiter) ■ Mental retardation (i.e., $IQ \leq 75$) ■ Gastrointestinal hamartomas ■ Fibrocystic disease of the breast ■ Lipomas ■ Fibromas ■ Genitourinary tumors (e.g., uterine fibroids, renal cell carcinoma) or ■ Genitourinary structural malformations ■ Uterine fibroids
Operational diagnosis in an individual (any of the following):
<ol style="list-style-type: none"> 1. Mucocutaneous lesions alone, if <ol style="list-style-type: none"> a. There are six or more facial papules, of which three or more must be trichilemmoma, or b. Cutaneous facial papules and oral mucosal papillomatosis, or c. Oral mucosal papillomatosis and acral keratoses, or d. More than six palmoplantar keratosis 2. Two or more major criteria, but one must include macrocephaly or Lhermitte–Duclos disease; or 3. One major and three minor criteria; or 4. Four minor criteria
Operational diagnosis in a family where one individual is diagnostic for Cowden syndrome:
<ol style="list-style-type: none"> a. One pathognomonic criterion; or b. Any one major criterion with or without minor criteria; or c. Two minor criteria; or d. History of Bannayan–Riley–Ruvalcaba syndrome⁵⁸

fibrocystic disease in 40% to 75% of females), gastrointestinal polyps ($\geq 80\%$), macrocephaly ($\leq 80\%$), and uterine fibroids (25% to 44% of females).^{68,69}

Genetic Testing

The *PTEN* tumor suppressor gene is a dual-specificity phosphatase with multiple and as yet incompletely understood roles in cellular regulation. It is known to signal down the PI3K/Akt pathway to cause G1 cell cycle arrest and apoptosis, and has also been shown to regulate cell-survival pathways, such as the mitogen-activated kinase pathway.⁷⁰ Although it is generally reported that germline *PTEN* mutations are found in 80% of patients with CS, based on initial reports in 1997,^{71–73} more recent data suggest that it is much lower,^{67–69} and there is reason to consider revising the diagnostic criteria.⁶⁸ A small number of studies suggest that gene deletions or rearrangements are rare in CS.^{74,75} Approximately 2% of all patients with CS in one study had a variant in the *PTEN* promoter.⁷⁴ Although not definitive, protein expression studies suggested that these variants could be deleterious. The new mutation rate for *PTEN* is unknown.

Testing criteria for CS have been developed and are updated annually by the National Comprehensive Cancer Network.⁷⁶ Clinical *PTEN* testing is available in a number of national laboratories.

Germline genetic variants were found in the *SDHB* and *SDHD* genes in one report in a cohort of patients with CS- or a CS-like phenotype.⁷⁷ None of the patients with genetic variants met current CS diagnostic criteria, however, and the clinical significance of these variants has been questioned, given that most had previously been identified as benign polymorphisms.⁷⁸ More recently, germline methylation of the *KILLIN* gene has been suggested to be related to CS as well.⁷⁹

Management

Management guidelines for individuals with CS have been adopted by the National Comprehensive Cancer Network⁷⁶ and include annual physical examinations, monthly breast self-examinations, and a baseline thyroid ultrasound (with consideration of repeating annually), starting at the age of 18 years; clinical breast examinations every 6 months, starting at the age of 25 years; annual mammography and breast MRI screening starting at the age of 30 to 35 years; consideration of colonoscopy every 5 to 10 years, starting at the age of 35 years; consideration of an annual dermatologic examination; and consideration of participation in clinical trials for endometrial cell cancer screening.

SDHX/TMEM127/MAX

Clinical Features

Mutations in four genes of the succinate dehydrogenase (SDH) complex, *SDHA*, *SDHB*, *SDHC*, and *SDHD* (collectively referred to as *SDHX*), and several interacting genes have been shown to cause the autosomal dominant hereditary paraganglioma (PGL)–pheochromocytoma (PCC) syndrome. The SDH complex is part of both the mitochondrial–respiratory chain (complex II) and the Krebs cycle.⁸⁰ The specific clinical phenotype varies, somewhat depending on the gene involved, as discussed in the following.

Individuals with *SDHB* mutations tend to present with sympathetic PGLs and less commonly PCC and parasympathetic PGL. There is a higher rate of malignancy and mortality with *SDHB* mutations compared with other SDH genes.⁸⁰ An analysis of 378 published cases with *SDHB* mutations found that 78% had PGL (71% sympathetic) and 25% had PCC (all unilateral), with a mean age at presentation of 33 years.⁸¹ Up to 31% had malignant tumors. In one study of 32 patients with metastatic PCC/PGL whose tumor was diagnosed before age 20 years, 23 (72%) had *SDHB* mutations.⁸² The penetrance of *SDHB* mutations has been estimated to be 77% by the age of 50 years.⁸³ The risks for renal cell carcinoma and oncocytoma also appear to be increased.^{84,85}

SDHD mutations most commonly cause multifocal parasympathetic PGL. A review of the clinical features of 289 patients with *SDHD* mutations found that 92% had PGL (56% multiple), 24% had PCC (all unilateral), and only 4% had malignant disease.⁸¹ The mean age at presentation is 35 years,⁸⁶ and the penetrance is estimated to be 86% by the age of 50 years.⁸³ *SDHD* mutations appear to be maternally imprinted such that tumors develop only when a mutation is inherited from the father.⁸⁷ However, several rare cases of maternal transmission have been reported.^{88,89}

SDHC mutations are rare in patients with PCC/PGL. They mainly cause nonmalignant parasympathetic PGL (and rarely PCC) and were found in 4% of such patients in one study.⁹⁰ The average age at presentation is 43 years.⁸¹

More recently, mutations in the *SDHAF2* (also called *SDH5*), *SDHA*, *TMEM127*, and *MAX* genes have also been found in hereditary PGL/PCC. Given their rarity, and their recent discoveries, less is known about their clinical presentation. Mutations

in *SDHA*/*SDH5* have been described in a number of families with head and neck PGL, but to date no cases with PCC have been reported.^{91,92} It appears that there is genetic imprinting with paternal transmission required for tumor development.^{91,92} Biallelic *SDHA* mutations have been known to cause inherited juvenile encephalopathy/Leigh syndrome,⁹³ but it was only recently that heterozygous mutations have been found in a few individuals with PCC or PGL.^{94,95} Mutations in *TMEM127* were first identified in 2010⁹⁶ and were initially felt to be associated exclusively with PC.⁹⁷ However, several cases with extra-adrenal tumors have been reported.⁹⁸ *TMEM127* mutations are relatively rare causes of PCC and PGL—mutations were found in only 6 (1%) of 559 PCC cases and none of 72 PGL cases who did not carry mutations in *SDHB*, *SDHD*, *RET*, or *VHL*.⁹⁹ In addition, the age at diagnosis of PCC is not significantly earlier than average (41.5 years), and malignancy is infrequent.^{96,97} Exome sequencing was used to identify *MAX* gene mutations in 12 individuals with hereditary PCC in one study.¹⁰⁰ Most cases (67%) were bilateral, and an association with malignancy was suggested, as was the possibility that paternal transmission was required for tumor development.

Genetic Testing

Although approximately 10% of patients with PCC have a clinically apparent hereditary syndrome, studies have shown that up to 25% of “sporadic” cases also have germline mutations in either *SDHB*, *SDHD*, *RET*, or *VHL*.¹⁰¹ Similarly, analysis of 445 patients with PGL found mutations in *SDHB*, *SDHC*, or *SDHD* in 220 (50%).¹⁰² Whereas some have called for genetic testing for all PCC/PGL, others have called for a targeted approach. A number of algorithms have been proposed whereby testing decisions are based on a variety of factors including presence of clinical features, early age at diagnosis, location and laterality of tumor(s), positive family history, and presence of malignancy.^{81,103} Clinical testing is available in the United States for all of these genes except *MAX*.

Management

The management of PCC and PGL is primarily surgical, and it is critical that patients undergo preoperative catecholamine and metanephrine screening to detect functional disease, which could precipitate anesthesia-induced hypertensive crisis during surgery. For at-risk patients with known mutations, there are no consensus guidelines as to the appropriate screening protocols. Although it is generally felt that MRI and/or functional imaging and measurement of blood/urine metanephrines be performed on a regular basis, the specifics vary among centers.¹⁰⁴

VON HIPPEL-LINDAU AND PHEOCHROMOCYTOMA

von Hippel-Lindau disease (VHL) is not often characterized as an endocrine-related disorder. However, the presence of PC and, rarely, pancreatic neuroendocrine tumors in VHL warrants a brief discussion in this section. Herein, we will also briefly review the genetic approach to the patient presenting with sporadic PC, as this is not an uncommon reason for referral for genetic counseling and risk assessment, and a significant proportion of these individuals will have an underlying hereditary condition. Additional information about other VHL and other VHL-related tumors (i.e., renal cell carcinoma) can be found in the section on urinary tract cancers.

VHL is an inherited multisystem disease predisposing to retinal and central nervous system hemangioblastomas, renal cell carcinoma, PC, pancreatic islet cell tumors, and endolymphatic sac tumors. It has an estimated birth incidence of 1 in 36,000 per year¹⁰⁵ and is inherited in an autosomal dominant manner with a high degree of interfamilial and intrafamilial variability.¹⁰⁶ The penetrance is age dependent, but reaches ~95% by the age of 65 years.^{105,107} Four subtypes have been described on the basis of genotype–phenotype correlations.¹⁰⁷ PC is the main endocrine-related tumor associated with VHL. As in other hereditary syndromes, VHL-associated PCs are typically multifocal and/or bilateral and present at an earlier age than sporadic tumors and rarely metastatic.¹⁰⁷

PC can be seen in several different hereditary conditions in addition to VHL, including neurofibromatosis type 1, MEN2, and the hereditary paraganglioma/PC syndromes.¹⁰⁸ One study of 271 patients with apparently sporadic PC analyzed the *NF1* (diagnosis made on the basis of clinical features, not genetic testing), *RET*, *VHL*, *SDHB*, and *SDHD* genes.¹⁰⁹ Upon further scrutiny, 166 (25.9%) of the 271 had a positive family history, and in these 166 families, germline mutations were detected in *RET* ($n = 31$), *VHL* ($n = 56$), *NF1* ($n = 14$), *SDHB* ($n = 34$), or *SDHD* ($n = 31$). Interestingly, 12.7% of those with no other syndromic features and/or family history (after rigorous clinical evaluation) also carried mutations.

These data indicate that a significant proportion of individuals presenting with apparently sporadic PC are carriers of germline genetic mutations. Referral to a genetic specialist may be warranted in all cases of apparently isolated PC, but is certainly appropriate in those diagnosed at or younger than 35 years and those with metastatic disease or multifocal and/or bilateral disease. Several clinical and genetic screening algorithms have been proposed to assist clinicians in deciding which genes to test and in which order,^{52,109,110} as testing for mutations in five different genes in every patient may not be feasible or cost-effective.

Section 8 Sarcomas of Soft Tissue and Bone

89 Molecular Biology of Sarcomas

Samuel Singer, Torsten O. Nielsen, and Cristina R. Antonescu

INTRODUCTION

Sarcomas are life-threatening mesenchymal neoplasms that account for approximately 1% of all human cancers. They pose a significant therapeutic challenge because about 50% of patients with newly diagnosed sarcoma eventually die of disease. Sarcomas also pose significant diagnostic challenges because there are more than 70 histologic subtypes with unique molecular, pathologic, clinical, prognostic, and therapeutic features.

SOFT TISSUE SARCOMAS

The molecular genetic and cytogenetic characterization of soft tissue sarcoma has improved classification and has divided sarcomas into two broad groups: those with simple karyotypes and those with highly complex karyotypes. Figure 89.1 shows the molecular alterations found in some of the subtypes in each group. The first group consists of sarcomas with near-diploid, simple karyotypes and simple genetic alterations (translocations, inversions, or specific activating mutations). Translocation-associated sarcomas typically occur in young adults, with the highest incidence at age 30 to 50 years. Oncogenesis mostly results from transcriptional deregulation induced by fusion genes. The second group consists of sarcomas with aberrant, highly complex genomes. The peak incidence for these complex sarcoma types is at age 50 to 70 years. These complex sarcoma subtypes commonly have alterations in cell-cycle genes *TP53*, *MDM2*, *RBI*, and *INK4a* and defects in specific growth-factor signaling pathways, but the critical subtype-specific molecular alterations that drive sarcomagenesis largely remain to be discovered. This information will be essential for the development of therapeutics that can selectively target the driver genetic alterations required for sarcoma survival. This idea is best illustrated by imatinib, a small molecule that inhibits *ABL*, *KIT*, and platelet-derived growth factor receptor alpha (*PDGFRA*) tyrosine kinases. The discovery that gastrointestinal stromal tumors (GIST) have activating mutations in *KIT* and *PDGFRA* led to rapid clinical development of imatinib for GIST, in which it proved to be an effective, low toxicity therapy (see Chapter 55 for a discussion of the molecular biology of GIST). This success illustrates how targeting a sarcoma-specific oncogenic mechanism can lead to dramatic responses.

Figure 89.2 shows the histologic appearance of the major soft tissue sarcoma subtypes, and Table 89.1 outlines diagnostic histologic characteristics and molecular and cytogenetic abnormalities.

TRANSLOCATION-ASSOCIATED SOFT TISSUE SARCOMAS

Myxoid/Round Cell Liposarcoma

Myxoid liposarcomas typically arise in the thigh or other deep soft tissues in adults (peak age, 30 to 50 years). Myxoid liposarcomas

can usually be diagnosed with confidence by its characteristic morphology: a myxoid matrix, a plexiform vasculature, and lipoblasts. These features may, however, be partially lost in its high-grade form, *round cell liposarcoma*. Nearly all myxoid/round cell liposarcomas carry a balanced translocation, $t(12;16)(q13;p11)$,¹ fusing *FUS* (also known as *TLS*) with *DDIT3* (aka *CHOP*, *GADD153*).² In rare cases, *EWSR1* substitutes for its homolog *FUS*. At least 12 *FUS-DDIT3* transcript variants have been reported,^{3,4} and several are known to induce a sarcoma phenotype in model systems.^{5,6} The translocations fuse 5' exons of *FUS* (encoding transcriptional regulatory domains that interact with the RNA polymerase II complex⁷) to the full coding sequence of *DDIT3*, a leucine-zipper transcription factor with roles in cell cycle control,⁸ adipocytic differentiation,⁹ and stress response.¹⁰ The fusion oncoprotein binds cofactors including *C/EBPβ* to deregulate gene expression, although few direct targets have been validated to date.^{11,12} One result is activation of critical pathways, including those related to angiogenesis (interleukin 8 [IL-8]), early adipose differentiation (*PPARγ*), growth factor signaling (insulinlike growth factor [IGF], *RET*), and cell-cycle control (cyclin D, *CDK4*).¹²⁻¹⁵ Another result is repression of miR-486¹⁶ and IL-24,¹⁷ which might otherwise act as tumor suppressors.

Clinically, evidence for *FUS-DDIT3* translocations from reverse transcription polymerase chain reaction (RT-PCR)³ or fluorescence in situ hybridization (FISH)¹⁸ can help confirm the diagnosis and may be useful for small biopsies dominated by a round cell component. Fusion subtype, however, appears to have little prognostic value independent of stage and grade. In general, molecular markers in myxoid liposarcoma have been difficult to test for independent prognostic value, given the difficulty of assembling large series.¹⁹ Nevertheless, high levels of p53, IGF1R/IGF2, *AXL*, and *RET* may be adverse factors.^{13,20,21} In addition, mutations in *PIK3CA*, found in 18% of myxoid/round cell liposarcomas, were associated with a worse outcome.²²

Myxoid liposarcomas have dense microvasculature and high expression of IL-8¹² and vascular endothelial growth factor (VEGF).²³ These characteristics suggest a value for antiangiogenic therapies and may underlie the observed sensitivity to radiotherapy²⁴ and trabectedin.²⁵ Trabectedin may also function by disrupting the binding of *FUS-DDIT3* to target promoters.¹¹ Agents designed to target *FUS-DDIT3* are not yet available.

Ewing Sarcoma

Ewing family tumors appear most commonly in adolescents and young adults; primary sites are most often in bone but can also be in soft tissues. A range of aggressive small blue round cell tumors have been subsumed under the general term *Ewing sarcoma family tumor* because of common pathogenomic chromosomal translocations.^{26,27} *EWSR1*, the common 5' translocation partner, is fused to one of several ETS family transcription factor genes

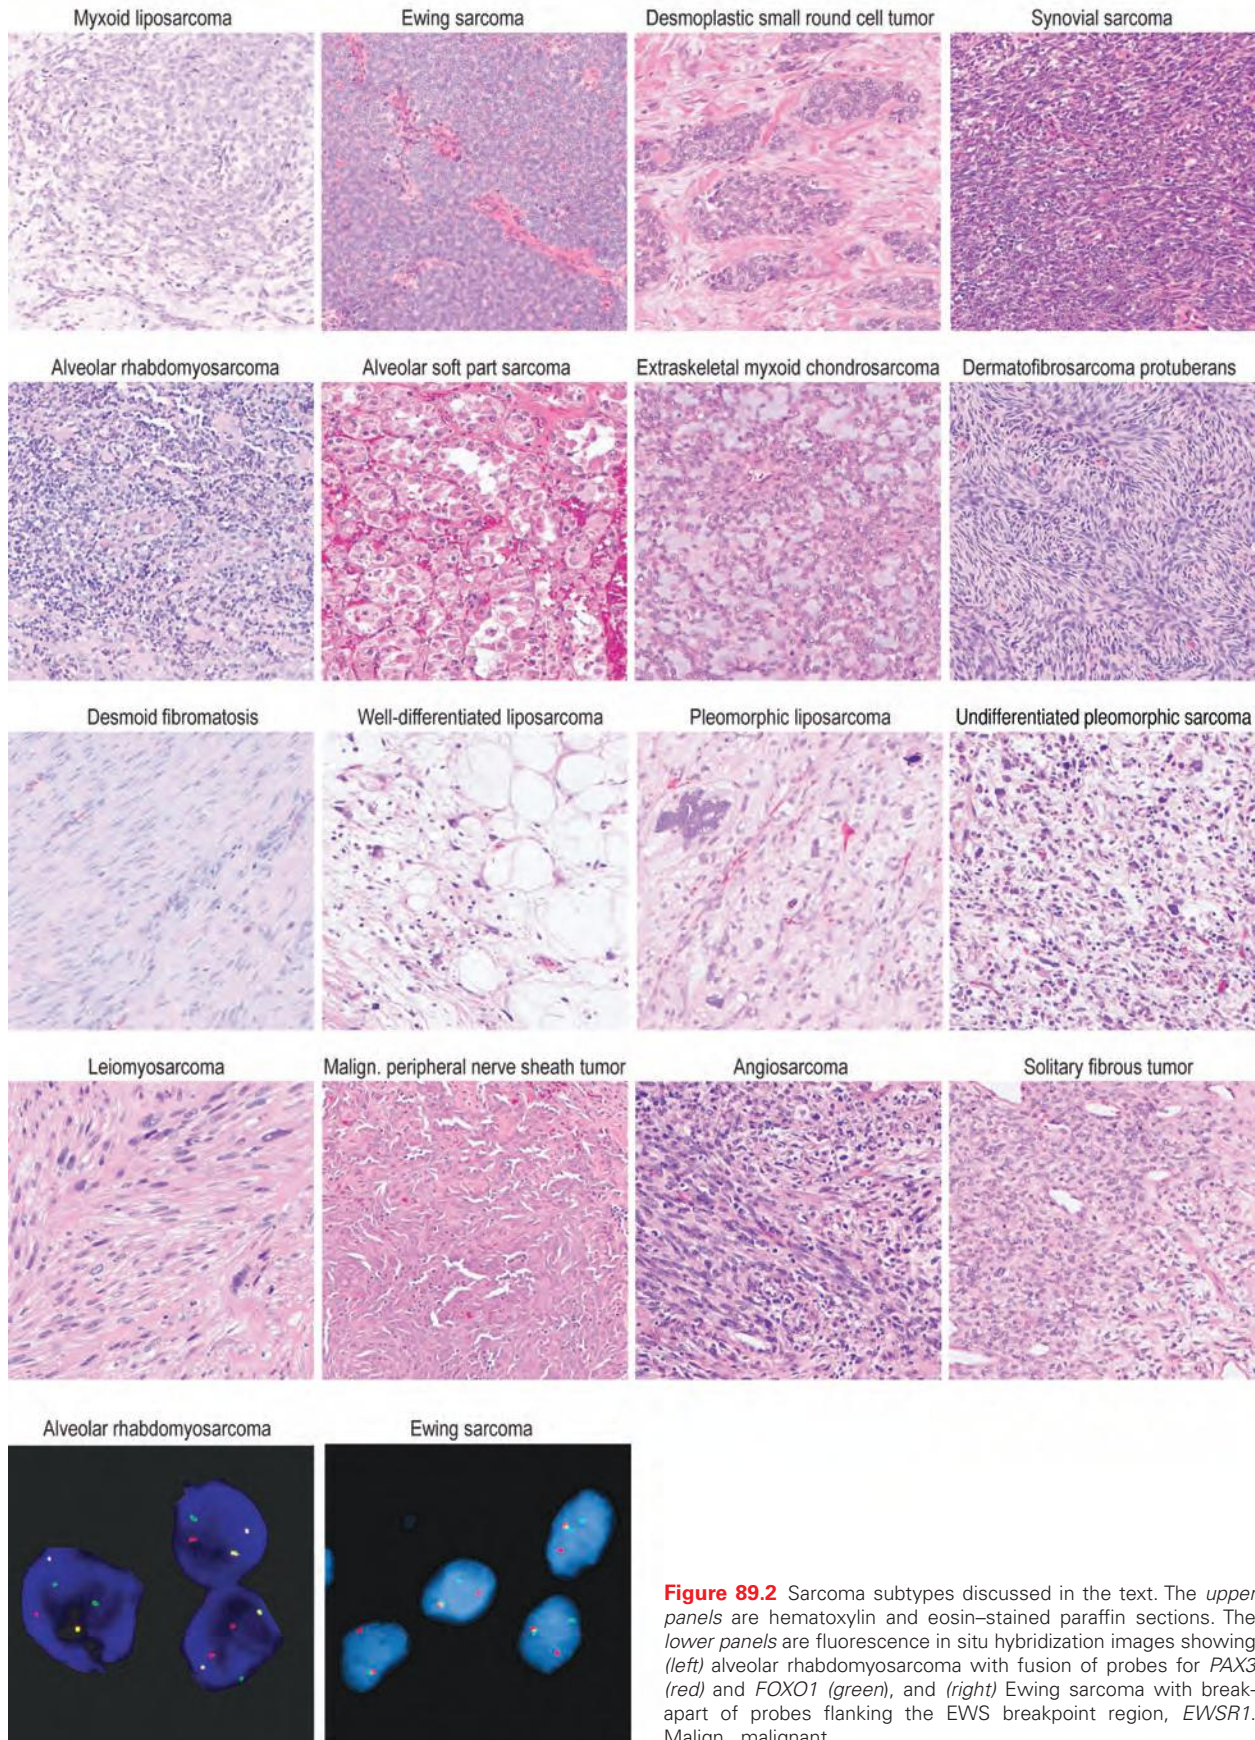

Figure 89.1 Nucleotide and copy number alterations in soft tissue sarcoma. The outer ring indicates the chromosomal position. The second through fifth rings represent four subtypes with complex karyotypes. The three inner rings represent subtypes with simple karyotypes. The plots show the statistical significance of genomic aberrations, with amplification in red and deletion in blue. Green curves indicate the chromosomal breakpoints of pathognomonic translocations in myxoid/round-cell liposarcoma and synovial sarcoma. Genes harboring somatic nucleotide alterations are indicated with green circles whose size is proportional to their frequency of occurrence. MYXF, myxofibrosarcoma; PLEO, pleomorphic liposarcoma; LMS, leiomyosarcoma; DEDIFF, dedifferentiated liposarcoma; Myxoid, myxoid/round cell liposarcoma. (Courtesy of Barry S. Taylor, Computational Biology Center, Memorial Sloan-Kettering Cancer. Adapted from Barretina J, Taylor BS, Banerji S, et al. Subtype-specific genomic alterations define new targets for soft tissue sarcoma therapy. *Nat Genet* 2010;42:715–721.)

(usually *FLII*).²⁸ In the chimeric protein, EWSR1 provides, at minimum, its N-terminal transcriptional regulatory domain²⁹ and loses its RNA recognition domain. The ETS factor provides its C-terminal DNA-binding domain and loses its native transactivation domain. Several direct transcriptional targets for the fusion oncoprotein are supported by strong evidence. In Ewing sarcoma tissue, some of these targets are upregulated (*PTPL1*,³⁰ *PRKCB*,³¹ *DAX1/NR0B1*³²) and some repressed (*FOXO1*,³³ *TGFBR2*, *LOX*,³⁴ *IGFBP3*,³⁵ and the *Let-7* microRNA precursor³⁶), but gene repression, mediated by cofactors, appears to predominate.³⁷ The net result is the activation of pathways driving proliferation and

cell survival³⁸ and the repression of pathways promoting mesenchymal differentiation.^{39,40}

Molecular confirmation of an *EWSR1* translocation can be critical for patient management because many of the clinical, morphologic, and immunophenotypic features of Ewing sarcoma are shared with entities such as mesenchymal chondrosarcoma and small cell osteosarcoma. Commercially available *EWSR1* split-apart FISH probes are valuable ancillary diagnostic tools (see Fig. 89.2)⁴¹; RT-PCR alternatives are complicated by the need to cover the many alternative fusion sites, but offer the advantage of identifying the specific fusion.⁴²

PRACTICE OF ONCOLOGY

Figure 89.2 Sarcoma subtypes discussed in the text. The upper panels are hematoxylin and eosin–stained paraffin sections. The lower panels are fluorescence in situ hybridization images showing (left) alveolar rhabdomyosarcoma with fusion of probes for *PAX3* (red) and *FOXO1* (green), and (right) Ewing sarcoma with break-apart of probes flanking the EWS breakpoint region, *EWSR1*. Malign., malignant.

TABLE 89.1

Cytogenetic and Molecular Abnormalities in Soft Tissue Sarcomas

Disease	Diagnostic Morphology or Immunohistochemistry	Cytogenetic Event	Molecular Abnormality	Molecular Diagnostic ^a
Myxoid/round cell liposarcoma	Lipoblasts, plexiform vasculature, myxoid matrix	t(12;16)(q13;p11) t(12;22)(q13;q12)	<i>FUS-DDIT3</i> (>90%) <i>EWSR1-DDIT3</i> (<5%)	<i>DDIT3</i> breaks (FISH) ^{18,276}
Ewing sarcoma family tumor	Small, blue, round cells; CD99 and FLI1 expression; lack of lymphoid biomarker expression	t(11;22)(q24;q12) t(21;22)(q22;q12) Alternative events: fusions of 22q12 with 7p22, 17q22, 2q33; inv 22q12; t(16;21)(p11;q22)	<i>EWSR1-FLI1</i> (>80%) <i>EWSR1-ERG</i> (10%–15%) Other ETS family partners: <i>ETV1</i> , <i>ETV4</i> , <i>FEV</i> , <i>PATZ1</i> (~5%) <i>FUS-ERG</i> (<1%)	<i>EWSR1</i> breaks (FISH) ⁴¹ or RT-PCR
Desmoplastic small round cell tumor	Small, blue, round cell islands in dense stroma; positive for keratin, desmin, vimentin, and WT1	t(11;22)(p13;q12)	<i>EWSR1-WT1</i> (>75%)	<i>EWSR1</i> breaks (FISH) ⁴¹
Synovial sarcoma	Biphasic histology, positive for TLE1 ⁶¹	t(X;18)(p11;q11) (>90%)	<i>SYT-SSX1</i> (66%), <i>SYT-SSX2</i> (33%), <i>SYT-SSX4</i> (<1%)	<i>SYT</i> breaks (FISH) ²⁷⁷
Alveolar rhabdomyosarcoma	Small, blue cells expressing desmin, myogenin, myoD1	t(2;13)(q35;q14) t(1;13)(p36;q14)	<i>PAX3-FOXO1</i> (~80%) <i>PAX7-FOXO1</i> (~20%) <i>PAX3-NCOA1</i> (<1%) <i>PAX3-NCOA2</i> (<1%)	<i>PAX3/7</i> type-specific FISH or RT-PCR ²⁷⁸
Alveolar soft-part sarcoma	Nested polygonal cells in vascular network; positive for TFE3 ²⁷⁹	t(X;17)(p11;q25)	<i>ASPSCR1-TFE3</i> (>90%)	<i>ASPSCR1-TFE3</i> RT-PCR ²⁸⁰ or <i>TFE3</i> FISH ⁹³
Dermatofibrosarcoma protuberans	Bland spindle cells, storiform and honeycomb growth in subcutis, positive for CD34	Rings derived from t(17;22) (>75%) t(17;22)(q22; q13.1) ^{103,104,281} (10%)	<i>COL1A1-PDGFB</i>	
Embryonal rhabdomyosarcoma	Spindle cells and rhabdomyoblasts, positive for desmin and myogenin	Trisomies 2q, 8 and 20 (>75%)	LOH at 11p15 (>75%)	
Extraskeletal myxoid chondrosarcoma	Bland epithelioid cells arranged in reticular pattern in myxoid stroma	t(9;22)(q22;q12) t(9;17)(q22;q11) t(9;15)(q22;q21) t(3;9)(q12;q22)	<i>EWSR1-NR4A3</i> (75%) <i>TAF15-NR4A3</i> (<10%) <i>TCF12-NR4A3</i> (<10%) <i>TFG-NR4A3</i> (<5%)	<i>EWSR1</i> breaks (FISH); RT-PCR ^{112–114}
Endometrial stromal tumor	Bland spindle cells, positive for CD10 and ER	t(7;17)(p15;q21)	<i>JAZF1-SUZ12</i> (30%)	
Clear cell sarcoma	Nested epithelioid cells with clear or amphophilic cytoplasm, positive for S100 and HMB-45	t(12;22)(q13;q12) t(2;22)(q34;q12)	<i>EWSR1-ATF1</i> (>75%) <i>EWSR1-CREB1</i> (<5%)	<i>EWSR1</i> breaks (FISH) ^{41,282}
Infantile fibrosarcoma	Monomorphic spindle cells, herringbone pattern	t(12;15)(p13;q25)	<i>ETV6-NTRK3</i> (>75%)	FISH, RT-PCR
Inflammatory myofibroblastic tumor	Myofibroblastic cells with lymphoplasmacytic infiltrate, positive for ALK	t(1;2)(q25;p23) t(2;19)(p23;p13) t(2;17)(p23;q23)	<i>ALK-TPM34</i> <i>ALK-TPM</i> <i>ALK-CLTC</i>	<i>ALK</i> breaks (FISH)
Solitary fibrous tumor	Monomorphic spindle cells, collagenous stroma, and staghorn vasculature; STAT6 expression	12q13 inversion	<i>NAB2-STAT6</i> (>95%)	RT-PCR
Gastrointestinal stromal tumor	Spindle (70%), epithelioid (20%) or mixed (10%) morphology, positive for CD117 (KIT), DOG1, and CD34	Monosomies 14 and 22 (>75%) Deletion of 1p (>25)	<i>KIT</i> or <i>PDGFRA</i> mutation (>90%) ^{283,284}	PCR mutation analysis

(continued)

TABLE 89.1

Cytogenetic and Molecular Abnormalities in Soft Tissue Sarcomas (continued)

Disease	Diagnostic Morphology or Immunohistochemistry	Cytogenetic Event	Molecular Abnormality	Molecular Diagnostic ^a
Desmoid fibromatosis	Bland myofibroblastic-type cells, fascicular growth, nuclear positivity for β -catenin	Trisomies 8 and 20 (30%)	<i>APC</i> inactivation by mutation/deletion (10%) <i>CTNNB1</i> (β -catenin) mutations (85%)	IHC for β -catenin expression
Well-differentiated/dedifferentiated liposarcoma	Atypical multinucleated stromal cells, lipoblasts, positive for MDM2, CDK4	12q13-15 rings and giant markers	<i>MDM2</i> and <i>CDK4</i> amplification (>85%)	<i>MDM2</i> amplification (FISH)
Pleomorphic liposarcoma	Pleomorphic spindle and giant cells, pleomorphic lipoblasts	Complex ^b (>90%)		None
Myxofibrosarcoma and undifferentiated pleomorphic sarcoma	Pleomorphic spindle and giant cells, storiform growth, variable myxoid stroma	Complex ^b >90%)	<i>SKP2</i> amplification	None
Leiomyosarcoma	Elongated fusiform cells with eosinophilic cytoplasm, in intersecting fascicles, positive for desmin and smooth muscle actin	Complex ^b (>50%) Deletions of 1p	<i>RB1</i> point mutations/deletions	None
Malignant peripheral nerve sheath tumor	Monomorphic spindle cells, high mitotic count, geographic necrosis	Complex ^b (90%)	<i>NF1</i> mutation, loss or deletion (>50%)	None

^a Refers to molecular tests that can be run on formalin-fixed paraffin-embedded material for molecular confirmation of diagnosis: quantitative RT-PCR of transcripts,²⁷⁸ or FISH to interphase genomic DNA.²⁸⁵

^b Complex karyotypes containing multiple numerical and structural chromosomal aberrations.

FISH, fluorescence in situ hybridization; RT-PCR, reverse transcription polymerase chain reaction; LOH, loss of heterozygosity; IHC, immunohistochemistry.

Several agents (including inhibitors of IGF/mammalian target of rapamycin [mTOR], histone deacetylase, and cyclin-dependent kinase⁴³) that target translocation-induced mechanisms and pathways are currently in clinical trials for Ewing sarcoma, and strategies to inhibit the oncoprotein itself are in active development.⁴³⁻⁴⁵

Desmoplastic Small Round Cell Tumor

In desmoplastic small round cell tumors, the same 5' portions of *EWSR1* involved in Ewing sarcomas are fused to *WT1*,^{46,47} a tumor suppressor deleted in Wilms tumor.⁴⁸ The chimeric protein includes the last three *WT1* DNA-binding zinc finger domains. Despite some similarities to Ewing sarcoma family tumors, desmoplastic small round cell tumors are rarely cured with aggressive conventional chemotherapy combined with surgical debulking; prognosis is dismal, so new therapies are needed.^{49,50} Several targets of *EWSR1-WT1* have been identified. *EWSR1-WT1* directly induces *PDGFA* expression,⁵¹ which explains the desmoplastic background and, along with *VEGFA* and *VEGFR2* overexpression, accounts for the observed partial responses to sunitinib.⁵² *IL2RB* is also induced, and its downstream JAK/STAT and AKT/mTOR signaling pathways appear active,^{46,53,54} representing potential targets for novel treatment approaches.

Synovial Sarcoma

Synovial sarcoma differs from most translocation-associated sarcomas in that the genes involved in its defining translocation, t(X;18) (p11;q11), encode epigenetic regulators, not transcription factors that bind DNA directly.⁵⁵ The translocation fuses the widely expressed

SS18 (aka *SYT*) gene with an *SSX* gene normally expressed only in testis.⁵⁶ In the fusion oncoprotein, *SS18*, which forms part of the BAF chromatin remodeling complex,⁵⁷ retains all but the last eight amino acids from its C-terminal transcriptional activation domain. The *SSX* partner (*SSX1*, 2, or 4) retains only its C-terminal 78-residue repressor domain, which confers nuclear localization in association with Polycomb proteins.⁵⁸ The forced expression of *SS18-SSX* in mesenchymal stem cells⁵⁹ or conditional expression in mice^{55,60} recapitulates synovial sarcoma. Neither *SS18* nor *SSX* carries a DNA-binding motif; however, the chimeric oncoprotein gains at least two abnormal functions affecting epigenetic gene regulation. The retained C-terminus of *SSX* binds *TLE1*, a highly expressed diagnostic marker of synovial sarcoma⁶¹ that recruits Polycomb repressor complex proteins. *SS18* binds the transcription factor *ATF2*, thereby directing the complex to promoters bearing cAMP response elements (CRE). The net result is Polycomb-mediated epigenetic repression of *ATF2* target genes, including the tumor suppressors *EGR1* and *CDKN2A*.⁶² Also, when *SS18-SSX* replaces native *SS18* in BAF complexes, the *SMARCB1* (*SNF5*) component is evicted.⁶³ This latter event increases Polycomb activity and induces hyperactivity of stem cell-associated programs,⁶⁴ a feature of synovial sarcoma.⁶⁵ Key genes and oncogenic pathways that become activated, directly or indirectly, in synovial sarcoma include histone deacetylases,⁶² *SOX2*,⁶⁵ *Wnt*/ β -catenin,⁶⁶ *TWIST1*,⁶⁷ *FGFR2*,⁶⁸ *BCL2*,⁶⁹ and the Akt/mTOR pathway⁷⁰ via IGF2.^{59,71,72} Therefore, these represent candidates for targeted therapy approaches in the absence of known drugs that inhibit *SS18-SSX* directly.

Copy number alterations are more common in adult than in pediatric patients, and both copy number alterations and an expression signature of genes related to mitosis and chromosome function are associated with metastasis.⁷³

Alveolar Rhabdomyosarcoma

In alveolar rhabdomyosarcoma, an aggressive cancer of older children and adolescents, the transcriptional activation domain of FOXO1 (i.e., FKHR) from 13q14 is fused to the DNA-binding domain of paired box transcription factor PAX3 (2q35) or PAX7 (1p36).^{74,75} Until recently, about 20% of cases were thought to be translocation negative, but in fact, such tumors represent histologic variants of embryonal rhabdomyosarcoma.⁷⁶ Translocations involving PAX3 may be associated with a worse prognosis than those involving PAX7.⁷⁷ Thus, to optimize patient care, the diagnosis should be confirmed by FISH (see Fig. 89.2) and/or RT-PCR.⁷⁸ Either translocation results in a high-level nuclear expression of a chimeric transcription factor that abnormally activates PAX targets, many of which are involved in neurogenesis and are not expressed in normal skeletal muscle.^{79,80} Recently, PAX3-FOXO1 fusion mRNA and chimeric protein were found to be expressed transiently during normal fetal muscle development (i.e., in cells without the DNA translocations).⁸¹ Direct targets of PAX3-FOXO1 include P-cadherin (*CDH3*),⁸² *GREM1*, *DAPK1*, and *MYO1*,⁸³ as well as *PDGFRA*. Inhibitors of *PDGFRA* are effective in mouse models.⁸⁴ The list of targetable kinases expressed in alveolar rhabdomyosarcoma also includes *IGF1R* and *ALK*.^{85–87} Another probable direct target of PAX3-FOXO1 is the cell-cycle regulator *SKP2*,⁸⁸ perhaps helping explain why alveolar rhabdomyosarcoma is responsive to conventional cytotoxic chemotherapy.

Alveolar Soft-Part Sarcoma

Alveolar soft-part sarcoma has a clinical presentation and pathogenomic molecular event with many similarities to other translocation-associated sarcomas.⁸⁹ In this disease, the 5' half of the widely expressed *ASPCRI* (i.e., *ASPL*) gene on 17q25 is fused to exon 3 or 4 of *TFE3* on Xp11, the latter retaining its transcriptional activation, basic helix-loop-helix, and leucine zipper domains.⁹⁰ Interestingly, similar fusions are present in a subset of renal cell carcinomas, particularly those arising in younger patients,⁹¹ and in a subset of perivascular epithelioid cell neoplasms.⁹² Although alveolar soft-part sarcoma has distinctive histology, two useful diagnostic adjuncts are the detection of *TFE3* rearrangements by FISH⁹³ and the detection of translocations by RT-PCR or by immunohistochemistry for *TFE3*.^{94,95} Kobos et al.⁹⁶ combined expression profiling, chromatin immunoprecipitation, and functional validation to identify a CACGTG consensus motif in genes transcriptionally activated by the *ASPCRI*-*TFE3* oncoprotein. Their list of validated direct targets⁹⁷ includes *MET* and angiogenic mediators, which is consistent with previous studies.^{97–99} Antiangiogenic therapy is effective in xenograft models.¹⁰⁰ A single-arm phase II study of the VEGFR inhibitor cediranib in metastatic alveolar soft-part sarcoma showed a high rate of disease control in association with downregulation of angiogenic genes (including *ANGPT2*), supporting advanced trials of antiangiogenic agents.¹⁰¹

Dermatofibrosarcoma Protuberans

A hallmark of dermatofibrosarcoma protuberans (DFSP) is supernumerary ring chromosomes that contain material from chromosomes 17 and 22,^{102–104} or less commonly, an unbalanced der(22)t(17;22)(q21-23;q13). The molecular consequence of both types of aberration is the overexpression of the PDGF beta (*PDGFB*) gene on chromosome 22, through fusion with the collagen gene *COL1A1* on chromosome 17.^{105,106} The same fusion gene is also seen in two histologic variants: giant cell fibroblastoma and Bednar tumor (pigmented DFSP). FISH and comparative genomic hybridization (CGH) studies have indicated that increased *COL1A1-PDGFB* copy number is associated with fibrosarcomatous transformation of DFSP, although the copy number increase is not an invariable feature of these cases.^{107,108}

The *COL1A1-PDGFB* fusion product signals through the PDGF receptor in an autocrine loop.¹⁰⁹ This signaling can be blocked using tyrosine-kinase inhibitors acting at PDGFR, such as imatinib. A number of clinical studies have shown a high response rate to imatinib therapy in both locally advanced and metastatic DFSP.^{102,110,111} These results support the concept that DFSP cells depend on aberrant activation of PDGF signaling for proliferation and survival.

Extraskelatal Myxoid Chondrosarcoma

Most extraskelatal myxoid chondrosarcomas show reciprocal translocations that fuse *NR4A3* in 9q22-q31.1 with one of four partners: *EWSR1* in 22q12 (the most common), *TAF15* in 17q11, *TCF12* in 15q21, or *TFG* in 3q12.^{112–114} Because these fusion genes have not been described in any other tumor type, they represent useful diagnostic markers. The four different fusion partners have unknown prognostic significance.

NR4A3 encodes a ubiquitously expressed orphan nuclear receptor also known as NOR-1, TEC, MINOR, or CHN.¹¹⁵ The t(9;22) fuses the transactivation domain of *EWSR1* to the full length of *NR4A3*. Analogous to *EWSR1-ETS* fusions, the *EWSR1-NR4A3* fusion protein not only displays strong transcriptional activity, but also regulates RNA splicing.¹¹⁶

TAF15, like *EWSR1* and *FUS*, belongs to the FET family, and contains a characteristic 87-amino acid RNA recognition motif implicated in protein-RNA binding.¹¹⁷ The N-terminal regions of *EWSR1*, *FUS*, and *TAF15* contain degenerate repeats of the SYGQ motif and mediate powerful transcriptional activation when fused to the heterologous DNA-binding domains of a variety of transcription factors.¹¹⁸

By gene profiling, extraskelatal myxoid chondrosarcomas constitute a distinct genomic entity, showing upregulation of several genes, including *NMB*, *DKK1*, *DNER*, and *CLCN3*.¹¹⁹ In situ hybridization confirmed that *NMB* is highly expressed in extraskelatal myxoid chondrosarcoma but not in other sarcoma types, suggesting its potential value as a diagnostic marker.

Solitary Fibrous Tumor and Hemangiopericytoma

Solitary fibrous tumor (SFT) and hemangiopericytoma share similar histopathologic features and are now classified as a single biologic entity.¹²⁰ In a recent study using paired-end transcriptome sequencing, a recurrent *NAB2-STAT6* fusion was identified in virtually all SFTs, regardless of anatomic location (pleura, meninges, or soft tissue).¹²¹ In the normal genome, *NAB2* and *STAT6* are adjacent genes on chromosome 12q13 that are transcribed in opposite directions, but in SFT, the fusion is the result of a chromosomal inversion, fusing *NAB2* and *STAT6* in a common direction of transcription.

In contrast to the known activity of *NAB2* as a repressor of early growth response protein 1 (*EGR1*) activity, the *NAB2-STAT6* fusion induces expression of *EGR1* target genes. In an RNA-sequencing analysis of seven SFTs and 282 other tumor samples, the SFTs showed a high-level expression of both *EGR1* target genes, including *NAB2*, *NAB1*, *IGF2*, *FGF2*, and *PDGFD*, and receptor tyrosine kinases, such as *FGFR1* and *NTRK1*.¹²¹ Overexpression of other tyrosine-kinase receptor genes, such as *DDR1* and *ERBB2*, has been seen in array-based profiling.¹²²

IGF2 is uniformly overexpressed in SFT, regardless of anatomic location.¹²² *IGF2* is imprinted on the paternal allele in most adult tissues, and *IGF2* overexpression in SFTs was related to a loss of imprinting. Although *IGF2* acts by binding to *IGF1R*, SFTs do not show up-regulation of *IGF1R*, and it was suggested that *IGF2* signaling occurs through the insulin receptor A pathway.¹²³ Overexpression of *IGF2* and consequent activation of the insulin

receptor may also explain why a subset of SFT patients presents with hypoglycemia. This syndrome, known as *Doege-Potter syndrome*, has been associated with large tumor size and aggressive clinical behavior and is resolved by surgical resection of the lesion.¹²⁴

Although a *PDGFRB* mutation (D850V) was reported in a malignant pleural SFT,¹²⁵ none of the 39 SFTs tested subsequently showed mutation in this hot spot, nor did they show upregulation of *PDGFRB* mRNA.¹²²

SOFT TISSUE SARCOMAS OF SIMPLE KARYOTYPE ASSOCIATED WITH MUTATIONS

Desmoid Fibromatosis

Desmoid-type fibromatoses are locally infiltrative, clonal fibroblastic proliferations that arise in the deep soft tissues and never metastasize. Although about 70% result from mutations in adenomatous polyposis coli (*APC*) or *CTNNB1*, tumorigenesis may also be influenced by endocrine and physiologic factors such as pregnancy, trauma, and prior surgery. Desmoids are usually divided into two groups: sporadic desmoids and those in individuals with a heterozygous germ-line mutation in the *APC* gene (chromosome 5q). Although germ-line *APC* mutations also often result in familial adenomatous polyposis,¹²⁶ some desmoid patients harboring such a mutation have no polyposis. The desmoids in individuals with a germ-line *APC* mutation display inactivation of the second copy of *APC*, which usually occurs by point mutation or deletion.^{126,127}

Among sporadic desmoids, only a minority display *APC* inactivation. A majority (52% to 85%) have an activating point mutation in the β -catenin gene, *CTNNB1*.^{128,129} These *CTNNB1* mutations stabilize β -catenin, resulting in its overabundance. β -Catenin, a mediator of Wnt signaling, is negatively regulated by *APC*, so both *APC* inactivation and *CTNNB1* activating mutations result in the upregulation of the Wnt pathway. The specific *CTNNB1* mutation may have prognostic significance; patients with S45F-mutant desmoids were reported to have a 5-year recurrence-free survival of only 23%, compared with 57% for those with T41A-mutant tumors and 65% for those with wild-type *CTNNB1*.¹²⁸ These results raise the possibility that mutation status might aid in selecting patients for more aggressive therapy.

Based on the findings of *APC* inactivation or activating *CTNNB1* mutations in the majority of patients, the development of small-molecule β -catenin antagonists would be likely to provide significant benefit, particularly for patients with advanced disease in whom surgical resection is not feasible. Although such β -catenin-targeted agents are still in preclinical development, an inhibitor of matrix metalloproteinase, a downstream target of β -catenin, substantially reduced tumor volume and tumor invasion in a transgenic *Apc+/Apc^{1658N}* mouse model of aggressive fibromatosis.¹³⁰ Hedgehog signaling is activated in human and murine desmoid tumors. Inhibiting Hedgehog signaling reduced cell proliferation and β -catenin protein levels in human desmoid cell cultures and reduced the tumor size and number in a murine model.¹³¹ These results suggest Hedgehog antagonists as a promising therapy for desmoid patients.

Patients with desmoids were found to have elevated levels of PDGF-AA and PDGF-BB, leading to a trial of the tyrosine-kinase inhibitor imatinib in patients with advanced disease. Of 19 patients, 3 (16%) had a partial response to treatment and 4 additional patients had stable disease for more than 1 year; overall, the 1-year tumor control rate was 37%.¹³² The response in these tumors was thought to be mediated by inhibition of *PDGFRB* kinase activity. Sorafenib, a multitargeted tyrosine-kinase inhibitor, results in tumor shrinkage in 25% of desmoid patients and stable disease in 70%, along with symptom relief in 70% of patients.¹³³

COMPLEX SOFT TISSUE SARCOMA TYPES

Well-Differentiated and Dedifferentiated Liposarcoma

Well-differentiated and dedifferentiated liposarcomas represent the most common biologic group of liposarcoma. This group is characterized by amplification of 12q, which usually occurs in double minutes, ring chromosomes, and large marker chromosomes. In addition, the 12q13.2-q23.1 locus often harbors complex rearrangements (see Fig. 89.1).^{22,134,135} The amplified region generally includes the oncogenes *MDM2*, *HMGA2*, and *CDK4*, but 12q may contain additional driver genes. On the basis of the rearrangements and correlated overexpression results, possibilities include *NAV3*, *WIF1*, *MDM1*, *DYRK2*, *ELK3*, *DUSP6*, *YEATS4*, *TBK1*, and *FRS2*, which are amplified in ~14% to 80% of tumors. Aside from 12q aberrations, dedifferentiated liposarcomas contain significant amplifications of 1p, 1q, 5p, 6q, and 20q.^{22,134,135}

Amplification of *JUN* (on 1p32) has been suggested as the explanation for the block in adipocyte differentiation in undifferentiated sarcomas.¹³⁶ However, *JUN* is amplified or overexpressed in only a subset of dedifferentiated liposarcomas (DDLs).^{22,137} Another gene that may be involved in the differentiation phenotype is *C/EBP α* , which is underexpressed in many DDLs tissues and cell lines. Exogenously expressing *C/EBP α* resulted in a 50% decrease in proliferation, a G2/M arrest, apoptosis, and restoration of the ability to induce early adipogenesis markers.¹³⁸ CCAAT-enhancer-binding protein alpha (*C/EBP α*) expression independently predicts distant recurrence-free survival for patients with primary liposarcoma,¹³⁹ and loss of the 19q region encompassing *C/EBP α* is associated with poor outcomes in primary retroperitoneal DDLs.¹⁴⁰ In addition, *C/EBP α* downregulation may result from epigenetic defects; 24% of DDLs had *C/EBP α* promoter methylation and 8.3% had somatic mutations in the histone deacetylase HDAC1. Treating DDLs cells with a demethylating agent and the histone deacetylase inhibitor vorinostat increased *C/EBP α* expression 19-fold, decreased proliferation, induced apoptosis, and reduced xenograft tumor growth by 50% to 70%.¹⁴¹ Taken together, these results suggest that *C/EBP α* acts as a tumor suppressor in DDLs and that its loss may explain the undifferentiated state of DDLs.

A microarray analysis of gene expression has demonstrated that well-differentiated liposarcomas and DDLs have activation of cell-cycle and checkpoint pathways, including the upregulation of *CDK4*, *MDM2*, *CDK1*, *CDC7*, *TOP2A*, *PRC1*, *PLK1*, and cyclins B1, B2, and E2.^{142,143} Therefore, these pathways may be useful as therapeutic targets. In fact, nutlin-3a, a selective *MDM2* antagonist, induces apoptosis and inhibits the proliferation of DDLs cell lines at concentrations that do not affect normal adipose-derived stem cells.¹⁴² Furthermore, PD0332991, a selective *CDK4/CDK6* inhibitor, inhibits proliferation by inducing G1 cell-cycle arrest and senescence in DDLs cell lines and xenografts.²² In a recent phase II trial of PD0332991 in patients with advanced *CDK4*-amplified liposarcoma, 66% of patients were progression free at 12 weeks, and a subset had a radiographic response and prolonged stable disease.¹⁴⁴ These results provide a rationale for use of *MDM2* antagonists and *CDK4* inhibitors in patients with well-differentiated liposarcomas and DDLs.

Pleomorphic Liposarcoma

Pleomorphic liposarcoma, accounting for 5% of all liposarcomas, is the least common subtype. It is characterized by high chromosome counts and complex rearrangements, with many unidentifiable marker chromosomes and nonclonal alterations. A high-resolution single nucleotide polymorphism (SNP) array analysis has revealed multiple regions of significant copy number amplification and deletion.¹⁴⁵ The most common alteration, found in approximately

60% of tumors, was a deletion of 13q14.2-q14.3, including the *RBI* tumor suppressor. The next most common alteration was a loss of 17p13.1, including *TP53*. Both *RBI* and *TP53* deletions were a mixture of hemizygous loss and, less frequently, homozygous deletion. In addition, *TP53* point mutations were found in 17% of tumors.²² In *TP53*-mutant cells, antagonism of MDM2 by nutlin-3a enhances chemosensitivity,¹⁴⁶ suggesting the potential therapeutic utility of combining nutlin-3a with chemotherapy in *TP53*-mutant pleomorphic liposarcoma. Small molecules that reactivate mutant *TP53*, such as PRIMA-1 (APR-246),¹⁴⁷ are presently in phase I trials.

A third genetic alteration identified in an SNP analysis was the deletion of 17q11.2, including the tumor suppressor *NF1*. Among 24 pleomorphic liposarcomas, 9 (38%) had *NF1* loss, including 1 case of a homozygous deletion and 2 cases of a mutation of the nondeleted allele.²² Because a loss of *NF1* function appears to activate the RAS and mTOR pathways, the frequent *NF1* aberrations suggest that MEK or mTOR inhibitors may have clinical utility.

Myxofibrosarcoma and Undifferentiated Pleomorphic Sarcoma (Malignant Fibrous Histiocytoma)

Pathologists now regard myxofibrosarcoma as a distinct tumor type with clearly defined criteria for diagnosis.^{120,148,149} Undifferentiated pleomorphic sarcoma, however, is less well defined, and it remains controversial whether it represents either (1) a pleomorphic sarcoma showing fibroblastic/myofibroblastic differentiation and thus sharing a common set of genomic alterations with myxofibrosarcoma, or (2) an end-stage undifferentiated morphologic pattern with genomic alterations distinct from those of myxofibrosarcoma.

Myxofibrosarcoma

Myxofibrosarcoma, also known as myxoid variant of malignant fibrous histiocytoma, is a malignant fibroblastic lesion with variably myxoid stroma (at least 10%) composed of hyaluronic acid and solid sheets of spindled and pleomorphic tumor cells. Karyotypes tend to be highly complex, often with multiple numerical and structural rearrangements and with chromosome numbers in the triploid or tetraploid range.¹⁵⁰⁻¹⁵² No consistent chromosomal aberration has emerged. In general, karyotype complexity is greater in high-grade lesions and in recurrences.¹⁵²

In an SNP array analysis of 38 myxofibrosarcomas, approximately 55% harbored chromosome 5p amplification.²² This region contains *RICTOR* (a binding partner of mTOR), *CDH9*, and *LIFR*. Other amplified regions included several discontinuous loci on 1p and 1q spanning *PI4KB*, *ETV3*, and *MCL1*, among others. *MCL1*, an antiapoptotic gene, was concomitantly overexpressed in these tumors. Myxofibrosarcomas also harbored deletions of tumor suppressors, including *CDKN2A/CDKN2B*, *RBI*, *TP53*, *NF1*, and *PTEN*. These events demonstrate an extensive loss of function in several known tumor suppressors.²²

Undifferentiated Pleomorphic Sarcoma (Malignant Fibrous Histiocytoma)

Over 50% of soft tissue sarcomas occurring in older adults are histologically pleomorphic and high grade. Most have traditionally been classified as malignant fibrous histiocytoma (MFH).^{153,154} MFH was originally defined as a malignant pleomorphic spindle cell neoplasm showing fibroblastic and histiocytic differentiation. More recently, pathologists have accepted that this morphology may be shared by a wide range of malignant neoplasms.¹⁵⁵ Many sarcomas that were previously classified as pleomorphic MFH, on careful immunohistochemical and histopathologic analyses, revealed a specific line of differentiation and could be reclassified as myxofibrosarcoma (30%), myogenic sarcoma (30%), liposarcoma (4%), malignant peripheral

nerve sheath tumor (2%), or soft tissue osteosarcoma (3%), whereas about 30% had no specific line of differentiation or were myofibroblastic.¹⁴⁸ The term *undifferentiated pleomorphic sarcoma* (UPS) is now reserved for pleomorphic sarcomas that show no definable line of differentiation by current technology.

Because of this change in diagnostic criteria, the genetic basis of UPS is difficult to evaluate. Among the more than 60 cases in the Mitelman Database of Chromosome Alterations in Cancer described as storiform or pleomorphic MFH or MFH not otherwise specified, the karyotypes are highly complex. Most have chromosome numbers in the triploid or tetraploid range, but a few are near haploid.¹⁵⁶⁻¹⁶⁰ Telomeric associations, ring chromosomes, and dicentric chromosomes are common. In a CGH study of 33 tumors, 25 of which were UPSs as currently defined, numerous copy number changes were found. The most frequent (found in 50% to 65% of tumors) were gains in chromosome 1p (1p33-p32, 1p31, and 1p21), 1q21, and 20q13 and losses in 1q41, 2q36-q37, 10q25-q26, 13q13-q14, 13q14-q21, and 16q12.¹⁶¹ The copy number profiles of the majority of UPSs closely resembled those of leiomyosarcomas¹⁶¹⁻¹⁶⁴ or pleomorphic or dedifferentiated liposarcomas.¹⁶⁵⁻¹⁶⁷ Mutations and/or deletions of *TP53*, *RBI*, and *INK4a* have been suggested to be drivers of oncogenesis.^{162,168-171}

Recent work suggests that the stemlike tumor initiating cells (side population cells) isolated from UPS show activation of both the Hedgehog and Notch pathways. Inhibition of these pathways in UPS xenograft models decreased the proportion of side population cells and suppressed tumor self-renewal. This work shows that targeting signaling pathways activated in a small subpopulation of tumor-initiating cells has a dramatic effect on tumor self-renewal and may be a promising approach for these undifferentiated tumors.¹⁷²

Leiomyosarcoma

Leiomyosarcoma is defined as a malignant tumor with evidence of smooth muscle differentiation. Karyotypes tend to be complex, with amplifications, gains, and losses involving multiple chromosomes.¹⁷³⁻¹⁷⁵ Frequently observed aberrations include losses of 1p12-pter, 2p, 13q14-q21 (including *RBI*),¹⁷⁶ 10q (including *PTEN*),¹⁷⁷ and 16q and gains of 17p, 8q, and 1q21-31; these aberrations have been associated with aggressive clinical behavior. The myocardin (*MYOCD*) gene on 17p is significantly amplified and overexpressed in retroperitoneal tumors. Knockdown of *MYOCD* in leiomyosarcoma cell lines harboring this amplification decreases smooth muscle differentiation and inhibits cell migration.¹⁷⁸ In an analysis of copy number alterations in 27 leiomyosarcomas,²² deletions, which were more common than amplifications, encompassed known tumor suppressors such as *TP53*, *BRCA2*, *RBI*, and *FANCA*. The most prominent changes were chromosome 10 deletions (50% to 70% of cases) (see Fig. 89.1). Indeed, genetic inactivation of *Pten* (human 10q23.21) in smooth muscle in mice recapitulates human leiomyosarcoma,¹⁷⁹ suggesting that 10q loss occurs early in leiomyosarcomagenesis. Moreover, partial inactivation of *Pten* and *Tp53* in the smooth muscle lineage in mice results in the development of high-grade pleomorphic sarcomas and leiomyosarcomas with complex karyotypes.¹⁸⁰ The sarcomas deficient in both *Pten* and *Tp53* showed upregulated notch signaling and a greater metastatic potential, which could be attenuated by a gamma-secretase inhibitor.¹⁸⁰ In addition to *PTEN* inactivation, we identified homozygous deletions in *MTOR*. Because *PTEN* is a repressor of Akt, both these events suggest a critical role for aberrant Akt-mTOR signaling in leiomyosarcoma. mTOR inhibitors such as everolimus (RAD001) and temsirolimus have shown some efficacy in patients with leiomyosarcoma in clinical trials.^{181,182}

RBI deletion is common in leiomyosarcomas, with 70% harboring heterozygous deletions and 8% harboring homozygous deletions. A role for *RBI* deletion in leiomyosarcoma fits with the high incidence of leiomyosarcoma in individuals with hereditary retinoblastoma.¹⁸³

Malignant Peripheral Nerve Sheath Tumor

Malignant peripheral nerve sheath tumors (MPNST) are highly aggressive soft tissue sarcomas that rarely occur in the general population, but are much more common in patients with neurofibromatosis type 1 (NF1), a hereditary tumor predisposition syndrome caused by heterozygous mutations of the *NF1* gene. The MPNSTs in NF1 patients typically arise from neurofibromas. NF1 patients' lifetime risk of developing MPNST is 8% to 13%, contrasting with the 0.001% risk in the general population.^{184,185}

The *NF1* gene is implicated in sporadic as well as NF1-associated MPNST. About 70% of sporadic and NF1-associated MPNSTs display monoallelic or biallelic loss at the *NF1* locus on 17q.^{186–188} *NF1* encodes neurofibromin, a protein that accelerates Ras–GTP hydrolysis and thus negatively regulates Ras.¹⁸⁹ In individuals with NF1, neurofibromas develop when an unknown cell type in the Schwann cell lineage loses its remaining functional *NF1* gene (by mutation, deletion, or loss of heterozygosity), leading to neurofibromin loss and subsequent activation of Ras signaling.^{190–192}

Both sporadic and NF1-associated MPNSTs display complex karyotypes and clonal chromosomal aberrations.^{150,193,194} In CGH analyses of MPNSTs, the most frequent minimal regions of gain were 1q24.1–q24.2, 1q24.3–q25.1, 8p23.1–p12, 9q34.11–q34.13, and 17q23.2–q25.3.¹⁹⁵ The 17q gain was associated with poor survival and with the overexpression of genes previously implicated in cancer: *TOP2A*, *ETV4*, *ERBB2*, and *BIRC5*.^{195–197} Other frequent alterations include rearrangement or loss of 9p21 and 13q14, resulting in inactivation of *CDKN2A* (encoding the p16INK4A and p14ARF cell cycle inhibitory proteins) and *RBI1*, respectively. In fact, in a recent high-resolution CGH analysis of NF1-associated MPNST, the most frequently deleted locus (33% of cases) encompassed the *CDKN2A*, *CDKN2B*, and *MTAP* genes on 9p21.3.¹⁹¹ Thus, these studies implicate the p16INK4A–RBI1 pathway, as did another study.¹⁹⁸

Other recent studies have implicated the p19ARF–MDM2–p53¹⁹⁹ and EGFR pathways in MPNST oncogenesis.^{200,201} *TP53* (on 17p13) is frequently inactivated in MPNST through mutations or deletions, correlating with the frequent loss of 17p.¹⁹⁴ Building on these observations, MPNST driver genes were sought in a Sleeping Beauty (SB) transposon-based somatic mutagenesis screen in mice bearing transgenes that confer a somatic loss of p53 function and/or overexpression of human EGFR.²⁰² EGFR overexpression and p53 mutation cooperated to significantly increase neurofibroma and MPNST formation, effects that were enhanced by SB mutagenesis. The mutations found in the highest percentage of MPNSTs in this genetic screen were in *Pten* and *Nf1*, suggesting that these mutations cooperate to drive MPNST development. In addition, the researchers found that *Foxr2* acts as a protooncogene by promoting anchorage-independent MPNST cell growth and tumorigenicity.²⁰²

NF1-deficient Schwann cells derived from human neurofibromas show an activation of mTOR, even in the absence of growth factors. Furthermore, both these cells and transformed mouse cells with knockdown of *Nf1* are highly sensitive to the mTOR inhibitor rapamycin.²⁰³ Finally, in a genetically engineered murine model, rapamycin potently suppresses the growth of aggressive NF1-associated malignancies by suppressing the mTOR target cyclin D1. These results demonstrate that mTOR inhibitors may be an effective targeted therapy for patients with neurofibromatosis and MPNST.

Recent work has shown that the chemokine receptor CXCR4 is highly expressed in NF1-associated MPNST and that CXCR4, along with its ligand CXCL12, promotes MPNST growth by stimulating cyclin D1 expression. The highly specific CXCR4 antagonist AMD3100 decreased growth of MPNST cell lines, MPNST allografts, and MPNST tumors in transgenic mouse models of spontaneous MPNST. These results suggest that targeting autocrine cell cycle progression regulated by CXCR4/CXCL12 may represent a promising therapy for MPNST.²⁰⁴

The inactivation of NF1 and the consequent activation of the Ras/Raf/MAPK pathway in the majority of MPNSTs supported targeting B-Raf with the B-Raf tyrosine-kinase inhibitor sorafenib.

MPNST cell lines are sensitive to sorafenib at nanomolar concentrations, and this was found to be mediated by the suppression of cyclin D1 and hypophosphorylation of RBI1, resulting in G1 cell-cycle arrest.²⁰⁵ A phase II trial of sorafenib in patients with metastatic MPNST was recently completed. Although none of the 12 patients with MPNST had Response Evaluation Criteria in Solid Tumors (RECIST) responses, 3 had stable disease and 2 had regression or cystification of metastatic disease.²⁰⁶

Angiosarcoma

Angiosarcomas are rare vascular malignancies of endothelial cell differentiation that arise either de novo or secondary to radiation therapy or chronic lymphedema. By expression profiling, angiosarcomas are characterized by upregulation of vascular-specific receptor tyrosine kinases, including *TIE1*, *KDR* (*VEGFR2*), *TEK* (*TIE2*), and *FLT1* (*VEGFR1*).²⁰⁷ Full sequencing of these genes identified mutations in *KDR* in 10% of angiosarcoma patients, all of whom had tumors in the breast, with or without prior radiation. *KDR* was mutated in its extracellular immunoglobulinlike C2 domain, transmembrane domain, or kinase domain. *KDR* mutations were typically associated with strong *KDR* protein expression, although no gains in *KDR* copy number were detected. *KDR* mutants expressed in COS-7 cells showed ligand-independent activation of the kinase, which was inhibited with specific *KDR* inhibitors.²⁰⁷ In contrast with other sarcoma types, angiosarcoma showed downregulation of VEGF ligand expression (*VEGFA* and *VEGFB*), in keeping with the constitutive activation of *KDR* independent of exogenous VEGF.²⁰⁷ These results provide a basis for the activity of VEGFR-directed therapy in de novo and radiation-induced angiosarcoma.

In a recent array-CGH study, recurrent genetic abnormalities were identified in radiation- and lymphedema-associated angiosarcomas but not de novo angiosarcomas.²⁰⁸ The most frequent recurrent changes were high-level amplifications on chromosome 8q24.21 (50%), followed by amplification on 10p12.33 (33%) and 5q35.3 (11%). A high-level amplification of *MYC* on 8q24.21 was confirmed by FISH in most angiosarcomas associated with radiation and chronic lymphedema, but only in a minority of de novo tumors.^{209,210} *MYC* amplification was not found to predispose patients to a higher grade morphology or increased proliferation. These findings suggest that primary and secondary angiosarcoma, despite their similar morphology, are genetically distinct.

BONE AND CARTILAGINOUS TUMORS

CARTILAGINOUS TUMORS

Cartilaginous tumors represent the most common primary bone tumor. The cartilaginous tumors all produce chondroid matrix, at least focally.¹²⁰ The most common benign tumors are enchondromas and osteochondromas; they may serve as precursors to chondrosarcoma.

Enchondroma

Enchondromas may occur as solitary lesions in the metaphysis of bone or as multiple lesions, as is found in Ollier disease or Maffucci syndrome.²¹¹ Enchondromas have constitutively active Hedgehog signaling, which blocks normal chondrocyte differentiation and drives proliferation.²¹² Heterozygous somatic mutations in *PTHRI*, which encodes the receptor for parathyroid hormone–like hormone (PTHrH), have been found in approximately 15% of patients with Ollier disease.^{213–215} *PTHRI* mutation disrupts the normal Indian Hedgehog–PTHrH feedback loop, leading to activated Hedgehog signaling²¹³ and, presumably, to pathogenesis of Ollier disease in some patients.²¹⁵ The genetic deficit in Maffucci syndrome is unknown.

Osteochondroma

Osteochondroma is a cartilage-capped bony outgrowth from the metaphysis of bone. Osteochondromas can be solitary or multiple, as seen in multiple osteochondromas syndrome (MO), which is caused by dominant germ-line mutations in the tumor-suppressor exostosin gene family, specifically *EXT1* (located on 8q) or *EXT2* (located on 11p).²¹⁶ Loss of the remaining wild-type allele is seen in about 38% of sporadic and in 25% of hereditary osteochondromas.^{217,218} A mouse model having biallelic inactivation of *EXT1* recapitulates the morphology found in human MO.^{219,220} *EXT1* and *EXT2* encode glycosyltransferases that catalyze chain elongation of heparan sulfate on proteoglycans²²¹; defective heparan sulfate synthesis has been shown to affect the diffusion of Hedgehog ligands in the extracellular space, which in turn enables growth-plate chondrocyte growth in the wrong direction.²²² It also interferes with the ossification of the perichondrium so as to facilitate osteochondromagenesis.²²³

Chondrosarcoma

Chondrosarcoma is a malignant cartilaginous matrix-producing tumor with diverse morphologic features. It tends to occur in older patients with a peak incidence at ages 40 to 70. Low-grade chondrosarcomas rarely metastasize but may progress to high-grade chondrosarcoma, which metastasizes in about 70% of patients. Some chondrosarcomas arise from benign lesions (enchondromas or osteochondromas); these are termed secondary chondrosarcomas.¹²⁰

A prominent genetic alteration detected in cartilaginous tumors is the somatic mutation of isocitrate dehydrogenase (IDH) genes. In the initial study, *IDH1* and *IDH2* were mutated in 81 of 145 cartilaginous tumors (56%).²²⁴ A more recent study confirmed the presence of *IDH1* and *IDH2* mutations in 61% of chondrosarcomas.²²⁵ Among cartilaginous tumors, *IDH* mutations appear to be confined to enchondromas, periosteal chondrosarcomas, and central (intramedullary) chondrosarcomas of conventional or dedifferentiated histology.^{224,226} *IDH* mutations have not been found in secondary peripheral chondrosarcomas, which instead share some of the molecular characteristics of osteochondromas. *IDH1* and *IDH2* mutations also appear to be absent in osteochondromas or osteosarcomas, including chondroblastic osteosarcomas, and so mutation detection may be useful in diagnosis.

The common *IDH* mutations in chondrosarcoma affect *IDH1* R132 (~90% of *IDH* mutant cases) and *IDH2* at the homologous position, R172 (~10%). These mutations are also common in glioma and acute myeloid leukemia. The mutations block the ability of the enzymes to convert isocitrate to α -ketoglutarate, which in turn increases the levels of HIF1A, a subunit of a transcription factor that facilitates tumor growth in hypoxic environments.²²⁷ HIF1A is highly expressed in high-grade central chondrosarcoma.^{228,229}

IDH1 R132 and *IDH2* R172 mutations confer on the enzymes a new ability to convert α -ketoglutarate to R(-)-2-hydroxyglutarate (2HG), resulting in markedly elevated levels of 2HG.^{230,231} 2HG itself appears to be oncogenic and has been shown to induce CpG island DNA hypermethylation in low-grade gliomas,²³² acute myeloid leukemia,²³³ and chondrosarcoma²³⁴ containing *IDH1* and *IDH2* mutations. Across all these cancer types, the increased production of 2HG is associated with the inhibition of ten-eleven translocation dioxygenase (TET)-mediated DNA demethylation, leading to a hypermethylation phenotype that affects genes of the retinoic acid receptor activation pathway²³⁴ and, in chondrosarcoma, affects genes implicated in stem cell maintenance and differentiation.²³⁵ The expression of an *IDH2* mutant in mesenchymal progenitor cells is oncogenic in vitro and in vivo and leads to DNA hypermethylation and a differentiation block, which is reversible with DNA demethylating agents.²³⁵ Thus, for patients with *IDH*-mutant chondrosarcomas, there may be a therapeutic potential for demethylating agents or for selective inhibitors of the mutant *IDH* proteins, such as an *IDH1* R132 mutant inhibitor currently in development.²³⁶

A recent whole exome sequencing study²³⁷ showed that 37% of chondrosarcomas have insertions, deletions, or rearrangements of *COL2A1*, which encodes the alpha chain of type II collagen fibers—the major collagen constituent of articular cartilage. The researchers postulated that such mutations may interfere with the production of mature collagen fibrils. They also identified mutations in *IDH1/2* (59%), *TP53* (20%), and genes of the *RB1* pathway (33%) and the Hedgehog pathway (18%).

Other potentially targetable abnormalities in chondrosarcoma include the Hedgehog pathway, the IGF pathway, *CDK4*, *MDM2*, and *SRC*. Hedgehog signaling in primary central chondrosarcoma is constitutively activated, and activation is thought to occur early in tumorigenesis and serves to maintain chondrocytes in a proliferative state.^{212,238} Hedgehog inhibitors such as cyclopamine and triparanol inhibit chondrosarcoma cell growth in vitro and in xenografts to varying degrees.²¹² These results suggest that patients with conventional chondrosarcoma may benefit from some of the newer Hedgehog pathway inhibitors, such as the selective smoothed inhibitor vismodegib (GDC-0449, recently approved for basal cell carcinoma).²³⁹⁻²⁴¹ Unlike primary central chondrosarcoma, secondary peripheral chondrosarcoma actually has decreased Hedgehog signaling,²⁴² suggesting that Hedgehog blockade might not be effective for the peripheral subtype. *Gli2* overexpression in a mouse model induces benign cartilage tumors, whereas *Gli2* overexpression combined with *p53* (*Trp53*) deficiency results in the development of tumors that resemble chondrosarcoma by negatively regulating apoptosis through activated IGF signaling.²⁴³ Thus, the inhibition of IGF signaling may block chondrosarcoma progression and may also serve as an attractive therapeutic target. Kinome profiling has demonstrated *SRC* pathway activation in chondrosarcoma cell lines, and indeed, the *SRC* inhibitor dasatinib decreased chondrosarcoma cell viability.²⁴⁴

OSTEOSARCOMA

Osteosarcoma is a primary bone malignancy that arises most frequently in the long bones from osteoid-producing cells adjacent to growth plates, typically in children and adolescents.²⁴⁵ Osteosarcomas are characterized by complex DNA copy number alterations with few recurrent alterations and a high level of genomic instability. Most osteosarcomas are sporadic. Risk factors include prior radiation therapy and chemotherapy.²⁴⁶ Familial syndromes associated with osteosarcoma include Rothmund-Thomson syndrome,²⁴⁷ Li-Fraumeni syndrome (associated with *TP53* mutation), and hereditary retinoblastoma. Children with hereditary retinoblastoma exhibit up to 1,000 times the incidence of osteosarcoma compared to the general population. In addition, alterations affecting *RB1* have been found in up to 80% of primary osteosarcoma samples.²⁴⁸⁻²⁵⁰ About 20% of osteosarcomas have either a deletion of *CDKN2A* (encoding p16-INK4A) or an amplification of *CDK4*²⁵¹; this finding, along with the reciprocal relationship between *RB1* and *CDKN2A* alterations,²⁵² suggests that G1/S deregulation by either *RB1* loss, *CDK4* amplification, or *CDKN2A* loss is nearly universal in osteosarcoma.

Another gene significantly associated with osteosarcoma is *TP53*. The frequency of somatic *TP53* mutations in osteosarcomas ranges from 19% to 38%,^{253,254} and *TP53* mutations are associated with high levels of genomic instability.²⁵⁴ An additional 5% to 10% of osteosarcomas harbor amplification of *MDM2*.²⁵⁵ *TP53* mutations in osteosarcomas are frequently associated with hypermethylation of *HIC1* (hypermethylated in cancer 1). Specifically, *HIC1* was hypermethylated in 12 out of 29 human osteosarcomas with *TP53* mutations (41%) compared to 2 out of 24 tumors without *TP53* mutations (8%; $p = 0.007$).²⁵⁶ Experiments in mice with heterozygous deletion of both *Hic1* and *Trp53* have demonstrated cooperation between these two genes in osteosarcomagenesis.²⁵⁶ All these results suggest that the loss of *HIC1* function may complement *TP53* mutations in the development of a subset of human osteosarcomas.

Array CGH of conventional osteosarcoma, which accounts for 75% of osteosarcomas, has shown that 1p36, 6p21, 8q24, 16p13, 17p11, and 19p13 are recurrently gained/amplified²⁵⁷⁻²⁶⁰ and 2q, 6p, 8p, 10p, and 17p13 are recurrently lost/deleted.^{258,261} High copy gains and/or amplifications of chromosome arms 6p, 8q, and 17p are frequently reported and are believed to confer a more aggressive disease course.²⁶² A high copy number gain of the *MYC* oncogene at 8q24 was found in 43% of osteosarcomas.²⁶³ Other potential oncogenes on 8q24 include *RECQL4* and *EXT1*. Germ-line *RECQL4* helicase-inactivating mutations lead to Rothmund-Thomson syndrome²⁶⁴ and *EXT1* mutations lead to multiple exostoses.²⁶⁵ Both syndromes include a strong predisposition to osteosarcoma.

FUTURE DIRECTIONS: NEXT-GENERATION SEQUENCING AND FUNCTIONAL SCREENS

New targeted therapies are desperately needed for the ~5,800 patients who die each year from sarcoma in the United States.²⁶⁶ A key challenge will be to identify the alterations that drive sarcomagenesis for each subtype of sarcoma. Once these driver alterations are identified, new small molecules to target them can be sought through a combination of functional screens, high-throughput compound screens, combinatorial chemistry, and structural biology information. Use of next-generation sequencing technologies can vastly expand our knowledge of the mutations, translocations, epigenetic alterations, and aberrant signaling pathways associated with specific sarcoma types and subtypes. Concurrent massively parallel sequencing experiments and integrative analysis now enable genome-wide analysis of copy number alterations, structural

rearrangements, expressed coding mutations, alternative splice forms, digital expression, chimeric/fusion transcripts, and DNA methylation status. This approach will provide a deeper view of the sarcoma genome than was previously possible. For example, on a single tumor sample, it is now possible to resequence all of the protein-coding regions of the human genome, generate detailed transcriptome profiles (RNA-seq),²⁶⁷ and perform genome-wide profiling of epigenetic marks and chromatin structures using other sequence-based methods (e.g., chromatin immunoprecipitation sequencing [ChIP-seq], methyl-seq, and DNase-seq).²⁶⁸ In gene expression studies, microarrays are being replaced by sequence-based methods because RNA-seq provides far more precision on transcript levels, alternative splicing, and sequence variation in identified genes. RNA-seq has an additional advantage in that it can identify rare transcripts without prior knowledge of a particular gene.²⁶⁷⁻²⁷⁰ These sequence-based methods, when integrated with data from high-throughput RNA interference screens in cell lines harboring the genetic alterations found in human sarcoma samples, will substantially enhance our ability to identify and target the signaling pathways and proteins driving sarcomagenesis.

Smart compounds, reflecting the three-dimensional structure of the targeted protein, may then be designed using high-throughput biochemical screens capable of identifying low-affinity compounds, together with sensitive biophysical techniques such as nuclear magnetic resonance, x-ray diffraction, and protein-ligand cocrystallography.²⁷¹⁻²⁷⁴ The resulting physicochemical data should facilitate the virtual screening of library structures for their three-dimensional fit with pharmacophores²⁷⁵ and speed the discovery of new selective small-molecule inhibitors targeting the signaling pathways essential for sarcoma growth and survival.

90 Soft Tissue Sarcoma

Samuel Singer, William D. Tap, Aimee M. Crago, and Brian O'Sullivan

INTRODUCTION

Tumors arising in the soft tissue form a diverse and complex group, as they may display varying degrees of mesenchymal differentiation. Most soft tissue tumors are benign and are usually cured with a simple surgical excision. Soft tissue sarcomas account for <1% of the overall human burden of malignant tumors but remain life-threatening, and approximately 40% of patients with newly diagnosed soft tissue sarcoma die of the disease, corresponding to approximately 4,000 deaths each year in the United States.¹ Soft tissue sarcoma, diagnosed at an early stage, is eminently curable. When diagnosed at the time of extensive local or metastatic disease, it is rarely curable. The relatively small number of cases and the great diversity in histopathologic features, anatomic sites, and biological behaviors have made comprehensive understanding of these disease entities difficult. A better understanding is urgently needed to accelerate the development of new treatments.

INCIDENCE AND ETIOLOGY

Epidemiology

Benign mesenchymal tumors are 100-fold more common than soft tissue sarcomas.² The annual international incidence of soft tissue sarcoma is estimated to be between 1.4 and 5.0 cases per 100,000; the true incidence remains difficult to determine because of variable reporting practices and inaccurate diagnosis.³⁻⁸ Incidence patterns vary considerably by histologic type and subtype.^{7,9} For most types of soft tissue sarcoma, incidence increases progressively with age from approximately 1 to 2 per 100,000 at age 15, to approximately 6 per 100,000 at age 49, and to as high as approximately 20 per 100,000 at age 80.^{7,9}

Etiology and Risk Factors

Most soft tissue sarcomas are believed to be sporadic and have no clearly defined cause. In a small proportion of cases, researchers have identified predisposing or associated factors, including genetic factors, lymphedema, prior radiation therapy, and carcinogens.

Genetic Factors

A range of heritable genetic syndromes are associated with soft tissue neoplasms.¹⁰ Desmoid tumors occur in patients with familial adenomatous polyposis, a disorder caused by germline mutations in the *APC* gene. Malignant peripheral nerve sheath tumors (MPNST) develop in neurofibromas in patients with neurofibromatosis 1 (NF1), caused by germline mutations in the *NF1* gene. Patients with NF1 have an estimated lifetime risk of MPNST of 8% to 13%.¹¹ Li-Fraumeni syndrome is a rare, highly penetrant familial cancer phenotype usually associated with germline

mutations in *TP53*, the gene for tumor suppressor p53.¹² Eighty percent of patients with this syndrome develop cancer by age 45, and the index tumors in 36% of patients are soft tissue or bone sarcomas of diverse histology.¹³ Heritable retinoblastoma gene (*RBI*) mutations are associated with an increased risk of bone and soft tissue sarcoma. For instance, patients with *RBI* mutations have a 36% cumulative incidence over 50 years of sarcoma in previously irradiated tissue.¹⁴ Most of the excess cancer risk in *RBI* mutation carriers who survive retinoblastoma can probably be prevented by limiting exposure to DNA-damaging agents such as radiotherapy, tobacco, and ultraviolet light.¹⁵ Similarly, radiotherapy should be avoided in patients with sarcoma with a known germline mutation in *RBI*.

Lymphedema

Lymphedema has long been established as a factor in the development of angiosarcoma. The best-recognized association is with the postmastectomy, postirradiated lymphedematous arm.¹⁶ This is not a radiation-induced sarcoma because the tumors develop outside as well as inside the irradiated field. Similar advanced sarcomas have been seen after chronic lymphedema caused by filarial infection.¹⁷ The oncogenic mechanism remains unknown, but one hypothesis, based on the frequent proliferation of lymphatic vessels in the edematous tissue, is that the block of the lymphatics stimulates growth factors and cytokines, leading to proliferation of vessels and lymphatics.¹⁸ Others have postulated that the edematous tissue results in a regional immune deficiency that enables mutant cells to escape the host's immune surveillance.¹⁹

Radiation

It has been known since 1922 that radiation exposure can cause soft tissue and bone sarcoma. Soft tissue sarcomas are one of the more common types of radiation-associated tumors, both in the general population²⁰⁻²³ and in individuals with cancer susceptibility syndromes.¹⁴ Radiation-associated sarcomas are most often seen in diseases that are commonly treated with radiotherapy and in those in which patient survival is typically long. The prime candidate diseases are breast cancer, lymphoma, genitourinary cancer, and head and neck cancer.²⁴ Children are at risk due to the time latency involved. In a review of 130 patients with primary radiation-associated sarcoma, the median interval between radiotherapy and development of a radiation-associated sarcoma was 10 years (range, 1.3 to 74.0).²⁴ This interval varied significantly by histologic type, with the shortest latency observed in liposarcoma (median, 4.3 years) and longest in leiomyosarcoma (LMS) (median, 23.5 years). The most common histologic types of radiation-associated sarcomas were pleomorphic malignant histiocytoma (PMFH; also known as undifferentiated pleomorphic sarcomas [UPS]; 26%), angiosarcoma (21%), fibrosarcoma (12%), LMS (12%), and MPNST (9%).

The molecular mechanisms of radiation-associated sarcomas are poorly understood. Interestingly, they have a reputation for

originating close to the penumbra of radiotherapy fields, perhaps because incomplete damage in normal tissues may result in mutagenic responses and disorganized reparative proliferation that can eventually trigger tumor induction.

Although uncommon, radiation-induced sarcomas usually have a poor prognosis.²⁴ A multivariate analysis of five common high-grade types of sarcoma showed that radiation-associated sarcoma had a worse disease-specific survival than sporadic soft tissue sarcoma ($p = 0.007$; hazard ratio = 1.7; 95% confidence interval [CI] = 1.1 to 2.4), independent of histologic type and other standard predictors. For PMFH—the most common radiation-associated sarcoma type—the 5-year disease-specific survival was 44%, compared to 66% for a matched cohort of sporadic PMFH patients ($p = 0.07$).

Given the increased use of radiation therapy as a primary treatment for breast cancer, concern has been expressed that the incidence of sarcoma might increase. In a retrospective review of data from the Surveillance, Epidemiology, and End Results database, Huang and Mackillop²¹ analyzed the data on 194,798 women treated for breast cancer between 1973 and 1995. Although follow-up was somewhat short, they demonstrated a 16-fold increase in angiosarcoma in radiotherapy patients versus controls, and a two-fold increase in all soft tissue sarcoma in irradiated patients.

Another study cohort included 295,712 patients with primary cancers registered during 1953 to 2000 in the Finnish Cancer Registry.²⁵ In total, 147 sarcomas were observed (86% of which were soft tissue sarcomas), whereas 88.5 were expected from the national incidence. Among patients with prior breast cancer, 44 sarcomas were observed versus 28.9 expected, a ratio of 1.5 (95% CI = 1.1 to 2.0). After 10 years of follow-up, sarcoma risk was increased among patients who had received neither radiotherapy nor chemotherapy (observed to expected ratio 2.0; 95% CI = 1.3 to 3.0) but was higher in patients who had received chemotherapy and in patients who had received radiotherapy (observed to expected ratio 4.2; 95% CI = 2.9 to 5.8), especially those treated before age 55. These results confirm that the risk of sarcoma is increased after 10 years in tumors other than retinoblastoma but is also independently related to younger age of exposure to radiation, although the risk is also influenced by chemotherapy.²⁵

Trauma

Whether trauma is a predisposing factor is controversial. Abdominal desmoid tumors commonly follow parturition and may be located in the bed of a prior surgery. Moreover, desmoids in the extremity, both localized and multifocal, may be associated with antecedent vigorous physical activity.²⁶ Some authors have speculated that injuries during active sport may predispose to sarcomas in general, and in turn there has been concern that operative trauma, including arthroplasty surgery, may increase soft tissue sarcoma risk. However, Scandinavian studies on more than 100,000 patients who had undergone total hip or knee arthroplasty showed no increased risk of sarcoma, and there were no cases of sarcoma presenting at the site of operation.²⁷ An injury may merely draw attention to a mass, without being a causative factor.

Chemical Agents

Several chemical carcinogens have an established role in the development of hepatic angiosarcomas: thorotrast, vinyl chloride, and arsenic (including Fowler 1% arsenic solution).¹³ The role of other chemical agents in sarcomagenesis remains controversial. Some studies have suggested a link between phenoxy herbicide exposure and development of sarcoma,²⁸ and soft tissue sarcoma was associated with high occupational exposures in a large industrial cohort.^{29,30} However, other studies, including more recent case-control studies, have not confirmed this relationship.³¹ Other authors have pointed to the inherent problems in occupational epidemiology in relation to soft tissue sarcoma,

among which are possible recall bias in self-reported exposure data; inconsistent classification of soft tissue sarcomas in the International Classification of Diseases, which is organ based; and, because of the rarity of soft tissue sarcomas, difficulty in assembling a sufficient number of study participants. Exposure to dioxin (contained in Agent Orange) has been suggested as a risk factor for sarcoma³²; however, none of the reported associations are statistically significant, and several studies found no association.^{33–35}

ANATOMIC AND AGE DISTRIBUTION AND PATHOLOGY

Anatomic and Age Distribution

Soft tissue sarcomas can occur in any site throughout the body. A total of 45% are located in the extremities, with 30% of all lesions occurring in the lower limb (most commonly in the thigh); 38% are intra-abdominal, divided between visceral (21%) and retroperitoneal (17%); 10% are truncal; and 5% are head and neck (Fig. 90.1). Soft tissue sarcomas become more common with increased age, and the median age at diagnosis is 65 years. However, the median age varies significantly by histologic type and subtype. In general, the median age of onset tends to be 20 to 50 years in the translocation-associated sarcomas and 50 to 70 years in the complex sarcoma types (Fig. 90.2).

Pathologic Classification and Defining the Biological Potential

Soft tissue tumors, although clinically often nondistinctive, form a varied and complex group that may show a wide range of differentiation³⁶ (Table 90.1). Their underlying histiogenesis has not been clearly defined. Except for subcutaneous lipomas or benign smooth muscle tumors, there is very little evidence that these lesions arise from their mature (differentiated) tissue counterparts. In fact, many liposarcomas arise at sites devoid of adipose tissue, and most rhabdomyosarcomas, which have molecular markers suggesting a myoid origin, develop in locations that lack voluntary muscle.

Soft tissue tumors may be benign, malignant, or borderline. The ratio of benign to malignant tumors is more than 100:1. Soft tissue tumors are notorious for the ease with which benign and malignant cases may be confused, particularly in small biopsy samples. Sarcoma histologic type is generally an important predictor of distinctive patterns of behavior and prognosis. Although many published series have combined all the histologic subtypes of sarcoma, the importance of such subtyping is exemplified by liposarcoma, in which the five histologic subtypes (well differentiated, dedifferentiated, myxoid, round cell, and pleomorphic) have totally different biologies and patterns of behavior.^{37–40} A further clear demonstration is the importance in pleomorphic sarcomas of myogenic differentiation, which is associated with a substantially increased risk of metastasis.⁴¹

As part of the World Health Organization classification of soft tissue tumors, it is now recommended to divide soft tissue tumors into four categories: benign, intermediate (locally aggressive), intermediate (rarely metastasizing), and malignant.³⁶ Most benign tumors do not recur locally, and those that do recur usually are not locally invasive and can be cured with complete surgical excision. Intermediate, locally aggressive soft tissue tumors often recur locally and are associated with a locally infiltrative growth pattern. Lesions in this category, such as desmoids, do not have any potential to metastasize but typically require wide excision with a margin of normal tissue for good local control. Intermediate rarely metastasizing tumors are often locally aggressive and

Figure 90.1 Distribution by histologic subtype and site of soft tissue sarcomas in 8,959 patients undergoing surgical resection at Memorial Sloan Kettering Cancer Center from 1982 through 2013. The retroperitoneal/abdominal category excludes visceral sarcomas. PNET, primitive neuroectodermal tumor; MPNST, malignant peripheral nerve sheath tumor; GIST, gastrointestinal stromal tumor; PMFH, pleomorphic malignant fibrous histiocytoma; WD/DD, well-differentiated and dedifferentiated.

occasionally give rise to distant metastases. The risk of metastasis, usually to lymph nodes or lung, is typically <2%, but is not reliably predictable based on histology. Examples of intermediate rarely metastasizing tumors include plexiform fibrohistiocytic tumor and angiomatoid fibrous histiocytoma. Malignant tumors (soft tissue sarcomas), in addition to potential for local invasion

and recurrence, have a significant risk of distant metastasis, ranging in most instances from 10% to 100%, depending on histologic type and grade. Some histologically low-grade sarcomas (myxofibrosarcoma, well-differentiated liposarcoma) have a metastatic risk of only 2% to 10%, but these tumor types may progress to more aggressive tumors, acquiring a higher risk of distant spread.

Figure 90.2 Age at diagnosis for sarcoma subtypes. The boxes show median and interquartile range, and the whiskers show range (with outliers excluded) for 8,959 patients undergoing surgical resection at Memorial Sloan Kettering Cancer Center from 1982 through 2013. Sarcoma subtypes with simple genotypes, shown in green, are associated with younger median age at diagnosis than those with complex genotypes, shown in blue. PNET, primitive neuroectodermal tumor; MPNST, malignant peripheral nerve sheath tumor; GIST, gastrointestinal stromal tumor; WD/DD, well-differentiated and dedifferentiated; PMFH pleomorphic malignant fibrous histiocytoma.

PRACTICE OF ONCOLOGY

MPNST, malignant peripheral nerve sheath tumor.

Modified from Fletcher CDM, Bridge JA, Hogendoorn P, et al., eds. *WHO Classification of Tumours of Soft Tissue and Bone*. 4th ed. Lyon, France: IARC Press; 2013.

Clinical and Pathologic Features of Specific Soft Tissue Tumor Types

The distribution of adult soft tissue sarcomas by histologic subtype and anatomic site is shown in Fig. 90.1. Overall, the three most common histologic subtypes are liposarcoma, LMS, and UPS/PMFH.

Fibroblastic and Myofibroblastic Tumors

Fibroblastic and myofibroblastic tumors represent a very large subset of mesenchymal tumors. These lesions are generally composed of fibroblasts and myofibroblasts in varying proportions and may be confused with reactive or reparative processes or alternatively with malignant fibrosarcomas. In addition, some fibrous proliferations of infancy and childhood resemble lesions in the adult but have a better prognosis. With improved understanding of the molecular events that lead to formation of fibroblastic and myofibroblastic tumors, both low- and high-grade forms of the lesions have been reproducibly characterized, although a variety of names are still used to designate identical or overlapping entities.³⁶ Among recent changes in the description of this subset of soft tissue lesions is the inclusion of dermatofibrosarcoma protuberans as a tumor of fibroblastic or myofibroblastic origin. The following sections summarize the features of the most common fibroblastic and myofibroblastic lesions with focus on sarcomas and those that may be mistaken for sarcoma.

Elastofibroma

Elastofibromas are rare, slow-growing benign tumors characteristically arising between the chest wall and the lower part of the

scapula. They may occur bilaterally, and they may grow to large size. Rarely the tumors are observed at the infraolecranon area or near the ischial tuberosities. Elastofibromas have been considered reactive lesions, and they are thought to be associated with repetitive manual tasks. Up to a third of cases are familial, and bilateral subscapular lesions in this context can be diagnosed based on history and imaging alone. For unilateral spontaneous disease, biopsy is commonly employed; histologically, the lesions consist of swollen eosinophilic collagen and elastic fibers with associated fibroblast-like cells. The tumors have copy number alterations in both clonal and nonclonal patterns.^{42,43} If the diagnosis of elastofibroma is definitive, surgical resection can be reserved for the symptomatic patient.^{44,45}

Fibroma

Fibroma is a nonspecific term usually applied to a group of poorly defined lesions in the skin or soft tissue. Management centers on complete surgical resection. While they can recur locally, metastases are not reported. Fibromas are characterized by a collagenous stroma with fibroblastic and myofibroblastic cells rarely demonstrating signs of atypia. While they can occur in unusual locations such as cardiac ventricle, they are more commonly observed in the skin, on the ovary, or associated with tendon sheaths. Nuchal-type fibromas, most commonly found in the posterior neck, are associated with male sex and diabetes mellitus; unlike common fibromas, nuchal-type fibromas can be infiltrative. Histologically similar are fibromas associated with Gardner syndrome, caused by germline APC mutation. These fibromas, which can be found on any area of the body, are commonly associated with metachronous desmoid tumors.

Nodular Fasciitis

Nodular fasciitis is a benign lesion usually seen in adults aged 20 to 40 years. The lesions typically grow rapidly over several weeks and reach 1 to 2 cm but rarely >5 cm. Pain and tenderness are common. The upper extremity is the most common site, especially the volar aspect of the forearm. Nodular fasciitis generally arises in the subcutaneous fascia or the superficial portions of the deep fascia. However, intra-articular fasciitis has been reported. Histologically, the lesions are nodular and nonencapsulated, showing plump mature fibroblasts arranged in short, irregular, or intersecting bundles; some lesions show hyalinization. Over 90% of these tumors have a genomic rearrangement affecting the *USP6* gene, most commonly in the form of a *MYH9-USP6* translocation.^{46,47} Because of their high cellular clarity, rapid growth, and high mitotic activity, these lesions are often confused with fibrosarcoma. They are, however, clinically benign; they generally regress spontaneously and recurrence after local excision is uncommon. Computed tomography (CT) and magnetic resonance imaging (MRI) characteristics are not pathognomonic, although they may show either a solid or some partially cystic changes, usually in the subcutaneous tissues.

Myositis Ossificans

Myositis ossificans is usually associated with trauma. The lesion is a benign disorder that histologically is composed of fibrous tissue and bone. Fibro-osseous pseudotumor of the digits may reflect a similar histopathologic entity. Despite its name, myositis ossificans is not necessarily confined to the muscle, nor is inflammation a prominent feature. The condition usually presents in athletic young adults as a tender soft tissue mass. Over a period of weeks, the mass usually becomes firm to hard. Radiographs show calcification several weeks after the lesion appears. Histologically the mass consists of fibroblastic tissue, often with prominent mitotic activity. Nonetheless, this process is benign and may be managed conservatively. It is important to distinguish between myositis ossificans and sarcoma, especially extraskelatal osteosarcoma. In general, myositis ossificans displays a more ordered growth pattern than osteosarcoma with cellular elements found in the center of the tumor and calcified regions almost exclusively in the periphery.

Superficial Fibromatosis

Superficial fibromatoses arise from the fascia or aponeuroses and generally are small and slow growing; they may be more common in patients with diabetes mellitus. Palmar fibromatosis is associated with flexion contractures (Dupuytren contracture) and is by far the most common form, affecting as many as one in five persons aged 65 years and older. This condition is more common in men than in women and tends to be familial. Although benign, these lesions tend to recur after simple excision. Plantar fibromatosis (Ledderhose disease) tends to occur in a somewhat younger age group but may occur with greater frequency in patients with palmar fibromatosis. Much less common is penile fibromatosis (Peyronie disease), which causes pain and curvature of the penis on erection. The fibrous mass in Peyronie disease primarily involves fascial structures, the corpus cavernosum, and rarely the corpus spongiosum. Peyronie disease is more common in men with palmar and plantar fibromatosis than in the general population. Any of the superficial fibromatoses may be managed by surgical excision, though more recently injection with collagenase or treatment with calcium channel blockers has been shown to have efficacy and may reduce the need for surgery.

Desmoid Tumor

Desmoid tumors (deep or aggressive fibromatosis) are rare lesions with an estimated incidence of two to four individuals per million. Histologically, desmoids are bland tumors, with uniform-appearing spindle cells in a densely hyalinized background. On a microscopic level, they are observed to infiltrate into surrounding normal tissues.⁴⁸ Desmoids most commonly occur in the abdominal wall

(particularly after pregnancy), in the mesentery of the small bowel, and in the extremity. Multifocal lesions are known to occur in a subset of young patients (often diagnosed between ages 10 to 25).^{26,49}

Desmoids do not metastasize, but can be locally aggressive, causing pain, joint contracture, or bowel obstruction. Surgical resection has been the mainstay of therapy. However, compared to other soft tissue sarcomas, desmoids, especially those in the extremities or chest wall, have high local recurrence rates (~15% at 5 years). Nevertheless, individual desmoids exhibit a wide range of behaviors. While some tumors recur after multiple attempts at resection, some never recur, and it is now recognized that some desmoids remain stable in size without any type of intervention. In rare instances, desmoid tumors can cause death, which can result from local compression of vital structures (particularly in the head and neck), fistulization to the bowel by intraabdominal lesions, or injury related to aggressive attempts at resection.

Desmoids, in 85% of cases, have a mutation in exon 3 of the *CTNNB1* gene that activates β -catenin.⁵⁰ In a small proportion of desmoids, β -catenin is activated because of germline mutation in the *APC* gene; these desmoids occur in parallel with familial adenomatous polyposis (classic or attenuated) in Gardner syndrome.^{51,52} Presence and site of *CTNNB1* mutation has been reported to be associated with patient outcome,⁵⁰ but this has not been validated and its use in prognostication is highly controversial.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is a generally indolent lesion characterized by translocation of the *COL1A1* and *PDGFRB* genes.⁵³ The resultant fusion protein activates platelet-derived growth factor (PDGF) receptor signaling, which likely underlies oncogenesis. The tumor, composed of mononuclear spindle cells, is a relatively monomorphous lesion. It involves both dermis and subcutis. DFSP is histologically similar to benign fibrous histiocytoma but grows in a more infiltrative pattern, spreading along connective tissue septa often with unpredictable radial extensions and multifocal nodules. The center of the tumor consists of uniform plump fibroblasts arranged in a distinct ordered pattern. Unlike fibrous histiocytoma, DFSP stains positive for CD34. Variants with melanin pigmentation (Bednar tumor), prominent myxoid stroma, myoid differentiation, and plaque-like morphology are recognized and may be confused with other types of soft tissue sarcomas.

DFSP is a rare sarcoma, but one of the most common cutaneous forms. This lesion typically presents in early or mid-adult life, beginning as a nodular cutaneous mass anywhere in the body. Growth is usually slow but persistent, and over many years it becomes protuberant and satellite nodules become visible. The gold standard of treatment remains surgery, though the infiltrative nature and multifocality of the lesion have historically led to high rates of local recurrence (up to 50% after simple excision in some series). However, when gross margins of ≥ 2 cm are planned, most tumors can be completely resected, and in the context of complete microscopic resection, 5-year local recurrence rates are $\leq 5\%$.⁵⁴⁻⁵⁶ Tumors with positive or close surgical margins in anatomically complex sites (e.g., near the brachial plexus) have an elevated risk of local recurrence, which is ameliorated with adjuvant radiotherapy.⁵⁷ Postoperative radiotherapy is also indicated in the rare patient who has unresectable macroscopic disease. DFSP is sensitive to imatinib,⁵⁸⁻⁶² probably because of constitutive activation of the PDGF receptor. The drug is now approved by the US Food and Drug Administration as the first line of treatment for advanced and metastatic disease. Metastasis (to lung or lymph nodes) occurs infrequently and generally only in the context of fibrosarcomatous degeneration, a high-grade form of the cancer.^{54,63}

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumor (IMT) has gone under the names inflammatory pseudotumor and plasma cell granuloma, among others. Its histology is heterogeneous, with variable group-

ing of spindle, fibroblastic-myofibroblastic, and inflammatory-type cells. The variable appearance may result from the tumor's genetic heterogeneity. While *ALK* rearrangements are common in the myofibroblastic component of the tumors,^{64,65} they occur in <70% of patients (almost exclusively in patients under 40). *ALK* is fused to a range of N-terminal partners, including *RANBP2* and *TPM3*.⁶⁶ Rarely, the *HMGA2* gene on chromosome 12 is rearranged.⁶⁷ Inflammatory components of the tumor do not have *ALK* fusions.^{68,69}

IMT is a locally aggressive process. Many of the tumors occur in the thoracic and abdominal cavities, where they may appear as infiltrative or lobulated lesions on imaging studies.^{70,71} Size and location may cause symptoms related to compression of adjacent organs (e.g., bowel obstruction). Diagnosis of IMT is often difficult to confirm preoperatively; therefore, surgical resection may be both diagnostic and therapeutic. When complete resection is possible, it is curative in ~75% of cases. Metastasis is rare (<5%), but local recurrence is more common.⁷² Treatment of patients with advanced disease has been guided by the *ALK* fusions,^{73–75} and patients with *ALK*-positive advanced IMT have responded to crizotinib (according to Response Evaluation Criteria in Solid Tumors [RECIST]).^{76,77} In patients without an *ALK* fusion, treatment for locally aggressive disease is palliative, recognizing that few tumors have metastatic potential and the disease is rarely fatal (5-year survival of 87%). Of note, about 33% of patients with IMT develop a paraneoplastic syndrome including fever, growth failure, malaise, weight loss, anemia, and thrombocytosis.

Solitary Fibrous Tumor/Hemangiopericytoma

Solitary fibrous tumors (SFT) are identified by a prominent hemangiopericytoma-like branching vascular pattern. SFT encompasses fat-forming SFT and those lesions previously called hemangiopericytomas and giant cell angiofibromas, the latter containing giant multinucleated stromal cells and pseudo-vacuolar spaces. SFTs generally appear as slow-growing, well-circumscribed, painless masses. Histologically, they consist of tightly packed cells around thin-walled vascular channels of varying caliber. SFT cells stain for CD34 but not for factor VIII-related antigen. The lesions likely all have a *NAB2-STAT6* fusion protein that results in aberrant activation of *EGR1* target genes, including *IGF2* and *FGFR1*.^{78,79}

SFT may be found at any location in middle-aged adults (median age, 50). Occasional cases occur in children and adolescents. The adult form is most common in the thorax, pelvis, retroperitoneum, orbit, and lower extremity. Many SFTs are indolent and surgically cured, although some behave like other high-grade sarcomas. Risk factors for metastases include size >10 cm and mitotic rate >4 per 10 high-power fields.⁸⁰ Rarely, patients present with a very large SFT and hypoglycemia (Doege-Potter syndrome), which is associated with production of a form of insulin-like growth factor (IGF) 2 by these tumors.^{81–84} SFTs are highly resistant to standard doxorubicin-based chemotherapy, but sunitinib and sorafenib have activity.^{85,86}

Fibrosarcoma

Adult fibrosarcoma is uncommon (approximately 1% of adult sarcomas).⁸⁷ The tumor typically has many copy number alterations, though these do not appear to affect a single driver oncogene or tumor suppressor.⁸⁸ Fibrosarcoma is a malignant or intermediate (rarely metastasizing) tumor, composed of relatively homogenous spindle cells with variable collagen production and rare pleomorphism. Classical fibrosarcomas have a herringbone pattern on light microscopy. Like most soft tissue sarcomas with complex karyotypes, fibrosarcomas usually involve the deep tissues of the extremities, trunk, head, and neck of middle-aged and older adults. Some arise in the field of previous radiotherapy. Rarely, fibrosarcomas arise in the ovary or other unusual sites such as the trachea.

Infantile fibrosarcomas mimic the adult form histologically but are characterized by *ETV6-NTRK3* fusion and appear to be more indolent than the adult-type tumor.^{89,90}

Myxofibrosarcoma

Myxofibrosarcoma, formerly known as a myxoid variant of malignant fibrous histiocytoma (MFH), is a common type of soft tissue sarcoma. It usually occurs as a painless mass in the limbs and trunk of elderly adults. Histology shows a fibroblastic lesion with pleomorphism, a characteristic curvilinear vascular pattern, and at least a 10% myxoid component.^{41,91,92} Local recurrence occurs in up to 50% of cases, and is associated with tumors having a ≥75% myxoid component.^{93–96} However, a more recent study that treated 80% of patients with myxofibrosarcoma with adjuvant radiation found only a 14.6% local recurrence rate at 5 years and a 24% 5-year cumulative incidence of distant recurrence.⁹⁷

Low-grade myxofibrosarcoma may progress to high grade in subsequent local recurrences and thus acquire a higher probability for metastatic spread. The most common sites of metastases are lung, bone, and lymph nodes. The overall 5-year survival is 60% to 70%.^{93–96} The 5-year disease-specific survival was 80% for patients presenting to Memorial Sloan Kettering Cancer Center (MSKCC) with primary myxofibrosarcoma of the extremity and trunk.

So-Called Fibrohistiocytic Tumors

The concept of fibrohistiocytic differentiation has been challenged, and it is now regarded as a poorly defined morphologic descriptor of histiocytic differentiation. The so-called fibrohistiocytic tumors, originally thought to arise from histiocytes that had fibroblastic potential, are almost certainly fibroblastic in origin. Thus, *fibrohistiocytic* is merely descriptive of their appearance; virtually none of these lesions show true histiocytic differentiation.⁹⁸

Tenosynovial Giant Cell Tumor of Soft Tissue

The tenosynovial giant cell tumors of soft tissue encompasses entities previously called giant cell tumors of the tendon sheath, nodular tenosynovitis, or pigmented villonodular synovitis. These lesions contain multinucleate giant cells, siderophages, foam cells, and inflammatory cells. They are characterized by a t(1;2) translocation involving the colony stimulating factor 1 gene (*CSF1*) and most frequently *COL6A3*. This translocation leads to an increased level of *CSF1*, which is thought to modulate the inflammatory infiltrate noted in these tumors.^{99–101} Three forms of the lesions are recognized: nodular, diffuse, and malignant. Not surprisingly, the form is predictive of biological behavior.¹⁰² The nodular form, which has the greatest abundance of giant cells, is typically a well-circumscribed nodule in the digits. In contrast, the diffuse form has infiltrative borders and most commonly occurs in the large joints (e.g., knee, wrist, foot) or the surrounding soft tissue (e.g., thigh). They can be intra-articular. The malignant-type form demonstrates increased mitotic count and nuclear dysmorphism; these tumors likely have additional molecular alterations (other than *COL6A3-CSF1* translocation) that drive disease progression. Malignant-type tumors may metastasize to lung or lymph nodes.

Surgery is the mainstay of treatment. The recurrence rate is just 10% to 20% for nodular tumors, but 18% to 50% for diffuse-type tumors. With adjuvant radiation, rates of local recurrence may be under 10%.^{103,104} Nevertheless, radiation is rarely used because of risk of joint fibrosis and secondary malignancies. Instead, recurrent or unresectable disease can be treated with a trial of imatinib, an inhibitor of the *CSF1* receptor.¹⁰⁵ Imatinib treatment results in disease stabilization in approximately 75% of patients. However, imatinib appears less effective in the rare diffuse-type tenosynovial giant cell tumors that have a malignant component.¹⁰⁶ Because of their metastatic potential, malignant-type tumors should be managed aggressively as high-grade sarcomas. Multiple recurrent lesions that threaten limb integrity can be controlled with radiotherapy in both the tendon sheath and intra-articular forms.¹⁰³

Fibrous Histiocytoma

Fibrous histiocytomas are benign tumors that usually present as solitary, slow-growing nodules, although up to one-third are multiple. Histologically, they consist of fibroblastic and histiocytic cells often arranged in a cartwheel or storiform pattern. When such lesions occur in the skin, they are often called *dermatofibromas* or *sclerosing hemangiomas*. Superficial lesions usually are cured by simple excision. Deeper lesions should be resected with a wider margin of normal tissue to prevent local recurrence.

In rare cases, fibrous histiocytomas are aggressive (“malignant dermatofibromas”). These lesions have a propensity for local recurrence, have been reported to metastasize, and, in a few patients, can cause death. Copy number alterations have been detected in these tumors, suggesting an underlying molecular aberrancy resulting in an invasive phenotype.¹⁰⁷

Xanthoma

Xanthoma refers to a collection of lipid-laden histiocytes and is seen in diseases associated with hyperlipidemia. These lesions are generally cutaneous or subcutaneous but may involve deep soft tissues. Presumably, xanthomas are reactive lesions.

Adipocytic Tumors

Lipoma

Lipomas are the most common benign soft tissue neoplasm. They usually arise in subcutaneous tissue, most frequently in trunk and proximal limbs. Although deep-seated benign lipomas do occur in the mediastinum or retroperitoneum, most fatty neoplasms in the retroperitoneum should be approached surgically as atypical lipomatous tumor/well-differentiated liposarcoma. Most lipomas are soft, painless, slow-growing, and solitary; however, 2% to 3% of patients have multiple lesions that are occasionally seen in a familial pattern. *Lipomatosis* is a term applied to a poorly circumscribed overgrowth of mature adipose tissue that grows in an infiltrating pattern. Solitary lipomas are lobulated lesions composed of fat cells. They are well circumscribed, being demarcated from surrounding fat by a thin, fibrous capsule. Most subcutaneous, solitary lipomas show reproducible cytogenetic aberrations: translocations involving 12q13–15, rearrangements of 13q, or rearrangements involving 6p21–33.¹⁰⁸ In spindle cell lipoma, mature fat is replaced by collagen-forming spindle cells; this lesion typically arises in the posterior neck and shoulder in men between the ages of 45 and 65 years. Spindle cell lipomas show consistent chromosomal aberrations of 13q and 16q.¹⁰⁹ Local excision of lipoma and these variants is generally curative, with local recurrence after simple excision in no more than 1% to 2% of cases.

Intramuscular lipomas differ from their more superficial counterparts by usually being both poorly circumscribed and infiltrative (in ~90% of cases). Intramuscular lipomas typically present in midadult life as slow-growing, deep-seated masses most often located in the thigh or trunk. In a patient with a deep-seated fatty tumor, it is important to exclude atypical lipomatous tumor (see “Liposarcoma”), which tends to be more common than intramuscular lipoma.

Angiolipomas present as subcutaneous nodules, usually in young adults, and in >50% of cases are multiple. The most common site is the upper extremity. Angiolipomas rarely grow >2 cm, but they often are painful, especially during their initial growth period. Microscopically, these tumors consist of adipocytes with interspersed vascular structures. Myxoid and fibroblastic angiolipomas are recognized.

Hibernoma

Hibernoma is a rare, slow-growing, benign neoplasm that resembles the glandular brown fat of hibernating animals. The literature consists primarily of case reports. Most of these tumors arise within

the thorax, though hibernomas of the trunk, retroperitoneum, and extremities are also reported. Excision is generally curative.

Angiomyolipoma

The term *angiomyolipoma* is used for a nonmetastasizing renal tumor composed of fat, smooth muscle, and blood vessels. Angiomyolipomas of the liver have also been described. Angiomyolipoma is more common in women than in men and is seen in patients with tuberous sclerosis, caused by germline mutations in *TSC1* or *TSC2*. In addition, sporadic angiomyolipomas sometimes have mutation or loss of *TSC1* or *TSC2*, which function upstream of mammalian target of rapamycin (mTOR) signaling.^{110–114} Thus angiomyolipomas may be sensitive to mTOR inhibitors.^{110,115–117} Although angiomyolipoma is usually well demarcated from normal kidney, it may extend into the surrounding retroperitoneum. Angiomyolipomas may be solitary or multicentric, and they may produce abdominal pain or hematuria. Wide excision is curative, but tumors that are asymptomatic and not enlarging may be observed.

Liposarcoma

Liposarcoma is primarily a tumor of adults, with a peak incidence between ages 50 and 65 years. It accounts for at least 20% of all soft tissue sarcoma in adults. Liposarcoma may occur anywhere in the body, although the most common sites are thigh and retroperitoneum. Liposarcoma can be divided into three main biological groups: (1) atypical lipomatous tumor/well-differentiated (ALT/WD) liposarcoma and dedifferentiated liposarcoma, (2) myxoid-round cell, and (3) pleomorphic. Each of these groups has distinctive morphology, natural history, and karyotypic and genetic aberrations, which can be of considerable help in diagnosis.

ALT/WD liposarcoma is a locally aggressive, nonmetastasizing, malignant mesenchymal neoplasm composed of proliferating mature adipocytes with significant variation in cell size and nuclear atypia, at least in foci. ALT/WD liposarcoma usually presents as a deep-seated, painless, enlarging mass that over many years can attain a very large size. ALT/WD liposarcomas can be divided into four main morphologic subtypes: adipocytic (lipomalike), sclerosing, inflammatory, and spindle cell. The characteristic cytogenetic abnormality detected in most ALT/WD liposarcomas is supernumerary ring and giant marker chromosomes with amplification of the 12q13–15 region. This region contains the known oncogenes *CDK4*, *MDM2*, and *HMG2*, which were found amplified in 95%, 87%, and 76% of ALT/WD, respectively.¹¹⁸ Only 1 of 55 ALT/WD liposarcoma tumors had no 12q amplification. Location is an important predictor of outcome in patients with ALT/WD liposarcoma. Extremity tumors rarely recur and have essentially no mortality. In a series at MSKCC, all cases that recurred did so after 5 years and had a significant component of sclerosing morphology.¹¹⁹ In contrast, retroperitoneal and mediastinal tumors may recur repeatedly and eventually result in death from uncontrolled local effects; they may also dedifferentiate and metastasize. Dedifferentiation occurs in up to 20% of ALT/WD liposarcomas, with higher risk in deep locations such as the retroperitoneum. In a series of 99 patients with primary retroperitoneal ALT/WD liposarcoma, the 5-year disease-specific survival was 83% and 5-year probability of freedom from local recurrence was 54%.⁴⁰

Dedifferentiated liposarcoma is defined as an ALT/WD liposarcoma, either primary tumor or recurrence, that shows abrupt transition to a region of nonlipogenic sarcoma at least several millimeters in diameter. Radiologic imaging typically shows coexistence of fatty and nonfatty solid components, which in the retroperitoneum may be discontinuous. Macroscopically, dedifferentiated liposarcoma consists of large multinodular yellow masses containing distinct nonlipomatous (dedifferentiated) areas, which are solid and often tan-gray. The dedifferentiated areas may contain areas of necrosis and hemorrhage. Dedifferentiated liposarcoma appears to have a lower risk of distant metastasis than other high-grade pleomorphic sarcomas. Nevertheless, among 65 patients

with primary retroperitoneal dedifferentiated liposarcoma, 5-year disease-specific survival was only 20% and 3-year local and distant recurrence-free survival was 17% and 70%, respectively.⁴⁰ Dedifferentiated liposarcoma, like ALT/WD, is characterized by ring or giant marker chromosomes and by amplification of the 12q13–15 region. Some other copy number alterations occur at substantially higher frequency in dedifferentiated liposarcoma than in ALT/WD and are thus associated with progression. These include losses centered at 3p14–21, 3q29, 9p22–24, 10p15, 11q23–24, 17q21, and 19q13, and gains at 17p11 and 20q11. Of these progression-associated copy number alterations, the most common, 11q23–24, was noted in 42% of dedifferentiated liposarcoma compared with 4% of ALT/WD. The 11q23–24 loss was associated with genomic complexity and distinct morphology, whereas loss of 19q13 predicted poor prognosis.¹¹⁸

Myxoid or round cell liposarcoma accounts for approximately 40% of liposarcomas. The tumor consists of small, evenly dispersed oval or plump cells with little cytoplasm in a myxoid matrix containing a variable number of fat cells. A small number of signet-ring cells and multivacuolated lipoblasts are often present but are not required for diagnosis. The myxoid-round cell subtype usually occurs in the deep soft tissues of the extremities; in >66% of cases it occurs in the thigh musculature.⁹¹ Rarely, myxoid-round cell liposarcoma may arise in the retroperitoneum or in the subcutaneous tissue. More than 90% of myxoid-round cell liposarcomas have a t(12;16)(q13-14;p11) translocation.¹²⁰ High histologic grade, defined as $\geq 5\%$ round cell component, is a predictor of worse outcome in localized myxoid-round cell liposarcoma. Patients with these high-grade lesions have a 5-year survival of 50%.^{37,121} In general, pure myxoid lesions (0% to 5% round cell areas) are considered low grade and are associated with a 90% 5-year survival. In contrast to other liposarcoma types, myxoid-round cell liposarcomas tend to metastasize to unusual sites in soft tissue or bone, with multifocal synchronous or metachronous spread to fat pad areas in the retroperitoneum and axilla occurring even in the absence of pulmonary metastasis.^{39,121,122} These lesions are also unusual among soft tissue sarcomas in their extraordinarily high response rate to radiotherapy¹²³ and their substantial sensitivity to ifosfamide³⁸ and to the DNA minor groove-binding drug trabectedin.^{124–126}

Pleomorphic liposarcoma, as the name implies, is a pleomorphic, high-grade, highly malignant sarcoma containing variable numbers of pleomorphic lipoblasts. Mitotic activity is high, and hemorrhage or necrosis is common. Pleomorphic liposarcoma accounts for <5% of all liposarcomas. Most arise in patients older than 50 years and occur in deep soft tissue of the extremities (lower more frequently than upper). Clinically, they metastasize early to lung in >50% of patients, and these patients usually die within a short time. Pleomorphic liposarcomas typically have high chromosome counts, complex structural rearrangements, and multiple regions of significant copy number amplification and deletion.¹²⁷ They appear to be somewhat sensitive to gemcitabine-based¹²⁸ and ifosfamide-based chemotherapy.³⁸

Smooth Muscle Tumors

Leiomyoma

Leiomyomas are benign smooth muscle tumors that are quite common in the uterus and the gastrointestinal (GI) tract. Leiomyoma may also occur deep within the extremities, abdominal cavity, or retroperitoneum. Their histologic appearance is benign, with uniform, spindle-shaped nuclei in cells that appear similar to those of normal smooth muscle. Immunohistochemically, the cells are positive for smooth muscle markers such as smooth muscle actin. Angiomyoma is a histologic subtype of leiomyoma that tends to develop on the extremity at ages 30 to 60. Leiomyomas in women often express estrogen and progesterone receptors, which appear to activate Wnt signaling to promote proliferation of tumor stem cells.¹²⁹ These hormone-regulated tumors may regress at

menopause. When they are symptomatic, hormone-regulated tumors can generally be cured by surgical resection; for hormone-receptor-negative tumors, surgery is the treatment of choice.

In three rare clinical scenarios involving symptomatic leiomyomas, management may be difficult. First, cutaneous leiomyoma is a form that arises from the piloerector muscles of the skin. The nodules most often arise on the extensor surfaces of the extremities, and they may follow a dermatomal distribution. Multiple painful tumors may be observed. Although these cutaneous leiomyomas are histologically benign, they frequently recur after surgical excision, and they are often so numerous that excision is not possible. Second, intravenous leiomyomatosis is a rare condition in which nodules of benign smooth muscle tissue grow within the veins of the myometrium and may extend into the uterine and hypogastric veins. Rarely, these tumors extend up the inferior vena cava into the heart. The third management challenge is with diffuse peritoneal leiomyomatosis, which often occurs in association with pregnancy. Compression of adjacent organs may cause obstruction, as in other instances of sarcomatosis.

Leiomyosarcoma

LMSs are malignant lesions that develop from the smooth muscle of blood vessels, visceral structures, or the uterine corpus. Soft tissue LMS usually occurs in middle-aged or older adults and is the predominant sarcoma arising from larger blood vessels. LMSs may arise in any location, but more than half are located in retroperitoneal/intra-abdominal and pelvic sites, most commonly the uterus (see Chapter 73). The tumors are composed of spindle-shaped cells with markers of smooth muscle differentiation such as SMA or desmin. Unlike leiomyoma, however, LMS has many mitotic spindles and may have nuclear and cellular pleomorphism. The LMS genome is characterized by instability and numerous copy number alterations. While most of the copy number alterations are not recurrent, loss of *TP53* and *PTEN* tumor suppressors is common. Recent reports also demonstrate that recurrent mutations in the *MED12* oncogene occur in LMS (at least in uterine lesions).^{130,131}

LMSs can arise in any vessel and may present insidiously with signs of venous outflow obstruction or pain related to encasement of nearby nerves. LMS of the inferior vena cava can present with the Budd-Chiari syndrome.¹³² Treatment of choice is surgical resection. Arterial bypass may be performed. Venous reconstruction, however, is rarely successful, as vein grafts rarely remain patent for prolonged periods. Moreover, patients generally develop collateral veins during the months after resection. Therefore, venous reconstruction can be deferred even in the context of inferior vena cava resection.¹³² Tumor grade and size predict risk of disease-related death; retroperitoneal lesions are generally large and high grade, resulting in recurrence risks of >50%.¹³³ Small LMS-like lesions in the dermis carry no discernable risk of metastasis, and the old term of “cutaneous LMS” has generally been replaced by “atypical intradermal smooth muscle neoplasms.”¹³⁴

Skeletal Muscle Tumors

Rhabdomyoma

Nonmalignant tumors of striated muscle—rhabdomyomas—are rare but are clinically benign. They are subdivided into adult, fetal, and genital type lesions; cardiac rhabdomyomas are associated with the tuberous sclerosis syndrome. Adult and fetal rhabdomyomas are most commonly identified in the head and neck. Rhabdomyoma can be distinguished from rhabdomyosarcoma by its lack of nuclear atypia. Pathogenesis appears to be related to activation of the hedgehog pathway; fetal rhabdomyoma may occur in individuals with a germline mutation in the hedgehog inhibitor *PTCH1*, which is associated with basal cell nevus syndrome. Rhabdomyomas, if symptomatic, are managed with surgical resection.

Rhabdomyosarcomas

Rhabdomyosarcomas (malignant tumors showing skeletal differentiation) are aggressive malignancies that are the most common soft tissue sarcomas of infants and children. Treatment of rhabdomyosarcoma nearly always requires multimodal therapy, typically employing surgery, radiation, and chemotherapy based on a vincristine-dactinomycin-cyclophosphamide backbone.^{135,136} The recognized types are embryonal, alveolar, and pleomorphic.

Embryonal Rhabdomyosarcoma. Embryonal rhabdomyosarcoma is a small-cell tumor showing features of embryonic skeletal muscle. It usually arises in the orbit or genitourinary tract in children, though rare cases arise in adolescents and adults. The botryoid type, which frequently originates in mucosa-lined visceral organs such as the vagina and the urinary bladder, generally grows as a polypoid tumor. Genomic analysis demonstrates that these tumors have various copy number alterations that may directly or indirectly affect activity of oncogenes and tumor suppressors such as RB1, p53, RAS, hedgehog, FGFR4, Akt, ALK, Notch, and β -catenin.¹³⁷⁻¹⁴⁰ These findings have not yet led to clinically useful targeted therapies, but chemotherapy and radiation are very effective for pediatric embryonal rhabdomyosarcomas, even metastatic cases. Embryonal rhabdomyosarcomas in adults usually regress in response to pediatric chemotherapy regimens, but survival is worse for adults than for children.¹⁴¹ Factors strongly associated with poor prognosis in adults are metastatic disease at presentation and poor response to chemotherapy.¹⁴²

Alveolar Rhabdomyosarcoma. Unlike the embryonal type, alveolar rhabdomyosarcoma is observed more commonly in adolescents and adults than in younger children. For younger children, alveolar rhabdomyosarcoma appears to have a worse prognosis than embryonal rhabdomyosarcoma. Histologically, the lesion is composed of ill-defined aggregates of poorly differentiated round or oval cells that frequently show central loss of cellular cohesion and formation of irregular "alveolar" spaces. They cytologically resemble lymphoma cells and show partial skeletal differentiation. In most cases, specific translocations create a *PAX3-FOXO1* fusion gene (in the majority of patients) or a *PAX7-FOXO1* fusion (in a smaller subset); rarely fusion-negative lesions are diagnosed.^{143,144} These fusion genes have prognostic significance (see Chapter 89), so fusion gene status, irrespective of histology, is a critical factor in risk stratification.^{145,146} Some tumors have amplification of the *PAX7-FOXO1* fusion, which is associated with improved outcome though the underlying molecular mechanisms have not been delineated.¹⁴⁷ As in embryonal rhabdomyosarcoma, gene amplifications result in activation of a range of oncogenes. These include *FGFR4*, *ALK*, *CDK4*, and *MYCN*.¹⁴⁸

Pleomorphic Rhabdomyosarcoma. Pleomorphic rhabdomyosarcoma is the most common form of rhabdomyosarcoma in adults and can be associated with prior radiation. Histologically, the tumors have pleomorphic round cells and spindle cells with atypical nuclei and markers of skeletal muscle differentiation. They are characterized by complex copy number alterations. The prognosis for these pleomorphic tumors is poor, and in one series, 28 of 38 patients (74%) died of the disease.¹⁴⁹ Treatment is surgical, but, because of the poor prognosis, eligible patients are given adjuvant radiation and chemotherapy. These tumors are less sensitive to systemic therapies than are embryonal or alveolar rhabdomyosarcomas, but some respond to anthracyclines and ifosfamide; in addition, anecdotes indicate some sensitivity to gemcitabine-based chemotherapy.¹²⁸

Vascular Tumors

Hemangioma

Hemangiomas are among the most common soft tissue tumors. Many are present at birth and regress spontaneously; others

are noted incidentally on imaging studies. They tend to be asymptomatic; however, some grow rapidly, impinge on vital structures, or cause consumptive thrombocytopenias. Imaging studies generally demonstrate a peripherally enhancing mass with lipomatous regions and spiculated calcium deposits. Management by observation is generally safe. For symptomatic disease, surgical resection is generally curative; sclerotherapy has recently been studied. Diffuse hemangiomatosis in the bone or lungs may be treated effectively with systemic interferon.

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma is a low-grade vascular lesion without structured vessels, but with tumor cells arranged in nests and cords. Epithelioid hemangioendotheliomas occur in the bone and associated soft tissues. In malignant disease, multifocal lesions are often observed, generally within the same limb. Metastases may occur in lung, lymph nodes, and bone.¹⁵⁰ A fusion between the N-terminus of *WWTR1* and the C-terminus of *CAMTA1* occurs almost uniformly in these lesions, but not other vascular tumors.^{151,152} Surgical resection is the treatment of choice; however, multifocal disease often recurs. Nevertheless, <20% of patients die of disease. A phase 2 trial has suggested that treatment with bevacizumab may slow progression or induce partial response in the majority of patients.¹⁵³

Angiosarcoma

Angiosarcoma is a malignant tumor composed of malignant cells that morphologically resemble endothelium to various extents. Angiosarcoma is currently considered to include those tumors previously termed lymphangiosarcoma because of their similarities in histology and outcomes.³⁶ Most angiosarcomas develop in the skin or superficial soft tissue; <25% are in deep soft tissue.¹⁵⁴ The disease occurs most commonly in the context of lymphedema (Stewart Treves syndrome) or after prior radiation (particularly radiation for breast cancer).¹⁶ Lymphedema-associated angiosarcoma presents difficulties for surgical planning because poor wound healing may compromise the ability to perform limb-sparing procedures. Another challenge is that lymphedema-associated angiosarcoma has high rates of both local and distal recurrence.¹⁵⁵ Multicentric angiosarcomas on the scalp and face of elderly men typically show unremitting progression, which can cause severe ulceration and infection and eventually metastasis. Features reported to be associated with poor outcome include patient age, tumor depth, and size,^{154,156,157} but in general death from disease is common, with the median time to disease-specific death as short as 3 years in some patient subsets. Surgical resection is rarely curative; however, angiosarcomas are relatively sensitive, at least for brief periods of time, to anthracycline-based chemotherapy and taxanes.^{158,159} The discovery of *KDR* mutations and amplification of *MYC* and *FLT4* has led to the investigation of antiangiogenic therapies in this disease.^{160,161}

Perivascular Tumors

Glomus Tumor

Glomus tumors are rare soft tissue lesions that are almost always benign.¹⁶² The tumors appear to develop from smooth muscle cells associated with the glomus body, a modified arteriovenous anastomosis in the skin involved in thermal regulation. Unlike most soft tissue tumors, glomus tumors can cause considerable pain. They are most commonly found in the distal extremities (subungual region, hand, wrist, and foot) of young adults, though extradigital lesions are reported.¹⁶³ The appropriate treatment is complete local excision. Most patients have sporadic, solitary tumors, for which the underlying genomic alterations are unclear. However, about 10% of patients have multiple lesions, many of

them familial. Some of these patients have heterozygous germline mutations in the *GLMN* or *NF1* genes.^{164,165}

Neural Tumors

Neurofibroma

Solitary neurofibromas are small, slow-growing cutaneous or subcutaneous nodules that usually arise during the third decade of life. Neurofibromas may occur in unidentifiable cutaneous nerves or in larger trunks. Within an identifiable larger nerve, they expand into a fusiform mass and often extend into soft tissue; they are well defined and they may be nodular. Histologically, they show spindle-shaped cells in a myxoid stroma that contains collagen fibers. Multiple neurofibromas may be associated with *NF1* (von Recklinghausen disease), a common genetic disorder caused by an autosomal dominant mutation at the 17q11.2 locus and affecting 1 in 3,000 live births. Clinical features of *NF1* include café au lait spots, pigmented hamartomas of the iris, and neurofibromas of several types. Cutaneous neurofibromas arise in the skin in all patients with *NF1*, with sizes varying from millimeters to centimeters, and some may be painful. Plexiform neurofibromas are larger lesions that affect the large segments of a nerve, thickening and distorting the nerve with greater dysesthetic pain. The difficult distinction is neurofibroma versus MPNST, which may develop in patients with *NF1*. MPNST is usually distinguished based on rapid growth and increasing symptoms, and is confirmed by biopsy.

Benign Schwannoma

Benign schwannoma, also called neurilemmoma, occurs most commonly in people between the age of 20 and 50 years. Common sites include the head and neck, the flexor surfaces of the extremities, and the paravertebral area of the retroperitoneum. The lesion grows slowly, and if superficial is usually small at the time of diagnosis, but it can reach large size in the retroperitoneum without symptoms. The tumor is usually encapsulated and consists of two components: an ordered cellular region (Antoni A area) and a loose, myxoid component (Antoni B area). Fortunately, diagnosis can often be made by percutaneous core or needle biopsy in patients with lesions in the retroperitoneum, where morbidity of operation is to be avoided. The cellular variant is the lesion most often seen late in life as a painless vertebral mass.¹⁶⁶ Complete resection is curative in most patients.

Granular Cell Tumor

Granular cell tumor is a rare tumor, probably of neural origin. It typically presents in adults as a small, poorly circumscribed subcutaneous mass, commonly seen in the oral cavity, and it is only rarely malignant. Granular cell tumors have been seen in all parts of the body, including the pancreas and bile duct. They can occur in multiple sites. Metastases have been reported in approximately 2% of cases, although most reports are single cases.

Malignant Peripheral Nerve Sheath Tumor

MPNSTs are highly aggressive soft tissue sarcomas that rarely occur sporadically in the general population. They may, however, occur with a lifetime incidence of 8% to 13% in patients with *NF1*, an autosomal dominant tumor predisposition syndrome caused by germline mutations in the *NF1* gene.¹¹ Most MPNSTs are associated with major nerves of the body wall and extremities and typically affect adults in the third to fifth decades of life. The lower extremity and the retroperitoneum are the most common sites, but MPNSTs can arise anywhere in the body. These tumors originate from the nerve sheath rather than from the nerve itself. There is also an MPNST with rhabdomyosarcomatous elements, termed a triton tumor, suggesting that the Schwann cell may be the source of a variety of heterologous elements in nerve sheath tumors.¹⁶⁷

Tumor cells are usually elongated, with frequent mitoses, and are arranged in a hypocellular myxoid stroma; pronounced atypia and epithelioid features are also characteristic. The majority of MPNSTs are high grade and characteristically stain for the S-100 protein. Weak S-100 staining in an MPNST is associated with undifferentiated tumors and a five-fold higher risk of distant metastasis.¹⁶⁸ Tumor size and p53 expression remain the most important independent predictors of disease-specific survival.^{168,169} Two recent studies have suggested that patients with *NF1*-associated MPNST have a worse outcome compared to patients with sporadic MPNST,^{170,171} and in one study this outcome difference was independent of tumor size.¹⁷¹

Complete surgical resection with or without adjuvant radiotherapy remains the most important treatment for those patients with primary disease. The role of neoadjuvant chemotherapy for patients with large primary and locally recurrent MPNSTs remains controversial. Overall response rates to chemotherapy are 21%, with improved outcomes noted when ifosfamide is added to adriamycin regimens.¹⁷² With an increasing understanding of the signaling pathways activated in MPNSTs, sorafenib, which targets the mitogen-activated protein kinase pathway, has been tested in single cases and in a histology-specific clinical trial.^{173,174} Patients with *NF1* may be difficult to evaluate, independent of the features of the tumor itself. Staging and follow-up assessments are confounded by the detection of other nodules and masses that, although generally representing benign neurofibromas, need to be distinguished from recurrent local or metastatic disease or a second neurogenic sarcoma.

Extraskelatal Chondro-Osseous Tumors

Extraskelatal Osteosarcoma

Extraskelatal osteosarcomas are rare, high-grade sarcomas defined by production of malignant osteoid and bone. By definition, they are not attached to the skeleton. Unlike typical osteogenic sarcoma of bone, these tumors rarely occur before age 20, and most patients are older than 50 years. Most extraskelatal osteosarcomas arise in the extremities, although they have been reported in other sites, including breast, retroperitoneum, urinary bladder, and other visceral organs. Similar to those osteosarcomas arising from bone, extraskelatal osteosarcomas are highly heterogeneous on the microscopic level. Giant cells are a common feature, but no recurrent genomic events have been characterized. Surgical resection is generally used as single-modality treatment in this disease. Unlike osteogenic sarcoma arising from bone, extraskelatal osteosarcoma is not generally treated with adjuvant chemotherapy, although at least one series indicates a better outcome for patients treated with agents usually employed for classic osteogenic sarcomas.¹⁷⁵

Tumors of Uncertain Differentiation

For most tumors in this category, there is no clear consensus as to the line of differentiation. However, for some tumors, such as synovial sarcoma and clear cell sarcoma, a line of differentiation can be clearly delineated, but no cellular counterpart in normal mesenchymal tissues can be defined.

Myxoma

Intramuscular myxoma is a rare tumor that occurs in adults, usually in the large muscles of the extremities. Myxomas consist of spindle cells without nuclear atypia. The stroma is composed of abundant myxoid tissue. The tumors are not highly vascular and do not enhance on MRI. Increased cellularity has been noted in a subset of lesions, termed "cellular myxomas."¹⁷⁶ Because of the high myxoid component and subset of cellular lesions, myxomas can appear similar to myxofibrosarcomas on biopsy. An aid to diagnosis is mutations in the *GNAS1* gene, which are common in spontaneous myxoma as compared to myxofibrosarcoma.^{177,178}

Multiple intramuscular myxomas occur in association with fibrous dysplasia (Mazabraud syndrome).

Angiomyxoma

Aggressive angiomyxoma is a soft tissue tumor generally identified in the pelvis or perineum of middle aged and older women. The tumors have a highly myxoid stroma with significant vasculature and small spindle or stellate cells without nuclear atypia. Aggressive angiomyxomas typically can slowly grow to large size and generally do not cause obstructive symptoms. Local recurrence is common after surgical resection and can result in considerable morbidity, given the location of these tumors, but distant metastases do not occur. Tumors express high levels of estrogen and progesterone receptors, and advanced disease may be managed with gonadotropin-releasing hormone agonists such as leuprolide. The tumor-initiating cell for angiomyxoma has not been characterized, but rearrangement of *HMGA2* has been observed and appears to be associated with high expression of this oncogene.¹⁷⁹

Neoplasms with Perivascular Epithelioid Cell Differentiation (PEComas)

The family of tumors known as PEComas are associated with neoplastic cells within the walls of blood vessels in the tumors. PEComas include clear cell “sugar” tumors of the lung, angiomyolipomas, and lymphangiomyomatosis (LAM). LAM is characterized by progressive interstitial infiltration of lungs by smooth muscle cells, resulting in cystic changes. It is a rare, progressive cystic lung disease predominantly affecting younger women of reproductive age. In end stages, LAM has been treated by lung transplantation.¹⁸⁰ Angiomyolipomas are benign lesions that may grow quite large, but can safely be observed in most clinical scenarios (see “Adipocytic Tumors”). While angiomyolipomas or LAM do not metastasize, malignant forms of PEComa occur. PEComas such as angiomyolipomas or LAM are found in patients with tuberous sclerosis, and thus it is not surprising that *TSC2* or *TSC1* mutations or deletions are also found in sporadic lesions.^{110,113,181,182} Surgical resection may be sufficient to manage isolated tumors, but for metastatic disease or unresectable lesions, inhibitors of mTOR can be an effective treatment.^{115,183–185}

Synovial Sarcoma

Synovial sarcoma is a spindle cell tumor with varying extents of epithelial differentiation, including gland formation, and is genetically distinct based on specific chromosomal translocations. Synovial sarcomas may be diagnosed at any age but the majority occur in young adults, between 15 and 35 years of age, and more commonly in males.¹⁸⁶ Over 80% arise in deep soft tissue of the extremities, with about 50% in the lower limbs and most of the remainder in the upper limbs. Synovial sarcoma generally does not originate from synovial tissue, and it may be encountered in regions without apparent relationship to synovial structures, including the head and neck (<10%), thoracic and abdominal wall (<10%), or intrathoracic sites. Synovial sarcoma usually presents as a slow-growing mass with or without pain. Histologically, it may be monophasic or biphasic (i.e., composed of two morphologically distinct types of cells). Biphasic tumors have a characteristic pattern of epithelial cells surrounded by a spindle cell or fibrous component. Monophasic synovial sarcomas may be either fibrous or epithelial type, although the epithelial type is extremely rare. Calcification, with or without ossification, is seen in up to 10% of tumors, and synovial sarcoma may be confused with other calcifying tumors (e.g., thyroid neoplasms, which may exhibit calcification). The spindle cells stain positive for keratin, epithelial membrane antigen, and vimentin. S-100 staining may give positive results.

Nearly all synovial sarcomas contain a chromosomal translocation, *t(X;18)(p11.2;q11.2)*.¹⁸⁷ With the observation that 100% of biphasic and 96% of monophasic synovial sarcomas possess this

translocation, it has become the gold standard in diagnosing synovial sarcoma.¹⁸⁸ The translocation fuses the *SS18 (SYT)* gene with either *SSX1*, *SSX2*, or *SSX4*; the specific *SSX* gene involved may have prognostic significance.^{189,190} A recent study has suggested that metastasis in both pediatric and adult synovial sarcoma is strongly associated with genome complexity and with a gene expression signature related to mitotic control.¹⁹¹

Extraskelatal Myxoid Chondrosarcoma

Extraskelatal myxoid chondrosarcoma (EMC) is a malignant tumor characterized by a multinodular growth pattern and by chondroblastlike cells arranged in cords, clusters, or delicate networks within an abundant myxoid matrix. It occurs most commonly in the deep soft tissues of the proximal extremities and limb girdles in patients older than 35 years; two-thirds of patients are male. In contrast to the more common skeletal chondrosarcoma of bone, EMC seldom contains mature cartilage, and there is no convincing evidence of cartilaginous differentiation. Ultrastructurally, EMC is characterized by densely packed intracisternal microtubules and prominent mitochondria, whereas these are not apparent in skeletal chondrosarcoma. In addition, a nonrandom reciprocal translocation *t(9;22)*, fusing the *EWSR1* and *NR4A3* genes, is present in about 50% of EMCs^{192–194} and is not seen in skeletal chondrosarcoma, which supports the idea that the two diseases have different molecular lineages. A second subgroup of EMC is characterized by a *t(9,17)* translocation joining *TAF15* and *NR4A3*.¹⁹⁵ EMCs usually grow slowly and long survival is typical, even in patients with metastases, which usually occur in the lung.¹⁹⁶ Nevertheless, with prolonged follow-up, late local recurrence and metastasis are common. EMC is generally resistant to standard chemotherapy,¹⁹⁷ but sunitinib has produced significant tumor regressions in two patients with advanced EMC.¹⁹⁸

Alveolar Soft Part Sarcoma

Alveolar soft part sarcoma (ASPS) is a rare tumor comprising <1% of soft tissue sarcomas. The tumors are poorly circumscribed lesions that are composed of large epithelioid cells with abundant eosinophilic cytoplasm. The cells are generally arranged in a pseudoalveolar pattern with a highly vascular surrounding stroma. ASPS harbors a *t(17-X)(p11.2;q25)* translocation, resulting in the highly specific *ASPSCR1-TFE3* fusion protein.¹⁹⁹ Like most translocation-associated sarcomas, ASPS is most commonly diagnosed in young adults. Females outnumber males, especially among patients younger than age 20.^{200,201}

ASPS often presents in the lower extremities, most commonly the thigh,^{201,202} as a painless mass. The tumor grows slowly, and patients may remain asymptomatic over years, even with metastatic disease.²⁰³ Local recurrence after surgery is rare, but ultimate prognosis is poor because ASPS characteristically metastasizes early and is essentially impervious to standard chemotherapy agents. In a large study from MSKCC, the survival rate of patients without metastases at diagnosis was 60% at 5 years, 38% at 10 years, and 15% at 20 years.²⁰¹ The *ASPSCR1-TFE3* fusion protein activates transcription of the *MET* oncogene, which drives growth of ASPS cells.²⁰⁴ Ongoing trials are examining the efficacy of *MET* inhibitors such as crizotinib in this tumor.²⁰⁵ The tumors also overexpress angiogenic receptor tyrosine kinases, and indeed targeted inhibitors such as sunitinib and bevacizumab have some efficacy for ASPS.^{206–208}

Epithelioid Sarcoma

Epithelioid sarcoma, characterized by epithelioid and less commonly spindle-shaped cells, generally arises in the extremities. It occurs in two forms: distal-type (conventional) epithelioid sarcoma, occurring most commonly on the volar aspects of the hands and feet, and proximal-type, occurring most commonly on the perineum, groin, thigh, buttock, or less commonly the axilla. The proximal-type variant consists of large epithelioid carcinoma-like cells with pronounced cytologic atypia and prominent nucleoli frequently exhibiting rhabdoid

features.²⁰⁹ It often grows in a multinodular pattern. Both proximal- and distal-type epithelioid sarcomas often have central regions of necrosis when examined histologically. Tumors located in deep tissue may spread along fascia planes, and thus epithelioid sarcoma requires extensive wide excision for complete tumor removal. Epithelioid sarcoma is also one of the few sarcomas in which lymph node metastases are fairly common, occurring in 20% of patients. Gross nodal disease should be biopsied, and if disease is present but the patient has no apparent distant metastases, a complete lymph node dissection should be considered. The role of sentinel node biopsy is highly debatable, with no proven effect on outcome.

Prognosis for patients with epithelioid sarcoma is generally poor. In a recent series that included 54 patients with localized disease,²¹⁰ the 5-year local recurrence-free survival was 54%, distant recurrence-free survival 53%, and overall survival 62%. Independent predictors of worse survival were higher grade and deep location. Epithelioid sarcoma is moderately sensitive to chemotherapy, although responses are typically short lived. Compared with the distal variant, the proximal variant is associated with a more aggressive clinical course, resistance to radiation and chemotherapy, and worse disease-specific survival.^{209,211–214} Genetic analysis of epithelioid sarcoma is beginning to define molecular mechanisms for pathogenesis. Aberrations that have been seen include loss of the *SMARCB1* tumor suppressor and upregulation of the epidermal growth factor receptor and mTOR pathways. Combined inhibition of these two pathways inhibited epithelioid sarcoma cell growth in vitro and in a xenograft model.^{215,216}

Clear Cell Sarcoma (Melanoma of Soft Parts)

Clear cell sarcoma, initially described by Enzinger,²¹⁷ is a sarcoma with melanocytic differentiation, typically involving the tendons and aponeuroses of young adults. The lesions are composed of epithelioid-type cells clustered in nests, each surrounded by collagenous bands. Clear cell sarcoma presents as a slowly growing soft tissue mass. Up to 50% of patients have pain or tenderness. Because its cells contain melanin and it tends to metastasize to regional nodes, clear cell sarcoma is considered to behave more like a melanoma than a soft tissue sarcoma. Genomic profiling and cluster analysis has also grouped these lesions more with melanoma than with sarcomas.²¹⁸ However, unlike melanoma, clear cell sarcoma typically has a chromosomal translocation. In >75% of cases, this is t(12;22), fusing the *EWSRI* and *ATF1* genes.²¹⁹ The fusion product activates the kinase MET, giving hope that MET inhibitors will have activity against this group of tumors.²²⁰

The treatment of choice is surgical resection. Gross disease in the lymph node basin is removed in tandem with wide resection of the primary tumor. Given the propensity of this subtype to nodal metastasis, sentinel node biopsy can be considered, though its clinical utility is debated.²²¹ Size is a prognostic factor in outcome, and the majority of tumors are <5 cm at diagnosis. Metastasis is common, and 5-year survival approaches 50%. Chemotherapy has limited benefit, with platinum-containing regimens offering the most potential benefit, though recent reports suggest that antiangiogenic treatment (e.g., sorafenib and sunitinib) may have activity.^{222,223}

Desmoplastic Small Round Cell Tumor

Desmoplastic small round cell tumor is composed of monotonous blue cells as stained on hematoxylin and eosin stain. The cells have little cytoplasm and may be arranged in nests or in an infiltrative pattern within a prominent desmoplastic stroma.²²⁴ The tumors are characterized by a specific t(11;22) translocation, fusing the *EWSRI* and *WT1* genes.^{225,226} The disease usually arises in children and young adults, in whom abdominal sarcomatosis is a common presentation. For this reason, prognosis is generally poor and management can be difficult. In a review of 40 histologically proven cases, only 30% of patients were alive at 3 years from diagnosis.²²⁷ Surgical resection is possible for isolated tumors, but more commonly, patients are managed with front-line chemotherapy

followed by debulking. Factors associated with improved overall survival are gross total resection and good responses to chemotherapy agents, such as that used for Ewing sarcoma.^{227,228}

Undifferentiated/Unclassified Tumors

High-Grade Undifferentiated Pleomorphic Sarcoma/Pleomorphic Malignant Fibrous Histiocytoma

MFH was originally defined as a malignant pleomorphic spindle cell tumor with fibroblastic and histiocytic differentiation. However, pathologists now agree that this morphology may be shared by a wide range of malignancies.⁹⁸ Careful immunohistochemical and histopathologic analysis showed that many sarcomas previously classified as pleomorphic MFH had a specific line of differentiation and could be reclassified as myxofibrosarcoma (30%), myogenic sarcoma (30%), myofibroblastic sarcoma (11%), liposarcoma (4%), soft tissue osteosarcoma (3%), or malignant peripheral nerve sheath tumor (2%), whereas only 16% had no specific line of differentiation.⁴¹ Thus, the term UPS is now reserved for pleomorphic sarcomas that by current technology show no definable line of differentiation.^{41,92,98} UPS characteristically is a tumor of later adult life with peak incidence at ages 60 to 70. UPS usually presents as a painless, deep-seated mass; the most common site is the lower extremity, followed by the upper extremity. A subset of UPSs arise at the site of prior radiotherapy²⁴ and very rare cases arise at the site of chronic ulceration. About 5% of patients present with metastasis, typically to lung. Clinical and pathologic studies have shown a remarkable degree of heterogeneity of morphologic and biological features, prognosis, and treatment response. UPS typically has an aggressive clinical course, with many patients developing metastatic disease within 3 years of diagnosis. The 5-year disease-specific survival was 65% for patients presenting to MSKCC with primary UPS of the extremity and trunk.

Histologic Grading

After establishing the diagnosis of sarcoma, the most critical piece of information the pathologist can provide to the clinician is histologic grade. Grading, based on morphologic features only, evaluates the degree of malignancy and predicts outcomes, mainly the probability of distant relapse. The pathologic features that define grade include mitotic index, necrosis, cellularity, pleomorphism, and histologic type and subtype or differentiation; the two most important factors seem to be the mitotic index and the extent of necrosis.^{91,229} Unfortunately, the criteria for grading are neither specific nor standardized, and there is no general consensus on the morphologic criteria to use. Several grading systems are used: a four-grade system (Broders),²³⁰ three-grade systems such as the National Cancer Institute (NCI) grading system²³¹ and that of the Sarcoma Group of the French Fédération Nationale des Centres de Lutte Contre le Cancer (FNCLCC),²³² and a two-grade system as is used at MSKCC.²³³ All of these grading systems have proven to correlate with overall survival and disease-free survival.

In general, the two most widely used grading systems are the NCI system²³¹ and the FNCLCC system.²³⁴ Both are three-tier systems (high/intermediate/low). A comparative study showed that the prediction of distant metastasis and tumor mortality was slightly better with the FNCLCC system than with the NCI system.²³² However, two studies have evaluated the interobserver reproducibility of the FNCLCC system and showed only 60% to 75% agreement on tumor grade and 61% to 75% agreement on histologic type.^{235,236} This high level of disagreement (25% to 40%) even among expert sarcoma pathologists emphasizes the importance of histologic peer review and the need for more objective systems for sarcoma grading and classification.^{235–237} In fact, neither the FNCLCC nor NCI system has been formally endorsed

by either the World Health Organization⁹¹ or the Association of Directors of Anatomic and Surgical Pathology.²³⁸

In the MSKCC system, grade is classified as high or low based on the degree of mitotic activity, necrosis, cellularity, and tumor differentiation.²³³ Grade in this system has excellent correlation with clinical outcome in many histologic types and has proven to be one of the most important independent predictors of disease-specific survival.²³⁹ In addition, this system avoids the management dilemma of an “intermediate” grade, which in most institutions would be lumped with and treated as high-grade sarcoma, potentially resulting in overtreatment. The authors recognize that in certain situations (approximately 5% to 10% of cases), the distinction between low- and high-grade tumors can be quite difficult, and therefore an intermediate grade would seem the most suitable. These difficult cases can be graded most appropriately by using systematic sampling and thorough examination.

Although there is widespread use of some form of grading system in the diagnosis and management of sarcomas, there is also agreement that no current grading system performs well for every type of sarcoma. For multiple reasons, certain histologic types of sarcoma do not lend themselves well to grading. An example is myxoid/round cell liposarcoma, where round cell histology in just >5% of tumor area is sufficient to predict high-grade behavior, with a >50% risk of distant metastasis.¹²¹ In addition, unequivocal characterization of grade is difficult in large lesions, especially in tumors that can reach 2 or 3 kg.

The lack of standardization on grading has obvious clinical implications. In adjuvant chemotherapy trials, high grade is defined differently at different centers, which makes it hazardous to compare results between trials or to combine results of multiple trials. For example, tumors of 240 patients who participated in the Scandinavian Sarcoma Group adjuvant trial for high-grade extremity sarcoma were reviewed by a panel of reference pathologists. Eligibility was limited to patients with grade 3 or 4 sarcomas in a four-grade system. On review, 5% of the patients were considered ineligible because their tumors were low grade.²³⁵ In addition, the original pathologists and the reference pathologists had considerable discordance with regard to whether a lesion was grade 3 or 4. Although the adjuvant regimen did not affect survival, a difference in survival was noted between patients with tumors of these two grades as assigned by the reference pathologists.

Grading needs to be adapted to the modern management of patients with sarcoma, who often undergo a limited core biopsy rather than an open incisional biopsy. Grading on such limited material needs to be complemented with imaging and molecular data. Extent of necrosis may best be evaluated by imaging studies because they enable macroscopic examination of the entire tumor. Both MRI and magnetic resonance spectroscopy have been used to assess necrosis, chemotherapy response, and grade in sarcoma. Mitotic index is difficult to determine on limited core biopsy material, and MIB-1 (Ki-67) scores of proliferation may be more reproducible²⁴⁰ and have better predictive value than grading using mitotic index.²⁴¹ Other molecular characteristics, such as mutation or nuclear overexpression of TP53 and high Ki-67 proliferation index, are associated with high grade and poor survival.²⁴² A gene expression signature of 67 genes related to mitosis and chromosome management, the Complexity Index in Sarcomas was an independent predictor of metastasis outcome even adjusting for histologic subtype and FNCLCC grade and is superior to the FNCLCC grading system in determining metastatic outcome for sarcoma patients.^{243,244}

DIAGNOSIS AND STAGING

Clinical Features

The presence of soft tissue sarcoma almost invariably is suggested by the development of a mass. This mass is usually large, is often

painless, and may be associated by the patient with an episode of injury. Approximately one-third present with a size <5 cm, one-third with a size 5 to 10 cm, and one-third with a size >10 cm. The focus of the clinical evaluation is to determine the likelihood of a benign or malignant soft tissue tumor, the involvement of muscular or neurovascular structures, and the ease with which biopsy or subsequent excision can be performed. Size becomes an important feature (see “Prognostic Factors”), and definitive diagnosis depends on biopsy results and histologic confirmation.

Differential Diagnosis

The differential diagnosis of a soft tissue mass includes, in addition to sarcoma, a variety of benign lesions, as well as primary or metastatic carcinoma, melanoma, and lymphoma. The major concern when confronted with a soft tissue mass is determining whether the lesion is benign or malignant. In most patients with small lesions, or even on occasion large lesions, the important distinction is lipoma, the most common soft tissue tumor, versus other tumors. Most benign lesions are located in superficial (dermal or subcutaneous) soft tissue. This differentiation may be simple, but it becomes more difficult as the more aggressive and underappreciated inherently benign lesions are considered. Particularly difficult is myositis ossificans. The patient often has a history of trauma and often presents with a large, firm-to-hard lesion that, on plain film, may have intrinsic calcification. However, these signs do not preclude a malignant lesion. With myositis ossificans, Tru-Cut (CareFusion Corporation, San Diego, CA) needle biopsy or open biopsy is often accompanied by aggressive hemorrhage, which suggests a vascular neoplasm. In most cases, diagnosis can be made fairly accurately by either plain film or MRI scan. Certainly, myositis ossificans should be suspected when there is a significant history of trauma and the lesion is particularly hard and has inherent calcification.

For diagnosis to be accurate, the biopsy must be adequate and representative of the tumor, and the tissue must be well fixed and well stained. Antibodies for immunohistochemical staining are available commercially, and this technique is readily applicable to paraffin-embedded tissues. The most useful immunohistochemical markers are the intermediate filaments (e.g., vimentin, keratin, desmin), leukocyte common antigen, and S-100. In addition, the pathologist should be prepared to process tissue from selected cases for electron microscopy, cytogenetic studies, or molecular analysis. This requires that the clinician and pathologist communicate before the biopsy is performed to ensure that the necessary steps are taken in handling the tissue.

Cytogenetic analyses reveal specific clonal chromosomal aberrations, most commonly reciprocal translocations, in the majority of sarcomas.^{225,245–248} Among these are 11 different translocations involving the *EWSR1* gene or its family members (*FUS*, *TAF15*) found in five different sarcomas. In a significant subset of sarcomas, translocations can be diagnostically and occasionally prognostically useful. Because conventional cytogenetic analysis is labor intensive and requires short-term culture of the sarcoma cells, molecular genetic techniques (e.g., reverse-transcriptase polymerase chain reaction and fluorescence in situ hybridization [FISH]) may be useful diagnostic adjuncts, particularly for diagnosing and distinguishing among the small cell sarcomas. Oligonucleotide and complementary DNA arrays may eventually add to the sophistication of determining the diagnosis and prognosis of such tumors.²⁴⁸ FISH testing for specific chromosomal abnormalities is now feasible for routine diagnostic use. FISH is also useful to identify supernumerary ring chromosomes, seen in mesenchymal neoplasms of low or borderline malignancy, such as dermatofibrosarcoma protuberans. Table 89.1 in Chapter 89 (“Molecular Biology of Sarcomas”) describes some of the genetic changes identified in soft tissue sarcomas.

As might be expected, there can be considerable disagreement among pathologists on the specific histologic diagnosis in

individual cases. When a panel of expert pathologists reviewed pathologic material from 424 patients who entered into Eastern Cooperative Oncology Group sarcoma trials, 10% of cases were rejected as not being sarcoma, and 16% were the subject of disagreement on the histologic subtype.²⁴⁹ In the Scandinavian Sarcoma Group experience, the specific histologic diagnosis was disputed in 20% of cases.²³⁵ Of 1,463 histologic specimens obtained from patients with connective tissue tumors in France and Italy, grade and histologic subtype were confirmed by an expert pathologist in only 56% of cases. The discordance for 35% of patients was a different characterization of histologic subtype or grade, and in 8% was complete discordance (recharacterized as benign, different histology, or not a sarcoma).²⁵⁰ With increasing familiarity with the immunohistochemical and genetic studies needed to diagnose soft tissue sarcoma, the rate of this discordance may be decreasing.

Imaging

Imaging studies for soft tissue sarcoma vary, depending to some extent on the site. They involve evaluation of both the primary lesion and the potential site of metastasis. Evaluation of the primary lesion in the extremity and head and neck predominantly is by either CT or MRI. Although MRI provides some increased definition, a Radiology Diagnostic Oncology Group study comparing these modalities showed no benefit of MRI over CT.²⁵¹ For the primary sarcoma of intra-abdominal, chest, or retroperitoneal locations, a spiral CT scan is preferable to MRI because air-tissue interface and motion artifacts often degrade MRI quality. In addition, spiral CT allows both the primary and potential for metastasis to be assessed in a single study. What is clear in this era of cost containment is that imaging with multiple modalities, all focusing on the same entity, is not required.

Positron Emission Tomography

Positron emission tomography (PET) has a number of potential uses in sarcoma management, although it has yet to gain universal acceptance. The standard uptake value in ¹⁸F-fluorodeoxyglucose (FDG) PET has been associated with histopathologic grade, cellularity, mitotic activity, MIB-1 labeling index, and TP53 overexpression, but it has never been proven to provide independent prognostic information and frequently fails to distinguish benign tumors from low-grade sarcomas.²⁵²⁻²⁵⁴

PET may also become useful for determining early responses to systemic therapy for soft tissue sarcoma. Specifically for primary extremity sarcomas, response by FDG-PET was superior to radiologic tumor size changes as a predictor of outcome after treatment with neoadjuvant chemotherapy.²⁵⁵⁻²⁵⁸ Similar results have been found for pediatric sarcomas. FDG-PET has been used for the early prediction of chemosensitivity in patients with soft tissue sarcomas who received neoadjuvant chemotherapy; the accuracy was 83% and positive predictive value for responders was 92%.²⁵⁹ Further studies are needed to determine if FDG-PET is sufficiently specific and accurate in determining chemotherapy response to alter clinical decisions on continuing, discontinuing, or modifying the treatment.

The current role of PET seems to be primarily in the identification of unsuspected sites of metastasis in patients with recurrent high-grade tumors, given the high rate of metastatic disease in this setting.

Imaging Sites of Metastasis

As important as imaging studies of the primary lesion is evaluation of possible sites of metastasis. For patients with extremity lesions, most metastases (70%) go to the lung.²⁶⁰ For patients with retroperitoneal or visceral lesions, a much more common site for

metastases is the liver, with lung only a secondary site. Nevertheless, no site is immune from soft tissue sarcoma metastasis, and other patterns can be identified (e.g., intra-abdominal soft tissue metastases or pelvic or spinal bony metastases of extremity myxoid or round cell liposarcomas).^{122,261}

Lymph node metastases are uncommon, except for certain histologic types usually associated with childhood sarcoma.²⁶² In the MSKCC experience,²⁶² 3.7% of 1,066 patients with extremity soft tissue sarcoma had lymph node metastasis. Higher prevalence was seen in epithelioid sarcoma, 3 of 15; rhabdomyosarcoma, 4 of 21; clear cell sarcoma, 2 of 18; and angiosarcoma, 2 of 18. These findings were confirmed by a report from the Royal Marsden Hospital,²⁶³ with 3.4% of 2,127 patients having regional lymph node metastasis. Again, prevalence was higher with rhabdomyosarcoma, epithelioid sarcoma, and angiosarcoma. Thus, for these subtypes, the draining lymph node basin should be subjected to careful clinical examination and complete imaging if indicated.

Patients with visceral and retroperitoneal lesions should have their liver imaged as part of the initial abdominal CT or MRI. For extremity sarcomas, imaging for metastasis is less important for patients with low-grade or small superficial high-grade extremity lesions, and simple chest radiography will suffice. Conversely, for patients with deep or large high-grade extremity lesions, for which the risk of metastatic disease is significant, more extensive evaluation with a CT scan of the chest is often preferred. Although CT is the most commonly used modality to evaluate pulmonary metastases, it is more expensive than radiographs, delivers a higher radiation dose, and may give false-positive results because of small, indeterminate pulmonary nodules. One study correlated thoracotomy with CT and found that only 60% of malignant nodules <6 mm in size were found at thoracotomy.²⁶⁴ It is unclear if there is a better imaging modality to evaluate metastases of <1 cm. Newer techniques, such as FDG-PET, are being used to evaluate distant metastases and, when combined with CT and conventional imaging, may improve the diagnostic accuracy of preoperative staging. However, overstaging remains a problem in 12% of patients, and PET-CT remains limited in evaluating pulmonary metastases of <1 cm.²⁶⁵ FDG-PET lacks specificity in its ability to distinguish between low-grade malignancies and benign entities. An additional concern is that many low-grade sarcoma types and several high-grade types, like round cell liposarcoma, do not reliably show uptake for FDG, further limiting its routine use for staging sarcoma patients.

Biopsy

Biopsy can be used to evaluate malignancy, histologic grade, and sometimes histologic type. Precise knowledge of these features enables the treating physician to tailor the treatment plan to the tumor's predicted pattern of local growth, risk of metastasis, and likely sites of distant spread. Either an incisional biopsy or several Tru-Cut core biopsies are required to obtain enough tissue for definitive diagnosis and accurate grading. The biopsy incision or core track should be placed in a location that can be completely excised at the time of definitive resection with minimal sacrifice of overlying skin. Excisional biopsy should be avoided, especially for lesions >3 cm in size, as the contamination of surrounding tissue planes may require the definitive resection to be more extensive.

In general, the important issue with biopsy is the adequacy of the sample. Sufficient viable tissue is required that is both representative of the lesion and available for histopathologic evaluation, immunohistochemistry, and, when necessary, cytogenetics and electron microscopy. As molecular markers become a factor in diagnosis, meticulous attention to the adequacy of biopsy, tissue preservation, and evaluation will be paramount.

Value of Tru-Cut Biopsy

Several studies have examined the value of Tru-Cut biopsy.²⁶⁶ Its accuracy is lower than for incisional biopsy, though substantially

higher than for frozen section, and Tru-Cut biopsy has the advantage that it can be done in an office setting.

Fine Needle Aspiration Cytology

Fine needle aspiration (FNA) cytology has been examined by a number of authors but is usually used only for the confirmation of recurrence rather than for the primary diagnosis. Particular problems with FNA are the limited sampling and lack of tissue architecture, which degrade diagnostic accuracy. In addition, the amount of tissue collected usually does not allow for ancillary molecular diagnostic techniques.

Some authors have argued that biopsy itself is not justified if FNA is available. Rydholm²⁶⁷ suggested that open biopsy is never indicated, arguing that open biopsy risks local tumor spread and increases both the magnitude of the subsequent operation and the need for adjuvant radiation therapy. Using FNA, the surgeon proceeds directly to open operation. However, this requires referral before antecedent biopsy, a relatively uncontrollable event in the United States. Other authors suggest that this approach results in the referral of 10 patients with benign lesions for every sarcoma patient, certainly an untenable situation under our care system.

The no-biopsy approach presupposes that all that is required is a malignant sarcoma diagnosis and that the type or grade of sarcoma does not determine therapy. The use of FNA in patients with large sarcomas who are candidates for neoadjuvant therapy is also problematic due to difficulty in grading and subtyping these tumors accurately from such small samples. However, proponents argue that immunohistochemistry, electron microscopy, DNA cytology, and chromosomal analysis, all of which can be performed on FNA specimens, will ensure the appropriateness of this approach. However, the authors still favor obtaining adequate tissue from several Tru-Cut cores or an incisional biopsy to determine a definitive histologic diagnosis and grade before initiating treatment.

Frozen Section

In some institutions, frozen section is the diagnostic tool of choice. For diagnosis of malignancy, frozen section is accurate, but for histopathologic subtypes and grade, it is inferior to permanent sections of either Tru-Cut or incisional biopsy.²⁶⁶

Sarcoma Staging

The intent of staging systems is to group patients according to their probability of metastasis, disease-specific survival, or overall survival. The major staging used for soft tissue sarcoma is the system developed by the American Joint Committee on Cancer (AJCC). This system, first developed in 1992, has undergone significant changes, based on both histologic and clinical information. The current 2010 AJCC TNM (tumor, node, metastasis) system (Table 90.2) incorporates histologic type, histologic grade, tumor size, depth, regional lymph node involvement, and distant metastasis. It incorporates four major changes compared with the 2002 system. First, it excludes four histologic types: gastrointestinal stromal tumor (GIST), desmoid tumor, Kaposi sarcoma, and infantile fibrosarcoma. Second, it adds three histologic types: angiosarcoma, extraskeletal Ewing sarcoma, and dermatofibrosarcoma protuberans. Third, it reclassifies N1 disease from stage IV to stage III. Fourth, grading has changed from a four-grade to a three-grade system, although it accommodates two-, three-, and four-tiered grading systems.²⁶⁸

Analysis of the primary extremity soft tissue sarcomas seen at MSKCC during 1982 to 2009 suggests that the AJCC 2010 staging system nicely discriminates the probability of metastasis and disease-specific survival (Fig. 90.3 and Table 90.2). However, the AJCC staging still has limitations. A recent analysis suggested that risk assessment would be improved by increasing the number of primary tumor size categories from two to four. The analysis also suggested

TABLE 90.2

that patients with N1 M0 disease, whom the AJCC 2010 has moved to stage III, in fact have survival intermediate between that of other stage III patients and the stage IV patients.²⁶⁹ Unfortunately, this system still fails to adequately account for sarcomas located in the retroperitoneum and may incompletely account for the influence of specific histologic subtypes on outcome. There is as yet no adequate staging system for retroperitoneal or intra-abdominal lesions.

Nomograms

The accuracy of predicting patient outcomes can be increased by integrating multiple clinical and histologic features in a predictive model such as a nomogram. To predict sarcoma-specific survival, MSKCC researchers developed nomograms that integrate information on patient age and tumor size, grade (low versus high), depth, site, and histopathology. Nomograms are available for both primary lesions²⁷⁰ and locally recurrent²⁷¹ lesions. These nomograms can be readily transferred to handheld personal organizers for instant calculation of disease-specific survival probability. Because no current grading system performs well for every histologic type of sarcoma, the authors' groups have recently developed his-

Figure 90.3 Disease-specific survival for patients with extremity soft tissue sarcoma according to the 2010 American Joint Committee on Cancer staging system. The data are for 3,322 patients seen at Memorial Sloan Kettering Cancer Center from 1982 through 2013.

tology-specific nomograms in liposarcoma,³⁷ synovial sarcoma,²⁷² and GIST.²⁷³ Site-specific retroperitoneal nomograms have been developed^{274–276} as well as a local recurrence nomogram for patients with primary extremity sarcoma to improve selection for adjuvant radiation.²⁷⁷ As new molecular and genetic biomarkers are discovered and shown to have prognostic value, they can be incorporated into nomograms along with conventional clinical-pathologic variables. This would enable the treating physician to design a treatment strategy tailored to an individual patient's risk of relapse and potential for an aggressive clinical course.

Histologic and Prognostic Factors for Primary Extremity and Truncal Sarcoma

Histopathology is related to anatomic site (see Fig. 90.1), and the common histologic types in the extremities and trunk are liposarcoma, myxofibrosarcoma, UPS/PMFH, and synovial sarcoma. Clinical and pathologic factors that influence outcome were determined from analysis of prospectively collected data from 1,041 patients older than 16 years with localized soft tissue sarcoma of the extremity.²³⁹ The 5-year survival rate was 76%, with a median follow-up of 4 years. Factors that increased risk of local recurrence were age, recurrent disease at presentation, positive margin, and fibrosarcoma or MPNST histology. Factors that increased the risk of disease-specific death were tumor size, depth, and grade, recurrent presentation, positive margin, and MPNST or LMS histology.

Distant recurrence was associated with tumor size, depth, and grade, recurrent presentation, LMS histology, and, to a lesser extent, any nonliposarcoma histology. High-grade lesions have a much greater risk of developing a distant metastasis in the first 30 months. Even low-grade lesions, however, have a slow but inexorable increase in risk of metastasis over the long term.²³⁹ Prognostic factors clearly vary with time. Grade is a dominant factor in early metastasis, but in late recurrence initial size becomes equally important.²⁷⁸ Postmetastasis survival for most patients is independent of factors involved in the primary presentation, although an association has been found with tumor size.

Bone invasion and neurovascular invasion have historically been considered bad prognostic features. However, bone invasion is relatively uncommon in soft tissue sarcoma, so it has not been uniformly included in any staging system.

Five-year survival does not guarantee cure. An analysis of patients disease-free 5 years after the diagnosis and treatment of extremity lesions showed that 9% would go on to have a recurrence in the next 5 years.²⁷⁹ Unfortunately, survival has not measurably improved with time when corrected for stage.²⁸⁰ A review of 1,261 completely resected extremity lesions by 5-year increments for 1982 to 2001 suggested that disease-specific actuarial 5-year survival remained unchanged (approximately 79%) over 20 years. For high-risk patients (those with high-grade, deep tumors of >10 cm), disease-specific survival remains at around 50%.

Site of disease is a clear determinant of outcome and an important prognostic factor. Patients with extremity and superficial trunk lesions certainly do better than patients with retroperitoneal and visceral sarcomas (Fig. 90.4). Death from local recurrence is uncommon in those with extremity lesions but occurs frequently in patients with retroperitoneal liposarcoma.

Innumerable molecular markers have been defined for soft tissue sarcoma—some with prognostic implications—but they have not been included in staging systems. However, the authors expect them to become increasingly important variables.

Diagnostic and Prognostic Factors for Primary Retroperitoneal/Intra-Abdominal Sarcoma

Most patients with retroperitoneal or intra-abdominal sarcoma present with an asymptomatic abdominal mass. On occasion pain

Figure 90.4 Disease-specific survival by site of soft tissue sarcoma. The data are for 6,382 patients admitted to Memorial Sloan Kettering Cancer Center from 1982 through 2013. Patients with retroperitoneal or visceral sarcomas did worse than patients with extremity lesions.

is present, and less common symptoms include GI bleeding, incomplete obstruction, and neurologic symptoms related to retroperitoneal invasion or pressure on neurovascular structures. In one report, only 27% of patients with retroperitoneal sarcoma had neurologic symptoms, which primarily were related to an expanding retroperitoneal mass.²⁸¹ Weight loss is uncommon, and incidental diagnosis is the norm. The diagnosis is usually suspected on finding a soft tissue mass on abdominal CT or MRI. Often the diagnosis is clear without biopsy, and many proceed directly to operative resection in the absence of a clinical trial. FNA biopsy or CT-guided core biopsy has a limited role in the routine diagnostic evaluation of these patients. CT-guided core biopsy is indicated if abdominal lymphoma, germ cell tumor, or carcinoma is strongly suspected. Preoperative biopsy is also indicated for patients who present with distant metastasis or advanced local disease that on abdominal or pelvic imaging appears to be difficult to completely remove surgically without substantial morbidity. In most patients, exploratory laparotomy should be performed and the diagnosis made at operation, unless (1) the patient's tumor is clearly unresectable, (2) neoadjuvant chemotherapy or radiotherapy is needed to attempt to make the tumor more resectable, or (3) the patient will be undergoing preoperative investigational treatment.

CT remains the primary modality for evaluation of retroperitoneal and visceral sarcomas. Because the most likely site of visceral metastasis is the liver followed by lung, a CT scan of the chest, abdomen, and pelvis encompasses the primary lesion and the most likely sites of metastasis in a single examination.

Retroperitoneal or intra-abdominal sarcomas (excluding visceral sarcomas such as GIST) account for approximately 15% of all soft tissue sarcomas. The most common histologic types in the retroperitoneum are liposarcoma (60%), LMS (22%), solitary fibrous tumor (5%), and MPNST (2%). Among primary retroperitoneal liposarcomas (excluding pleomorphic liposarcoma and liposarcoma not otherwise specified), about 50% are low grade, with 46% and 3% classified as well differentiated and myxoid, respectively, and 50% are high grade with 49% and 2% classified as dedifferentiated and round cell liposarcoma, respectively.

An analysis of 278 patients with primary retroperitoneal sarcoma²⁸² showed that grade and completeness of resection were the most important independent prognostic factors for disease-specific survival, with incompletely resected patients having survival similar to that of patients whose disease was unresectable from the outset. In this same study, histology and grade were both significantly associated with local recurrence, with liposarcoma having a 2.6-fold

Figure 90.5 Disease-specific survival for patients with primary retroperitoneal/intra-abdominal sarcoma, according to histology. The data are for 632 patients with primary retroperitoneal or intraabdominal sarcoma admitted to Memorial Sloan Kettering Cancer Center from 1982 through 2010. Low-grade liposarcoma consists of well-differentiated and myxoid subtypes. High-grade liposarcoma consists of dedifferentiated, round cell, and pleomorphic subtypes. The most common histologic types vary widely in disease-specific survival ($p < 0.0001$). Disease-specific survival at 5 years was 92% for patients with primary low-grade liposarcoma compared with 50% for patients with primary high-grade liposarcoma. For the group as a whole, disease-specific survival was 69% at 5 years and 55% at 10 years. MPNST, malignant peripheral nerve sheath tumor.

greater risk of local recurrence compared to other histologic types. Other studies have shown that for patients with retroperitoneal or intra-abdominal sarcomas, similar to patients with extremity sarcomas, the histologic type is an important prognostic factor for disease-specific survival, with this outcome worse for patients with MPNST and patients with LMS than for patients with solitary fibrous tumor (Fig. 90.5). Liposarcoma subtype provides additional prognostic information for disease-specific survival (see Fig. 90.5). In a multivariate analysis of liposarcoma, histologic subtype, completeness of resection, age, and contiguous organ resection were all independent predictors of disease-specific survival, with hazard ratios of 6 for subtype and 3.8 for completeness of resection.⁴⁰

MANAGEMENT BY PRESENTATION STATUS, EXTENT OF DISEASE, AND ANATOMIC LOCATION

Management of Extremity and Truncal Sarcoma

Surgical Management of Primary Localized Disease

Although surgery remains the principal therapeutic modality in soft tissue sarcoma, the extent of surgery required, along with the optimum combination of radiotherapy and chemotherapy, remains controversial. The individual patient's clinical and pathologic characteristics—particularly the pattern of spread expected for the patient's histologic subtype—should be used to design the most effective treatment plan. Figure 90.6 shows a suggested algorithm for management of patients with extremity or truncal disease.

Extent of Surgical Resection. The most extensive resection, amputation, should be only rarely indicated for soft tissue sarcoma. At MSKCC, the amputation rate, which was 50% in the late 1960s, is now <5%. Outcomes from amputation versus limb-sparing surgery for extremity lesions were addressed by a prospective, randomized trial with well over 10 years' follow-up. Although local recurrence is greater in those undergoing limb-sparing operation plus irradiation than in those undergoing amputation, disease-free survival is not different.²⁸³ Moreover, the level of handicap can be significantly lower in patients treated with limb-sparing surgery.²⁸⁴ Amputation should be reserved for tumors that cannot

be resected by any other means, in patients without evidence of metastatic disease and with potential for good long-term functional rehabilitation.

For these reasons, surgery for extremity or truncal tumors most often consists of wide en bloc resection. Historical attempts to resect all muscle bundles from origin to exertion have been supplanted by an encompassing resection, aiming to obtain a 1-cm margin of uninvolved tissue in all directions. Two-centimeter margins are employed for histologic subtypes with infiltrative borders (e.g., DFSP or myxofibrosarcoma). For certain low-grade histologic types, however, even 1-cm margins are not required for excellent local control. For example, well-differentiated liposarcomas of the extremities require only complete excision with a minimal surrounding margin, as the majority of these tumors will not recur, even after a limited or microscopically positive margin excision, as long as the excision is complete. Skin surrounding the biopsy site, tethered to the tumor, or showing neovascularization in association with an underlying lesion should be removed with the specimen; myocutaneous flaps may be considered when a significant defect results or adjuvant radiation will be required. The limiting factor in obtaining wide margins is usually neurovascular or, occasionally, bony juxtaposition. Because very few soft tissue sarcomas invade bone directly, bone rarely needs to be resected; periosteum can be removed to provide an adequate margin when soft tissue sarcoma abuts the bone. Similarly, perineurium can be removed with the tumor to provide margins when the tumor is directly adjacent to a major motor nerve. In rare instances, a major nerve or vascular bundle is encased by a soft tissue sarcoma. Low-grade lesions may be bivalved to preserve the nerve; however, in the case of a high-grade tumor, resection may be required. Vascular bypass can be performed for arterial resections. Bracing can be used to compensate for removal of femoral or sciatic nerves.

Indications for Adjuvant Therapy. As detailed in the next section, radiation therapy should be added to limb-sparing surgery for some high-risk patients. Neoadjuvant chemotherapy or investigational approaches should also be considered for patients with high-grade lesions >10 cm and for those with synovial sarcoma or myxoid/round cell liposarcoma >5 cm (subtypes highly responsive to chemotherapy) (see “Chemotherapy for Primary Localized Extremity/Truncal Sarcoma”).

A significant subset of subcutaneous and intramuscular sarcomas can be treated by wide excision alone, with a local recurrence rate of only 8% to 20%.^{285–287} For example, in patients with small lesions (<5 cm), complete surgical excision with margins of >1 cm

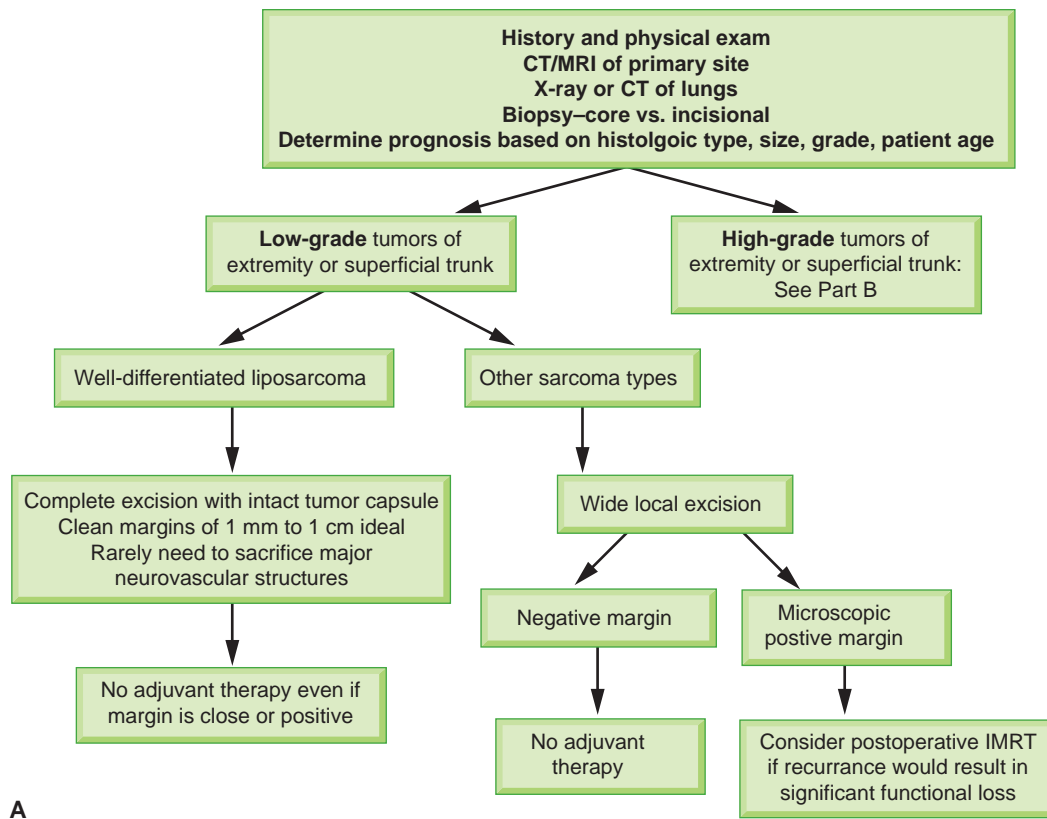

Figure 90.6 Management algorithm for extremity and superficial truncal soft tissue sarcoma. **(A)** Low-grade sarcomas. **(B)** High-grade sarcomas. Note that although postoperative intensity-modulated radiation therapy (IMRT) is mentioned in the algorithm, preoperative IMRT could be used in the same types of patients. CT, computed tomography; MRI, magnetic resonance imaging; RC, round cell; Pleo, pleomorphic; LS, liposarcoma; BRT, brachytherapy. (continued)

is usually sufficient without the need for any adjuvant therapy. Indeed, in a group of 159 patients with small primary tumors resected with negative margins, adjuvant radiotherapy showed no benefit: the 5-year local control rate was 77% in those selected to receive adjuvant radiation, compared to 92% in those undergoing surgery alone ($p = 0.08$). If, however, the margin is positive, the authors' policy is to administer radiotherapy to patients with high-grade tumors even if the tumor was ≤ 5 cm. In contrast, patients with large, low-grade lesions such as atypical lipomatous tumors rarely require radiation therapy, as local recurrence rates are low ($<10\%$) in patients treated with surgery alone.¹¹⁹

Another factor that should be considered is whether the patient has had a prior unplanned excision (i.e., excision without adequate preoperative staging or consideration of the need to remove normal tissue around tumor). At Princess Margaret Hospital, the rate of local recurrence was significantly higher in patients who were treated after unplanned excision on the outside than in patients who received their treatment at the institution (22% versus 7%; $p = 0.03$).²⁸⁸ Unplanned excision is very common in community settings when small soft tissue lesions are excised under the presumption that they are benign. In these cases, the authors attempt a re-excision if at all feasible; otherwise, patients are strongly considered for adjuvant irradiation.

Radiation Therapy for Primary Localized Extremity or Truncal Sarcoma

The goals of adjuvant radiotherapy in the management of soft tissue sarcoma are to enhance local control, preserve function, and achieve acceptable cosmesis by contributing to tissue preservation. Adjuvant radiation should be added to the surgical resection for most deep, large (>5 cm), high-grade sarcomas if the excision

margin is close, particularly with extramuscular involvement, or if a local recurrence would necessitate amputation or the sacrifice of a major neurovascular bundle.^{289,290} Superficial lesions and smaller contained lesions confined to individual muscles may be managed with surgery alone in expert hands.^{257,291} For most other situations, however, evidence strongly suggests that surgery that does not achieve wide clearance through normal tissue has a significantly higher rate of local failure, and even some small lesions may behave adversely.

That adjuvant radiotherapy enhances local control with conservative surgical resection in soft tissue sarcoma overall has been demonstrated in two randomized clinical trials, one using external beam radiation therapy (EBRT) and the other using brachytherapy (BRT).^{289,290} However, whether the addition of radiotherapy confers a benefit for small (<5 cm) high-grade lesions is controversial.²⁹²

The contemporary era has brought newer techniques for radiotherapy planning and delivery that permit unprecedented accuracy in the use of both BRT and EBRT.

External Beam Radiation Therapy. EBRT is the most popular adjuvant radiotherapy approach, perhaps because EBRT relies less than does BRT on special technical and operational requirements. Nevertheless, EBRT requires comprehensive and multidisciplinary pretreatment consultation and accurate pathologic and radiologic assessment.

Postoperative Versus Preoperative External Beam Radiation Therapy. Postoperative EBRT was the first and remains the most widely practiced local adjuvant approach, in part because it does not require that surgery be postponed and because it allows for sterilization of microscopic nests of residual disease. Its use is supported

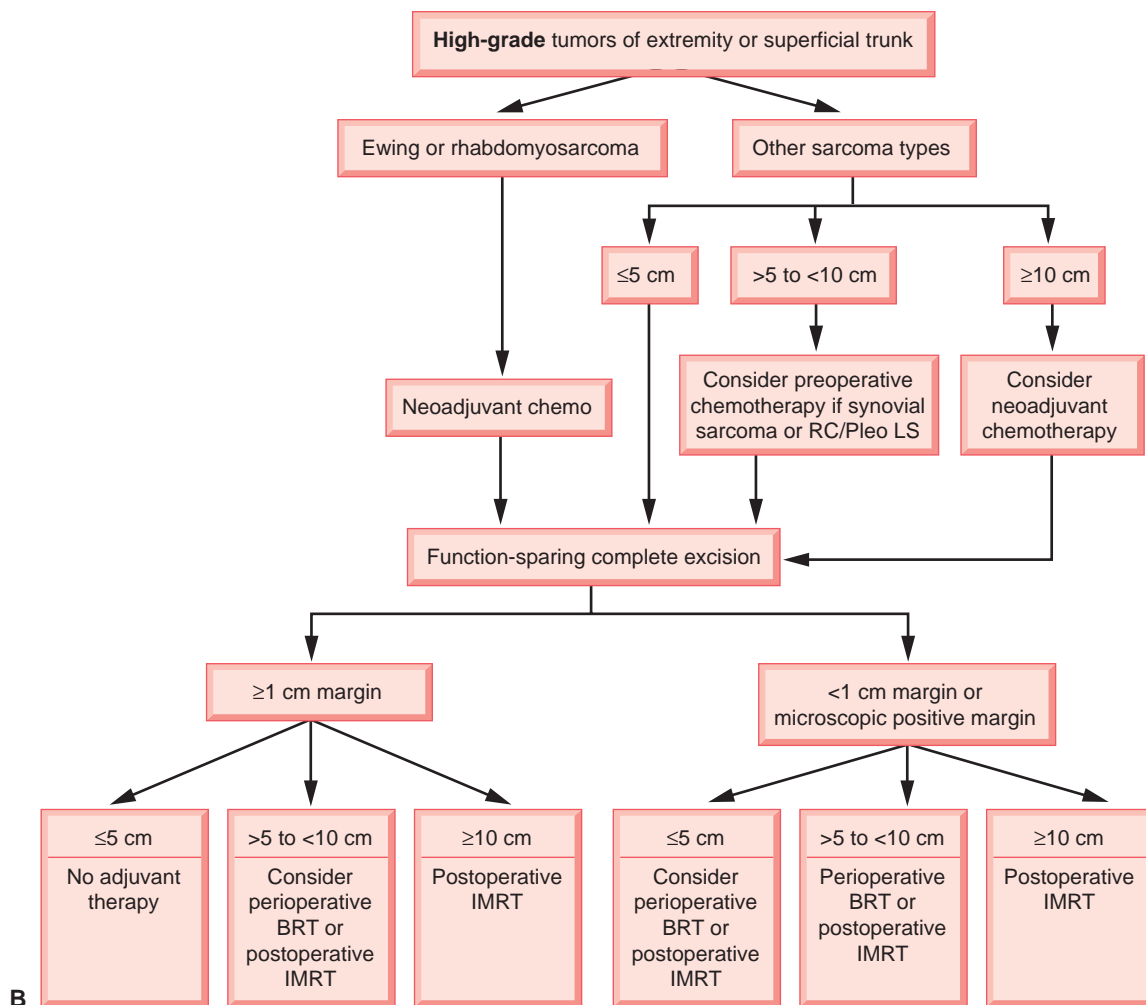

Figure 90.6 (Continued)

by numerous single-institution studies and by a randomized trial that showed better local control from conservative surgery followed by EBRT than from surgery alone.²⁹⁰ Although the postoperative EBRT resulted in significantly worse limb strength, edema, and range of motion, these deficits were often transient and had few measurable effects on activities of daily life or global quality of life.²⁹⁰ Preoperative EBRT, however, has not been subjected to a randomized comparison against surgery alone.

Both preoperative and postoperative EBRT have their advantages and disadvantages. An advantage of postoperative EBRT is that the entire pathology specimen and final margins are available for pathologic analysis, helping to determine the need for further therapy. A major limitation is that the target is less precisely defined, and therefore volume is larger and dose is higher, resulting in greater late tissue morbidity. With preoperative EBRT, on the other hand, not only is the treatment volume well defined, but the blood supply is intact. The intact vascular supply may reduce the fraction of hypoxic cells particularly at the tumor margins, which under hypoxic conditions tend to be radioresistant, and thus may decrease the dose needed compared to postoperative radiotherapy. Confirmation of this principle, however, remains elusive. The major drawback of preoperative radiotherapy, as detailed subsequently, is that irradiation increases the risk of acute wound complications upon surgery. Which approach is superior remains unclear.

In a trial assessing EBRT sequencing, the Canadian Sarcoma Group randomized 190 patients with extremity soft tissue sarcoma

to preoperative or postoperative radiotherapy. Preoperative radiotherapy doubled the risk of early acute wound complication, although this observation seems to apply almost exclusively to lower limb lesions.²⁹³ In the 5-year results from this trial,²⁹⁴ the preoperative and postoperative arms were nearly identical for local control (93% versus 92%, respectively) and metastatic relapse-free survival (67% versus 69%). In addition, the preoperative and postoperative arms did not differ significantly in overall survival (73% versus 67%; $p = 0.5$) or cause-specific survival (78% versus 73%; $p = 0.6$). Recently, a meta-analysis of pre- versus postoperative radiation in localized resectable soft tissue sarcoma suggested that the risk of local recurrence may be lower after preoperative radiation, and that the risk of metastatic spread is not increased with the delay in surgical resection necessary to complete preoperative radiotherapy.²⁹⁵

In the Canadian randomized trial, functional outcomes were collected prospectively.²⁹⁶ The trial design specified two validated instruments in addition an observer-based instrument.²⁹⁶ At 6 weeks after surgery, the preoperative group had inferior function, with worse bodily pain scores on all three rating instruments. However, at 3 to 12 months after surgery, the two groups showed no differences in these rating scores.²⁹⁶ It can be concluded that, for most of the first posttreatment year, the timing of radiotherapy has minimal effect on the function of patients with soft tissue sarcoma. The 2-year function and morbidity results²⁹⁷ show deteriorating late tissue sequelae (fibrosis and edema) in patients in the postoperative arm, resulting from larger radiotherapy doses and volumes.

Of note, patients with significant fibrosis or edema had significantly lower function scores. In addition, patients who received the higher doses—most of them in the postoperative group—may eventually have a higher rate of bone fractures. These disadvantages of postoperative EBRT may override the higher frequency of acute wound complications with preoperative EBRT, although patients who do experience wound complications continue to experience some impaired function.²⁹⁸

Intensity-Modulated Radiation Therapy. The past decade witnessed an unprecedented improvement in delivery of EBRT to complex volumes and shapes. Leading these advances is intensity-modulated radiation therapy (IMRT),²⁹⁹ which uses computer algorithms for inverse planning and treatment delivery. IMRT may be particularly applicable to complex anatomic volumes such as retroperitoneal sarcoma juxtapositioned to liver or paraspinal lesions, for which conformal avoidance of liver or of kidney and spinal cord is necessary.³⁰⁰ Avoidance of bone is also possible,^{301,302} and the risk of radiation-induced fracture of a weight-bearing bone may be reduced by using specific IMRT dose avoidance objectives (see “Serious Complications of Primary Treatment”).

IMRT in the treatment of soft tissue sarcoma appears to enhance normal tissue protection while maintaining oncologic control. Notably, a recent phase 2 trial of preoperative IMRT in lower extremity sarcoma conducted at the Princess Margaret Hospital indicated a 5-year local recurrence-free survival of 88% and very favorable doses to bone (mean dose 26.2 Gy, \pm 8 Gy) and vulnerable soft tissues, in addition to absence of bone fractures and a reduction in the number and severity of wound complications.³⁰³ IMRT was associated with a similar 5-year local recurrence-free survival (92%) at MSKCC.³⁰⁴ The local control results for both IMRT studies were also very similar to those with conventional EBRT in both arms of the aforementioned Canadian trial that compared preoperative to postoperative radiotherapy.²⁹⁴ Taken together, these results indicate that any superiority of IMRT over conventional EBRT is not likely to be based on tumor control but on a reduction in acute and late toxicity. This especially applies to serious problems such as bone fracture.^{303,305} Wound complications may also be influenced by reduction in the volume of soft tissue irradiated, especially if the immediate tissues to be used for the wound closure can be spared.³⁰³

Volume Issues in External Beam Radiation Therapy. Given the generally favorable oncologic results after EBRT, a priority is ameliorating toxicity to normal tissue by exploring reduced treatment intensity, including administered doses or volumes. Prospective assessments of the volumes irradiated in EBRT are emerging, and these results will likely update the guidelines outlining optimal radiotherapy target volumes for EBRT.^{301–303}

Targets are defined differently for preoperative versus postoperative radiotherapy. Preoperative radiotherapy can focus on the extent of definable disease (determined using imaging), and the target is based on the anatomic location, containment by barriers to spread (especially intact fascial planes), and allowance for geometric uncertainty related to potential variation in patient setup and physiologic movement. Special situations must also be considered, such as lesions arising in extracompartmental spaces such as the femoral triangle, antecubital space, and popliteal space, because these lesions have the ability to extend considerable distances proximally and distally with less anatomic restraint. Such lesions may spread to the neurovascular bundle early. The radiotherapy margins should reflect this and include undisturbed tissue planes and barriers to tumor incursion.

To cover any microscopic disease, the clinical target volume (CTV) for preoperative radiotherapy generally includes margins amounting to 4 cm longitudinally and 1.5 cm axially. This translates into field coverage approximately 5 cm long, allowing for beam penumbra and treatment uncertainties such as patient movement. Some controversy regarding planning of field coverage

has persisted. A recent Radiation Therapy Oncology Group consensus panel, after reviewing data regarding the local extension of soft tissue sarcomas, set guidelines that included 3-cm longitudinal coverage and 1.5-cm radial coverage.³⁰⁶ However, these recommendations were not based on outcome efficacy results and conflict slightly with international recommendations provided by members of various cooperative clinical trials groups.³⁰⁷ The latter recommendations suggest that the 4-cm CTV longitudinal coverage should be maintained until contrary data emerge, as it is based on the only available prospective clinical trial data (the original Canadian preoperative versus postoperative trial), and because histologic assessment of adjacent tissues suggest that microscopic sarcoma cells may be present up to 4 cm away from the gross tumor volume.^{293,308} This longitudinal margin was also used in the recent Princess Margaret Hospital phase 2 prospective trial in lower extremity lesions, which is the only prospective outcome data with IMRT at this time.³⁰³

Postoperative radiotherapy volumes are significantly larger because they ideally encompass all surgically manipulated tissues, with the recognition that this is impossible in some anatomic sites due to the proximity of critical anatomy. In addition, because surgery has disrupted the anatomic planes and they no longer provide containment barriers to tumor growth, the entire CTV extending 4 cm beyond the surgically manipulated tissue must be considered high risk and thus treated for at least the first phase of irradiation (e.g., an appropriate dose is 50 Gy). Subsequently, the volume is reduced to the immediate tumor bed. Alternatively, with a single-phase IMRT approach, a higher dose could be delivered to the small high-risk volume while using a more moderate dose for the more peripheral regions of the CTV.

The international clinical trials group consensus panel mentioned earlier also generally recommended that the CTV extend 4 cm longitudinally beyond the surgically manipulated tissues.³⁰⁷ Currently, the volume of postoperative radiotherapy is being investigated in a randomized phase 3 trial conducted by the United Kingdom National Cancer Research Network. The trial compares a standard volume (5 cm longitudinal margin to gross tumor volume or 1 cm from the surgical scar, whichever is longer in the cranio-caudal direction and 2 cm axial margin) versus an experimental volume (2 cm longitudinal margin to gross tumor volume and 2 cm axial margin). Patients in both arms of the study will receive 66 Gy over 6.5 weeks; patients in the standard arm, but not the experimental arm, will have a volume reduction after 25 fractions (50 Gy). The goal is to assess if a reduced volume of postoperative radiotherapy will increase limb function without compromising local control.³⁰⁹

A final issue concerning choice of irradiation target volume concerns the definition of the areas that may harbor disease and especially whether the risk area should include any peripheral edema that surrounds the tumor. A study noted previously from the Princess Margaret Hospital, which correlated MRI characteristics with pathologic features, suggests that in some cases the edema does harbor sarcoma cells.³⁰⁸

Dose Issues in External Beam Radiation Therapy. The dose of radiotherapy represents an additional unexplored area. The preoperative dose used in most institutions is approximately 50 Gy in daily fractions of 1.8 to 2.0 Gy over approximately 5 weeks. Generally, a postoperative boost is administered only if the surgical margins are positive, and the benefit of this boost is unclear. For example, for patients who had positive surgical margins, Delaney et al.³¹⁰ reported that the factors associated with local control included total radiotherapy dose >64 Gy (delivered as pre-, post-, or preoperative with a postoperative boost), with the implication that a boost is beneficial following preoperative radiotherapy. A different conclusion was drawn from a retrospective study at the Princess Margaret Hospital of patients with extremity soft tissue sarcoma and positive surgical margins. All patients had been treated with preoperative radiotherapy (50 Gy); 41 received a postoperative

boost (typically 16 Gy) and 52 received no other radiotherapy. A common reason for omission of boost was wound complications, which tend to occur in more extensive and adverse cases. Despite this, patients who received a postoperative boost had worse 5-year estimated local recurrence-free survival (74% compared to 90% for preoperative radiotherapy only).³¹¹ This is consistent with recent pooled results from two Harvard groups, which showed no additional benefit to the radiotherapy boost in patients who had a positive surgical margin after preoperative radiotherapy and resection.³¹² Consequently at the Princess Margaret Hospital a postoperative boost is not used for patients with microscopically positive resection margins.

Adjuvant Brachytherapy. The fundamental interest in BRT stems from the ability to focus the dose directly on the tumor bed, thereby potentially improving the therapeutic ratio. Very high dose levels in the vicinity of the radioactive sources and the rapid dose fall-off permit dose intensification while protecting the surrounding normal tissue. Therefore, BRT usually spares more normal tissue than EBRT, except when precision techniques such as IMRT are used. Moreover, patients usually complete all their treatment in about 2 weeks compared to 6 to 7 weeks with EBRT, thereby limiting repopulation of residual tumor cells. The technical aspects of BRT differ from those of EBRT, and specific guidelines for its use and technical delivery have been published. BRT, unlike EBRT, requires a specific collaboration between surgical and radiation oncologists. With BRT, unlike in postoperative irradiation, no attempts are made to treat large margins or to include the scar and the drainage site, although it is acknowledged that this approach has not been formally compared with EBRT in similar cases.

The efficacy of BRT was compared to that of IMRT among 134 patients with primary high-grade extremity sarcoma in recent data from MSKCC.³⁰⁴ The BRT and IMRT groups were similar in terms of traditional prognostic factors, although the IMRT group had a significantly greater proportion of patients with positive or close margins, large tumors, and bone or nerve manipulation. The median follow-up was approximately 4 years. The 5-year local control rate was 92% for the IMRT group compared to 81% for the BRT group ($p = 0.04$). On multivariate analysis, IMRT was the only predictor of improved local control ($p = 0.04$).³⁰⁴ Earlier evidence from MSKCC suggests that BRT may not provide optimal results in regions unsuited for ideal implant geometry, such as in more proximal regions of the limb.²⁹²

In patients treated with BRT as the sole radiotherapy, the dose is usually 45 Gy given over 4 to 6 days, and when given as a boost, the dose is usually 15 to 20 Gy from BRT plus 45 to 50 Gy from EBRT. Of importance, the catheters are loaded no sooner than the sixth postoperative day to allow time for wound healing.³¹³ The most commonly used isotope is low-dose-rate ¹⁹²Ir; however, high-activity ¹²⁵I is occasionally used in young patients or to protect the gonads. High-dose-rate ¹⁹²Ir has been advocated to take advantage of its radiation safety and dose-optimization capabilities.

The BRT CTV may be difficult to define, but in general it is represented by the volume of tissue considered at risk for microscopic extension of tumor and includes the tumor bed visualized on radiographic studies and under direct inspection intraoperatively. The results with adjuvant BRT suggest that radiation treatment directed to the tumor bed plus a 2-cm margin is adequate.³¹⁴ Although there is no consensus on the exact size of the margin beyond the tumor bed, generally at least 2 cm longitudinally and 1 cm axially are recommended.^{307,315} These volumes would seem to approximate those for preoperative radiotherapy.

Adjuvant BRT has been evaluated in a randomized trial. Patients who underwent complete gross resection were randomly assigned to receive adjuvant BRT ($n = 78$) or no further therapy ($n = 86$). The 10-year actuarial local control rates were 81% in the BRT group and 67% in the no-BRT group ($p = 0.03$). This improvement in local control, however, was limited to patients with histologically high-grade tumors, whose local control was 89%

in the BRT group and 64% in the no-BRT group ($p = 0.001$).²⁸⁹ The adjuvant BRT did not improve local control in patients with low-grade tumors as the local recurrence rates of 27% (BRT) and 22% (no BRT) were not statistically different.³¹⁶ Rigorous psychofunctional testing of 38 long-term survivors in this trial revealed no significant differences in functional outcome between the BRT group and the no-BRT group. The BRT group did, however, have higher levels of anxiety, depression, and appreciation of illness.³¹⁷

BRT is often used in combination with EBRT, but whether all patients need this combination is unclear.³¹⁸ An MSKCC study evaluated 105 patients with primary or locally recurrent high-grade soft tissue sarcomas who were treated with wide local excision and radiotherapy: BRT (87 patients) or BRT and EBRT (18 patients). At a median follow-up of 22 months, the two groups had no statistically significant difference in 2-year actuarial local control rate: 82% in the BRT group and 90% in the BRT plus EBRT group ($p = 0.32$).³¹⁹ However, case selection was such that the two groups are not completely comparable. Notably, patients were selected for EBRT if they had a positive margin (56%) or if anatomic considerations led to concern about the adequacy of dose coverage with BRT.

BRT is particularly useful when the surgical plan involves resection margins being close. In this situation, if the surgical and pathologic findings are satisfactory, the unused BRT catheters can be removed. Alternatively, BRT allows early delivery of radiation to a reduced and select volume mapped precisely by the intraoperative findings. The American Brachytherapy Society has recommended against BRT as a sole treatment modality in several situations: (1) the CTV cannot be adequately encompassed in the implant geometry, (2) the proximity of critical anatomy is expected to prevent administration of a meaningful dose, (3) the resection margins are positive, and (4) the skin is involved with tumor.³²⁰ In such situations, EBRT may be used alone or with BRT.

High-dose-rate (HDR) BRT has some potential advantages over low-dose-rate BRT, although the experience with HDR BRT for sarcoma is still limited. A typical HDR dose is approximately 36 Gy in 10 fractions using a 6-hour interfraction interval, though some authors have used higher doses.³²¹ Guided by the more abundant breast cancer experience, a dose of 32 to 34 Gy in twice-daily fractions of 3.4 to 4.0 Gy over 4 to 5 days³²²⁻³²⁴ seems useful and safe, though even here there have been reports of fat necrosis in later follow-up.³²⁴ In sarcoma management, authors have observed wound healing complications with HDR BRT.^{325,326} In addition, caution should probably be exercised when placing catheters in contact with neurovascular structures, and when such contact cannot be avoided the dose per fraction should probably be curtailed. As yet, no large series evaluating HDR BRT for sarcoma is available, and no studies have directly compared HDR to low-dose-rate BRT. Comparisons are difficult due to nonstandardization of target volumes, dose prescription points, and the delivered dose. However, low-dose-rate BRT may expose the staff caring for patients to radiation, whereas HDR BRT does not. In addition, the HDR approach offers the potential for outpatient delivery.

Sarcomas involving neurovascular structures present a challenge in achieving control while maintaining function. Intraoperative BRT, alone or combined with EBRT, has been used in this setting. A 5-year 69% actuarial survival rate and 90% local relapse-free rate was reported for 79 patients with primary disease. No amputation was required, although 8 of the 79 (10%) had grade 3-4 peripheral neuropathy and fibrosis, and 2 experienced vascular damage. Despite this, the authors considered that intraoperative BRT offers an acceptable conservative option for this particularly adverse presentation.³²⁷

Intraoperative HDR, a rarely used approach, has been used for the treatment of retroperitoneal sarcoma (see "Retroperitoneal Sarcoma").

Technical Enhancement of Radiotherapy Delivery. IMRT can now be administered very precisely using reference to the

position of external surrogate markers or implanted and/or anatomic fiducials to permit the determination of tumor coordinates in all three planes. High-dose, single fraction treatments are often termed stereotactic radiosurgery (SRS), and high-dose, fractionated treatments are variously termed stereotactic radiotherapy or stereotactic body radiotherapy. These approaches are used for very adverse presentations of sarcoma, such as primary spinal sarcoma. Levine et al.³²⁸ used SRS to treat 14 patients with primary spine sarcoma. In seven patients, the treatment was definitive, and all seven had excellent pain relief and were alive with a mean follow-up of 33 months, although two patients had recurrence of tumor and were retreated. Surgery and adjuvant SRS were used in the other seven patients, of whom five remain free from recurrence at a mean follow-up of 43.5 months. Notably, even though the SRS doses were in the mean range of 30 Gy in three fractions, none of these patients had spinal injury from SRS.

High-dose photon/proton radiotherapy has shown promising results. In a phase 2 study, high-dose photon/proton radiotherapy was administered with or without resection for the management of primary, nonmetastatic spine, and paraspinal sarcomas. For 50 patients with a median follow-up of 48 months, the 5-year actuarial rates of local control, recurrence-free survival, and overall survival were 78%, 63%, and 87%, respectively. Three sacral neuropathies appeared after 77.12 to 77.4 Gy equivalents.³²⁹

Other forms of particle beam radiotherapy are discussed in the “Definitive Radiation” section.

Definitive Radiation. Surgery remains the main treatment for patients with sarcoma of the extremity, and every effort should be made to attempt resection. However, in some patients with unresectable disease or medical contraindications to operation, definitive radiation can be considered for palliation. In a study of 112 patients treated with definitive irradiation to a median total dose of 64 Gy,^{330,331} the 5-year rates of local control and overall survival were 45% and 35%, respectively. Local control at 5 years was 51%, 45%, and 9% for tumors <5 cm, 5 to 10 cm, and >10 cm, respectively. Five-year outcomes were worse for patients who received doses of <63 Gy than for those receiving higher doses; local control was 22% versus 60% and overall survival was 14% versus 52%. Complications, however, were more frequent at doses of 68 Gy or more. Thus, the therapeutic window appears to be 63 to 68 Gy.³³⁰

Similar findings were reported for 57 patients treated with definitive photon beam irradiation to 44 to 88 Gy. The 5-year local control rate was 28%.³³² An additional 15 patients were treated with neutrons without obvious benefit over photons.

Other investigators have considered neutron radiotherapy either alone or in combination with photon beam irradiation. The attraction of neutrons is their high linear energy transfer and lower oxygen enhancement ratio compared to X-rays and the consequent possibility of eliminating hypoxic cells. In addition, neutron irradiation results in less repair of sublethal and potentially lethal damage and less variation in radiosensitivity over the phases of the cell cycle. Unfortunately, all of these biological features also pertain to normal tissue, which implies that late toxicity is likely to be heightened, given the absence of the usual protection afforded by fractionation that occurs with more conventional photon treatment schedules. In a review of the European experience, patients with inoperable tumors or with gross disease after surgery and treated with neutron radiotherapy had a local control rate of 50%, but the rate of severe complications ranged from 6.6% when neutron therapy was used as a boost to 50% when used alone.³³³ Schwartz et al.³³⁴ reported a North American experience of fast neutron therapy in a heterogeneous series of bone and in soft tissue sarcomas. Among the 34 patients with unresectable disease, the local relapse-free survival at 1 year was estimated as 62%. Within the entire series of 66 patients, serious chronic radiation-related complications occurred in 10 patients (15%), all of whom had had high neutron doses, large radiotherapy fields, or both.

Another high linear energy transfer method that has been used for the treatment of unresectable soft tissue sarcoma is carbon ion radiotherapy.³³⁵ Although not widely available, this technology has substantially better ability to target tissues safely compared to neutrons because of the enormous energy release at the end of its range. In addition, it offers excellent physical dose distribution and higher relative biological effectiveness. Sugahara et al.³³⁵ described promising results for unresectable sarcomas of both bone and soft tissue with 5-year local control rates of 76% in a small study ($n = 17$, 9 primary and 8 recurrent). Serizawa et al.³³⁶ reported the results of carbon ion radiotherapy for 24 patients with unresectable high-grade retroperitoneal sarcomas, 16 with primary disease, and 8 with recurrent disease. The dose ranged from 52.8 to 73.6 Gy equivalents in 16 fixed fractions over 4 weeks. Overall survival rates were 75% at 2 years and 50% at 5 years. Local control rates were favorably 77% and 69% at 2 and 5 years, respectively. Notably, toxicities were low, with no GI tract complications and no toxicity greater than grade 2. These results suggest that carbon ions may be an alternative to surgery with acceptable morbidity for unresectable sarcomas.

Spot scanning proton beam therapy has been used in the curative treatment of soft tissue sarcomas located in the vicinity of critical structures such as the spinal cord, optic apparatus, bowel, and kidney, with local control comparable to that with EBRT and with acceptable toxicity.^{337,338}

Hyperfractionated photon beam radiation has been combined with intravenous iododeoxyuridine as a radiosensitizer. Among 36 patients treated in this fashion, and with a median follow-up of 4 years, the local control rate was 60%.³³⁹

Definitive radiation combined with chemotherapy is described under “Combined Chemoradiotherapy for Primary Localized Extremity/Truncal Sarcoma.”

Chemotherapy for Primary Localized Extremity/Truncal Sarcoma

Surgery and radiation therapy remain the mainstay for local control of soft tissue sarcoma. Because up to half of patients with primary non-GIST sarcomas who achieve adequate local control of disease will develop distant metastasis, it was hoped that adjuvant chemotherapy would help to decrease the frequency of distant metastasis and increase overall survival. Anthracyclines are the agents most active against metastatic sarcoma, so they have been universally employed in adjuvant trials, alone or in combination.

More than 15 studies of adjuvant therapy for soft tissue sarcoma have been performed (Table 90.3), but most of them were small and therefore lack statistical power to detect small changes in overall survival. Among the larger randomized trials, one trial with 104 patients showed some benefit to adjuvant epirubicin (an anthracycline) plus ifosfamide.³⁴⁰ Overall survival at 5 years was better in the chemotherapy arm ($p = 0.04$), although neither overall survival as a whole nor disease-specific survival was significantly different between arms ($p = 0.05$). Interpretation of the trial was complicated by subtle imbalances in the distribution of patients on the control and treatment arms. Nevertheless, this study has been used as a rationale for adjuvant ifosfamide plus an anthracycline. Another large, randomized trial showed some benefit to adjuvant cyclophosphamide, vincristine, doxorubicin, and dacarbazine (CYVADIC) for patients with sarcoma in the head, neck, or trunk, but not for those with sarcoma in the extremities.³⁴¹

Other randomized trials have shown no benefit to anthracycline-based in the adjuvant³⁴²⁻³⁴⁴ or neoadjuvant (preoperative)³⁴⁵ setting. This includes the largest trial to date of adjuvant chemotherapy for patients with sarcoma, which examined adjuvant doxorubicin plus ifosfamide; however, this trial has been criticized for using a low ifosfamide dose and for heterogeneity in tumor site, size, and grade.³⁴⁴ The trial had nonsignificant improvements in survival outcomes in patients with grade III tumors, limb lesions, and tumors >10 cm; these characteristics continue to be indications for considering adjuvant or neoadjuvant therapy in some specialty centers.

Note: Significant differences between chemotherapy and control are indicated by **bold type**. DFS and OS are not necessarily indicated at the median follow-up time.

^a Some patients on the control arm received chemotherapy.

The small size of most adjuvant chemotherapy trials in sarcoma makes interpretation difficult because they lacked statistical power to detect small (e.g., 10% to 20%) changes in overall survival. Therefore, several meta-analyses have been performed,³⁴⁶ the most rigorous of which was published in 1997,³⁴⁷ then updated in 2008.³⁴⁸ Tumor histology for each patient was recorded, but pathology review was not centralized. The 2008 update included 18 trials and 1,953 patients. Chemotherapy was associated with significantly lower risk of local recurrence (odds ratio [OR] = 0.73; 95% CI = 0.56 to 0.94; $p = 0.02$). Overall survival was not significantly improved with single-agent doxorubicin (OR = 0.84; 95% CI = 0.68 to 1.03; $p = 0.09$), but it was improved with doxorubicin combined with ifosfamide (OR = 0.56; 95% CI = 0.36 to 0.85; $p = 0.01$). With the updated data, the absolute risk reduction for death was 5% with adjuvant doxorubicin alone and 11% for doxorubicin combined with ifosfamide.³⁴⁸

Note that the adjuvant chemotherapy trials have two possible sources of bias. First, in several of the older studies, a significant proportion of patients were ineligible for analysis. Second, patients who enroll in clinical trials are healthier overall and survive longer than nonrandomized patients, as demonstrated in a study from the Mayo Clinic.³⁴⁹ In addition, some of the older trials included a number of patients with low-grade or small tumors.

If there is a benefit to adjuvant or neoadjuvant chemotherapy for patients with soft tissue sarcoma overall, it is small. Neoadjuvant chemotherapy has been particularly successful with pediatric sarcomas such as rhabdomyosarcoma and soft tissue Ewing sarcoma, and there is some substantiation of benefit for synovial sarcomas and myxoid-round cell liposarcomas, two subtypes that are chemosensitive in the metastatic setting.³⁸ The best standard of care that can be offered is a thorough discussion with patients regarding possible options and outcomes.

As previously noted, preoperative chemotherapy has been very successful in the management of predominantly pediatric sarcomas such as Ewing sarcoma and osteosarcoma. This approach has been extended to adult soft tissue sarcomas. Preoperative chemotherapy can make subsequent surgery easier. It also potentially treats micrometastatic disease early, before acquisition of resistance. In addition, before surgery the primary vasculature is still intact for drug delivery. Preoperative chemotherapy can guide postoperative treatment based on pathologic review of the tissue response after chemotherapy. In experimental models, preoperative chemotherapy eliminates a postoperative surge in growth of metastases noted after resection of primary tumors.²⁹⁸

Isolated Limb Perfusion. Perfusion of limbs requires isolating the arterial and venous system of the limb by means of a tourniquet and obtaining access to arteries and veins that supply the limb. The arterial and venous supplies of the limb are connected to an extracorporeal circulation system to reoxygenate and circulate the blood. After isolation of the limb, care is taken to ensure that there is no leakage of the circuit into the systemic circulation; technetium-labeled albumin is injected into the circuit, and a probe is used over the heart to ensure isolation of the bypass circuit. Because mild hyperthermia may make chemotherapy more effective in some clinical settings, the blood of the circuit is often warmed to 39°C to 40°C.

Limb perfusion has involved a number of chemotherapeutic agents, such as melphalan, nitrogen mustard, dactinomycin, and doxorubicin. The most effective has been melphalan when given with tumor necrosis factor (TNF). The largest reported series using this technique included 246 patients with primary or recurrent sarcomas that would otherwise require amputation or marked loss of function.³⁵⁰ These patients were treated with one and occasionally two isolated limb perfusion sessions. After isolation of the extremity, melphalan (10 to 13 mg/L limb volume) was perfused into the limb with a dose of TNF 10 times the lethal dose for humans, under mild hyperthermic conditions. The omission of TNF led to a decrease in tissue dose of melphalan, probably because TNF affects

the tumor vasculature. Residual tumor was surgically removed 2 to 4 months after limb perfusion. With a median follow-up of 3 years, 71% of patients had successful limb salvage. Later, a randomized trial demonstrated that lowering the TNF dose to 0.5 mg reduced systemic toxicity without reducing the objective response rate.³⁵¹

It is difficult to compare isolated limb perfusion to standard chemotherapy, given the heterogeneity of patients in the two types of studies. In aggregate, the response rate does appear to be higher in the perfusion studies than in the infusion studies. However, isolated limb perfusion requires substantial expertise and specialized dedicated equipment. Complications of this technique include shock (from systemic leak of TNF); infection; chronic damage to skin, muscles, and nerve; persistent edema; and arterial or venous thrombosis. Experience has led to a decrease in the incidence and severity of complications. Isolated limb perfusion does appear to hold promise for at least a subset of patients who would otherwise require amputation for local control and has been approved for such patients in Europe. Studies are under way to examine the use of regional limb infusion, which would not require bypass machines, as a simplified means of treating otherwise unresectable extremity sarcomas and whether local perfusion may be a viable method for managing patients with pelvic sarcoma.³⁵²

Combined Chemoradiotherapy for Primary Localized Extremity/Truncal Sarcoma

High-risk soft tissue sarcomas (i.e., those of large size, deep location, and high grade) present a significant dual threat: locally and at distant sites. For this reason, researchers at the Massachusetts General Hospital explored a dose-intense chemoradiation strategy in 48 patients with localized, high-grade, large (>8 cm) soft tissue sarcomas of an extremity.³⁵³ The protocol consisted of three courses of doxorubicin, ifosfamide, mesna, and dacarbazine (MAID) interdigitated with two 22-Gy courses of radiation (11 fractions each). Patients with microscopically positive surgical margins received a 16-Gy boost dose (in eight fractions). Their 7-year actuarial disease-specific survival was 81% and overall survival 79%.³⁵⁴ Among matched historical controls, survival was significantly lower: 50% and 45%, respectively ($p < 0.005$). As expected, toxicities in the chemoradiation group included significant wound-healing complications in the lower limbs (in 29%).³⁵⁵ One patient died from late marrow dysfunction attributed to chemotherapy. A multicenter study that included 64 patients treated according to the same protocol also showed significant toxicity, with three patients (5%) having experienced fatal toxicities (myelodysplasia in two and sepsis in one). Moreover, another 53 patients (83%) experienced a variety of grade 4 toxicities, and 5 patients required amputation.³⁵⁶ At almost 8 years of follow-up, overall survival approximated 70%, which the authors consider compares favorably to expected outcomes for the high-risk cases included in the protocol.³⁵⁷ Clearly, the use of early neoadjuvant chemoradiotherapy delivered in this fashion is appealing for patients at very highest risk. However, the results require confirmation in prospective trials, especially because of the local and systemic toxicity associated with the protocol.³⁵⁵

Multimodal Management of Locally Recurrent Extremity/Truncal Sarcoma

Local recurrence remains a significant factor in long-term morbidity and mortality. Locally recurrent sarcomas are difficult to treat and are more likely to recur, probably as a result of prior contamination of tissue planes as well as intrinsically aggressive tumor biology. Follow-up data confirm that salvage is almost invariably possible, but there is no impact on long-term survival. For patients who undergo resection of their recurrent lesion, important factors in outcome are the size and timing of the recurrence.³⁵⁸ Patients with a local recurrence that grew to >5 cm in <16 months had a 4-year disease-specific survival of 18%, compared to 81% for patients with a local recurrence of ≤5 cm in >16 months.

Surgery. Repeat resection is the treatment of choice for locally recurrent soft tissue sarcoma in almost any site that is amenable to low-morbidity surgical resection. Repeat resection usually encompasses all palpable tumor and all potential microscopic foci present in adjacent tissues traversed during previous surgical procedures. Assuming the recurrent disease can be surgically resected, adjuvant radiation therapy should be considered for the vast majority of patients.

Radiotherapy. Radiotherapy in the recurrent setting should follow the same principles applicable to the treatment of primary tumors. However, the issues are more complex and often dominated by two confounding issues. First, tissue planes will likely have been disrupted from prior interventions and the true anatomic areas at risk are difficult to define, so there is often need to compromise in the choice of target volumes. Second and more problematic is prior radiotherapy, which results in serious concerns about long-term morbidity, especially affecting bone and neurovascular tissues. The substantial rates of serious complications for salvage reoperation and reirradiation³⁵⁹ indicate that salvage therapy should be performed cautiously with careful monitoring of side effects.

Torres et al.³⁶⁰ retrospectively reviewed 62 patients who had undergone prior resection and EBRT, being treated for an isolated first local recurrence of soft tissue sarcoma arising within a previously irradiated field. Local control rates were similar for patients undergoing reirradiation compared to those who did not undergo reirradiation, but complications that required outpatient or surgical management were more common in reirradiated patients (80% versus 17%; $p < 0.001$). The authors have acknowledged that selection for the different treatments may confound interpretation of these results. A study at the Princess Margaret Hospital examined patients with recurrent disease treated with surgery with or without reirradiation (predominantly BRT).³⁶¹ The local control rate among 10 reirradiated patients was 100%, compared to only 36% among the 11 patients treated with no further irradiation. However, follow-up was short: median, 24 months. As a general principle, if radiotherapy is used in a previously irradiated field, BRT is often recommended. However, the possibility of complications is real and these decisions must be approached cautiously.³⁶¹⁻³⁶³

When EBRT is used, various strategies can be considered to ameliorate the risk from reirradiation. First, precision techniques such as IMRT should generally be used to optimize volume with exclusion of uninvolved tissues. Second, preoperative, rather than postoperative, radiotherapy may be used to reduce dose and volume to the lowest level possible. Third, treatments may involve a smaller dose per fraction to minimize damage to late responding normal tissues; these fractionation approaches normally require treatment more than once per day. Intraoperative radiotherapy (IORT) has also been considered for salvage therapy, and careful dose limitation to major nerves, ureters, and kidneys may reduce related complications in complex anatomic regions.^{364,365} Salvage IORT was analyzed in a multicenter study of 103 patients managed from 1986 to 2012; the 5-year local control was 60%, and 16% of patients had toxicities of grade 3 or greater.³⁶⁶

Management of Primary Localized Retroperitoneal Sarcoma

Surgical Management of Primary Localized Retroperitoneal Sarcoma

For retroperitoneal sarcomas, as for extremity or truncal sarcomas, primary surgical resection is the dominant therapeutic modality. A treatment algorithm is shown in Fig. 90.7. Preoperative bowel preparation is important, not because of tumor invasion, but because resection without encompassing the intestine is often technically difficult. For retroperitoneal tumors situated near a

kidney, it is important to evaluate renal function, in particular to establish adequate contralateral renal function, to allow nephrectomy when appropriate.

The major issue in resection of visceral and retroperitoneal lesions is adequate exposure. Thoracoabdominal incisions, rectus-dividing incisions, and incisions extending through the inguinal ligament into the thigh may improve exposure and enhance the ability to achieve a complete resection. The availability of venovenous bypass, adequate and appropriate anesthetic, and blood replacement therapy are all important issues for many of these large lesions.

Although resection of adjacent organs is common,²⁸¹ there is only limited evidence that a more extensive resection of adjacent organs affects long-term survival. Two retrospective studies have attempted to examine the role of aggressive surgery with wide margins (including resection of uninvolved adjacent organs) in patients with primary retroperitoneal sarcoma. Both studies show a reduction in the cumulative incidence of local recurrence with aggressive surgery treatment, but no improvement in overall survival, an increase in operative morbidity, and a high (11%) reoperation rate.^{367,368} In addition, both these series have significant problems with patient selection bias, unequal follow-up times, and heterogeneous adjuvant radiation and chemotherapy strategies between treatment groups, making interpretation of the local recurrence results difficult. The sacrifice of uninvolved organs beyond what is required to achieve a complete retroperitoneal sarcoma resection should not be performed on a routine basis unless part of a clinical trial, as more extended resections do not seem to improve survival. Further insight into the value of resection of adjacent organs comes from two reviews,^{281,369} in which nephrectomy was performed in 46% of cases but the kidney itself was rarely involved. For example, in one of these reviews,²⁸¹ only 2 of 30 nephrectomy specimens showed true parenchymal invasion. The resection of a kidney makes little sense when the vena cava is the closest margin. Nevertheless, resection of the kidney is often necessary because of encompassment of the kidney or involvement of the hilar renal vasculature.

The overriding principle is not to be reluctant to resect adjacent organs should they be involved by tumor. Conversely, one should not resect uninvolved organs if they are not the limiting factor for the tumor margin.

The primary factor in outcome is complete surgical resection, followed by the grade of the lesion. Illustrating the importance of complete resection, in a series 693 adult patients with primary retroperitoneal sarcoma resected at MSKCC, the 10-year disease-specific survival for those who had incomplete resection (18%) was substantially worse than that of patients who had complete resection (53% for those with negative margins and 54% for those with positive margins). There is some evidence that incomplete resection is associated with prolonged survival.³⁷⁰

Resectability rates vary widely but seem independent of histologic type, grade, or size.²⁸¹ The basis for unresectability is usually the presence of peritoneal implants or extensive vascular involvement. Operation should be reserved for those patients for whom complete resection is at least possible, if not probable, and for patients in whom palliation can be achieved. However, it is often difficult to decide how much palliation can be achieved by incomplete removal of tumor.

Retroperitoneal sarcomas remain a major clinical challenge. Most of these tumors are large, making it difficult to obtain adequate margins of resection. Compounding the problem, the proximity of normal organs such as small bowel, large bowel, kidney, and liver makes delivery of therapeutic doses of radiation therapy either difficult or impossible.

Jaques et al.²⁸¹ reported the experience with 114 patients at MSKCC from 1982 to 1987. Half of the patients had liposarcoma, whereas 29% had LMS. A total of 65% of patients with primary sarcoma underwent a complete resection; of these, 53% required adjacent organ resection and 40% required resection of more than one adjacent organ. Despite complete resection, local recurrence

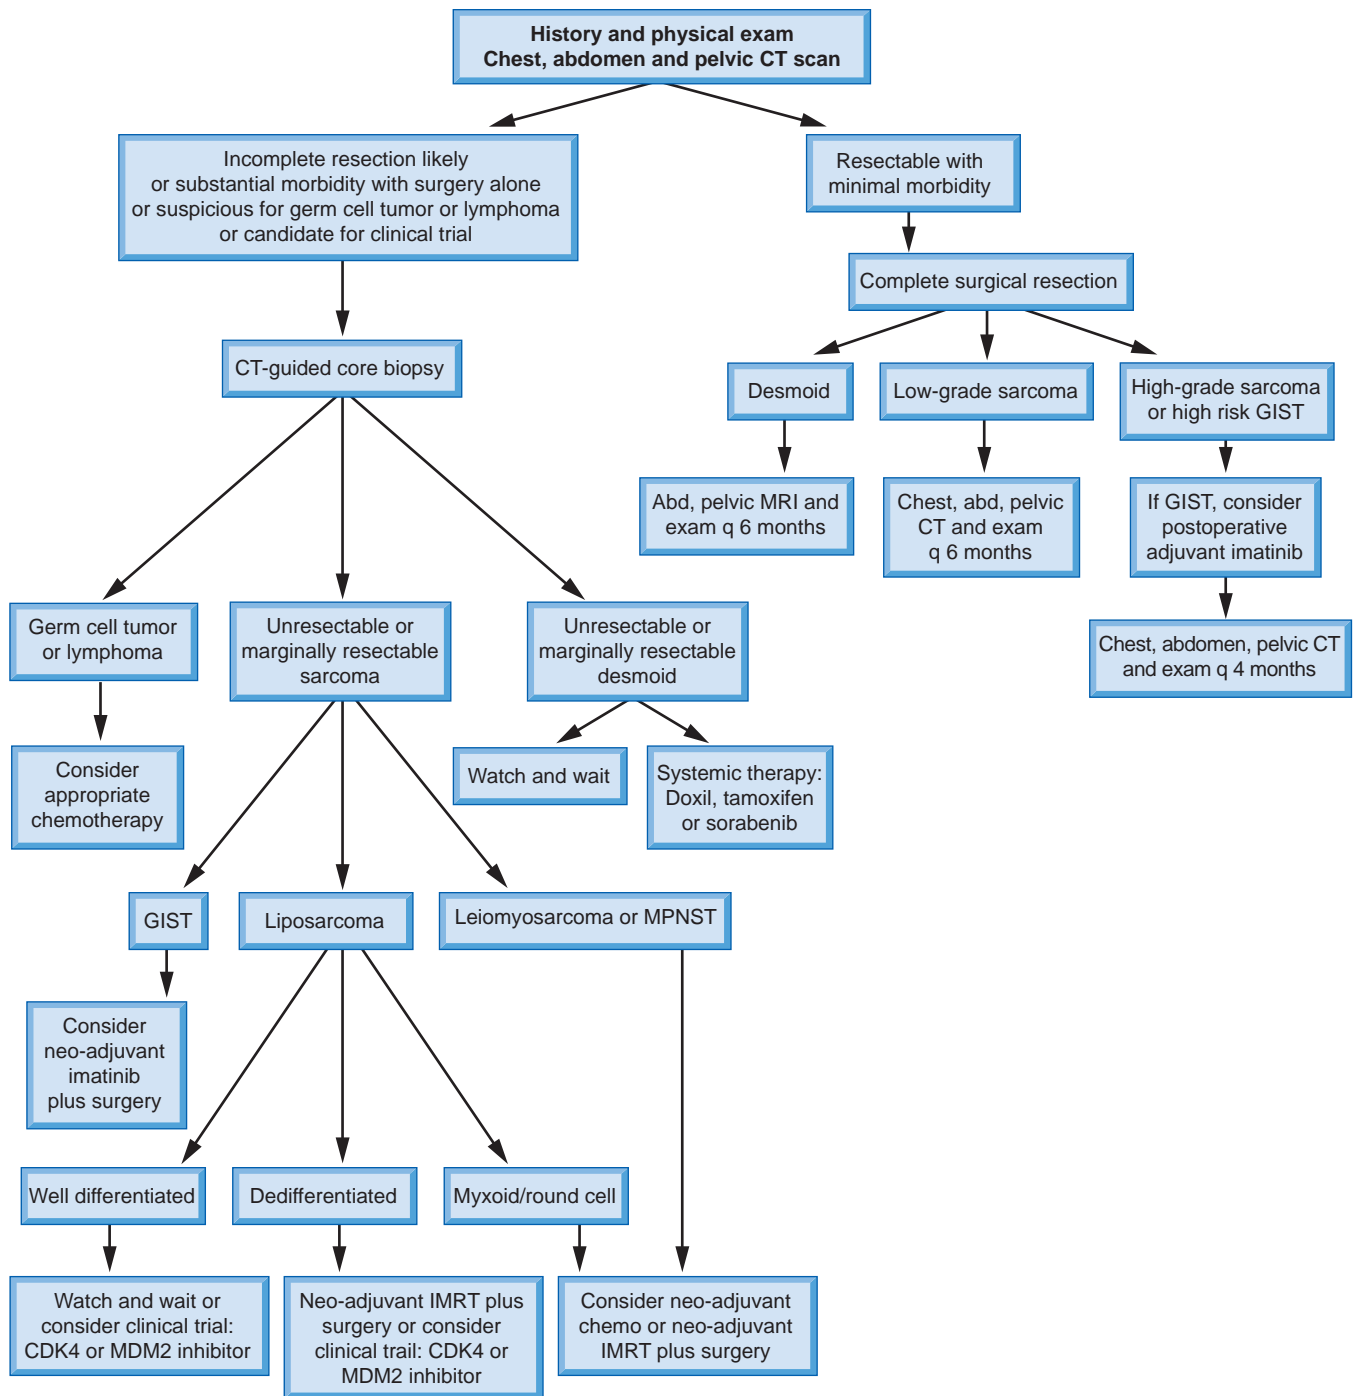

Figure 90.7 Algorithm for the management of retroperitoneal and visceral sarcoma. CT, computed tomography; MRI, magnetic resonance imaging; GIST, gastrointestinal stromal tumor; MPNST, malignant peripheral nerve sheath tumor; IMRT, intensity-modulated radiation therapy.

developed in 40% to 50% of cases. There is a clear need for adjuvant local therapy. Of importance, local recurrence is a problem for both high-grade and low-grade lesions. Jaques et al.²⁸¹ reported similar local recurrence rates, but very different times to recurrence: a median of 15 months for high-grade and 42 months for low-grade sarcomas.

Radiation Therapy for Primary Localized Retroperitoneal Sarcoma

The retroperitoneum is a site that may be particularly suited to preoperative radiotherapy for sarcoma, because the tumor has

frequently displaced bowel from the target volume. Postoperatively, in contrast, loops of bowel are frequently tethered or fixed within the target area. Postoperative radiation for retroperitoneal sarcoma has high toxicity and unproven efficacy; it can also complicate surgery for later recurrences. Therefore, it is not recommended.

Trials involving preoperative radiotherapy for retroperitoneal sarcoma conducted at the MD Anderson Cancer Center³⁷¹ and the Princess Margaret Hospital^{372,373} are instructive because the acute toxicity of preoperative radiotherapy was prospectively separated from overall toxicity, and the evidence supports an excellent tolerance profile. In the Princess Margaret Hospital study, 40 patients received median preoperative radiotherapy doses of

45 Gy in 25 fractions; the median radiation volume exceeded 7 L. After 9 years' median follow-up, overall survival was 70% at 5 years and 64% at 10 years, which compares favorably to historical controls.³⁷³ BRT, used postoperatively in selected cases, was associated with toxicity and did not appear to improve tumor outcome. The MD Anderson Cancer Center trial evaluated 35 patients treated with doxorubicin concurrent with escalating doses of radiotherapy (18 to 54 Gy) at 1.8-Gy/fraction; IORT with electron beam was also attempted when feasible.³⁷¹ The two studies had qualitatively similar results. In a pooled analysis of these studies, of the 72 patients eligible for preoperative radiotherapy, only 2 (3%) did not receive the entire planned radiation course because of radiation-related toxicity, 1 because of tumor approximating the liver and the other because of grade 3 anorexia.³⁷⁴

With the need to deliver higher doses of radiation to the tumor and lower doses to surrounding tissue, there has been an interest in IORT.³⁷⁵ Petersen et al.³⁷⁶ at the Mayo Clinic reported on 87 patients who were treated with IORT, supplemented by EBRT in 92% of patients. With a median follow-up of 3 years, the 5-year local control rate was 58% and survival was 50%. In a randomized trial at the NCI,³⁷⁷ 35 patients with surgically resected sarcomas of the retroperitoneum were randomly assigned to receive IORT (20 Gy) followed by low-dose EBRT (35 to 40 Gy) or to higher-dose EBRT alone (50 to 55 Gy). Local control was significantly better for patients who received IORT, but there was no impact on survival. Patients in the IORT arm, who also received misonidazole, had a higher incidence of peripheral neuropathy than those who received EBRT alone. On the other hand, those who received higher-dose EBRT alone had a higher incidence of radiation enteritis.

At MSKCC, resection was combined with EBRT and HDR intraoperative BRT at 12 to 15 Gy in an attempt to optimize treatment effect and minimize toxicity to critical anatomy.³⁷⁸ This phase 1 and 2 trial included 32 patients with primary and recurrent retroperitoneal sarcoma. Twenty-five of the patients also received postoperative EBRT (45 to 50.4 Gy). Median follow-up was 33 months, and 5-year local recurrence-free survival was 62%. Five-year actuarial rates of local control were 74% for primary tumors and 54% for recurrent tumors. Treatment-related morbidity was observed in 34% of patients. The most common complication was GI obstruction (six patients, 19%: five grade 3, one grade 5), followed by GI fistula (three patients, 9%: two grade 3, one grade 5). Peripheral neuropathy, a common complication of IORT, developed in only two patients (6%, both grade 2). Treatment-related mortality was 6% ($n = 2$). Given the morbidity associated with IORT and its inherent limitations in large tumor beds, IORT is unlikely to be applicable to most primary retroperitoneal sarcomas.

The ideal radiation approach is one that could dose-escalate preoperative radiation. With conventional radiation, the preoperative dose cannot be escalated beyond 50.4 Gy without incurring excessive toxicity. However, dose-painting IMRT allows targeted dose escalation to areas at highest risk. The posterior structures, where there are no intestines, can receive 60 Gy, while the remaining tumor volume receives 50.4 Gy, thus respecting the tolerance. A report from the University of Alabama showed the feasibility of such an approach.³⁷⁹ Fourteen patients were treated with preoperative radiation to the whole target volume to 45 Gy, then the area that was judged to be at risk for positive margin was separately boosted with IMRT to bring the total dose to 57.5 Gy. Only one patient experienced grade 3 nausea and vomiting. Eleven patients had complete resection with negative margins. With a median follow-up of 12 months, there was no late toxicity related to radiation. Further dosimetric studies showed the technical feasibility of delivering doses as high as 75.2 to 82.8 Gy using this technique.³⁷⁹

On a similar theme, Yoon et al.³⁸⁰ suggested a coordinated strategy to optimize radiotherapy target coverage without enhancing toxicity by combining advanced radiotherapy techniques, including proton-beam radiotherapy, with aggressive en bloc resection.

Another interesting IMRT strategy for retroperitoneal sarcoma is to focus entirely on the posterior tumor attachment without attempting to include the remaining tumor mass in the irradiated target volume. This approach was assessed in a prospective study of patients with liposarcoma. Twenty-nine patients were treated with radiation to the posterior tumor area followed by surgery; matched patients treated with surgery alone served as controls. Although the tolerance profile was excellent, neither local control nor disease-specific survival was improved over that in the control group.³⁸¹

The true benefit of IMRT—or any radiation therapy—for patients with retroperitoneal sarcoma is continuously debated among physicians who treat this disease. In an attempt to provide definitive guidance, the European Organisation for Research and Treatment of Cancer (EORTC) has opened a randomized, phase 3 trial (EORTC 62092 - 22092) to examine relapse-free survival in patients treated with neoadjuvant radiation compared to those treated with surgery alone.³⁸² Until the results become available, surgical resection alone remains the standard of care for patients with retroperitoneal sarcoma.

Chemotherapy for Primary Localized Retroperitoneal Sarcoma

The most common histologic types in the retroperitoneum (well-differentiated liposarcoma, dedifferentiated liposarcoma, LMS, and MPNST) are typically not very responsive to conventional chemotherapy, and chemotherapy has never been shown to improve survival. Thus, chemotherapy is rarely indicated in the adjuvant setting for patients with completely resected primary retroperitoneal sarcoma. For patients with locally advanced primary retroperitoneal sarcoma that is unresectable or marginally resectable, neoadjuvant chemotherapy may be indicated based on histologic type as it enables assessment of response in individual patients and occasionally may improve resectability (see Fig. 90.7).

Combined Chemoradiotherapy for Primary Localized Retroperitoneal Sarcoma

One of the difficulties in managing retroperitoneal sarcoma relates to the disparate nature of the histologic subtypes. Large, low-grade liposarcomas constitute about 50% of lesions and present a prodigious challenge because of their potential for late local recurrence, often leading to death. The remaining tumors are of intermediate and high grade, with LMS a frequent histology, and not only recur locally (often rapidly) but have a significant tendency to peritoneal seeding as well as metastasis to liver and other sites. Retroperitoneal sarcomas of all histologies often present as relatively large lesions due to asymptomatic growth within the abdomen. Because of the adverse nature of these sarcomas, a potential strategy is combined chemotherapy and radiotherapy as a neoadjuvant to surgery. However, not many groups have approached this problem specifically, presumably in large part due to the paucity of evidence for a benefit of chemotherapy in these tumors, as outlined previously. Another reason is the wish to minimize toxicity in patients already burdened with medical issues related to the treatment of large tumors.

The feasibility of preoperative combined chemoradiotherapy was demonstrated in a prospective trial from MD Anderson Group.³⁷¹ Eligibility was limited to intermediate- and high-grade tumor. Doxorubicin was infused at a low dose (20 mg/m² per week for 4 to 5 weeks). Radiation was delivered in escalating doses ranging from 18 Gy to 50.4 Gy total radiation. The protocol also included a 15-Gy electron-beam IORT boost to the bed of the resected tumor. The radiation was very well tolerated, with only 2 (18%) of 11 patients having grade 3 or 4 nausea. These promising feasibility results remain experimental and ideally should prompt the design of randomized trials to address the efficacies of the different elements of the protocol.

Multimodal Management of Locally Recurrent Retroperitoneal Sarcoma

Surgery. Retroperitoneal recurrences are often detected on routine screening with imaging, or patients may present with pain or nonspecific symptoms. After workup to determine the extent of disease, patients with isolated local recurrence should be carefully evaluated to determine feasibility of re-resection. Because current chemotherapy is ineffective for the majority of patients with liposarcoma and because toxicity limits adequate dosing by radiation therapy, complete surgical resection remains the most effective treatment modality. When complete gross resection can be achieved, operation for local recurrence should be attempted. Complete resection is usually possible in 80% of patients presenting with first recurrence and in 60% to 70% of patients presenting with second or subsequent recurrence of their retroperitoneal sarcoma. Surgery may be combined with neoadjuvant systemic therapy or IMRT dependent on the histologic type or subtype, growth rate, and extent of disease.

The most difficult decisions in retroperitoneal liposarcoma are whether a patient is likely to benefit from reoperation and when to perform the reoperation; often a period of monitoring is appropriate. With the aim of informing decisions on the likely benefit from re-resection, an analysis at MSKCC assessed factors that predict survival after re-resection.³⁸³ Of 105 patients who had local recurrence after complete resection of a primary retroperitoneal liposarcoma, 61 underwent complete resection of their first local recurrence. The independent predictors of disease-specific survival were local recurrence size and growth rate and primary histologic variant and grade. Despite aggressive operative management, patients with a local recurrence growth rate >1 cm per month had poor outcomes that were similar to those of patients who were not treated with resection. Only patients with local recurrence growth rates of <0.9 cm per month had improved survival following aggressive resection of the local recurrence. Based on these results, for patients presenting with asymptomatic local recurrence and growth rates ≥ 1 cm per month, we now recommend treatment with systemic chemotherapy or novel targeted therapy trials. Surgery is considered in this subgroup only if they develop symptoms, such as obstruction or bleeding, that do not respond to medical management. If the local recurrence growth rate is <1 cm per month, immediate surgery is recommended for all symptomatic patients and for asymptomatic patients whose local recurrence is impinging on critical structures (particularly if further growth may result in the need to sacrifice critical organs) or has a solid appearance on CT scan (suspicious for dedifferentiation). Many asymptomatic patients with a well-differentiated-appearing local recurrence that is well away from critical structures may be safely followed off any therapy and monitored to determine if they develop other sites of disease before recommending complete surgical resection. Such an approach can extend the interval between surgical resections, and it enables the surgeon to be more confident that all sites of known disease are encompassed with the planned procedure. Debulking, however, has limited overall value in terms of long-term survival of patients with recurrent lesions.

Radiotherapy. Many variables must be considered in deciding whether to use radiotherapy for locally recurrent retroperitoneal sarcoma. If diffuse intra-abdominal recurrence is present, then an accurate delineation of a target volume is unlikely to be feasible. With each successive recurrence, the situation becomes ever more challenging, and the chances of significant acute and chronic complications from reirradiation increase exponentially. Reirradiation is especially associated with increased morbidity due to adhesions from previous procedures. However, when complete gross resection appears technically feasible and the patient is asymptomatic and otherwise well, the authors favor aggressive treatment, preferably combined with preoperative radiotherapy to a conventional volume if the patient has had no prior radiotherapy.

If prior radiotherapy has been used, subsequent treatment is much more complicated, and alternative strategies may be considered. These need to be determined case by case, but possibilities include using IMRT to a limited region of the retroperitoneum preoperatively. In centers with access to them, IORT or proton beam may provide additional options. In all these deliberations, one needs to recognize that the value of radiotherapy remains unproven and the main motivation to use it is the adverse behavior of the tumor. Most important, attempting to eradicate unresectable gross disease using radiotherapy is generally considered futile, and the dose required to attempt this has real potential to damage critical intra-abdominal structures.

Chemotherapy. Intraperitoneal chemotherapy after debulking of peritoneal metastases has been advocated but remains an investigational approach.

Serious Complications of Primary Treatment

Wound Complications

Wound complications, including infection and dehiscence, are common after resection of extremity sarcomas. Wound complications are exacerbated by adjuvant radiation and chemotherapy, which inhibit wound healing. Early studies on the effects of doxorubicin and X-rays on wound healing in animal models demonstrated that the timing and the combination of antineoplastic agents were critical factors.³⁸⁴ Radiation or chemotherapy used just before, or in close juxtaposition to, the time of wounding significantly impaired wound healing. This appeared to be due to inhibition of new collagen synthesis.

The influence of preoperative chemotherapy on the risk of wound complications is a complex topic.³⁸⁵ Perhaps the most comprehensive study is that from the MD Anderson Cancer Center.³⁸⁶ The authors compared morbidity of radical surgery for soft tissue sarcoma in 104 patients who received induction chemotherapy before surgery and in 204 patients who had surgery first. The most common complications were wound infections and other wound complications; more important, however, the incidence of surgical complications was no different for patients who underwent preoperative chemotherapy than for patients who underwent surgery alone, both for those with sarcomas of the limbs (34% versus 41%) and for those with retroperitoneal or visceral sarcomas (29% versus 34%). Note, however, that the data are sparse and entirely retrospective, and the effects of preoperative chemotherapy are often confounded by concomitant use of preoperative radiotherapy (e.g., in two concurrent radiotherapy plus MAID studies, discussed earlier in this chapter).³⁸⁶ Preoperative chemotherapy is often delivered by the intra-arterial route, often combined with radiotherapy at the same time, with apparently greater morbidity than when radiotherapy is given alone.³⁸⁷ Therefore, the risks of intra-arterial preoperative chemotherapy cannot safely be inferred from the results with the “usual” intravenous chemotherapy.

The effects of adjuvant BRT on wound complications have been studied at MSKCC. One finding is that, when radiation delivery via afterloading catheters begins more than 5 days after surgery, the rate of major wound complications falls, approaching that with surgery alone.³¹³ In the randomized BRT trial,³¹⁹ the overall rate of wound complications (wound infection or the need for further operative intervention) in the BRT arm (24%) did not differ significantly from that in the control arm (15%; $p = 0.18$). However, the rate of reoperation was higher in the BRT arm (9% versus 1%; $p = 0.03$). The other covariable that contributed to wound reoperation was the width of the excised skin. If the width was >4 cm, the reoperation rate was 9%, but if the width was ≤ 4 cm, the rate was 1% ($p = 0.02$).

These types of complications are not unique to BRT but have been shown with external beam irradiation as well.^{290,388} In the Canadian trial discussed earlier,²⁹³ which compared preoperative

and postoperative irradiation in 190 patients, wound complication was a primary end point of the study. Wound complications were defined as secondary wound surgery, hospital admission for wound care, or need for deep packing or prolonged dressings within 120 days after tumor resection. Patients undergoing preoperative radiation had a significantly higher rate of wound complications than those undergoing postoperative radiation (35% versus 17%; $p = 0.01$).²⁹³ The rates of wound complications in both arms were higher than those in many other studies, most probably because of methods of assessment. In this study, the criteria for an acute wound complication were prospectively applied with a specific requirement for reporting at frequent intervals for the initial 4 months after surgery. In studies using retrospective evaluation, in contrast, complications such as prolonged dressings or packing (often administered to outpatients) may be overlooked.

The rate of wound complications may be reduced by the implementation of IMRT protocols in major referral centers. Careful planning may minimize radiation exposure to planned skin flaps; however, to date outcomes have been variable, and widespread reproducibility of this methodology is difficult.³⁰² In situations in which wound complications may be anticipated (because of the magnitude of the wound, extent of the resection, prior radiation, and so on), serious consideration should be given to using fresh vascularized tissue in the form of transpositional or free grafts to cover the defect before the placement or delivery of radiation therapy. This approach appears to markedly diminish postoperative morbidity, although the point is difficult to prove because of possible selection bias: nonprimary closure is more common for patients expected to have larger tumors and more problematic resections. In the Canadian trial, the only significant variables associated with wound complication in multivariate analysis were the timing of radiotherapy (i.e., preoperative versus postoperative), the volume of tissue removed at surgery, and the location of the tumor (upper versus lower extremity). The manner of wound closure, comorbidity, age, smoking history, and treatment center had no apparent influence on the risk.²⁹⁴ Similar observations were made in the MD Anderson Cancer Center study.³⁸⁹

Note that the risk of wound complications appears to be almost entirely confined to lower-extremity lesions.^{293,377,389} This observation implies that, when deciding on the timing of radiotherapy, the risk of wound complications is a less important consideration for sites other than the lower extremities. This may make preoperative radiotherapy advantageous in sites for which restricting radiotherapy dose and volumes may have long-term benefit. Such sites include proximal arm (to protect overlying brachial plexus and lung) and the head and neck (to protect critical anatomy). In the authors' prospective series of patients with head and neck sarcomas treated with preoperative radiotherapy, wound complication rates were relatively low, even in patients with adverse anatomic presentations.³⁹⁰

Bone Fracture

Little is known about the impact of adjuvant radiation and chemotherapy on bone fracture. Among 145 patients with soft tissue sarcoma who underwent limb-sparing surgery and postoperative radiation with or without chemotherapy, the fracture rate was 6%.³⁹¹ For patients treated with adjuvant BRT in the MSKCC randomized trial, the rate of fracture was 4%, compared to 0% in the control arm, but difference was not statistically significant ($p = 0.2$).³⁹² A similar fracture risk (7%) was reported for 285 patients with soft tissue tumors treated by radiation and surgery, and that risk of fracture was not related to the dose, timing, and fractionation of radiation therapy.³⁹³ This series had a high rate of complications, including fracture nonunion (45%) and deep infection (20%). These authors suggested that prophylactic intramedullary fixation of the femur should be considered for patients who undergo resection of large tumors in the anterior compartment of the thigh requiring extensive periosteal stripping and adjuvant radiation therapy.

The factors associated with pathological fracture of the femur were analyzed in a study of 205 patients with soft tissue sarcoma of the thigh treated with adjuvant radiation (115 patients with BRT alone, 59 with EBRT alone, and 31 with both).³⁹⁴ The 5-year actuarial risk was 8.6%. On multivariate analysis, the only variable significantly associated with fracture was periosteal stripping ($p = 0.01$).³⁹⁴ Other factors were significant in a long-term prospective study from the Princess Margaret Hospital of 364 patients with lower-extremity sarcomas treated with adjuvant EBRT (without adjuvant chemotherapy). The rate of pathological fractures was significantly higher with higher radiotherapy doses (10% for 60 or 66 Gy versus 2% for 50 Gy), and was higher with postoperative than with preoperative radiation therapy.³⁹⁵

IMRT dosimetry factors associated with fracture risk were investigated in a case-control study at the Princess Margaret Hospital.³⁹⁶ The factors that appeared to reduce the risk of radiation-induced fracture were (1) volume of bone irradiated to ≥ 40 Gy kept below 64%, (2) mean dose to bone < 37 Gy, (3) maximum dose anywhere along the length of bone < 59 Gy, and perhaps (4) lower mean radiotherapy volume. Knowledge of these types of volumetric dosimetry data should facilitate the planning of dose objectives for IMRT. In fact, in short-term follow-up, patients treated with image-guided IMRT had no fractures in a recently reported series from the Princess Margaret Hospital group.³⁰³

Other Complications

Another complication encountered with adjuvant radiation is peripheral nerve damage. In the MSKCC randomized trial of BRT, the rate was 9% in the BRT arm compared to 5% in the control arm ($p = 0.5$).³¹⁹ In a study of 62 patients treated with postoperative radiation, the rate of peripheral nerve damage was 1.6%.³⁹⁷ Evolving results suggest that patients treated with postoperative radiotherapy also have worse rates of fibrosis and peripheral edema compared to those receiving preoperative radiotherapy.²⁹⁷

A common concern of practitioners is whether postoperative radiotherapy affects the bone and soft tissue grafts used for musculoskeletal reconstructions. Evidence suggests that postoperative radiotherapy can ordinarily be administered 3 to 4 weeks after grafting without detriment to the graft union.³⁹⁸ Soft tissue reconstruction (e.g., tissue transfer in the form of pedicle flaps, free flaps, or skin grafts) carries a theoretical risk of radiotherapy-related wound breakdown that may require reoperation. This risk has been shown to be very low (5%), and most tissue transfers tolerate subsequent adjuvant radiation therapy well.³⁹⁹ The authors have observed a higher rate of wound complications that necessitated reoperation in patients who received BRT. It is unclear whether flaps and skin grafts are inherently more susceptible to breakdown in the immediate postoperative period or whether this is a direct result of BRT.

Multimodal Management of Advanced Disease

Control of the primary tumor can be achieved in the vast majority of patients with soft tissue sarcoma, but close to one-half of patients with non-GIST sarcomas succumb to metastatic or locally advanced disease. Median survival from the time metastases are recognized is on the order of 12 months, and 20% to 25% of patients are alive at 2 years. Even the most active chemotherapeutic options are of limited value and are associated with serious and potentially life-threatening toxicity. Newer agents offer at least the hope of less toxicity and greater efficacy than anthracyclines and ifosfamide, at least for selected subtypes.

Outcomes in patients receiving systemic therapy for metastatic sarcoma were quantified in the SARcoma treatment and Burden of Illness in North America and Europe study of 213 patients treated in North America and Europe. Patients were treated with

an average of 2.7 lines of chemotherapy. A favorable response was observed in 83% of patients after treatment with first-line chemotherapy (most commonly adriamycin-based), but only 42% and 38% of patients treated with second- and third-line therapies, respectively. Median progression-free survival (PFS) after favorable response was only 8.3 months.⁴⁰⁰

Patients with metastatic sarcoma often feel well at the time that a radiograph or CT reveals metastases and may remain free of symptoms for months or years. Thus, with many patients, alleviation of symptoms is not an immediate concern, although progression is inevitable. Surgical resection can provide selected patients with prolonged periods of freedom from disease, and radiation therapy provides palliation for individual patients who have localized symptomatic metastases. Optimal treatment of patients with unresectable or metastatic soft tissue sarcoma requires an appreciation of the natural history of the disease, close attention to the individual patient, and an understanding of the benefits and limitations of the therapeutic options.

Surgical Resection of Metastatic Disease

Approximately 20% of patients with a soft tissue sarcoma of an extremity or the trunk develop pulmonary metastases, and in the majority, the lung remains the only clinically evident site of metastasis. The histopathology of 1,643 pulmonary metastases has been described.⁴⁰¹ Only 30% of all pulmonary metastases are detected at the time of diagnosis of the primary tumor; among those detected in follow-up, 80% are within 2 years of diagnosis. In retrospective series, 20% to 30% of patients who undergo metastasectomy are alive 5 years later.

In a series of 716 patients with primary extremity sarcoma treated at MSKCC, pulmonary-only metastases occurred in 19%, or 135 patients. Of these, 58% underwent thoracotomy, and 83% of those had a complete resection of their tumors. In the 65 patients who had a complete resection of their tumors, 69% had recurrence with pulmonary metastases as their only site of disease. Median survival time from complete resection was 19 months, and 3-year survival was 11% among all those presenting with lung metastasis only, 23% among those undergoing complete resection, and 0% among those who did not undergo thoracotomy.²⁶⁰ Incomplete resection was no better than no operation. Chemotherapy had no obvious effect on survival, whether or not the patients underwent thoracotomy. Moreover, at the MD Anderson Cancer Center, response to chemotherapy given before pulmonary resection did not predict improved outcome⁴⁰² (in contrast to the experience with chemotherapy for primary sarcoma). After resection of pulmonary metastases with curative intent, 40% to 80% of patients will have recurrence in the lung. Repeat resection is often possible.⁴⁰³ In a series of 86 patients who underwent repeat resection, predictors of poor survival included more than three lesions, a lesion >2 cm, and high-grade histology. If two or three of these factors were present, disease-specific survival was 10 months.

Histology-Specific Chemotherapy for Advanced Disease

Single Agents. Doxorubicin has been the mainstay of chemotherapy for advanced sarcoma. In recent trials that evaluated doxorubicin (75 mg/m²) as a front-line treatment, overall response rates were 14% for advanced disease and 20% for metastatic disease, and median PFS rates were 4.6 and 5.2 months, respectively.^{404,405} A dose-response relationship has been demonstrated.^{406,407} Studies with liposomal doxorubicin showed fewer side effects than those with doxorubicin and similar response rates, despite the fact that the liposomal doxorubicin studies may have had a relatively high proportion of resistant sarcoma subtypes, such as GIST.⁴⁰⁸

Ifosfamide has approximately the same efficacy as doxorubicin. In the past, ifosfamide dosing was limited by severe urothelial

toxicity (hemorrhagic cystitis). The uroprotective agent mesna has markedly changed the ability to administer both ifosfamide and cyclophosphamide, and ifosfamide doses as large as 14 to 18 g/m² or more over 1 to 2 weeks have been given.⁴⁰⁹ Some evidence suggests a dose-response relationship for ifosfamide.⁴¹⁰ This is borne out by the results of the many phase 2 trials examining the use of high-dose ifosfamide in metastatic soft tissue sarcoma. Higher doses of ifosfamide occasionally produce responses in patients who do not respond to lower doses of this or other alkylating agents. Note that synovial sarcoma appears to be particularly responsive to ifosfamide.⁴¹¹ A new, less toxic metabolite of ifosfamide, TH-302, is under study in phase 3 for patients with metastatic soft tissue sarcomas. TH-302 is a hypoxia-activated prodrug, a bromoisophosphoramide mustard that is reduced and activated under hypoxic conditions. Although data suggest that TH-302 synergizes with doxorubicin *in vitro*, it will be up to the randomized study to help determine whether TH-302 and doxorubicin truly have efficacy beyond that of doxorubicin alone or combined with ifosfamide.

A third drug with modest activity in sarcoma is dacarbazine.⁴¹² Dacarbazine has frequently been used in combination chemotherapy with doxorubicin (see “Combination Chemotherapy for Advanced Soft Tissue Sarcoma”). It is given in a variety of schedules, from intravenous continuous infusion as part of the MAID protocol to one large bolus. The major side effects of dacarbazine are nausea and vomiting, which have been substantially reduced with the use of serotonin-antagonist antiemetics. Antiemetic use allows for dacarbazine administration in a single treatment rather than in divided doses. Temozolomide, the oral equivalent of dacarbazine, appears to have some activity against LMSs as well.

Pazopanib, an inhibitor of multiple tyrosine kinases (vascular endothelial growth factors 1, 2, and 3, PDGF receptor A, PDGF receptor B, and KIT), has been evaluated for soft tissue sarcoma. The PALETTE study, a phase 3 randomized trial, enrolled 369 patients with metastatic nonadipocytic soft tissue sarcoma who had been treated with an anthracycline-based regimen. PFS was 4.6 months in patients who received pazopanib versus 1.6 months for those on placebo ($p < 0.0001$). Thus, pazopanib is now a viable systemic treatment for patients with advanced disease.⁴¹³ Ongoing studies are evaluating pazopanib in patients with adipocytic sarcomas and chondrosarcoma.

The most significant cytotoxic agent in soft tissue sarcomas is probably trabectedin (ecteinascidin, ET-743), with notable response rates in myxoid-round cell liposarcoma and some responses in LMS. Trabectedin binds the minor groove of DNA and bends the DNA, interfering with transcription and blocking cell cycle progression. Its potency appears to depend on the cell having an intact nucleotide excision repair system. Its toxicity is largely hematologic and hepatic, with significant posttreatment increases in levels of transaminases and occasionally alkaline phosphatase and bilirubin; these toxicities resolve spontaneously and appear to be mitigated with the use of glucocorticoids. In early studies enrolling patients with a variety of sarcoma subtypes, responses were noted in 14 of 189 patients (7%).⁴¹⁴ When tested as first-, second-, or third-line therapy, a 7% minor response rate was also noted.⁴¹⁵ The most exciting recent data regarding trabectedin are its reported activity against myxoid-round cell liposarcoma. In this subtype, the radiologic response rate of single-agent trabectedin is on the order of 50% to 60%—activity as great as that of imatinib in GIST.^{124–126,416} Based on these data, trabectedin was approved for use in Europe in 2007.^{415,417,418} Although it is not approved in the United States as of 2013, it remains available in an expanded access program. A phase 2 trial of trabectedin in LMS has been reported with response or stable disease in 60% of patients.⁴¹⁹ Trabectedin is also being evaluated in a randomized phase 3 study comparing the efficacy of trabectedin versus dacarbazine in patients with liposarcoma and LMS (NCT01343277) and in combination with doxorubicin in patients with uterine and nonuterine LMS.

As for other single agents, cisplatin and carboplatin have produced occasional responses in phase 2 trials. However, single-agent

vincristine, etoposide, and dactinomycin appear to be inactive in adult sarcomas, unlike in pediatric sarcomas. The taxanes also show little activity in sarcomas save for angiosarcoma. More recent data indicate that gemcitabine may have modest activity, dependent on the administration schedule.⁴²⁰ Few investigational drugs have demonstrated meaningful activity in soft tissue sarcoma, except for epirubicin, a close relative of doxorubicin, now approved for commercial use.

Immunotherapy for sarcoma, which was used in some of the earliest studies in sarcoma adjuvant chemotherapy, is seeing renewed interest, although little success. Cytokines alone appear to be ineffective in sarcoma, as does nonspecific immunotherapy with bacterial cell wall components. Clinical studies at the NCI and elsewhere are beginning to examine vaccines of peptides that represent the fusion proteins observed in specific sarcoma subtypes. Lymphokine-activated killer cell and other T-cell immunotherapy with cytokines was investigated in a very small number of patients at the NCI without any observed responses. Dendritic cell vaccines and other forms of tumor-specific immunotherapy are undergoing investigation and may be relevant to patients with soft tissue sarcoma. The most important development in immunotherapy for soft tissue sarcomas is responses to a T-cell therapy directed against NY-ESO-1, a “cancer-germ cell” antigen found in the majority of synovial sarcomas. Cytotoxic T cells directed against NY-ESO-1 are generated in vitro and used as a therapeutic agent. Among six patients with synovial sarcoma with tumor expression of the NY-ESO-1 protein, 4 (67%) responded to the therapy.⁴²¹ This suggests that at least a subset of sarcoma types can be modulated by immunotherapy for patient benefit. A phase 2 study of NY-ESO-1-directed T cells is ongoing as of September 2013.⁴²²

Combination Chemotherapy. A variety of chemotherapy combinations have been developed and examined in phase 2 trials. The typical backbone of combination regimens is doxorubicin (or its analogue epirubicin) with an alkylating agent, with or without other agents. One of the earliest combinations used was doxorubicin and dacarbazine, which has been well studied by the Southwest Oncology Group. Although initial analysis noted a 41% major response rate, a subsequent study of either a bolus or continuous infusion of the same regimen yielded a 17% response rate.⁴²³

CYVADIC has been widely used for sarcoma therapy in the United States and Europe. Although single-arm studies showed response rates as high as 71%, a randomized trial showed no significant difference in overall survival between patients given CYVADIC and those given doxorubicin as a single agent.⁴²⁴ The two-drug combinations of ifosfamide with either doxorubicin⁴²⁴ or epirubicin⁴²⁵ have consistently given response rates >25%.

MAID was proven effective in metastatic soft tissue sarcoma in a large, randomized phase 2 trial. This trial examined MAID versus doxorubicin and dacarbazine. The study showed an increased response rate in the MAID arm (32% versus 17%; $p < 0.002$).⁴²⁶ In results that underscore the increased toxicity of aggressive chemotherapy regimens, there were 8 toxicity-related deaths in the study, 7 among the 170 patients treated with 7.5 g/m² of ifosfamide per cycle. This dose was decreased to 6 g/m² during the course of the study. In a univariate analysis, the two-drug arm showed a survival advantage (13 months versus 12 months for MAID); however, this difference was not significant in a multivariate analysis. As noted later in this chapter under “Dose Intensity,” with the introduction of growth factors, the dose intensity of this regimen has become better tolerated.

The combination of cisplatin and mitomycin C with doxorubicin (MAP) yielded a 43% response rate in a study at the Mayo Clinic.⁴²⁷ The activity of the MAP regimen has been confirmed in a randomized Eastern Cooperative Oncology Group trial.⁴²⁸

The response rate is greater for ifosfamide combinations than for regimens without ifosfamide, highlighted in a 2008 meta-analysis.⁴²⁹ However, 1-year survival was no different with the addition of ifosfamide to other chemotherapy.

A meta-analysis of data from seven large EORTC studies provided a very useful assessment of predictors of outcome after doxorubicin- or epirubicin-containing combination chemotherapy.⁴³⁰ In multivariate analysis of data for 2,185 patients, whose overall median survival was 51 weeks, the significant predictors of overall survival included good performance status before chemotherapy, lack of liver involvement, low histopathologic grade, long disease-free interval (time since initial sarcoma diagnosis), and young age. The predictors of response to chemotherapy were lack of liver involvement, young age, high grade, and liposarcoma histology (all $p < 0.01$ in a multivariate analysis); LMS histology was not predictive independent of liver metastasis. Although lesions were not stratified by site, these data provide some of the best evidence that response rate does not necessarily correlate with overall survival. Furthermore, these data were collected before GIST was recognized as a distinct sarcoma subtype, and thus the question of liver metastases as a negative prognostic indicator becomes an open question.

Is combination chemotherapy better than single-agent doxorubicin for overall survival for patients with metastatic soft tissue sarcomas? Again, the concept arises that response rates may be dissociated from overall survival rates. Several phase 3 trials have compared combination chemotherapy with single-agent doxorubicin in patients with metastatic disease (Table 90.4), including two trials focused on uterine sarcoma. Several trials had better response rates with combination chemotherapy, but there was no survival advantage over single-agent doxorubicin. Complete responses during these studies were very rare and were not durable. These data argue that single agents are as effective as combination chemotherapy for patients with metastatic disease in terms of overall survival. However, some patients may be eligible for palliative resection of metastatic disease. For these patients, combination chemotherapy, which gives better response rates than single agents, can be considered.

A 2008 meta-analysis confirmed the benefit of combination chemotherapy in terms of response rate and the lack of benefit in terms of 1-year survival.⁴²⁹ Further confirmation comes from two large international, randomized studies that evaluated the efficacy of single-agent doxorubicin versus doxorubicin plus ifosfamide (EORTC 62012)⁴⁰⁴ or doxorubicin plus palifosfamide (PICASSO 3).⁴⁰⁵ Both studies were run in the first-line setting in patients with high-grade metastatic soft tissue sarcoma. EORTC 62012 evaluated the efficacy of doxorubicin (75 mg/m²) versus doxorubicin (75 mg/m²) plus ifosfamide (10 g/m² over 4 days) in 455 patients. At a median follow-up of 56 months, overall survival, the primary end point, was not significantly different: 14.3 months for the combination versus 12.8 months for single-agent doxorubicin. Of note, most of the patients in the doxorubicin arm received ifosfamide (off-study) as a second-line treatment, which may have affected survival results. The objective response rate of the combination was 26.5% versus 13.6% with doxorubicin, and median PFS was 7.4 months versus 4.6 months, respectively ($p = 0.002$). However, these benefits were achieved at the cost of toxicity, with significantly more grade 3 or greater hematologic toxicity in the combination arm.

PICASSO 3⁴⁰⁵ evaluated the efficacy of palifosfamide, a less toxic metabolite of ifosfamide,^{431,432} as first-line treatment in patients with intermediate- or high-grade metastatic soft tissue sarcoma. At 113 sites, 447 patients were randomized to doxorubicin (75 mg/m²) plus palifosfamide (150 mg/m² on days 1 to 3 of 21-day cycles) or doxorubicin plus placebo. At a median follow-up of 340 days, the two arms did not differ significantly in the primary endpoint, median PFS (5.98 months for doxorubicin plus palifosfamide versus 5.23 months for doxorubicin plus placebo; $p = 0.18$), nor did they differ in overall survival (15.9 months versus 16.9 months; $p = 0.7$). The overall response rate was 28.3% (doxorubicin plus palifosfamide) versus 19.9% (doxorubicin plus placebo).

These data underscore the need to pursue new directions, including seeking synergistic combinations of chemotherapies or

combinations of standard cytotoxic chemotherapy with immunotherapeutic approaches or with newer agents that may have more specific targets that would address the heterogeneity of sarcoma.

A combination that does appear to confer a survival benefit over single-agent chemotherapy is gemcitabine with docetaxel. Although as single agents gemcitabine and docetaxel have only borderline activity in sarcoma, the combination yielded a 53% response rate in a phase 2 study of patients with LMS, the great majority of whom had a uterine primary tumor.⁴³³ These data have been confirmed in two other phase 2 studies,^{434,435} and in a randomized phase 2 study of gemcitabine versus gemcitabine-docetaxel. In this study, the combination gave a RECIST response rate of 16% (versus 8% for the single agent).⁴³⁶ Moreover, the combination was associated with improved PFS and overall survival, the first such observation for a combination chemotherapy versus single agents. However, the combination was not compared to more standard single agents such as doxorubicin. Although other subtypes may respond to this combination, LMS and PMFH were the two subtypes that responded most reproducibly, highlighting the subtype specificity even with standard cytotoxic chemotherapy agents. However, the benefit of the combination of gemcitabine and docetaxel over gemcitabine alone, at least for LMS, has been refuted by a recent study from France of patients with LMS.⁴³⁷

A second gemcitabine combination that appears beneficial is gemcitabine plus dacarbazine. A recent phase 2 trial randomized pretreated patients to dacarbazine alone versus dacarbazine combined with gemcitabine.⁴³⁸ Stable disease or response was observed in 25% versus 49%, respectively ($p = 0.009$), and PFS also favored the combination ($p = 0.005$).

Dose Intensity. A central tenet of oncology is that response to chemotherapy is a function of dose intensity. However, toxicity limits the amount of chemotherapy that can be given in any one cycle. If dose could be increased, responses might be better.

Increases in dose intensity can be facilitated by better supportive care, such as the use of hematopoietic growth factors. Some of the aggressive regimens for treatment of metastatic sarcoma satisfy the American Society of Clinical Oncology guidelines for use of growth factors, given their high rate of associated febrile neutropenia.⁴³⁹ Granulocyte macrophage–colony-stimulating factor (GM-CSF, sargramostim) decreased the myelosuppression seen with combinations such as CYVADIC or MAID⁴³⁹ and high-dose ifosfamide. GM-CSF allowed for escalation of the dose of doxorubicin when given in combination with 5 g/m² of ifosfamide, with improvement in response rate.⁴⁴⁰ GM-CSF has also been shown to allow increased dose intensity of the MAP combination, allowing addition of ifosfamide.

Similarly, granulocyte colony-stimulating factor (filgrastim) has been widely used to increase dose intensity and decrease myelotoxicity of aggressive chemotherapeutic regimens such as MAID⁴⁴¹ or dose-escalated doxorubicin and ifosfamide. However, escalated doses (25% increase) in the MAID regimen do not appear to significantly increase the response rate. There may be other ways to achieve dose intensity. Ifosfamide at low dose over a long term (approximately 2 weeks) showed responses in patients who did not respond to other forms of chemotherapy. However, as mentioned previously, the responsiveness to a particular regimen may not translate into increased survival.

Unfortunately, the cardiac toxicity of doxorubicin and the nephrotoxicity and central nervous system toxicity of ifosfamide prevent much additional dose escalation. The next logical step is high-dose therapy with stem cell support, which remains investigational for pediatric sarcomas. Such treatment has been associated with long-term disease-free survival for a few patients with Ewing sarcoma, osteosarcoma, or rhabdomyosarcoma. Most of the patients, however, relapsed rapidly, despite the relative chemosensitivity of these sarcoma types. High-dose therapy with stem cell rescue should not be considered for patients with metastatic sarcoma outside the

setting of a clinical trial. Given the poor results of high-dose therapy, the pursuit of agents with better activity against specific sarcoma subtypes remains a priority for treatment of relapsed disease.

Protein-Targeted Molecular Therapy for Advanced Disease

With the success of imatinib in GIST and chronic myelogenous leukemia, investigators are examining agents that block specific proteins. Angiogenesis inhibition has emerged as a new frontier for treatment of solid tumors of all types, including sarcoma. However, little efficacy has been seen for interferons, TNP-470 (AGM-1470), or SU5416, a vascular endothelial growth factor pathway inhibitor.⁴⁴² Bevacizumab, a recombinant humanized antibody against vascular endothelial growth factor, was studied in patients with angiosarcoma and epithelioid hemangioendothelioma.¹⁵³ Among 30 evaluable patients, 4 had a partial response and 15 had stable disease with a median time to progression of 26 weeks. This is encouraging and suggests that inhibitors of angiogenesis may have activity in select sarcoma subtypes, specifically those of vascular origin. In addition, ongoing studies are evaluating the efficacy of angiogenesis inhibitors in combination with chemotherapy.

First- and second-generation tyrosine kinase inhibitors have yielded rather disappointing results when employed against non-GIST sarcomas. Imatinib was associated with a very low response rate in a study of 10 sarcoma subtypes.⁴⁴³ Sorafenib, which targets B-raf and vascular endothelial growth factor receptor-2, showed only minor activity in patients with soft tissue sarcomas, in particular angiosarcoma.¹⁷⁴

Newer targeted agents are beginning to be assessed, based on the specific biology of sarcoma subtypes. For example, well-differentiated and dedifferentiated liposarcomas demonstrate amplification of *CDK4* and *MDM2* genes on chromosome 12q. The *CDK4* inhibitor flavopiridol and the *MDM2* inhibitor nutlin-3 show antitumor activity in vitro.⁴⁴⁴ A *CDK4*-directed agent that appears active in clinical trials is the specific *CDK4/6* inhibitor PD0332991.^{445,446} A recent phase 2 trial enrolled patients with well-differentiated and dedifferentiated liposarcoma who were experiencing disease progression.⁴⁴⁵ The study was restricted to patients with *CDK4* amplification (assessed by FISH). The median PFS of the trial was 18 weeks, with 66% of the 29 evaluable patients having stable disease at 12 weeks. This greatly exceeded the study's primary endpoint and suggests activity of *CDK4/6* inhibitors in patients with well-differentiated and dedifferentiated liposarcomas.

Other targeted agents are under active examination in patients with soft tissue sarcoma. Ridaforolimus, in a phase 3 trial in patients who had reached maximum benefit from other chemotherapy, showed a statistically significant but small benefit: a 3-week improvement in PFS (17.7 weeks versus 14.6 weeks for placebo; $p = 0.01$).⁴⁴⁷ Pazopanib, on the other hand, showed a 3-month improvement in PFS over placebo, leading to its approval by the US Food and Drug Administration for use in patients with advanced soft tissue sarcoma (other than adipocytic subtypes or GIST) after failure of standard systemic therapies.⁴⁴⁸ Other new agents are under investigation in specific soft tissue sarcoma subtypes; some of these are discussed subsequently.

Recommendations for Patients with Advanced Disease

Low-grade tumors grow very slowly and may be less responsive to chemotherapy than higher-grade lesions. Accordingly, an asymptomatic patient with stable or only slowly progressive disease can be simply observed. Resection of metastatic disease, in particular lung metastases, provides some patients with long-term survival and can be considered if the lungs are the only site of remaining disease.²⁶⁰ In patients who present with completely

resectable lung metastasis from an extremity primary, perioperative chemotherapy does not appear to be associated with better disease-specific or pulmonary PFS. This suggests that systemic chemotherapy has minimal, if any, long-term impact on the outcome of patients undergoing pulmonary resection for extremity sarcoma metastatic to lung.⁴⁴⁹ Histology is of increasing importance in designing effective treatment regimens for patients who present with advanced disease so as to optimize response for the specific soft tissue sarcoma subtype.

Randomized studies have shown that combination chemotherapy can provide a better probability of a response than single-agent doxorubicin. However, overall survival for any combination chemotherapy has not been proven superior to that for single-agent doxorubicin. When a clinical response is needed—for example, before potential surgery for metastases—combinations of agents such as doxorubicin and ifosfamide should be considered, especially for patients with good performance status. For patients with poorer performance status, single-agent doxorubicin remains the standard of care. Pegylated liposomal doxorubicin can be considered in patients who would not tolerate the toxicity of doxorubicin, but the response rate may be lower than that of standard doxorubicin.

If the first-line therapy was doxorubicin alone, the second line can be single-agent ifosfamide or dacarbazine. For LMS, myxofibrosarcoma, PMFH, and perhaps other sarcoma subtypes, gemcitabine either alone or in combinations appears to be an excellent second-line alternative. Ifosfamide is useful against synovial sarcomas and myxoid-round cell and pleomorphic liposarcomas but less useful against LMSs. Dacarbazine has modest activity in soft tissue sarcoma and, with doxorubicin, constitutes a well-studied and well-tolerated combination in metastatic disease. Dacarbazine and temozolomide, an oral version of dacarbazine, show activity against LMS in particular. Patients with angiosarcoma may respond to taxanes, gemcitabine, vinorelbine, pegylated liposomal doxorubicin, sorafenib, as well as standard doxorubicin or ifosfamide chemotherapy. Rhabdomyosarcoma and Ewing sarcoma of soft tissue and bone both respond to single agents and combinations involving topoisomerase 1 inhibitors. Case reports suggest that patients with solitary fibrous tumors and extracranial myxoid chondrosarcomas may respond to sunitinib.^{198,450} Given the paucity of treatment options and the wide variety of newly available kinase-specific agents, patients with advanced sarcomas are candidates for enrollment in phase 1 and 2 studies of new therapies.

Management of Specific Histologic Subtypes and Sites

Responses of soft tissue sarcoma to chemotherapy differ among the histologic subtypes. Pediatric sarcomas (Ewing sarcoma, osteosarcoma, and rhabdomyosarcoma) are known for their relative sensitivity to chemotherapy. Among adult sarcomas, synovial sarcoma and round cell liposarcoma are generally responsive to chemotherapy. GIST, alveolar soft part sarcoma, and low- to intermediate-grade chondrosarcoma are notorious for their resistance to standard cytotoxic chemotherapy agents. Therefore, an imbalance in the subtypes of sarcoma between patient groups can markedly affect the comparability of the outcomes of those groups.

The site of disease is also an important factor in outcome. Among large, low-grade liposarcomas, those in the extremities are less likely to recur than those in the retroperitoneum. Anatomy of metastatic disease can also affect overall response rates. For example, metastases to liver are less likely to respond to chemotherapy than metastases to another site; however, this may represent the tendency of GISTs, which are relatively chemoresistant, to metastasize to the liver. Variations in the site of disease or metastasis pattern may account at least in part for the different responses noted in randomized trials of chemotherapy for soft tissue sarcoma.

The following subsections give examples of specific sites or subtypes of sarcoma and their characteristics.

Leiomyosarcoma

Insight into the differential response of LMS versus other subtypes such as liposarcoma, synovial sarcoma, or PMFH can be obtained from subset analyses from a variety of randomized studies. Note that subset analyses cannot substitute for primary trials, but they can be useful in generating hypotheses. Doxorubicin appears to be active against LMSs, but ifosfamide appears to add little to the response rate.⁴²⁸ This finding has been observed in other studies, but there may be contamination of the LMS group with what would today be classified as GISTs. For uterine LMSs, a modest response to ifosfamide was observed in one small study but not in most other studies.

Among the newer agents, trabectedin showed a 6% response rate in a study of LMS and liposarcoma.⁴⁵¹ Gemcitabine and combinations have activity in LMSs as well.^{128,433,435,452–456} In a small randomized trial for patients with metastatic or unresectable LMS (uterine and nonuterine), gemcitabine plus docetaxel showed no superiority over docetaxel alone in terms of response rate and PFS.⁴⁵⁷ Thus, single-agent gemcitabine may prove to be an option in these clinical scenarios. Other targeted agents have been largely disappointing in patients with LMS.

Treatment of uterine LMS is discussed in greater detail in the section titled “Uterine Sarcoma.”

Synovial Sarcoma

Patients with synovial sarcoma have relatively high rates of response to chemotherapy, but this may be due in part to patient factors. Compared to patients with other subtypes, patients with synovial sarcoma tend to be younger and therefore tend to have a better performance status, a positive predictor for response to chemotherapy in the EORTC database. A prognostic nomogram specific to primary synovial sarcoma enables the treating clinician to more precisely assess outcome for the individual patient and to identify those patients most likely to benefit from adjuvant or neoadjuvant chemotherapy.²⁷²

Ifosfamide-based chemotherapy, in a retrospective study of adult patients with primary extremity synovial sarcoma of ≥ 5 cm, was independently associated with improved disease-specific survival (hazard ratio = 0.3 compared to no chemotherapy; $p = 0.007$); the 4-year disease-specific survival rates were 88% with chemotherapy 67% with no chemotherapy.⁴⁵⁸ Adjuvant or neoadjuvant ifosfamide-based chemotherapy should therefore be considered in the treatment of adult patients with high-risk primary synovial sarcoma of the extremities.

Ifosfamide appears to be active in patients with advanced synovial sarcomas as well. In a study of 13 patients, ifosfamide (at a high dose of 14 to 18 g/m²) had a 100% response rate.

Newer protein-directed therapies have shown only modest activity in synovial sarcoma patients. Pazopanib was associated with an approximate 15% response rate,⁴⁵⁹ while its cousin sorafenib had a 0% response rate.¹⁷⁴ Sunitinib, mTOR inhibitors, and other kinase-specific agents are not well examined in synovial sarcoma to date. In the authors' experience, trabectedin has activity against synovial sarcoma. As previously noted, immunotherapy may be appropriate for a subset of patients.⁴²¹

Pediatric Sarcomas in Adult Populations

Adults may develop a number of pediatric sarcomas, including Ewing sarcoma (in soft tissue or bone), rhabdomyosarcoma (usually pleomorphic), and osteosarcoma. These diseases differ from typical adult sarcomas in that they are considered systemic diseases even if they appear to be localized at initial presentation. Ewing sarcoma and rhabdomyosarcoma are typically much more sensitive to chemotherapy than are other adult soft tissue sarcomas.⁴⁶⁰

For adults with rhabdomyosarcoma or Ewing sarcoma, the standard of care is adjuvant (or neoadjuvant) chemotherapy. In osteosarcoma, long-term survival has been achieved in pediatric patients with the use of adjuvant chemotherapy. Unfortunately, adults with osteosarcoma are generally more resistant to chemotherapy than are children. Adults with a typical osteosarcoma of bone should receive neoadjuvant or adjuvant chemotherapy in addition to therapy for local control of the tumor. However, extraskeletal osteosarcoma is treated like other soft tissue sarcomas, largely due to the low response rates to chemotherapy observed in patients with metastatic disease.

Typical regimens for small cell pediatric sarcomas, specifically rhabdomyosarcoma and Ewing sarcoma, include the combination of vincristine, doxorubicin, and cyclophosphamide (dactinomycin, in particular, for rhabdomyosarcoma) and the combination of ifosfamide and etoposide. The MAID regimen also shows activity in pediatric sarcomas. There is debate about whether adults do worse than pediatric patients with the same stage of disease. Adults may present with more advanced-stage disease than do children or adolescents. In addition, adults are less likely than children to tolerate the aggressive regimens of chemotherapy used against these diseases. However, one retrospective study showed that older patients with rhabdomyosarcoma tolerated chemotherapy as well as the pediatric population but fared worse overall.¹⁴¹ In Ewing sarcoma, the role of age in predicting outcome is controversial.⁴⁶¹ Adults with a sarcoma usually seen in pediatric populations should be included in pediatric protocols whenever feasible to help determine appropriate care for patients with these rare diagnoses.

A new target for therapy in pediatric sarcomas in adults and children alike is IGF 1 receptor (IGF1R), on the basis of the importance of IGF1R in Ewing sarcoma, rhabdomyosarcoma, and osteosarcoma.⁴⁶² Unfortunately, response rates for IGF1R antagonists are low, probably well under 20%, for entirely unclear reasons. Patients typically have relatively rapid progression after perceived minor benefits, suggesting that parallel pathways are at least in part to blame for the lack of greater activity of IGF1R antagonists as single agents.

Uterine Sarcoma

Uterine sarcomas are very rare, accounting for 3% to 7% of all uterine malignancies. The uterus is unique in that at least three different sarcomatous entities may arise from this organ: (1) LMS, a tumor of the endometrium; (2) endometrial stromal sarcoma (ESS), the least common type, which usually has very aggressive behavior; and (3) carcinosarcoma (also known as malignant mixed Müllerian tumor [MMMT]), composed of elements of carcinoma and sarcoma. Other uterine sarcomas such as rhabdomyosarcoma are uncommon.

For localized disease, surgery is the main treatment. The use of adjuvant radiation is controversial. Most studies showed some improvement in local control but not in survival. The efficacy of adjuvant radiation may be a function of disease subtype, because spread beyond the uterus (e.g., to lymph nodes) is common in patients with MMMT but less common in patients with LMS. The literature is well represented by EORTC study 55874, which examined radiation therapy versus surgery alone for 224 patients with International Federation of Gynecology and Obstetrics stage I or II uterine sarcoma.⁴⁶³ Patients who received radiation had a lower risk of local relapse, a benefit observed for patients with MMMT and not LMS.

Uterine Leiomyosarcoma. After resection of a uterine LMS, adjuvant radiation therapy is generally not employed unless there is overt pelvic side-wall involvement with sarcoma. This concept is supported by the negative results for LMS in the phase 3 randomized study from EORTC, although this study was relatively small.⁴⁶³

Metastatic uterine LMS is responsive to doxorubicin but less sensitive to ifosfamide and to cisplatin. Uterine LMS is particularly responsive to the combination of gemcitabine and docetaxel,⁴³⁵ apparently due to the synergy of this combination.⁴³⁶ This combination was superior to gemcitabine alone in a Bayesian adaptive randomized phase 2 study that examined both LMS and non-LMS sarcomas, but the number of patients with LMS was relatively small, and the number of uterine LMS smaller still.¹²⁸ However, a randomized study from France refutes the synergy of gemcitabine and docetaxel, at least for LMS.⁴³⁷ Another approach for LMS is vinorelbine and gemcitabine, a combination with at least modest activity, though not yet examined in a randomized fashion. Trabectedin has at least some activity in LMS as well.⁴¹⁶ In a phase 2 trial, 60% of patients had response or stable disease when treated with the drug.⁴¹⁹

Recently, the French Sarcoma Group reported encouraging response rates in uterine LMS to the combination of trabectedin plus doxorubicin.⁴⁶⁴ In this phase 2 study, the overall response rate was 55% and the median PFS at 12 weeks was 94%. These are encouraging data that warrant further investigations. Appropriately, a parallel study was performed in nonuterine LMS, recognizing the potential differences between uterine and nonuterine diseases. The results from the nonuterine cohort are forthcoming.

Although uterine LMS often expresses estrogen receptor or progesterone receptor, its rate of response to hormone therapy is very low. In a prospective trial of tamoxifen in treatment of uterine sarcomas, none of the 19 patients with LMS responded.⁴⁶⁵

Endometrial Stromal Sarcoma. The pathologic entity ESS is divided into low-grade ESS and undifferentiated uterine sarcoma (a high-grade lesion). Low-grade ESSs carry a t(7;17)(p15;q21) linking JAZF1 and SUZ12 (JJAZ1),⁴⁶⁶ whereas high-grade ESSs have now been linked to an essential translocation involving YWHAE and FAM22A (NUTM2A) or FAM22B (NUTM2B).⁴⁶⁷

Low-grade ESS, but not undifferentiated uterine sarcoma, expresses estrogen and progesterone receptors, and responses to hormonal therapy are seen more in this subtype than in perhaps any other form of sarcoma.

For adjuvant therapy in patients with low-grade ESS, estrogen antagonists may be considered based on small clinical trials⁴⁶⁸ but are of unproved benefit. There is no clear standard of care for undifferentiated endometrial sarcomas, although some investigators advocate for adjuvant chemotherapy.

In the recurrent setting, estrogen deprivation is an appropriate first-line therapy for low-grade ESS,⁴⁶⁸ and surgical debulking can be considered as well because the disease tends to have an indolent course. For metastatic undifferentiated uterine sarcoma (and recurrent low-grade ESS), ifosfamide is active, as may be doxorubicin.⁴⁶⁹

Desmoid Tumor

Surgery has been considered the gold standard for treatment of desmoid tumors. However, any attempt at complete wide excision must be balanced by consideration for preserving function and the knowledge that local recurrence is common, because there are alternatives for management. Desmoids can be controlled with systemic therapy,⁴⁷⁰⁻⁴⁷⁶ and they often either remain stable in size or occasionally regress spontaneously. For these reasons, in asymptomatic patients, an initial period of observation is often recommended to determine the biological behavior of the tumor. In a recent series of 142 patients with primary and locally recurrent desmoids, 83 patients were treated with such a "wait and see" policy, whereas 59 were initially offered medical therapy, mainly hormonal therapy and chemotherapy. The 5-year PFS was 50% for the "wait and see" group and 59% for the medically treated patients. This study suggests that many patients with primary and locally recurrent desmoids tumor can be safely managed by observation and thus can avoid the morbidity of surgery or radiotherapy.⁴⁷⁷

However, if a patient is symptomatic or progressing, consideration should be given to systemic therapy, surgery, or rarely radiation to prevent complications from disease progression.

Decisions on which of these modalities to employ can be guided by recent studies that have identified clinical factors predictive of postoperative recurrence. Risk of local recurrence is clearly associated with larger tumor size (>5 cm), site (particularly chest wall and extremity), and younger age at presentation, but not with microscopically positive margins. A nomogram to predict outcomes after resection has been developed and externally validated based data from almost 500 patients.^{478,479} Large extremity desmoids in young patients recur in >50% of cases whereas patients with small, abdominal wall tumors have cure rates of >90%.⁴⁷⁸ Surgery may, therefore, be employed for patients with small abdominal wall tumors if the tumor is growing or painful, whereas systemic therapy may be a better option for patients with unresectable disease or high risk of recurrence.

A range of systemic therapies has been employed in the management of desmoid tumors. A trial of nonsteroidal anti-inflammatory drugs or hormonal therapy can be considered in most patients. Sulindac and other nonsteroidal anti-inflammatory drugs have produced well-documented responses. There are anecdotal accounts of responses to hormonal manipulation such as tamoxifen, gonadotropin-releasing hormone agonists, or aromatase inhibitors. Responses have also been reported to single-agent doxorubicin and to less toxic liposomal pegylated doxorubicin,^{472,480,481} as well as to combination chemotherapy at either standard or relatively low doses.⁴⁸² Responses to any of these agents can be slow, with patients needing several months or even 1 to 2 years of therapy to achieve maximum benefit, and therefore therapy should not be abandoned for stable disease, although changes should be made for toxicity. Complete responses to any of these agents are exceptionally rare, and so the timing of discontinuation of therapy in a patient with responding disease remains a difficult question and requires clinical judgment.

Tyrosine kinase inhibitors have been examined in the management of desmoid tumors. The lesions may occasionally respond to imatinib, although, as with other systemic therapy, it remains somewhat unclear whether some of the responses are truly due to treatment.^{483,484} PDGF receptors have been identified in desmoid tumors, providing a possible mechanism of action of imatinib. Sorafenib administration has been associated with stable disease in 70% of patients, partial response in 25%, and significant improvement in symptoms in 70%.⁴⁸⁵ These responses may occur rapidly, with resolution of symptoms occurring in <2 weeks. In a few instances, patients who experienced a good response to sorafenib have stopped the drug with no evidence of tumor regrowth. The mechanism of response to sorafenib is unclear.

The role of adjuvant radiation in management of desmoid tumors is controversial. Specialists are reluctant to give high doses of radiation to young patients with a disease that may not progress and that will never metastasize. Most authors recommend against postoperative radiation for patients with negative resection margins. Postoperative radiation is, however, more debatable for patients with microscopically positive margins. When such patients are treated with surgery alone, the rates of local control are approximately 56%.⁴⁸⁶ Therefore, residual microscopic tumor from a primary lesion does not invariably lead to treatment failure, and adjuvant radiation may be omitted as long as local progression would not cause significant morbidity. The usual dose for adjuvant radiation for primary and most recurrent tumors is around 50 Gy.

Although adjuvant radiation is being used less, definitive radiation is emerging as an alternative to surgery. Ballo et al.⁴⁸⁷ reported a 5-year local control rate of 69% for patients treated with radiation for gross disease. Others have reported similar rates.⁴⁸⁶ The recommended dose for definitive radiation usually ranges from 56 Gy to 60 Gy. Although radiation is effective, many practitioners remain reluctant to prescribe it, given long-term risk of secondary malignancy and joint fibrosis in this young patient population.

Soft Tissue Sarcomas of the Hands and Feet

Wide local excision is the exception rather than the rule for sarcomas of the hands and feet due to the lack of muscular bulk and the proximity to neurovascular structures and bone. The overall prognosis is inferior to that of tumors at other sites in the extremity. At MSKCC, patients with hand tumors, even those ≤5 cm, had a survival rate significantly lower than that of patients with tumors at other distal extremity sites ($p = 0.0008$).⁴⁸⁸

Although the distal extremities have limited tolerance of radiotherapy, the data suggest that conservative resections with adjuvant radiotherapy should be considered for patients with sarcoma of the hand or foot. Lin et al.⁴⁸⁹ reported on 115 patients with soft tissue sarcomas of the hand or foot treated between 1980 and 1998. The majority (95%) were referred after surgery elsewhere. Patients treated with definitive wide re-excision had a 10-year local recurrence-free survival of 88%, which was significantly better than the 58% for patients who did not have re-excision ($p = 0.05$). Radiotherapy improved local control in patients who did not undergo re-excision but did not improve local control in the small number of patients who had definitive re-excision with negative margins. Immediate amputation did not confer a survival benefit. Thus, limb-sparing treatment is possible in many patients with soft tissue sarcomas of the hand and foot. Amputation should be reserved for cases in which the tumor cannot be excised (or re-excised) with adequate margins without sacrifice of functionally significant neurovascular or osseous structures.⁴⁸⁹ For patients who undergo adjuvant radiotherapy, special attention needs to be paid to technique to minimize complications and preserve function. Nevertheless, Bray et al.⁴⁹⁰ reported good functional outcomes among 20 patients with tumors of the hand and forearm who received adjuvant radiation. At a mean follow-up of 37 months, the local control rate was 88%. Eighty-eight percent of those who survived and did not require amputation were able to return to work and activities of daily living with minimal or no functional limitation.⁴⁹⁰

PALLIATIVE CARE

Surgery

Surgeons have long employed palliative procedures to relieve surgical emergencies such as obstruction, bleeding, and perforation. More recently, attention has been focused on alleviating the more chronic complaints, such as pain, nausea, vomiting, inability to eat, and anemia. The treating surgeon should not allow attempts to improve survival to overshadow the goals of minimizing morbidity and relieving symptoms, so that a terminal patient may die with dignity and without undue suffering and pain.

A prospective analysis of 1,022 palliative procedures from MSKCC⁴⁹¹ demonstrated initial symptom resolution in 80% of patients, although 25% of them required further intervention for recurrent symptoms and 29% for new symptoms. The symptomatic improvements were noted within 30 days. For patients who underwent repair of a pathological fracture, 87% had resolution of bone pain or instability symptoms; for patients undergoing palliative tumor excision, 83% had resolution of wound or tumor hygiene symptoms. For GI symptoms, upper GI obstruction was resolved in 79% of cases, whereas mid- or lower GI obstruction was resolved in 90% of cases. However, palliative procedures were associated with significant morbidity (40%) and mortality (11%) and with limited overall survival (approximately 6 months). Factors associated with poor palliative outcomes were poor performance status, poor nutrition, weight loss, and no previous cancer therapy.

In a retrospective study of patients with intra-abdominal sarcoma who underwent a palliative procedure,⁴⁹² 71% of patients had improvement of symptoms at 30 days after the palliative operation, but only 54% of patients remained symptom free after 100 days. Patients with GI tract obstructive symptoms fared worse: 54% had symptomatic relief at 30 days, but only 23% of patients

remained symptom free at 100 days. The operative morbidity was 29% overall and almost 50% among patients seeking to palliate GI obstruction. Postoperative mortality was 12%.⁴⁹²

In summary, decisions regarding the surgery for the palliation of symptoms from advanced sarcoma require precise surgical judgment that balances the medical prognosis of the sarcoma, the availability and success of nonsurgical treatments, and the individual patient's quality of life and life expectancy. Palliative decision making needs to be individualized and remain flexible as the sarcoma progresses. Decision making is best optimized through effective and frequent communication between the patient, family members, and the surgeon.

Palliative Radiation

Radiotherapy has a limited role in the palliation of soft tissue sarcoma. Notable applications are for relief of bone pain and for cessation of bleeding in fungating tumors; in both cases, response requires only moderate doses of radiation and can be rapid. However, radiotherapy is less effective for mass effects such as obstruction or compression, except for radiosensitive histologies such as rhabdomyosarcoma, myxoid-round cell liposarcoma, or synovial sarcoma. Palliative radiation is most relevant when a lesion lies in direct proximity to critical anatomy such as spine, small bowel, or base of skull and surgery is either impossible or undesirable.

New approaches to palliation that are being explored with promising results include hypofractionated dose schedules⁴⁹³ and the precision methods SRS⁴⁹⁴ and stereotactic body radiation therapy.⁴⁹⁵⁻⁴⁹⁷

Chemotherapy

The vast majority of the systemic therapy delivered to patients with metastatic sarcomas is given with palliative intent. Patients with poor performance status are poor candidates for systemic therapy, as they appear to have more adverse events for a given agent or regimen than more fit patients, and appear to benefit less frequently, again with newly diagnosed GIST being perhaps the exception to this rule. When standard chemotherapy agents are exhausted, there are no data that indicate that continuing any sort of systemic therapy is clinically beneficial, with the exception of imatinib in GIST. The means routinely employed to try to relieve symptoms of terminally ill patients include the use of pain medications orally, transdermally, intravenously, or intrathecally; oxygen as needed; and occasionally glucocorticoids. It is also worth emphasizing what is perhaps obvious but often brushed off in the course of a busy day: that even for very ill patients late in the course of their disease, communication with the patient and family will provide a sense of comfort.

FUTURE DIRECTIONS

Although the optimal combination and sequence of surgery, radiation, and chemotherapy remains controversial for sarcoma, optimal treatment increasingly depends on careful stratification of patients by histologic type and subtype and other important prognostic features. New methods for radiation delivery and tumor sensitization as well as continued advances in surgical reconstructive techniques will enable continued improvements in limb preservation and function as well as local control. However, despite these advances, almost 50% of patients with newly diagnosed sarcoma will eventually die from their disease. Metastatic sarcoma, whether

at the time of disease presentation or after local control of primary disease, remains an extremely difficult problem. The search for effective agents will be the focus of continuing research for patients with advanced disease. Outside a few responsive subtypes, the currently available chemotherapies have not improved survival and are associated with significant toxicity. Thus, there is a pressing need to develop new therapies based on selectively targeting the proteins and signaling pathways that drive the survival of specific sarcoma types and subtypes.

There is already a broad movement to identify and test antiangiogenic agents, specific kinase inhibitors, and novel chemotherapeutic agents such as trabectedin in an endeavor to match specific sarcoma subtypes to novel agents. A long effort to understand IGF1R signaling may pay off in the near future for pediatric sarcomas as well as a number of other cancers. Trials targeting the cell cycle (CDK4-RB1) and MDM2-p53 signaling pathways are currently under way in well-differentiated and dedifferentiated liposarcoma. Biological data and preclinical studies support trials using inhibitors of methylation and histone deacetylase in well-differentiated and dedifferentiated liposarcoma,⁴⁹⁸ inhibitors of histone deacetylase in synovial sarcoma⁴⁹⁹ and Ewing sarcoma,⁵⁰⁰ lysine-specific demethylase 1 inhibition strategies in rhabdomyosarcoma, synovial and Ewing sarcoma,^{501,502} and inhibitors of Hedgehog and Notch signaling in several sarcoma types.^{503,504}

In the longer term, some of the results of gene expression arrays, next-generation sequencing, proteomics, tissue arrays, and mouse models of sarcoma may lead to a more comprehensive and precise determination of key molecular genetic alterations that drive sarcomagenesis for specific sarcoma types and subtypes. This knowledge will improve our ability to design new therapeutics for individual patients and to predict response to such therapy based not only on histologic type and subtype but also on pathway activation in the individual patient.

Because sarcoma is a relatively rare disease, it will be particularly important to conduct clinical trials that select patients based on the upregulation of a particular protein or signaling pathway, as this will increase the chance that the trial will have positive results.

Some biological interventions may have promise, such as inhibitory RNA interference strategies or immunotherapy with vaccines, monoclonal antibodies, dendritic cells, or T cells. Vaccines of the characteristic fusion proteins of sarcomas (or peptides thereof) will be tested in the near future for their effectiveness in the appropriate subtypes of sarcoma, such as many pediatric sarcomas. Vaccines that incorporate dendritic cells appear to be effective immunogens in preclinical studies. Preparations of the immunogenic glycolipids found in sarcoma cell membranes may also provide interesting agents for therapy.

Another emerging new class of therapeutics for cancer is nanoscale particles. Advances in nanotechnology have enabled the design of nanoparticles (in the size range 1 to 100 nm) that can interact with biomolecules on both the cell surface and within the cell.⁵⁰⁵ Overexpressed cell-surface markers in sarcomas could be targeted to establish the presence of even single-cell metastases and to deliver high-potency chemotherapeutic or molecular agents to the cancer cell. Such selective nanoparticles could be used in the future to deliver antisense oligonucleotides or small interfering RNAs against cellular protein targets critical for sarcoma cell survival.

With an increasing number of molecular signaling pathways being actively investigated, the many new systemic treatments on the horizon, and the advances in selective radiation, drug, and nanoparticle delivery to sarcoma cells, outcomes for patients with sarcoma are likely to substantially improve in the coming decade.

91 Sarcomas of Bone

Richard J. O'Donnell, Steven G. DuBois, and Daphne A. Haas-Kogan

INTRODUCTION

Sarcomas, defined as connective tissue malignancies, can be said to constitute one of the five major oncologic subgroups, together with disorders of the solid organs (carcinomas), the hematologic system, the skin, and the neurologic organs. Of all cancer types, however, sarcomas are the most rare, and in fact, exceedingly so. Furthermore, sarcomas of bone occur at just one-fourth the frequency of sarcomas of soft tissue. However, while soft tissue sarcomas have a multitude of histologic subtypes subject to a variety of grading classification schemes, bone sarcomas have just three distinct categories: chondrosarcoma, Ewing sarcoma, and osteosarcoma. While soft tissue sarcomas are rare in young individuals and occur with increasing frequency as the middle to late decades progress, bone sarcomas, for the most part, are more common in children and young adults, with some exceptions in later years. While the gold standard of treatment for soft tissue sarcomas remains surgery and radiation therapy, with chemotherapy reserved for tumors that are deep, high grade, and large, the management of bone sarcomas varies considerably, according to histology, grade, and stage. Finally, all high-grade sarcomas, whether of bone or soft tissue, share an overall survival rate on the order of 55% to 70%.

In light of their extreme rarity, the varied and complex nature of the care programs often involving national or international protocols, the high stakes nature of limb salvage surgery, and the potential lethality of these tumors, the National Comprehensive Cancer Network (NCCN) has promulgated that, "Primary bone tumors and selected metastatic tumors should be evaluated and treated by a multidisciplinary team of physicians with demonstrated expertise in the management of these tumors."¹ The paramount and central nature of this statement cannot be gainsaid, as judgment regarding management of these uncommon tumors must necessarily be left to the experts. Nonetheless, even the most general reader would err in not seeking a broader fund of knowledge and a higher level of understanding of bone sarcomas, as the hopeful and instructive paradigms offered herein can be of benefit to all oncologic patients, across practice strata. This chapter therefore seeks to be a primer on the diagnosis, staging, treatment, and surveillance of sarcomas of bone, with information ranging from basic principles to detailed descriptions of complex algorithms. After reviewing incidence, etiology, anatomy, pathology, screening, diagnosis, and staging of bone sarcomas, management will be discussed by treatment modality, with attention to stage. Ewing sarcoma, the prototypical high-grade sarcoma presumed to be potentially metastatic at presentation, will be explored first, in terms of the historically agreed-upon gold standards of chemotherapy and radiation therapy. Next, high-grade conventional osteosarcoma will be discussed with regards to universally accepted chemotherapeutic concepts, and occasionally useful radiotherapy options. Surgery for low-grade chondrosarcoma and osteosarcoma lesions will then be undertaken. Limb salvage and amputation approaches for high-grade chondrosarcoma, osteosarcoma, and Ewing sarcoma lesions will be described together, as the local

control decision-making process for these three categories is similar. Finally, continuing care in terms of bone sarcoma surveillance and palliation will be considered.

INCIDENCE AND ETIOLOGY

According to the American Cancer Society, there are estimated to be just 15,040 new cases of sarcoma diagnosed in the United States in 2014.² Of these cases, 12,020 will involve the soft tissues, and just 3,020 will involve the bones and joints. This represents an incidence of <1 in 100,000 persons living in the United States per year. The true incidence of some bone malignancies, such as chondrosarcoma, is not well established, as low-grade lesions are relatively common, and no accurate registries exist. For high-grade osteosarcoma and Ewing sarcoma, the incidence is thought to be on the order of one per million.

Another way of illustrating the rarity of these tumors is to consider that bone sarcomas, which result in the third leading cause of cancer death in young individuals, are projected to result in as few as 166 deaths in those <20 years of age in 2014.³ In part, this remarkable statistic is attributable to the gratifying advances in multidisciplinary management of bone tumors, with 5-year relative survival rates of children up to 14 years of age has increased from 50% in 1978 to 78% in 2008.³

The etiology of bone sarcomas is not known with certainty.⁴⁻⁶ Mutation in the *TP53* gene places patients with Li-Fraumeni syndrome at risk for the development of osteosarcoma.⁷⁻¹¹ Mutation in the *RBI* gene is associated with osteosarcoma in patients with retinoblastoma.¹²⁻¹⁵ Rearrangements in the *EWS* and *EFT* genetic loci have been implicated in pathogenesis of Ewing sarcoma.¹⁶⁻¹⁹ The molecular pathogenesis of chondrosarcomas is less well understood, with a variety of genes and signaling pathways having been implicated to date, including *TP53*, hedgehog, insulin-like growth factor, cyclin-dependent kinase 4, hypoxia-inducible factor, matrix metalloproteinases, *SRC*, and *AKT*.²⁰ Other primary bone malignancies associated with mutations, specific translocations, and amplifications/gains include mesenchymal chondrosarcoma, epithelioid hemangioendothelioma, chordoma, low-grade (parosteal and intramedullary) osteosarcoma, and periosteal chondrosarcoma.⁶

Environmental factors are also known to be involved in the genesis of bone sarcomas. For example, ionizing radiation, either therapeutic or inadvertent, is thought to be responsible for approximately 3% of cases of bone sarcoma.^{4,21,22} Independent of radiation exposure, treatment with alkylating agents is known to increase osteosarcoma risk.^{4,23}

Some benign bone conditions predispose patients to bone sarcoma development. It is estimated that 0.3% of patients with Paget disease of bone will develop osteosarcoma, most often at an advanced age and with a 5-year survival rate of $\leq 4\%$.²⁴⁻²⁶ Fibrous dysplasia, including its polyostotic variants, McCune-Albright syndrome and Mazabraud syndrome, can rarely be associated with sarcomatous degeneration, including in less commonly encountered

locations such as the ribs, spine, and craniofacial region.^{27–31} Individuals with benign cartilage lesions are also subject to chondrosarcoma development. Osteochondromas, whether solitary or in the multiple, autosomal dominant form, are associated with chondrosarcomas that are predominantly low to intermediate grade³²; on a population level, the incidence of malignant change was estimated to be on the order of 0.9%.³³ Similarly, chondrosarcomas have been described in patients with preexisting solitary enchondromas or polyostotic enchondroma variants (Ollier and Maffucci syndromes).³⁴ Other benign tumors that can be premalignant include giant cell tumor, osteblastoma, and synovial chondromatosis.³⁵ Even nononcologic conditions such as chronic osteomyelitis^{36,37} and bone infarcts³⁸ can evolve into sarcomas (Fig. 91.1).

ANATOMY AND PATHOLOGY

Bone sarcomas can occur through the musculoskeletal system. Osteosarcomas are more prevalent in the appendicular skeleton, with the most prevalent sites being in the distal femur (32%), proximal tibia (15%), proximal humerus (8%), and proximal femur (5%).³⁹ This distribution corresponds to the relative activity of the physal plates in the growing skeleton. By contrast, Ewing sarcoma favors the axial skeleton, with the pelvis/sacrum (22%), proximal femur (10%), shoulder girdle (12%), and ribs (8%) being the most common locations, followed by the long bones and sacrum.³⁹ Chondrosarcoma similarly occurs most frequently in central regions: pelvis/sacrum (26%), shoulder girdle (14%), proximal femur (12%), and ribs (11%).³⁹ When found in the long bones, the epicenter of conventional osteosarcoma lesions tends to be in the metaphysis, with diaphyseal extension, whereas Ewing sarcoma often arises in the diaphysis with metaphyseal extension. Juxtacortical osteosarcoma and chondrosarcoma variants occur on the bone surface.

Some primary bone malignancies manifest in characteristic anatomic locations. Clear cell chondrosarcoma, for instance, most often arises in the femoral head.⁴⁰ Parosteal osteosarcoma favors the posterior distal femur.⁴¹ Periosteal osteosarcoma is found in the anterior tibial shaft.⁴² Adamantinoma is most frequently encountered in the tibia and/or fibula.⁴³ Chordoma has a predilection for the sacrum and the clivus.^{1,44}

Finally, several histologic equivalents of bone sarcomas can be found in soft tissues and joints. Extraskelatal osteosarcoma is a rare neoplasm that has a median survival of 46 months for patients with localized disease.⁴⁵ By contrast, extraosseous Ewing sarcoma has a prognosis similar to its primary bone counterpart.⁴⁶ Extraskelatal myxoid chondrosarcoma, also an aggressive soft tissue lesion with high rates of local/distant recurrence and delayed disease-associated death, is a misnomer insofar as the tumor is really of uncertain differentiation with no convincing evidence of cartilaginous differentiation.^{47,48} As a rule, it is exceedingly rare for a sarcoma of bone or soft tissue to occur in an intra-articular location, but chondrosarcomas of the synovium, arising de novo or secondary to synovial chondromatosis, have been described.⁴⁹

Gross anatomic pathology varies widely according to histologic subtype, grade, and anatomic location. Although the soft tissue component of many high-grade sarcomas of bone have a characteristic whitish, firm, “fish flesh” appearance, gross findings can run the gamut from heavily ossified areas to myxoid, friable, or frankly necrotic regions, even within the same specimen. As most high-grade bone sarcomas are >5 cm and associated with a soft tissue mass that is extracompartmental to bone, the tumor classification according to the Enneking system^{50,51} is most often “T2b.”

Microscopic pathology also varies considerably amongst the bone sarcomas. The prototypical bone sarcoma, a conventional high-grade osteosarcoma, consists, in most basic terms, of a spindle

Figure 91.1 (A) Anteroposterior plain radiograph of a 64-year-old man with polyostotic femoral and tibial bone infarcts secondary to alcoholism who developed a destructive distal femoral bone and soft tissue mass. (B) Axial T2-weighted magnetic resonance sequence demonstrating a 13 cm distal femoral bone and soft tissue mass with cortical destruction that proved to be a high-grade undifferentiated spindle cell sarcoma. Note the benign bone infarct in contralateral femoral diaphysis.

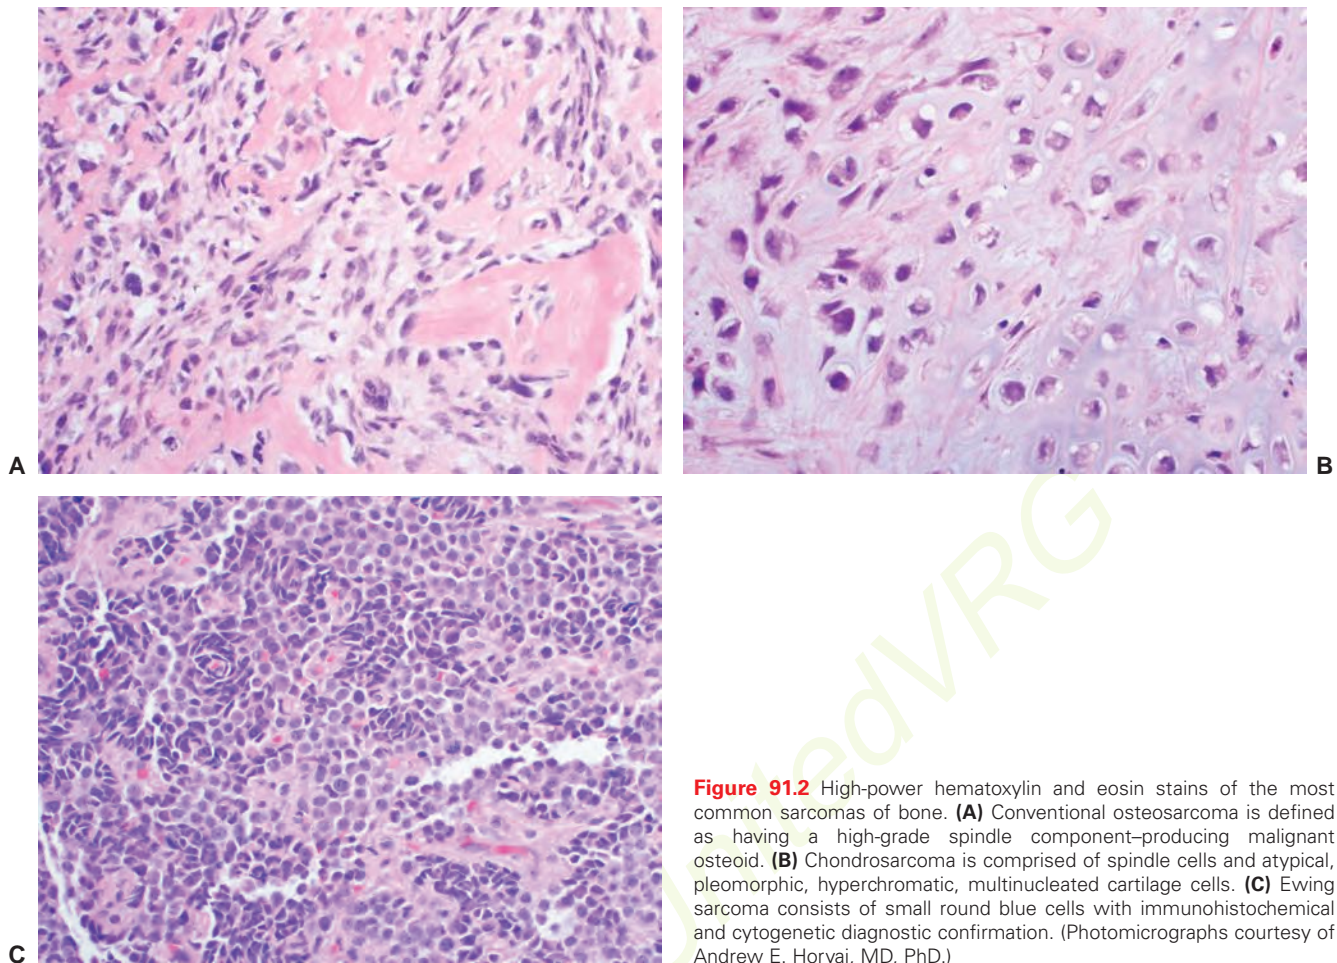

Figure 91.2 High-power hematoxylin and eosin stains of the most common sarcomas of bone. **(A)** Conventional osteosarcoma is defined as having a high-grade spindle component-producing malignant osteoid. **(B)** Chondrosarcoma is comprised of spindle cells and atypical, pleomorphic, hyperchromatic, multinucleated cartilage cells. **(C)** Ewing sarcoma consists of small round blue cells with immunohistochemical and cytogenetic diagnostic confirmation. (Photomicrographs courtesy of Andrew E. Horvai, MD, PhD.)

cell neoplasm that produces osteoid (Fig. 91.2A). A high-grade chondrosarcoma will have a spindle cell component admixed with malignant cartilaginous matrix (Fig. 91.2B). By contrast, Ewing sarcoma is a small round blue cell neoplasm for which the definitive diagnosis is suggested by immunohistochemical staining with CD-99 and confirmed by cytogenetic results of t(11:22) chromosomal translocation (Fig. 91.2C).

From a pathologic standpoint, the World Health Organization recognizes >25 different types of primary bone malignancies.⁴⁸ With the exception of plasma cell myeloma, primary non-Hodgkin lymphoma of bone, chondrosarcoma, conventional osteosarcoma, and Ewing sarcoma, the remaining entities are, for the most part, very rare (Table 91.1).

SCREENING

There exist no population-based screening tests applicable to the detection of bone sarcomas. However, a number of syndromic conditions that predispose to the development of primary bone malignancies are known (Table 91.2). Many of the implicated genetic diseases, such as Rothmund-Thomson and Werner syndromes, are exceedingly rare, and no clear algorithms exist for cancer screening. The same is true for more commonly encountered conditions that predispose to bone cancer, such as Li-Fraumeni syndrome, for which a recent workshop concluded, “further tests are needed to test screening protocols . . . which would be aimed at establishing effective screening regimens that take into account the wide diversity of disease phenotypes in *TP53* mutation carriers.”¹¹ For patients with predisposition diagnoses that are

relatively commonly encountered in orthopedic oncology offices, such as hereditary multiple hereditary exostoses, multiple enchondromatosis, polyostotic fibrous dysplasia, and Paget disease, several practical, generalized guidelines can be offered. Plain radiographs of bones that are moderately to severely affected should be obtained yearly. A limited skeletal survey of involved areas (including, as indicated, anteroposterior [AP] and lateral views of the humeri and femora; AP views of the pelvis and distal extremities) should be considered every 2 years. Magnetic resonance (MR), computed axial tomography (CT), and positron emission tomography (PET) screening should be considered based upon a patient’s family and personal clinical history. In all circumstances, care should be taken to limit radiation exposure with screening tests. However, as an individual ages, sarcoma risk increases, and so routine surveillance surveys should be offered, especially for deep-seated locations such as the pelvis and shoulder girdle, where most sarcomas in these conditions will become manifest.³³ Because malignancies in these deep-seated areas can become relatively large before symptoms develop, vigilance of occult locations is especially warranted.

DIAGNOSIS

It is nearly universally true of practice patterns within the United States that patients suspected of being at risk for having a bone sarcoma have first had a plain radiographic examination ordered by their initial point of contact within the health-care system. It is also very common for the primary care provider or general orthopedic surgeon to obtain an MR scan of the affected area (Table 91.3).

But once concern for the possibility of a bone sarcoma has been raised, further diagnostic tests, many of which are of a specialized nature and involve radiation exposure, should be deferred, and the patient should be immediately referred to a multidisciplinary center skilled in sarcoma management.¹

History

Good medicine starts with a thorough history. Aggressive bone lesions often give rise to pain before a mass is noted. The nature of the discomfort, in terms of its intensity, frequency, duration, pattern, localization, and aggravating/alleviating factors must be carefully assessed. The patient should be questioned regarding associated symptoms such as numbness, tingling, weakness, stiffness, instability, and gait abnormalities. Documentation of the characteristics of a mass, if present, must be obtained with respect to time course, growth pattern, and presence of localized erythema, warmth, and tenderness. Systemic findings such as fever, sweats, chills, weight loss, and fatigue need to be queried. A past personal and/or family medical history of conditions that predispose to bone malignancies must be explored. In many cases of even high-grade sarcomas, the history is that of an enlarging bone and soft tissue mass

that is less painful than might be expected. Knowledge gained regarding history can direct further evaluation away from or toward nonneoplastic, pseudotumorous, aggressive, metabolic, or secondary conditions that can mimic primary bone malignancies, such as osteomyelitis, eosinophilic granuloma, giant cell tumor of bone, osteoblastoma, metastatic disease, or Paget disease (Fig. 91.3).

Physical Examination

Although it may not narrow the differential list considerably, a thorough physical examination remains an essential part of the diagnostic pathway for sarcomas of bone. Café-au-lait spots can signal the presence of fibrous dysplasia; the integrity of the

Figure 91.3 A 36-year-old woman presented with lower leg pain and inability to bear weight that developed while jogging. **(A and B)** Plain tibial-fibular radiographs show a transverse distal tibial diaphyseal fracture through a very aggressive bone lesion. **(C)** A total body bone scan revealed intense uptake in the tibial shaft, but also in the ipsilateral sacroiliac region, indicating a polyostotic or metastatic process. **(D)** An axial magnetic resonance scan image documented the presence of a large tibial bone and soft tissue mass. **(E)** The benign diagnosis, which was suggested by the patient's history of familial Paget disease in her grandmother, mother, aunt and uncle, was confirmed by incisional biopsy. **(F and G)** Anteroposterior and lateral radiographs 2 years postfracture showed complete healing; the patient was successfully nonoperatively managed with a long leg cast and subsequent bisphosphonate administration.

integumentary system should be assessed for erythema, warmth, and drainage over the primary site. The size, location, mobility, and consistency of any mass, if present, should be carefully described. The presence or absence of regional lymphadenopathy must be noted. Orthopedic parameters, including limb length, active and passive ranges of motion, joint stability, and gait pattern, need to be reviewed. Finally, a pertinent neurovascular exam must be completed.

Diagnostic Studies

Though neither highly sensitive nor specific, laboratory testing should not be neglected in the evaluation of patients suspected of having a sarcoma of bone. A complete blood count, erythrocyte sedimentation rate, and C-reactive protein level can be helpful in ruling out infection. Alkaline phosphatase and lactic dehydrogenase are sometimes elevated in skeletal sarcomas; creatinine and calcium levels are also useful chemistry tests. Serum and urine immunoelectrophoretic analyses can assist in excluding myeloma, and a basic urinalysis can be used to screen for genitourinary health.

Radiologic imaging represents the bulk of diagnostic studies for aggressive bone conditions. Plain roentgenograms include orthogonal views of the primary skeletal site and two views of chest as an initial assessment of metastatic pulmonary disease. Nuclear medicine tests include technetium-99m total body bone, indium-labeled white blood cell, and PET scans. A bone scan aids in determination of primary site activity, and the presence or absence of polyostotic or metastatic disease. An indium scan can examine the possibility of osteomyelitis. A PET or PET/CT scan quantifies metabolic activity in the primary site and helps to exclude occult metastases. The utility of [F-18]-fluorodeoxy-D-glucose PET/CT scanning in the management of patients with bone sarcoma is well established, and should be considered to be a care standard.⁵²⁻⁵⁸ A dedicated chest CT scan is perhaps the most sensitive way to exclude distant disease in the lungs, which is the most common site of metastatic deposits in patients with sarcoma. CT scanning also has proven utility in studying axial primary sites and juxtacortical lesions, as well as in predicting pathologic fracture risk.⁵⁹ Often the best modality for documenting the extent of a primary bone and soft tissue mass is an MR scan, which should include the entire involved bone so as to make sure that skip metastases are not present. Specialized cross-sectional studies, including MR neurograms, MR angiograms, and CT angiograms are sometimes important to assist with surgical planning.

In the case of suspected primary bone malignancy, supreme caution must be taken with respect to the manner in which the biopsy is undertaken. Percutaneous fine needle or core procedures, especially when guided by imaging such as ultrasound, CT, or MR scanning, can be successful in establishing a diagnosis even in deep anatomic locations, especially if a soft tissue mass is present; this method has the advantage maximizing sampling throughout the mass while minimizing contamination.⁶⁰⁻⁶⁷ As sufficient material must be obtained to perform all histologic, immunohistochemical, cytometric, and cytogenetic studies, thereby allowing an accurate diagnosis, open (incisional) biopsies are often warranted, especially in pediatric cases where multi-institutional protocol studies request centralized pathologic review and other specialized testing. Excisional (resection) biopsy can be considered for smaller lesions that can be completely excised with negative margins and without undue functional compromise; an atypical or low-grade chondrosarcoma arising in an osteochondroma is an example of this type of biopsy procedure. Whenever an open biopsy procedure is chosen, careful attention must be paid to incisional length (short) and placement (in line with the definitive resection procedure), dissection planes (*through* rather than between muscular planes), and avoidance of neurovascular exposure, bleeding, and infection.⁶⁸⁻⁷¹ A skilled musculoskeletal pathologist should

be immediately available to review the frozen section, confirm the receipt of sufficient biopsy material, and perform direct handling of the specimen.⁷¹ Improperly performed biopsies can delay the start of care, prompt inappropriate treatment, preclude limb salvage by causing infection or contamination, and otherwise result in local recurrence and amputation. The risk of diagnostic errors and complications increases by as much as 12-fold when the biopsy is improperly done.⁶⁹ Because of these grave medical and medicolegal concerns, referral to a tertiary center skilled in the multidisciplinary bone sarcoma management *prior* to biopsy is strongly advised.¹

STAGING

Once all diagnostic studies are complete, formal oncologic staging concludes the pretreatment evaluation process. Staging should be performed according to TNM (tumor, node, metastasis) guidelines with principles set forth by the American Joint Committee on Cancer.⁷² For bone sarcomas, staging correlates directly with prognosis, which is of utmost importance when discussing expectations regarding outcomes with patients and families (Table 91.4).

MANAGEMENT BY DIAGNOSIS AND STAGE

Systemic Therapies for Ewing Sarcoma

Chemotherapy for Patients with Newly Diagnosed Ewing Sarcoma

Prior to the routine use of chemotherapy, nearly all patients with newly diagnosed Ewing sarcoma developed distant metastatic disease and ultimately died.⁷³⁻⁷⁵ These observations underscored the nearly universal presence of occult micrometastatic disease in patients with Ewing sarcoma. While local control measures (surgery and/or radiotherapy) are critical to the treatment of patients with Ewing sarcoma, systemic therapy is equally critical to attaining cure.

Early single-institution studies suggested that the regimen of vincristine, doxorubicin, actinomycin-D, and cyclophosphamide (VACA) was active in Ewing sarcoma.⁷⁴⁻⁷⁶ Follow-up cooperative group trials established the efficacy of VACA and began to refine

this regimen for Ewing sarcoma. For example, the first North American Intergroup Ewing Sarcoma Study (IESS-I) investigated the role of doxorubicin and whole lung radiation in the context of vincristine, dactinomycin, and cyclophosphamide.⁷⁷ Patients with newly diagnosed disease were randomized to one of three arms: vincristine, dactinomycin, and cyclophosphamide (VAC); VAC plus doxorubicin (VACA); or VAC with whole lung radiation. Among 342 eligible patients, patients randomized to VACA had significantly superior relapse-free survival compared to patients randomized to the other two arms. Patients randomized to receive VAC had the worst outcomes, and patients randomized to receive VAC with whole lung radiation had intermediate outcomes. These results definitively established the importance of doxorubicin in the management of Ewing sarcoma, but also demonstrated that whole lung radiation may prevent some cases of relapse even in the absence of documented lung metastasis.

Other national groups adopted the VACA regimen, with largely similar results. For example, the CESS-81 trial was a nonrandomized trial evaluating VACA in patients with localized Ewing sarcoma.⁷⁸ This group reported a 5-year disease-free survival rate of 54%. In addition, they identified large tumor size and poor histologic necrosis to neoadjuvant chemotherapy as potential adverse prognostic factors in this setting. The UK Children's Cancer Study Group conducted a similar trial, though the doxorubicin dose intensity was lower than in other trials.⁷⁹ They reported a 5-year relapse-free survival rate of 41% and suggested that this inferior outcome may be due to lower doxorubicin dose intensity. The French Society of Pediatric Oncology also treated patients with VACA and reported a 4-year disease-free survival rate of 52%.⁸⁰

Subsequent trials have built upon the success obtained with VACA. Strategies have included changing the dosing strategy in VACA and adding ifosfamide or ifosfamide/etoposide (IE). The French EW88 trial used this first approach to study a more protracted VACA treatment schedule in which cyclophosphamide was delivered daily for 7 days each cycle, with cycles repeated at 2-week intervals.⁸¹ In this nonrandomized trial, outcomes appeared to be superior compared to previous trials, though more intensive local control measures were also prescribed in this trial. Nevertheless, these results suggested that more frequent chemotherapy cycles were beneficial and/or that more protracted cyclophosphamide exposure was beneficial.

The second Intergroup Study (IESS-II) also sought to clarify the optimal mode of administration of VACA.⁸² Patients with newly diagnosed localized nonpelvic disease were randomized to one of two different VACA schedules. In the intensive schedule, patients received higher doses of doxorubicin and cyclophosphamide given in cycles administered every 3 weeks. In the protracted schedule, patients received lower doses of these agents and exposure of the cyclophosphamide was distributed across 6 sequential weeks. This design resulted in significantly greater early doxorubicin exposure in the intensive arm as well as a slightly higher cumulative doxorubicin exposure in that arm. Among 214 eligible patients, all outcome measures (relapse-free, disease-free, and overall survival) were superior for patients randomized to the intensive arm. These results emphasized the importance of early doxorubicin intensity and led to adoption of VACA administration in 3-week cycles as a standard approach in subsequent studies.

Based upon response rates of approximately 30% in patients with recurrent Ewing sarcoma, several groups investigated the role of ifosfamide or IE in patients with newly diagnosed disease. The French cooperative group conducted a nonrandomized trial in which ifosfamide replaced cyclophosphamide throughout neoadjuvant and adjuvant chemotherapy that also contained vincristine, doxorubicin, and dactinomycin.⁸³ Outcomes of the 65 localized patients treated with this strategy were compared to 95 patients treated on a previous French trial in which all patients received cyclophosphamide. Replacing cyclophosphamide with ifosfamide did not appear to improve outcomes compared to historic controls, suggesting that ifosfamide (without etoposide) is not active in this

setting or that eliminating cyclophosphamide exposure altogether was deleterious.

A nonrandomized trial from the UK Children's Cancer Study Group used a similar approach to study ifosfamide, but yielded a different result.⁸⁴ A total of 201 patients with localized disease were nonrandomly assigned to receive therapy with ifosfamide replacing cyclophosphamide. Compared to historic controls treated with cyclophosphamide, relapse-free and overall survival appeared more favorable with the use of ifosfamide.

The CESS-86 trial used a similar approach, though in a risk-stratified manner.⁸⁵ Patients with small, localized extremity tumors received VACA, whereas patients with either large tumors or axial tumors had ifosfamide substituted for cyclophosphamide (VAIA). Although patients treated with VAIA were predicted to have inferior outcomes due to adverse baseline risk factors, event-free survival was similar compared to patients with lower risk disease treated with VACA. These results suggested that the use of ifosfamide helped to mitigate the adverse impact of large tumor size and/or axial tumor site.

An Italian Cooperative Group trial nonrandomly evaluated the addition of ifosfamide to VACA in the neoadjuvant setting and the addition of IE in the adjuvant setting.⁸⁶ The trial included 160 patients with localized disease. Event-free and overall survival estimates were among the highest reported at that time, suggesting that ifosfamide and/or IE may have improved outcomes in this population.

The most definitive trial on the role of IE was North American Intergroup trial INT-0091.⁸⁷ Patients with newly diagnosed Ewing sarcoma were randomized at study entry to receive either standard therapy with vincristine, doxorubicin, and cyclophosphamide (VDC) administered every 3 weeks or VDC cycles alternating every 3 weeks with IE cycles. All patients received the same duration of therapy and the same cumulative dose of doxorubicin, with actinomycin-D substituted once patients received that cumulative doxorubicin dose. A total of 518 eligible patients were randomized, 398 of whom had localized disease at study entry. Among patients with localized disease, there was a statistically significant difference in 5-year event-free survival (54% for patients randomized to VDC versus 69% for patients randomized to VDC/IE). The addition of IE to VDC did not improve outcomes for patients with metastatic disease at initial presentation.^{87,88} This result established VDC/IE as a new North American standard of care for patients with newly diagnosed localized Ewing sarcoma.

The next generation of clinical trials from the Children's Oncology Group (COG) has sought to intensify the VDC/IE regimen. Intergroup trial INT-0154 was a randomized trial for patients with newly diagnosed localized Ewing sarcoma.⁸⁹ Patients were randomized at study entry to receive standard dose VDC/IE every 3 weeks or higher-dose VDC/IE. Patients in the experimental arm received higher doses of ifosfamide and cyclophosphamide during cycles of chemotherapy. All patients received approximately the same cumulative doses of chemotherapy such that patients on the experimental arm completed therapy earlier than patients on the standard arm. A total of 478 eligible patients were randomized. There was no statistically significant difference in event-free survival between the standard arm and the experimental arm, demonstrating that higher-dose therapy did not improve outcomes.

COG protocol AEWS0031 was also a randomized trial for patients with newly diagnosed localized Ewing sarcoma.⁹⁰ This trial sought to intensify therapy not by dose escalation, but rather by decreasing the interval between chemotherapy cycles (interval compression). Patients were randomized at study entry to receive standard therapy with VDC/IE cycles alternating every 3 weeks or to the experimental arm with VDC/IE cycles alternating every 2 weeks. A total of 568 eligible patients were randomized. Patients randomized to the interval-compressed arm had a significantly greater 5-year event-free survival (73% versus 65% for patients randomized to the standard arm). This trial established interval compressed VDC/IE as a new standard approach for patients with

localized Ewing sarcoma. Of note, the role of interval compression in patients with newly diagnosed metastatic Ewing sarcoma has not been evaluated.

The European Intergroup Cooperative Ewing's Sarcoma Study (EICESS)-92 trial sought to clarify the role of ifosfamide and etoposide based upon a risk classification strategy in which patients with small, localized tumors were deemed standard risk and patients with large localized tumors or any metastases were deemed high risk.⁹¹ All standard-risk patients received initial therapy with VAIA. These patients were then randomized to receive this same therapy in the adjuvant setting or this same therapy with cyclophosphamide substituting for ifosfamide. Among 155 randomized standard-risk patients, there was no difference in event-free or overall survival between patients who received ifosfamide or cyclophosphamide in the adjuvant setting. These results do not fully clarify the role of ifosfamide in this group as all patients received ifosfamide in the neoadjuvant setting.

High-risk patients in the EICESS-92 trial were randomized at enrollment to receive VAIA or VAIA plus etoposide.⁹¹ Among 492 randomized high-risk patients, there was a trend favoring the addition of etoposide. In particular, patients deemed high-risk due to large localized tumors appeared to benefit from the addition of etoposide, whereas patients with metastatic disease did not appear to benefit from etoposide. These results mirror those obtained from INT-0091 in which the addition of IE benefited patients with localized disease but not patients with metastatic disease.

Based upon this current body of evidence, a standard approach for newly diagnosed patients with localized Ewing sarcoma in North America is to use interval compressed VDC/IE according to AEWS0031. Many clinicians utilize this same regimen for patients with newly diagnosed metastatic disease, though data supporting a benefit of IE or of interval compression are lacking in this population. For both groups, participation in a cooperative group clinical trial should be strongly considered.

Chemotherapy for Patients with Recurrent Ewing Sarcoma

Historically, patients with recurrent Ewing sarcoma had few systemic options. Many such patients were retreated with chemotherapy combinations used as part of initial therapy. One series reported re-responses and durable remissions in patients treated with this strategy at relapse.⁹² Additional data suggest that higher dose ifosfamide (15 g/m²) may be active in patients with recurrent Ewing sarcoma who were treated with lower doses of ifosfamide as part of initial therapy.⁹³ Given greater options, many clinicians now opt to treat patients with new agents not previously used as part of initial therapy.

Currently, patients with recurrent Ewing sarcoma are candidates for clinical trials of novel agents or may be treated with a number of salvage chemotherapy regimens with documented activity in this setting. The combination of gemcitabine with docetaxel has shown modest activity in patients with recurrent Ewing sarcoma. Two single-institution case series reported no responses among four patients with recurrent Ewing sarcoma.^{94,95} A formal phase 2 trial of standard doses of gemcitabine and docetaxel reported 2 patients with partial responses among 14 patients with recurrent Ewing sarcoma.⁹⁶ In contrast, another case series reported four of six patients with recurrent Ewing sarcoma with objective responses with the use of higher-dose gemcitabine and docetaxel, suggesting that higher doses of this regimen may have greater activity in this disease.⁹⁷ A formal phase 2 trial of higher-dose gemcitabine together with standard-dose docetaxel reported one patient with a partial response among seven patients with recurrent Ewing sarcoma.⁹⁸ Taken together, these findings suggest a limited role for this regimen in the management of patients with recurrent Ewing sarcoma.

Camptothecin-based regimens are currently the most active available chemotherapy regimens for patients with relapsed Ewing

sarcoma. The combination of topotecan with cyclophosphamide has shown activity in this population. A Pediatric Oncology Group (POG) phase 2 trial of this combination included 17 patients with relapsed Ewing sarcoma, 2 with complete response, and 4 with a partial response for an objective response rate of 36%.⁹⁹ A retrospective analysis from the German cooperative group included 49 patients with relapsed Ewing sarcoma and disease evaluable for response.¹⁰⁰ On initial response assessment, 16 (33%) had a partial response. Based upon these findings in patients with recurrent Ewing sarcoma, the COG conducted a trial in patients with newly diagnosed metastatic Ewing sarcoma in which patients received an initial window of therapy with either two courses of topotecan monotherapy or topotecan plus cyclophosphamide.¹⁰¹ Topotecan monotherapy had only modest activity, but two courses of the combination of topotecan plus cyclophosphamide resulted in a response rate of 57%. Based upon these promising results in patients with relapsed or metastatic Ewing sarcoma, the current COG trial for patients with newly diagnosed localized disease (AEWS1031) is a randomized comparison of interval compressed VDC/IE to interval compressed VDC/IE with the addition alternating blocks of topotecan and cyclophosphamide (NCT01231906).

The combination of irinotecan and temozolimide has also shown activity in patients with relapsed Ewing sarcoma. In the initial pediatric phase 1 trial of this regimen, three of seven patients with Ewing sarcoma had objective responses.¹⁰² A multicenter retrospective analysis of 14 patients treated with this regimen showed a response rate of 29%.¹⁰³ Follow-up retrospective studies from other institutions reported response rates >60% in this same population.^{104,105} This combination is less myelosuppressive than topotecan/cyclophosphamide and may be given as an oral regimen. Given these properties, this combination may serve as a backbone for the development of new regimens that combine chemotherapy with novel agents.

Role of High-Dose Chemotherapy for Patients with Ewing Sarcoma

Given the finding that Ewing sarcoma is a chemosensitive tumor, several groups have evaluated the role of high-dose chemotherapy with autologous stem cell rescue in selected patients with high-risk disease. A single-institution retrospective study reported on the role of this approach in patients with recurrent Ewing sarcoma.¹⁰⁶ On univariate analysis, patients who received high-dose chemotherapy had superior overall survival. In order to try to control for selection bias that may have led to selection of the most favorable patients to receive high-dose chemotherapy, this group performed a multivariate survival analysis. Receipt of high-dose chemotherapy as a component of relapse therapy was associated with improved survival, even after controlling for variables thought to be prognostic at relapse, such as response to salvage therapy and time from diagnosis to relapse.

The majority of studies evaluating this modality have focused on patients with newly diagnosed metastatic Ewing sarcoma. Given the radiosensitivity of Ewing sarcoma, the Children's Cancer Group conducted a trial evaluating high-dose therapy using melphalan, etoposide, and total-body radiation as conditioning.¹⁰⁷ Thirty-two patients with newly diagnosed disease with metastases to the bone and/or bone marrow were nonrandomly assigned to high-dose therapy following induction chemotherapy. Event-free survival was 20% at 2 years and was identical to a historic control group treated with standard-dose chemotherapy, indicating that this regimen did not improve outcomes in this very high-risk patient population.

A series of multicenter trials treated patients with high-dose therapy with busulfan and melphalan conditioning.^{108,109} This approach appeared to be feasible following initial induction chemotherapy, though whether outcomes were improved by this approach is not clear in these uncontrolled trials. The Euro-Ewing group applied this approach to a larger group of patients with

metastatic disease beyond isolated lung metastases.¹¹⁰ In this very high-risk patient population, 3-year event-free survival was 27%, suggesting that any improvement in outcome from high-dose therapy was incremental.

One trial has been completed evaluating the role of high-dose chemotherapy in patients with high-risk localized Ewing sarcoma.¹¹¹ Patients received a common induction chemotherapy regimen and had response assessed at the time of local control (by histology for patients who underwent surgical local control or by imaging for patients who received radiation for local control). Patients with a poor response to induction chemotherapy were nonrandomly assigned to receive high-dose chemotherapy with busulfan and melphalan conditioning. Only a subset of patients assigned to receive high-dose chemotherapy did so. This selected subset had an event-free survival rate that was similar to patients with a good response who received ongoing standard-dose chemotherapy. Patients with a poor response to induction who did not go on to receive high-dose therapy had significantly inferior outcomes. These results suggest that high-dose therapy may have abrogated the anticipated poor outcomes for patients with a poor response to induction chemotherapy.

A lingering concern and area of controversy in this field is that patients with chemotherapy-responsive disease are both more likely to survive longer and more likely to be candidates for high-dose chemotherapy. In order to circumvent this selection bias, the Euro-Ewing group is conducting the first randomized trial of high-dose chemotherapy in this disease. Patients with newly diagnosed Ewing sarcoma and either isolated lung metastases or localized disease with poor response to initial chemotherapy are eligible. All patients receive induction chemotherapy with vincristine, ifosfamide, doxorubicin, and etoposide.¹¹² Patients randomized to undergo high-dose chemotherapy receive conditioning with busulfan and melphalan. Patients randomized to receive ongoing chemotherapy receive the combination of vincristine, doxorubicin, and ifosfamide. Until the results of this ongoing randomized trial become available, the role of high-dose chemotherapy for patients with Ewing sarcoma will remain controversial.

Novel Agents for Patients with Ewing Sarcoma

Despite understanding the critical role of *EWSR1* fusion oncogenes in the pathogenesis of Ewing sarcoma, strategies to target *EWSR1* fusion oncogenes and oncoproteins have been difficult to develop. One group used gene expression profiling to identify existing drugs that replicate the gene expression profile associated with *EWSR1/FLI1* knockdown.¹¹³ Cytarabine was one of the most effective drugs in modulating the gene expression profile to emulate that of Ewing sarcoma cells subjected to *EWSR1/FLI1* knockdown. The COG then conducted a phase 2 trial of cytarabine in patients with relapsed Ewing sarcoma, with no responses among 10 patients.¹¹⁴

Another novel agent, YK-4-279, was developed to interfere with the interaction of EWS-FLI1 protein and RNA helicase A, an important mediator of EWS-FLI1.¹¹⁵ This agent has shown preclinical activity against Ewing sarcoma models. Efforts to move this agent or agents with a similar mechanism of action in the clinic are ongoing.

A high-throughput screening study sought to identify existing agents that were able to reduce expression of EWS-FLI1 target genes.¹¹⁶ Mithramycin was the lead compound emerging from this screen. Follow-up experiments demonstrated preclinical activity against Ewing sarcoma models, leading to an ongoing clinical trial (NCT01610570).

Other novel approaches have tried to exploit additional vulnerabilities identified in laboratory studies of this disease. For example, a large body of literature has suggested that antiangiogenic strategies would be active against Ewing sarcoma.¹¹⁷ Based on these findings, several trials have been conducted. The COG conducted a trial using VDC/IE together with metronomic vinblastine and

celecoxib in patients with newly diagnosed metastatic Ewing sarcoma.¹¹⁸ This regimen was tolerable, but outcomes did not appear different from previous outcomes reported for this population. A pilot study of bevacizumab added to vincristine, irinotecan, and temozolomide included two patients with Ewing sarcoma, both with objective responses.¹¹⁹ A nonrandomized multicenter trial of topotecan, cyclophosphamide, and bevacizumab for patients with recurrent Ewing sarcoma is ongoing (NCT01492673).

The insulin-like growth factor 1 receptor (IGF1R) has also been the subject of intense study in preclinical and clinical studies of Ewing sarcoma. The majority of Ewing sarcoma cells and tumor samples express IGF1R.¹²⁰ *EWSR1/FLI1* expression reduces the expression of IGF-binding protein 3, an endogenous inhibitor of IGF1R pathway activation.¹²¹ Preclinical studies of IGF1R small molecular inhibitors or inhibitory anti-IGF1R monoclonal antibodies have demonstrated robust activity against Ewing sarcoma models.¹²²⁻¹²⁵ In early phase clinical trials of IGF1R monoclonal antibodies, several patients with recurrent Ewing sarcoma demonstrated objective responses.^{126,127} Several phase 2 trials specifically for patients with recurrent Ewing sarcoma were developed, and response rates of approximately 10% were observed without significant single-agent toxicity.^{126,128-130} Based upon these promising results in the recurrent setting, the COG is developing a trial of an IGF1R monoclonal antibody together with VDC/IE for patients with newly diagnosed metastatic Ewing sarcoma.

The mammalian target of rapamycin has also been implicated as a potential therapeutic target in Ewing sarcoma. Preclinical studies indicate that rapamycin can reduce levels of EWS/FLI1 protein and also induce an *EWSR1/FLI1*-inactive gene expression signature.^{113,131} In vitro and in vivo studies have shown antitumor activity of rapamycin as a single agent and in combination with cytotoxic chemotherapy.^{132,133} To date, no trials of mammalian target of rapamycin inhibition specifically for patients with Ewing sarcoma have been conducted. However, in a phase 1 trial of ridaforolimus, one patient with advanced Ewing sarcoma had a confirmed partial response.¹³⁴ One institution is conducting a trial in patients with high-risk Ewing sarcoma in which patients will receive a window of irinotecan, temozolomide, and temsirolimus prior to receiving interval-compressed chemotherapy (NCT01946529).

Most recently, laboratory studies suggest that Ewing sarcoma may be sensitive to inhibition of poly(adenosine diphosphate-ribose) polymerase (PARP). In a large-scale drug screen across myriad cancer histologies, Ewing sarcoma cell lines were found to be uniquely sensitive to the effects of a PARP inhibitor.¹³⁵ Another study sought to investigate the mechanism of this observation.¹³⁶ They noted that Ewing sarcoma cell lines have evidence of increased DNA damage, an effect that is potentiated in the presence of a PARP inhibitor. The use of a PARP inhibitor together with temozolomide resulted in dramatic preclinical responses compared to temozolomide alone or the PARP inhibitor alone. Based upon these observations, a phase 2 trial of olaparib has been conducted, with results pending (NCT01583543). Other trials of PARP inhibitors as single agents and in combination with other agents are in development.

Radiation Therapy for Patients with Newly Diagnosed Ewing Sarcoma

Advances in radiation delivery and target definition together with improvements in chemotherapy and surgery approaches technique have improved local control for patients with Ewing sarcoma. However, controversy has plagued decisions regarding local control measures particularly for pelvic primaries for which retrospective studies have indicated trends toward better local after surgery compared with radiotherapy, but failed to reach statistical significance. Such studies are fraught with selection bias as patients chosen for radiotherapy rather than resection tend to be those with larger tumors and less robust response to chemo-

therapy.^{137,138} Nonetheless, when feasible, surgery is generally the preferred local therapy modality and radiation is reserved for patients in whom anticipated morbidity from surgery is prohibitive. This leaves approximately 20% of children on COG studies receiving definitive radiation and 15% receiving adjuvant radiation for primary tumor control.

A prospective randomized trial comparing surgery and radiotherapy as local control modality for Ewing sarcoma at any primary site has never occurred and will never take place. Thus we are left with interpretation of data collected for cohorts in which local control decisions are made based on parameters including tumor location, size, response to chemotherapy, patient age, and patient preference based on expected morbidity of each procedure. One such informative study is an analysis of patients with pelvic Ewing sarcomas treated on INT-0091, a randomized controlled study that compared two chemotherapy regimens: VACA and VACA-IE.¹³⁹ Treating physicians chose the local control approach, be it surgery, radiation, or both. The authors sought to assess local control modality after adjusting for tumor size and chemotherapy type. Of the 75 studied patients, 12 underwent surgery, 44 received radiotherapy, and 19 received both. Local control rates (80% to 90%) were quite promising even in this group with unfavorable primary site. The 5-year cumulative incidence of local failure was 21% with no significant differences by tumor size or local control modality. However, there was a trend toward benefit in local control with VACA-IE chemotherapy (11% versus 30%; $p = 0.06$). Of note, despite lack of statistical significance, combined surgery and radiotherapy was associated with the lowest rates of local relapse (10.5% for surgery + radiotherapy compared with 25% for either surgery or radiotherapy alone).¹³⁹ Similar results, although again, not statistically significant, were reported for the entire cohort of patients, with 2% local recurrence for patients receiving combined modality treatment compared with 5% for surgery and 9% for radiotherapy alone ($p =$ not significant).⁸⁹ Not surprisingly, European studies have historically favored combined modality approaches for local control, with 63% of patients treated on EICESS 92 receiving combined surgery and radiation, 19% treated with surgery alone, and 18% with radiotherapy alone. Impressive local control rates were reported, with 95% when surgery was a component of local control compared with 75% when only radiotherapy was used.¹⁴⁰ A dearth of reports describes the durability of local therapy modalities and the functional outcome of each approach. With a particular focus on cure rates, contemporary clinical trials have emphasized event-free survival and overall survival as end points, but better information regarding functional outcomes is critical to informed decisions regarding local therapy modality for individual patients.

Although postoperative radiation has gained favor for patients receiving combined modality therapy for local control, consideration should be given to preoperative radiation for a select group of patients with Ewing sarcoma. For these patients, the goal of preoperative radiotherapy is not to allow an inoperable tumor to become operable, as the data for this approach is lacking for Ewing sarcoma. Rather, in patients for whom the choice of combined modality therapy is made, the rationale for preoperative radiation lies primarily in reducing side effects. Preoperative radiation may allow for smaller fields, less normal tissue exposure, and perhaps lower doses, as has been reported for adults in a prospective, randomized study for adults with soft tissue sarcomas.¹⁴¹

Appropriate uses of radiotherapy for patients with newly diagnosed Ewing sarcoma include definitive radiation therapy for unresectable tumors, adjuvant radiation for tumors with incomplete surgical resection or intraoperative spill, chest wall tumors with ipsilateral pleural-based secondary tumor nodules or positive pleural fluid cytology, and pathologically involved lymph nodes. Patients with complete resections (R0) after neoadjuvant chemotherapy with a clear margin (defined as no viable tumor at the cut surface) should not receive radiotherapy; there are some subtle points to be highlighted. These guidelines incorporate

not only the traditional factor of extent of surgical resection but also the parameter of percent of tumor necrosis more commonly used in European protocols. Thus, for resected tumors that have >90% necrosis, if the tissue at the margin is bland scar or loose fibrous tissue, margin status should be considered negative and no postoperative radiation should be administered. However, if inflammatory tissue or coagulative tumor necrosis is present at the margin (the cytoarchitecture of the tumor cells is preserved), postoperative radiotherapy is required. In contradistinction, for resected tumors with <90% necrosis, the cut surface of the resected tumor must be normal nonreactive tissue in order to be considered pathologically negative and radiotherapy avoided.

The role of preoperative radiotherapy must be carefully considered. Preoperative radiation should not be undertaken with the goal of rendering an inoperable tumor operable and should be considered only in resectable tumors in select sites such as pelvis and chest wall for which a higher risk of positive microscopic margins is present. Complete surgical excision should be undertaken within 2 weeks of 36 Gy of radiation. Standard radiotherapy doses are 50.4 Gy for microscopic residual and 55.8 Gy for gross residual disease.

One note of caution is in order for the administration of radiation to patients with Ewing sarcoma. High-dose chemotherapy with busulfan/melphalan is now often used for patients with metastatic disease. In late 2003, the pediatric oncology community was alerted to possible severe complications after busulfan/melphalan high-dose chemotherapy and irradiation of the spinal cord.¹⁴² And a subsequent amendment restricted the radiation dose to the spinal cord to 30 Gy after busulfan/melphalan high-dose therapy. To add to these concerns, in 2005, reports from France described severe gastrointestinal toxicities after busulfan/melphalan and pelvic radiotherapy. A detailed analysis of the European Ewing Tumor Working Initiative of National Groups Ewing Tumour Studies-99 study showed further serious toxicities with paraplegias and bowel obstructions leading to deaths.¹⁴³ However, in follow-up studies by the German Pediatric Oncology and Hematology Society group, similar severe toxicities were not observed. Although the German group did not confirm such severe toxicities, it must be noted that whereas the median follow-up for gastrointestinal side effects was longer than the longest period for development of radiation associated bowel toxicities in France, the median follow-up for spine toxicities was only 7 months and therefore caution must be exercised. These differing findings may also be the result of lower doses and smaller volumes in the German Pediatric Oncology and Hematology Society group compared to those used in France. Given the critical role of radiotherapy for local control in many patients with Ewing sarcoma, if radiation is anticipated as part of a multimodality approach to local control in patients with axial tumor sites, consideration should be given to avoiding busulfan/melphalan high-dose therapy.¹⁴⁴

Bone metastases in Ewing sarcoma receive the same dose of 55.8 Gy as does gross disease at the primary site. However, these metastatic sites are often treated at the completion of chemotherapy, months after local control measures, because protracted external beam radiation to such sites might include significant bone marrow volumes and ultimately compromise the ability to administer chemotherapy. Thus a role has emerged for hypofractionated stereotactic body radiotherapy (SBRT) for bone metastases. Safety of administration of such large doses to highly targeted volumes has been aided by improvements in immobilization and image-guidance techniques. Local control rates of 75% to 90% have been achieved by SBRT to spine metastases using 18 to 30 Gy in a single fraction or 24 to 60 Gy in five fractions.¹⁴⁵ In the setting of metastatic bone sarcomas in children, the advantages of SBRT to bone metastases are particularly appealing because completion of the radiation course in one to five fractions with equivalent disease control rates, as conventional fractionation offers the added advantages of minimizing interruptions in systemic therapy and irradiation of smaller volumes.¹⁴⁶

Systemic Therapies for Osteosarcoma

Chemotherapy for Patients with Newly Diagnosed Osteosarcoma

Chemotherapy plays little role in the management of patients with low-grade or surface osteosarcoma. Historically, there was controversy about the role of chemotherapy in the management of patients with high-grade osteosarcoma. In light of this controversy, the Multi-Institutional Osteosarcoma Study (MIOS) was conducted.¹⁴⁷ Patients with newly diagnosed localized extremity high-grade osteosarcoma were randomized after complete surgical resection to observation or to adjuvant chemotherapy. Chemotherapy consisted of 45 weeks of combination therapy including bleomycin, cyclophosphamide, and actinomycin-D (BCD) cycles, high-dose methotrexate cycles targeted to achieve 1,000 micromolar peak concentration, and cisplatin/doxorubicin cycles. Thirty-six eligible patients were randomized. Of the 18 patients randomized to adjuvant chemotherapy, 6 (33.3%) recurred. Of the 18 patients randomized to observation, 15 (83.3%) recurred and 2 of the 3 patients in this group who did not recur did not accept the outcome of the randomization and were treated with adjuvant chemotherapy. At 2 years from randomization, 66% of the patients randomized to receive adjuvant chemotherapy were relapse-free compared with only 17% of the patients randomized to observation. These results confirmed the significant impact of chemotherapy on outcomes of high-grade osteosarcoma, and this trial established a new standard of care for this disease.

The positive findings from the MIOS trial led to a number of subsequent trials designed to determine the optimal timing and type of chemotherapy. One trial compared adjuvant to neoadjuvant chemotherapy.¹⁴⁸ In this trial (POG-8651), patients with newly diagnosed localized resectable high-grade osteosarcoma were randomized at study entry to undergo immediate surgical resection followed by 42 weeks of adjuvant chemotherapy or to receive 10 weeks of neoadjuvant chemotherapy followed by surgery and then 32 weeks of adjuvant chemotherapy. Aside from the difference in timing of surgical resection, all patients received the same 42 weeks of chemotherapy using a similar regimen to that used in the MIOS trial. A total of 100 eligible patients were randomized. Overall survival, event-free survival, and rates of limb salvage surgery were similar between the two arms of the trial, demonstrating that timing of surgical resection did not impact outcomes. With these results, the use of neoadjuvant chemotherapy became more widespread as this approach allows more time for surgical planning and also allows one to assess the extent of histologic necrosis in response to neoadjuvant chemotherapy.

Two older trials sought to clarify the role and optimal dosing of methotrexate in patients with newly diagnosed localized osteosarcoma. In an Italian trial, patients were randomized to receive methotrexate 200 mg/m² or 2 g/m² as a component of multiagent adjuvant chemotherapy.¹⁴⁹ Outcomes were equivalent between the two groups. The UK Children's Cancer Study Group conducted a similar trial, though the doses of methotrexate under investigation were 690 mg/m² or 7.5 g/m².¹⁵⁰ Outcomes were again similar between the randomized groups, suggesting either that methotrexate does not contribute to disease control in osteosarcoma or that lower-dose methotrexate is adequate for efficacy of this agent.

A series of trials from the German/Austrian/Swiss Cooperative Osteosarcoma Study Group (COSS) has clarified the use of cisplatin and doxorubicin in osteosarcoma. In the COSS-80 trial, patients were randomized to chemotherapy with doxorubicin and methotrexate in all patients and either cisplatin or BCD. Outcomes were similar between arms.¹⁵¹ In the COSS-82 trial, patients were randomized to receive BCD and methotrexate or doxorubicin/cisplatin and methotrexate.¹⁵² Patients with good histologic response at the time of surgery continued to receive that same chemotherapy, whereas patients with poor histologic response received different salvage regimens. A total of 125

evaluable patients were randomized. Patients randomized to the BCD arm with no doxorubicin or cisplatin in the neoadjuvant setting had significantly inferior metastasis-free survival, even though these patients with poor histologic response received doxorubicin and cisplatin in the adjuvant setting. Together with the results of COSS-82, these findings highlighted the importance of early doxorubicin treatment in the management of osteosarcoma.

The European Osteosarcoma Intergroup completed a randomized trial to assess the role of high-dose methotrexate in patients with newly diagnosed localized extremity osteosarcoma.¹⁵³ Patients were randomized at study entry to chemotherapy with six cycles of doxorubicin and cisplatin or to that same regimen with a dose of high-dose methotrexate given 10 days prior to each cycle of doxorubicin and cisplatin. Surgical resection was planned at the same time in both arms of the trial such that patients receiving doxorubicin and cisplatin had time to receive three cycles prior to surgery, whereas patients receiving methotrexate had time to receive two cycles prior to surgery. Ninety-nine patients were randomized to each arm of the trial. Disease-free survival was superior for patients randomized to doxorubicin and cisplatin (57% at 5 years compared to 41% for patients randomized to also receive methotrexate). Because all patients received the same planned cumulative dose of doxorubicin and cisplatin, these results highlighted the importance of dose intensity of these agents in the treatment of osteosarcoma. Moreover, these results called into question the role of methotrexate, though the dose used in this trial was lower than used in more recent trials (8 g/m² versus 12 g/m²).

The European Osteosarcoma Intergroup conducted another randomized trial comparing six cycles of doxorubicin and cisplatin to a chemotherapy regimen similar to that used in the MIOS trial.¹⁵⁴ Patients with newly diagnosed localized resectable osteosarcoma were eligible, and 391 eligible patients were randomized. The proportion of patients with a good histologic response to neoadjuvant chemotherapy was similar between randomized groups. Progression-free and overall survival estimates were nearly identical between randomized groups. Based upon these findings, the group concluded that the shorter regimen with doxorubicin and cisplatin is preferable to the more complicated and longer regimen used in the MIOS trial. These results called into question the role of the BCD regimen used in the MIOS trial, which has now largely been abandoned.

This group conducted a subsequent trial evaluating interval compression to dose-intensify the doxorubicin/cisplatin regimen.¹⁵⁵ Patients with newly diagnosed localized osteosarcoma were randomized to receive six cycles of doxorubicin/cisplatin administered either every 3 weeks or every 2 weeks. Surgical resection occurred after two cycles in the every 3-week arm and after three cycles in the every 2-week arm. A total of 497 eligible patients were randomized. Patients in the every 2-week arm had a higher likelihood of achieving a good histologic response, though they had also received an additional cycle of neoadjuvant chemotherapy. Overall survival and progression-free survival were similar between groups, indicating that dose intensification by interval compression did not improve outcomes in this setting.

Based upon promising results in patients with recurrent osteosarcoma (see the following), another series of trials have evaluated the role of ifosfamide or ifosfamide with etoposide in the treatment of patients with osteosarcoma. The POG conducted a trial in patients with newly diagnosed metastatic osteosarcoma in which all patients received a window of therapy with two cycles of high-dose ifosfamide (12 g/m² per cycle) prior to surgical resection.¹⁵⁶ Patients then received adjuvant therapy with high-dose methotrexate, doxorubicin/cisplatin, and additional high-dose ifosfamide. Of 27 patients with response-evaluable disease, 8 patients (30%) had an objective radiographic response after the two cycles of window therapy. These results suggested that single-agent ifosfamide is an active regimen in this disease.

The Italian Sarcoma Group conducted a randomized trial evaluating the role of ifosfamide both in neoadjuvant and adjuvant phases of therapy.¹⁵⁷ Patients with localized osteosarcoma were

randomized to receive methotrexate, cisplatin, and doxorubicin with or without ifosfamide preoperatively. Patients randomized to not receive ifosfamide preoperatively could have ifosfamide added postoperatively if they had a poor histologic response to neoadjuvant chemotherapy without ifosfamide. Of 246 randomized patients, the proportion of patients with a good histologic response and event-free survival were similar between randomized groups. Given increased hematologic toxicity associated with the ifosfamide arm, the authors concluded that ifosfamide should be reserved for the adjuvant setting in patients with poor histologic response to neoadjuvant therapy without ifosfamide.

North American Intergroup study INT-0133 was a randomized phase 3 trial that included a comparison of patients treated with high-dose methotrexate + cisplatin + doxorubicin (MAP) chemotherapy or MAP plus ifosfamide (9 g/m² per course).¹⁵⁸ A total of 677 patients with newly diagnosed localized osteosarcoma were randomized. While the initial analysis of this randomization was complicated by a statistical interaction in the factorial design (described subsequently), a subsequent analysis with longer follow-up determined that the addition of ifosfamide to MAP chemotherapy did not impact the event-free or overall survival.¹⁵⁹

The POG conducted a trial for patients with newly diagnosed metastatic osteosarcoma in which all patients received two courses of IE prior to surgical resection of the primary tumor.¹⁶⁰ The overall response rate after two courses of IE was 59%. This study design allowed histologic response of the primary tumor to be assessed, with 65% of patients having at least 90% tumor necrosis after two cycles of IE.

The French SFOP OS94 trial sought to determine whether doxorubicin could be replaced by ifosfamide and etoposide in the management of patients with newly diagnosed localized osteosarcoma.¹⁶¹ Patients were randomized at study entry to receive neoadjuvant chemotherapy with high-dose methotrexate in all patients and either doxorubicin or IE. Adjuvant therapy was determined by histologic response to neoadjuvant chemotherapy. The primary end point was histologic necrosis at the time of surgery. Among 234 evaluable patients, there was a significantly higher rate of good histologic necrosis in patients randomized to IE compared to doxorubicin. These results demonstrate the activity of IE in this setting, though must be viewed in light of the fact that patients in the comparator arm received doxorubicin without cisplatin.

The first European-American osteosarcoma study 1 sought to clarify further the role of IE in patients with newly diagnosed resectable osteosarcoma. All patients received neoadjuvant chemotherapy with MAP, which has become a consensus standard neoadjuvant chemotherapy regimen for patients with newly diagnosed osteosarcoma. Patients with a good histologic response (<10% viable tumor) were eligible for randomization evaluating the role of adjuvant interferon (see the following). Patients without a good histologic response to neoadjuvant chemotherapy (≥10% viable tumor) were eligible to be randomized to receive ongoing adjuvant chemotherapy with MAP or to receive ongoing adjuvant chemotherapy with MAP with the addition of IE. This trial has closed to accrual, but results for this arm of the trial have not yet been reported.

Chemotherapy for Patients with Recurrent Osteosarcoma

Surgical resection of sites of recurrent disease remains a cornerstone of curative therapy at the time of relapse. Chemotherapy options are limited for patients with recurrent osteosarcoma. The combination of IE appears to be among the most active regimens for this population. For example, an initial phase 2 trial of this combination included eight patients with recurrent osteosarcoma, three of whom had an objective response.¹⁶² A follow-up phase 2 trial from the French Society of Pediatric Oncology demonstrated a 48% response rate with this regimen in a population that included largely patients with first recurrent disease.¹⁶³

The combination of gemcitabine and docetaxel has also been investigated for patients with recurrent osteosarcoma. Single-

institution case series have suggested some activity in this setting, mainly with disease stabilization,^{95,97} though one group reported objective responses in 3 of 10 patients with recurrent osteosarcoma.⁹⁴ Based in part upon these findings, two phase 2 trials have been conducted.^{96,164} Sixteen patients with recurrent osteosarcoma enrolled across both trials and only two patients had objective responses (partial response in both). These findings indicate that this regimen has only modest activity in this setting.

Novel Agents for Patients with Osteosarcoma

Multiple groups have attempted to improve outcomes for patients with advanced osteosarcoma by utilizing novel agents. A subgroup of trials has targeted antigens that are overexpressed on some osteosarcomas. Based upon reports of overexpression of human epidermal growth factor receptor 2 (HER2) in a subset of osteosarcoma, the COG conducted a phase 2 trial of trastuzumab together with intensive chemotherapy for patients with newly diagnosed HER2-expressing metastatic osteosarcoma.¹⁶⁵ A total of 41 patients with HER2-expressing tumors were nonrandomly assigned to receive trastuzumab plus chemotherapy, and 55 patients with HER2-negative tumors were nonrandomly assigned to receive chemotherapy. Event-free survival at 30 months was 32% in both cohorts, suggesting little benefit from the addition of trastuzumab.

Osteosarcomas commonly express cell surface disialoganglioside GD2.¹⁶⁶ As such, patients with advanced osteosarcoma have been included in clinical trials of therapeutic monoclonal antibodies targeting GD2. In one phase 1 trial of a murine monoclonal antibody, one of two patients with osteosarcoma had a mixed response.¹⁶⁷ Given high rates of human antimouse antibodies after receipt of the murine monoclonal antibody, a chimeric anti-GD2 antibody was generated and tested in a phase 1 trial.¹⁶⁸ One patient with osteosarcoma was treated and showed clinical evidence of disease stabilization, though ultimately progressed. Based upon these suggestions of clinical activity in osteosarcoma, a trial of a humanized anti-GD2 antibody in patients with advanced GD2-positive osteosarcoma is ongoing (NCT01662804).

Another group of trials has attempted to increase immune clearance of microscopic osteosarcoma cells. The use of muramyl tripeptide phosphatidylethanolamine (MTP-PE) to stimulate antitumor macrophages has been intensely studied in osteosarcoma. In an initial phase 2 trial, patients with recurrent or persistent pulmonary metastatic disease underwent surgical resection and then received adjuvant MTP-PE.¹⁶⁹ Compared to historic controls treated with adjuvant chemotherapy, 24 weeks of MTP-PE prolonged progression-free survival from 4.5 months to 9 months.

These findings stimulated the development of a randomized phase 3 clinical trial of the role of MTP-PE. North American Intergroup Study INT-0133 included 677 patients with localized osteosarcoma randomized to one of four treatment arms, including two arms that included 36 weeks of adjuvant MTP-PE given together with adjuvant chemotherapy.¹⁵⁸ Interpretation of this trial is complicated by the factorial trial design and by the presence of an interaction between the ifosfamide randomization (described previously) and the MTP-PE randomization. Specifically, MTP-PE appeared to prolong event-free survival only among patients also randomized to receive ifosfamide. Post hoc analysis of the trial with additional follow-up was performed. These analyses showed a trend toward prolonged event-free survival as well as a statistically significant increase in overall survival among patients randomized to receive MTP-PE.¹⁵⁹ This result was independent of the results of the ifosfamide randomization. INT-0133 also included a much smaller cohort of patients with newly diagnosed metastatic osteosarcoma. Patients randomized to receive MTP-PE had improved event-free and overall survival rates, though this portion of the trial was not powered to detect statistically significant differences in outcomes between randomized arms.¹⁷⁰ Based in part upon the findings from INT-0133, MTP-PE obtained regulatory approval in Europe for patients with osteosarcoma, though it is not used in North America.

In addition to MTP-PE, interferon has been studied as an immune strategy to reduce the risk of recurrence due to microscopic residual disease. Early results from Sweden demonstrated favorable outcomes in patients who received interferon as an adjuvant therapy following surgical resection of osteosarcoma, even in the absence of chemotherapy.¹⁷¹ The COSS-80 study included a randomization in which patients received or did not receive interferon in combination with multiagent chemotherapy.¹⁵¹ There was no difference in outcome according to randomized assignment. Given the results of the Swedish experience and concerns that interferon combined with chemotherapy may blunt the immunostimulatory effects of interferon, the European-American osteosarcoma study 1 trial included another randomized assessment of the role of interferon in patients with newly diagnosed resectable osteosarcoma. Patients with a good histologic response to neoadjuvant chemotherapy were randomized to receive or not receive weekly pegylated interferon-alpha-2b following the completion of all planned chemotherapy. The preliminary results of this randomization have been reported.¹⁷² Among 715 good-responder patients randomized in this portion of the trial, event-free survival was not statistically significantly different for patients randomized to interferon or not. While the final analyses from this trial are still pending, it does not appear as though adjuvant interferon improves outcomes in patients with a good response to neoadjuvant chemotherapy.

A large body of preclinical data demonstrates that bisphosphonates have direct antitumor activity in osteosarcoma.¹⁷³ Two studies have investigated the safety of adding a bisphosphonate to standard chemotherapy regimens used in the treatment of osteosarcoma. In one study, monthly pamidronate was administered along with methotrexate, doxorubicin, and cisplatin.¹⁷⁴ The toxicity profile was similar to the expected toxicity profile associated with the chemotherapy backbone and an increased incidence of complications associated with endoprostheses was not observed. In the second study, zoledronic acid was administered every 4 to 6 weeks along with a chemotherapy backbone that included methotrexate, doxorubicin, cisplatin, ifosfamide, and etoposide.¹⁷⁵ Zoledronic acid at standard doses was tolerable together with this intensive backbone. The size of these tolerability studies does not allow one to draw conclusions about the effect of bisphosphonates on event-free survival. An ongoing French randomized phase 3 trial will compare outcomes of patients randomized to treatment with chemotherapy and surgery to patients randomized to treatment with chemotherapy, surgery, and zoledronic acid (NCT00470223). The results of this trial will clarify the role of bisphosphonates in the treatment of newly diagnosed patients with osteosarcoma.

The Italian Sarcoma Group conducted a phase 2 trial of the multitargeted tyrosine kinase inhibitor sorafenib in patients with recurrent osteosarcoma.¹⁷⁶ Thirty-five patients >14 years of age enrolled and received sorafenib 400 mg orally twice daily. Three patients (8%) had confirmed partial responses. The 4-month progression-free survival rate was 46%, suggesting a degree of clinical benefit even in patients without an objective radiographic response.

The lung is the most common site of failure in patients with osteosarcoma. Therefore, strategies to reduce the risk of pulmonary relapse are a high priority in this disease. At least two trials have investigated inhalational therapies specifically to target pulmonary disease in osteosarcoma. The COG conducted a phase 2 trial of inhaled granulocyte macrophage-colony-stimulating factor (GM-CSF).¹⁷⁷ Forty-three patients with first pulmonary relapse of osteosarcoma were treated with inhaled GM-CSF twice daily on alternating weeks. In a subset of patients who had not yet undergone resection of recurrent disease, staged bilateral thoractomy allowed assessment of the biologic effects of inhaled GM-CSF. Inhaled GM-CSF did not result in significant recruitment of dendritic cells to lung metastases and did not appear to improve event-free survival. Another trial investigated inhaled cisplatin for patients with relapsed osteosarcoma.¹⁷⁸ Nineteen patients with advanced osteosarcoma involving the lung received inhaled cisplatin every 2 weeks. This therapy appeared tolerable, with limited

systemic toxicities. One patient had a confirmed partial response, and evaluation of inhaled cisplatin is ongoing as adjuvant therapy in patients with recurrent pulmonary metastatic disease that has been completely resected (NCT01650090).

Radiotherapy for Patients with Osteosarcoma

The mainstay of therapy for osteosarcoma has historically omitted radiation because osteosarcomas were thought to be radioresistant.¹⁷⁹ However, surgery and chemotherapy lead to suboptimal local control in challenging disease sites such as the spine and pelvis. Relatively low doses of 30 to 56 Gy for spine osteosarcomas and 56 to 68 Gy for pelvic disease yielded very disappointing local control rates of <20% in the few patients who were irradiated in the Cooperative Osteosarcoma Study Group.^{180,181} However, as higher radiation doses are used, so better local control rates are achieved for unresectable or marginally resectable tumors. Doses of 60 Gy, in 2.5 to 3 Gy once-daily fractions or 1.25 to 1.5 Gy in twice-daily fractions, resulted in local control of 60% in patients with unresectable osteosarcoma.¹⁸² The role of particle radiotherapy for the treatment of unresectable or incompletely resected is promising as well. Kamada et al.¹⁸³ reported local control rates of >70% in patients with unresected osteosarcoma treated with carbon ions. Ciernik et al.¹⁸⁴ reported on the Massachusetts General Hospital experience of 55 patients treated with mean dose of 68.4 Gy (standard deviation, 5.4 Gy) for whom 58.2% (range, 11% to 100%) of the dose was delivered using protons. Five-year local control was 72% and five-year overall survival was 67%. Grade 3 to 4 late toxicities were seen in 30.1% of patients, and two died of treatment-related second malignancies.¹⁸⁴ Thus with careful planning and respect for radiation tolerance of adjacent normal structures, radiation therapy can contribute to favorable clinical outcomes in patients with unresectable or marginally resectable osteosarcoma.

Surgical Therapies for Local Control of Sarcomas of Bone

The aforementioned review of systemic chemotherapeutic and local radiotherapeutic management options for bone sarcomas is necessarily directed toward the pediatric population, as this is the most commonly affected population. However, the same principles can and should be applied to adults with Ewing sarcoma, intermediate- to high-grade osteosarcoma, and high-grade and dedifferentiated chondrosarcomas.^{185,186} Especially for patients younger than 65 years of age who are in good cardiac health, neoadjuvant chemotherapy offers several potential advantages, including (1) immediate treatment not only of presumed "micro-metastatic disease," but also of the primary tumor, so as to make local control easier and/or safer; (2) time for the patient and family to plan and consider various limb salvage versus amputation options; and (3) the opportunity to assess histologic response to chemotherapy, so as to guide adjuvant treatment. For patients with lower-grade chondrosarcoma and osteosarcoma lesions, however, treatment usually consists of surgery only.

Surgery for Patients with Low- to Intermediate-Grade Chondrosarcoma and Osteosarcoma

Enchondromas are benign bone tumors that are exceedingly common, occurring in perhaps as much as 1% of the population. The distal femoral and proximal humeral metaphyseal regions are commonly affected, and patients with periarticular pain are often referred for orthopedic oncologic evaluation. In the vast majority of cases, the cartilage lesions are not thought to be the source of discomfort, and these lesions can be safely followed clinically and radiographically.¹⁸⁷ Subsequent imaging that shows increased plain radiographic lucency, especially if coupled with cortical breakthrough on MR scan, would raise concern that could prompt surgery. The histologic distinctions between a benign enchondroma,

Figure 91.4 A 53-year-old woman presented with a rather subtle plain radiographic finding of a proximal humeral metaphyseal lucency (**A**) after an area of uptake was noted on a screening bone scan obtained for her history of breast cancer. A T2-weighted axial image showed near-perforation of the lateral proximal humeral cortex by a multilobulated cartilage tumor (**B**). Her computed tomography-guided needle and final pathology were consistent with the diagnosis of an atypical cartilaginous neoplasm/low-grade chondrosarcoma, and she underwent aggressive intralesional treatment consisting of curettage, burring, hydrogen peroxide application, and cement packing. (**C**) Three-year postoperative films showed no sign of local recurrence, and she remained asymptomatic.

an atypical cartilaginous neoplasm, and a low-grade chondrosarcoma are notoriously difficult to establish, but >20% myxoid material and bone permeation are thought to be in keeping with a diagnosis of chondrosarcoma.¹⁸⁸ When this diagnosis is suspected, a PET/CT scan, a preoperative image-guided biopsy, and an intraoperative frozen section can be of assistance in guiding treatment. Localized intraosseous grade 1 chondrosarcoma lesions can be safely and effectively treated with aggressive curettage, burring, and adjuvant application (for instance, hydrogen peroxide washing and argon beam coagulation) prior to cement packing (Fig. 91.4). By contrast, most grade 2 chondrosarcoma lesions are treated, where possible, with resection and reconstruction (Fig. 91.5).

Low-grade osteosarcoma lesions include central and juxtacortical (both parosteal and periosteal) forms. Local control is

accomplished with wide resection with negative margins; reconstruction can generally be accomplished by allografts secured with internal fixation⁴¹ or with endoprostheses. The treatment of grade 2 periosoteal chondroblastic osteosarcomas, which often involve the anterior tibial shaft, is controversial as far as chemotherapy is concerned.^{42,189,190} Surgery consists of wide resection and reconstruction if possible, although amputation is sometimes necessary for distal lesions (Fig. 91.6).

Surgery for Patients with High-Grade Sarcomas of Bone

As previously mentioned, there exists no randomized study proving the superiority of surgery over radiation therapy for local control

Figure 91.5 A 74-year-old man with a history of left dorsal foot and ankle low-grade myxoid liposarcoma presented nearly 5 years later with a painful right acetabular bone lesion noted on an anteroposterior pelvis radiograph (**A**). The patient's tumor was evaluated with a magnetic resonance scan (**B**) and a positron emission tomography/computed tomography scan with a maximum standardized uptake value of 5.6. (**C**) His computed tomography-guided biopsy demonstrated an atypical chondrogenic neoplasm, but his final pathology after resection was consistent with a grade II chondrosarcoma. He was reconstructed with a complex cup-cage-cup total hip arthroplasty, and he was without evidence of disease at 1-year follow-up (**D**).

of Ewing sarcoma. Nonetheless, many patients with Ewing sarcoma, particularly extremity lesions, will undergo surgical resection; if margins are negative, adjuvant radiation can be avoided, thus minimizing the complications of growth arrest, deformity, skin and soft tissue induration, lymphedema, arthrofibrosis, osteonecrosis, fracture, and secondary malignancy. In general, then, surgical local control measures for patients with high-grade sarcomas of bone, whether Ewing sarcoma, chondrosarcoma (grade 3, dedifferentiated, mesenchymal, and clear cell), osteosarcoma (conventional, telangiectatic, small cell, and high-grade surface),

or other subtypes (fibrosarcoma, angiosarcoma, leiomyosarcoma, and undifferentiated pleomorphic) can be considered together. In many respects, the ultimate recommendation of a particular surgical control option rests less on histologic subtype of high-grade sarcoma than on a host of other factors, including patient age, disease stage, anatomic location, expected response to induction therapy, and patient/family socioeconomic and cultural factors, as well as capabilities and biases of the treatment team. Thus, surgical local control planning for each high-grade bone sarcoma patient must be individualized.

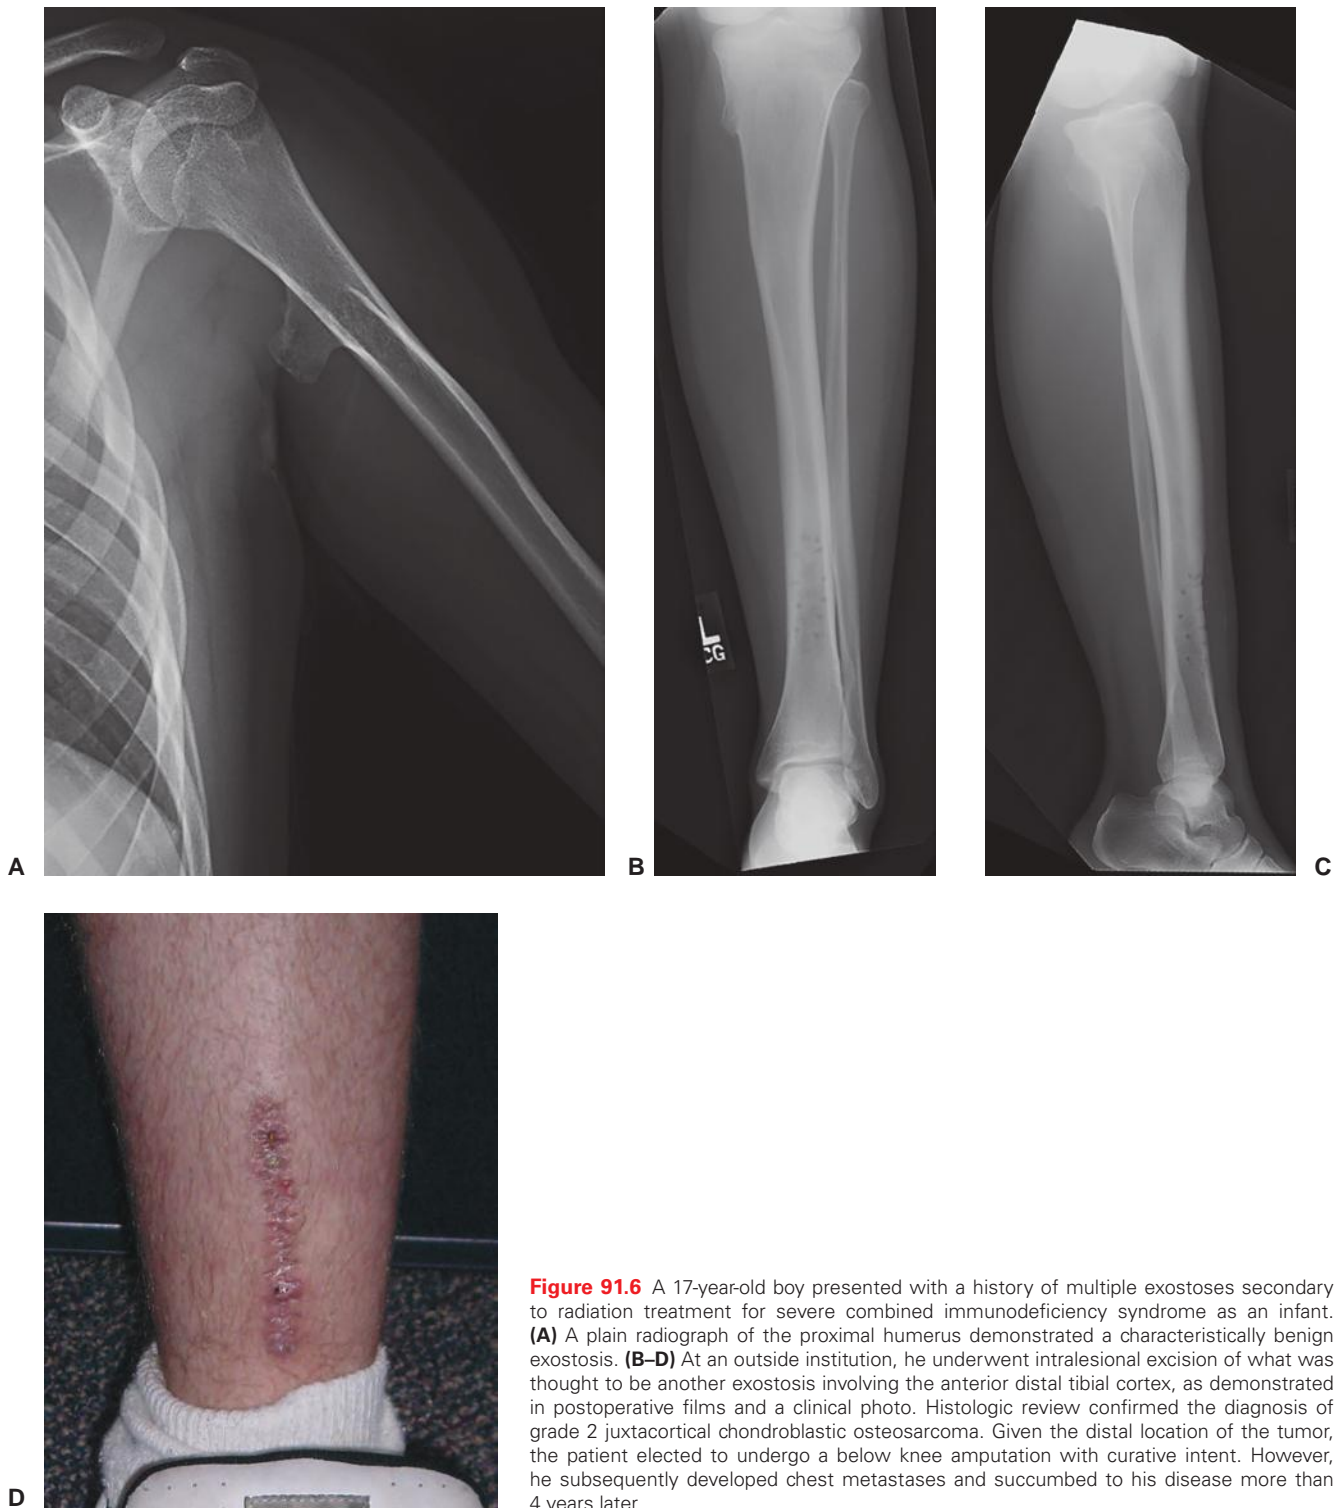

Figure 91.6 A 17-year-old boy presented with a history of multiple exostoses secondary to radiation treatment for severe combined immunodeficiency syndrome as an infant. **(A)** A plain radiograph of the proximal humerus demonstrated a characteristically benign exostosis. **(B–D)** At an outside institution, he underwent intralésional excision of what was thought to be another exostosis involving the anterior distal tibial cortex, as demonstrated in postoperative films and a clinical photo. Histologic review confirmed the diagnosis of grade 2 juxtacortical chondroblastic osteosarcoma. Given the distal location of the tumor, the patient elected to undergo a below knee amputation with curative intent. However, he subsequently developed chest metastases and succumbed to his disease more than 4 years later.

Amputation Versus Limb Salvage

Given the choice, most but not all, patients and families would select limb salvage as a local control option over amputation. With advanced imaging and modern reconstructive techniques, there exist few absolute contraindications to limb salvage. Relative contraindications to a limb salvage effort include major neurovascular involvement, very immature skeletal age, infection, lack of reconstruction (e.g., very distal anatomic location) or soft tissue coverage

options, contamination secondary to biopsy technique and complications, inability to obtain oncologically acceptable margins, and pathologic fracture. The most common reason to recommend amputation is major neurologic involvement by the tumor.

It should be kept in mind by patients, families, and treating physicians that the risk of local recurrence should not preclude a limb salvage effort. While distant metastasis and local recurrence after limb salvage sometimes are diagnosed at the same time, it is crucial to understand that there is no proof that local recurrence

causes metastasis. Instead, both phenomena are likely related only insofar as they independently confirm the very aggressive nature of a particular tumor. Indeed, studies comparing limb salvage versus amputation have shown no statistically significant differences, not only in terms of local recurrence and overall survival, but also with regards to social, psychological, and functional outcomes.¹⁹¹⁻¹⁹⁷ Economic analyses have shown that external prosthetic fitting costs more than limb salvage over the long term,¹⁹⁸ and limb salvage is considered by many to be cosmetically superior, but amputee patients have the advantage of needing fewer operations and being able to participate more readily in high impact and endurance type recreational activities.

Amputation: Concepts and Specialized Techniques

Whether involving the upper or lower extremity, amputations should be performed at the most distal level that would assure negative surgical margins while optimizing functional outcome. In general, longer residual limbs offer better biomechanical advantage and more options for prosthetic fitting. However, a through-knee amputation is superior to a very short above knee amputation, as the femoral condyles provide an “end-bearing” residual limb. Major ablative amputations such as hemipelvectomy should be employed only for curative intent, or rarely for palliation when no acceptable alternative exists.¹⁹⁹

In cases of lower extremity amputation between the midfemoral and midtibial levels, the intraoperative application of an immediate postoperative prosthetic device has proven to be effective for enhancing wound healing, decreasing swelling, and allowing immediate 25 lb. partial weight bearing on the first postoperative day, thereby avoiding the medical and psychological adverse effects of recumbency (Fig. 91.7). Although the immediate postoperative prosthetic is not recommended for dysvascular amputees, the technique has proven to be safe for oncology patients, including those receiving chemotherapy.²⁰⁰⁻²⁰³

Pediatric high-grade osteosarcoma and Ewing sarcoma commonly occur in the distal femur. For children of very young

skeletal age (roughly, girls <8 years old and boys <10 years old), use of expandable endoprotheses is not particularly feasible, because of the number of operations necessary to ensure limb length equality, and the attendant risks of infection, arthrofibrosis, and nerve palsy.^{204,205} Because a standard through-femoral amputation in young individuals would result in a very short residual limb, specialized reconstructive techniques have been devised. Rotationplasty utilizes the distal portion of the lower leg, ankle, and foot, with osteosynthesis of the proximal femoral and distal tibial diaphyses occurring after 180-degree rotation around the longitudinal axis.²⁰⁶⁻²⁰⁸ Although providing a longer residual limb that is functionally equivalent to a below knee level, rotationplasty is not universally accepted in the United States for reasons of cosmesis and prosthetic fitting. An excellent alternative is a turn-up-plasty, in which the osteosynthesis of the proximal tibia and distal femur occurs after 180-degree rotation in the coronal plane.^{209,210} This reconstruction preserves the viability of the proximal tibial physis, so that the result is effectively a “growing” end-bearing through knee amputation that is very cosmetically acceptable and easy to fit with an external prosthesis (Fig. 91.8).

One final major advance for amputees is the development of osseointegrated transdermal anchorage systems, which are particularly beneficial for high transfemoral amputees. Though under regulatory review in preparation for clinical trial in the United States, these concepts, which have been successfully employed for more than 20 years by Branemärk and colleagues in Sweden, are gaining increasing acceptance throughout the world.^{211,212} By being able to directly secure an external prosthetic device to the limb, patients enjoy a tremendous biomechanical advantage, without the need for conventional socket wear (Fig. 91.9). Prospective studies have demonstrated very good rates of implant retention, with excellent functional outcome in terms of prosthetic usage.^{213,214}

Limb Salvage: Options and Recent Advances

As mentioned previously, limb salvage can sometimes be achieved for high-grade bone sarcomas without surgery. This is quite commonly true for Ewing sarcoma, where radiation is used as

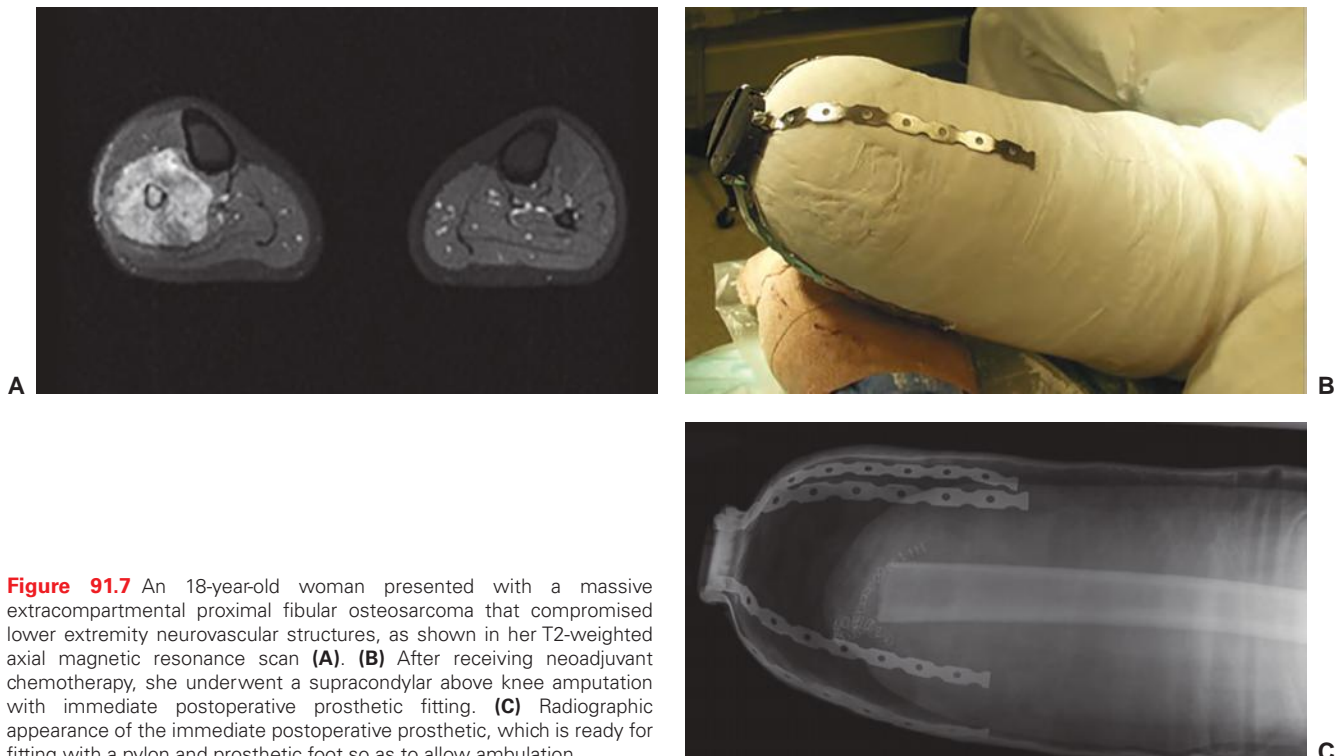

Figure 91.7 An 18-year-old woman presented with a massive extracompartmental proximal fibular osteosarcoma that compromised lower extremity neurovascular structures, as shown in her T2-weighted axial magnetic resonance scan (A). (B) After receiving neoadjuvant chemotherapy, she underwent a supracondylar above knee amputation with immediate postoperative prosthetic fitting. (C) Radiographic appearance of the immediate postoperative prosthetic, which is ready for fitting with a pylon and prosthetic foot so as to allow ambulation.

Figure 91.8 (A) Anteroposterior radiograph of a 3-year-old boy who presented with a large distal femoral high-grade conventional osteosarcoma. After receiving neoadjuvant chemotherapy, the patient underwent tibial turn-up-plasty, with a healed osteosynthesis site and preservation of the proximal tibial physal plate noted on a 14-month postoperative film (B). The result was functionally equivalent to a “growing” through knee amputation.

monotherapy for local control. Unresectable high-grade osteosarcoma and chondrosarcoma lesions involving the mobile spine, sacrum, and pelvis can also be treated with radiation therapy alone in hopes of achieving palliation, if not local control. For skeletal sarcomas involving “expendable” bones such as the scapula, clavicle, radius, ulna, ribs, iliac wing, and fibula, resection alone

(without reconstruction) often results in a successful limb salvage outcome (Fig. 91.10).

In most instances of limb salvage surgery, however, some form of reconstruction needs to be undertaken, and there are myriad methods. Autogenous bone grafts have historically been used for small defects, and in the present day, most commonly for

Figure 91.9 Osseointegrated transdermal anchorage system in a high transfemoral amputee (A) allows ease of external prosthetic application and enhanced functional outcome (B).

Figure 91.10 Three-year postoperative anteroposterior radiograph demonstrating medial clavicular resection for metastatic high-grade osteosarcoma in a 22-year-old woman with a history of distal femoral osteosarcoma treated 7 years previously.

vascularized fibular transfers, particularly for proximal humeral tumors^{215,216} (Fig. 91.11A). Frozen cadaveric osteoarticular and intercalary allografts were in vogue for sarcoma reconstruction in past decades, but complications of nonunion, infection, and fracture have limited their utility.^{217–219} Currently, allografts are most often used as part of alloprosthetic composites, principally in the proximal humerus, proximal femur, and proximal tibia.²²⁰

The majority of extremity limb salvage operations performed for high-grade sarcomas in the Western world are now accomplished with massive metallic endoprosthetic devices. These implants can be fabricated on a custom basis, but more frequently, modular segmental devices are assembled intraoperatively so as to conveniently replicate resection length. Fixation of these megaprotheses has traditionally been accomplished with long cemented or uncemented stems. A recent retrospective review of 2,174 patients who underwent conventional endoprosthetic reconstruction showed a high aseptic complication rate across anatomic sites: soft tissue failure (12%), aseptic loosening (19.1%), structural failure (17.4%), and tumor progression (17.4%).²²¹ In order to avoid the complications

of aseptic loosening secondary to stress shielding and particle-induced osteolysis, compressive osseointegration technology has been developed to allow stable fixation of endoprotheses to bone by way of an innovative spring-loaded system that applies up to 800 lb of compression force at the bone-prosthetic interface, thereby inducing bone hypertrophy.^{222–226} The device also enables salvage of very short metadiaphyseal segments and allows ease of revision in cases of infection, mechanical failure, or infection.^{227–230} Reports from several institutions have shown that compressive osseointegration reconstructions are similar or superior to conventional devices at intermediate term follow-up^{231–236} (Fig. 91.11B–D).

CONTINUING CARE: SURVEILLANCE AND PALLIATION

In caring for patients with sarcomas of bone, it is important to maintain focus on the overarching priorities: (1) life, (2) limb, (3) limb function, (4) limb length equalization, and (5) cosmesis, in

Figure 91.11 Examples of extremity limb salvage reconstruction. **(A)** One-year postoperative anteroposterior radiograph of a 30-year-old woman who underwent proximal humeral resection and reconstruction with a double-barreled vascularized fibular autograft for high-grade osteosarcoma. **(B)** Ten-year postoperative anteroposterior film of a man who presented at age 65 with a proximal femoral grade 3 chondrosarcoma, after having undergone resection and compressive osseointegration reconstruction. **(C)** Twelve-year postoperative anteroposterior radiograph of a man who presented at age 53 with a distal femoral grade 2 chondrosarcoma; note the bone hypertrophy at shaft-prosthetic interface. **(D)** Seven-year postoperative lateral radiograph of a woman who presented at age 21 with a high-grade undifferentiated proximal tibial osteosarcoma and underwent compressive osseointegration fixation.

that order.²³⁷ The lion's share of responsibility for overall survival lies with the medical oncology team. The burdens of local control and functional outcome fall mostly to the radiation and orthopedic surgical oncologists. When the "end-of-treatment" occurs, it is essential to remember that the caring continues. Primary physicians are ill-equipped to provide specialized surveillance care for these exceedingly rare tumors. Although increasing conditional survival as the years progress is a cause for optimism,²³⁸ clinical, laboratory, and radiologic parameters need to be followed for a decade or more, given the long tail of these potentially lethal conditions. The NCCN has recommended "physical examination, imaging (radiograph, MR [imaging] with or without CT) of the surgical site as clinically indicated, chest imaging (every 6 months for 5 years

and annually thereafter), and annual cross-sectional abdominal imaging."²³⁹ The evolving importance of PET/CT scan screening for accurate monitoring for local, regional, and distant recurrence has also been pointed out.²³⁹

When sarcomas of bone are incurable because of progressive metastatic and/or advanced unresectable locoregional disease, selective surgery, standard or experimental chemotherapy, targeted radiation, and expert symptom management must be offered to patients and their families.^{240,241} Palliative care should be provided according to NCCN precepts.²⁴² The authors echo the sentiment of colleagues who have pointed out, "we must always remember that as long as we have something to offer, patients hope for an improvement in their condition. It is this hope that keeps them alive."²⁴⁰

92 Cancer of the Skin

Sean R. Christensen and David J. Leffell

INTRODUCTION

One in five Americans will develop nonmelanoma skin cancer (NMSC) during his or her lifetime. NMSC is the most common human cancer, with an estimated annual incidence of >3 million in 2006 in the United States, higher than the incidence of lung cancer, breast cancer, prostate cancer, and colon cancer combined.¹⁻³ Despite growing public awareness of the harmful effects of sun and ultraviolet (UV) exposure, the incidence continues to rise. The increasing frequency of NMSC results from the age shift in the population (incidence of NMSC increases with age), high ambient solar irradiance, and increasing leisure time spent with natural or artificial UV exposure. Prognosis depends of biology and location of the lesion, as well as host characteristics.

Economic implications of NMSC are considerable. In the United States alone, Medicare spends \$13 billion each year on skin cancer care treatment. Added to this is the cost of treating precancerous lesions such as actinic keratoses (AK), which are increasingly common.

Prevention strategies aimed at reduction of known risk factors, patient education about the importance of early detection and treatment, and the search for more effective and tissue sparing therapies continues.

NONMELANOMA SKIN CANCER

DIAGNOSIS

Although many NMSCs present with classic clinical findings such as nodularity, tissue friability, and erythema, definitive diagnosis can be established only by tissue biopsy. Adequate tissue samples obtained in an atraumatic fashion is critical to histopathologic diagnosis. Skin biopsies may be performed by shave, punch, or fusiform excision. The type of biopsy performed should be based on the morphology of the primary lesion and clinical differential diagnosis. A shave biopsy is usually adequate for raised lesions such as nodular basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), or flat, superficial lesions such as SCC in situ (SCCIS). A punch biopsy is appropriate for lesions with a deeper dermal or subcutaneous extension such as dermatofibrosarcoma protuberans (DFSP). An excisional biopsy may be required for diagnosis of a dermal nodule when morphologic assessment of overall tumor architecture is crucial for proper diagnostic assessment, such as distinguishing between a benign dermatofibroma and a malignant fibrous tumor.

Shave Biopsy

Basic skin biopsy techniques are demonstrated in Fig. 92.1A. A shave biopsy is performed under clean conditions. In the authors' opinion, the use of a sterilized flexible razor blade, which can be

precisely manipulated by the operator to adjust the depth of the biopsy, is often superior to the use of a no. 15 scalpel. After the procedure, adequate hemostasis is achieved with topical application of aqueous aluminum chloride (20%), ferric subsulfate (Monsel solution), or electrocautery. Note that ferrous subsulfate may lead to permanent tattooing of the skin so it should not be used on the face unless there is a high likelihood of subsequent definitive surgical treatment.

Punch Biopsy

A punch biopsy is performed under local anesthesia, using a trephine or biopsy punch (Fig. 92.1B). The operator makes a circular incision to the level of the superficial fat, using a rotating or twisting motion of the trephine. Traction applied perpendicularly to the relaxed skin tension lines minimizes redundancy at closure. Hemostasis is achieved by placement of simple, nonabsorbable sutures that can be removed in 7 to 14 days depending on anatomic site. If the punch biopsy is small and not in a cosmetically crucial area, the resulting biopsy wound can often heal very well by second intention.

Excisional Biopsy

After local anesthesia has been achieved under sterile conditions, a scalpel is used to incise an ellipse to the level of the subcutis. Hemostasis is obtained with cautery as needed, and the wound is closed in a layered fashion using absorbable and, if needed removable epidermal sutures.

GENERAL APPROACH TO MANAGEMENT OF SKIN CANCER

The management of skin cancer is guided by the histologic and biologic nature of the tumor, the anatomic site, the underlying medical status of the patient, and whether the tumor is primary or recurrent. Accurate interpretation of the diagnostic biopsy is essential for appropriate clinical management. Depending on the biologic aggressiveness of the tumor, cancers of the skin may be excised or, in some cases of superficial tumors or precancerous lesions, eliminated in a less invasive fashion. Surgical options include conventional excision and Mohs micrographic surgery (MMS). Destructive modalities include curettage and cautery/electrodessication (C&D), cryosurgery, photodynamic therapy (PDT), and laser surgery. Other techniques are topical therapy (e.g., imiquimod, 5-fluorouracil [5-FU]), intralesional interferon, chemotherapy, and radiation therapy (RT). Other than conventional and Mohs surgery, none of these latter techniques provide information about the histologic completeness of the cancer ablation.

Figure 92.1 Biopsy techniques. Local anesthetic (lidocaine 1% with epinephrine, 1:100,000, unless contraindicated) is injected with a 30-gauge needle. A 30-gauge needle minimizes pain and tissue trauma. Unless otherwise specified, postbiopsy care involves daily cleansing with tap water followed by application of an emollient or an antibiotic ointment and a nonadherent dressing. Although popular in the past, the use of hydrogen peroxide is discouraged because of keratinocyte toxicity. Similarly, triple antibiotic ointments that include Neosporin (Johnson & Johnson, New Brunswick, NJ) or bacitracin may lead to contact dermatitis. For simple skin wounds, petroleum jelly has been shown to be as effective in facilitating healing as antibiotic ointment. **(A)** Shave biopsy. A scalpel blade is manipulated by the operator to adjust the depth of the biopsy. Hemostasis is achieved with topical application of aqueous aluminum chloride, ferrous subsulfate, or electrocautery. **(B)** Punch biopsy. The operator makes a circular incision to the level of the superficial fat, using a rotating or twisting motion of the trephine. Traction applied perpendicularly to the relaxed skin tension lines minimizes redundancy at closure. Hemostasis is commonly achieved by placement of sutures.

Excision

Excisional surgery involves the removal of the cancer and a margin of clinically uninvolved tissue, followed by layered closure or second intention healing. Frozen or permanent sections interpreted by the pathologist determine adequacy of margins. Margins are assessed from representative sections of the specimen in “bread-loaf” fashion, allowing for sampling of the surgical margin. This sampling may occasionally result in a false-negative assessment of clear margins, especially in cases of infiltrating or aggressive-growth cancers. A similar misdiagnosis may occur when one relies on vertically prepared frozen specimens for intraoperative margin control. Excision, especially when performed in a physician’s office rather than in a hospital operating room, is effective and cost-efficient for primary, small (<1 cm) NMSCs, without infiltrative or other high-risk features.

Mohs Micrographic Surgery

MMS facilitates optimal margin control and conservation of normal tissue, and it has become the standard of care in a variety of skin cancer subtypes. Individuals trained in the technique perform MMS in the office setting under local anesthesia. After gentle curettage to define the clinical gross margin of the cancer, a 45-degree tangential specimen of tumor with a minimal margin of clinically normal-appearing tissue is excised, precisely mapped in a horizontal fashion, and processed immediately by frozen section for microscopic examination (Fig. 92.2). Optimal margin control is obtained by examination of the entire lateral perimeter of the specimen and contiguous deep margin. Meticulous mapping allows for directed extirpation of any remaining tumor, resulting in a cure rate of >97% to 99% for primary BCC and SCC.⁴

A key defining feature of MMS is that the surgeon excises, maps, and reviews the specimen personally, minimizing the chance of error in tissue interpretation and orientation. MMS has gained acceptance as the treatment of choice for recurrent skin cancers, as well as for primary skin cancers located at anatomic sites that require maximal tissue conservation for preservation of function and cosmesis (Fig. 92.3). Guidelines for the appropriate use of MMS have been published that reinforce the advantages of this technique for selected high-risk tumors.⁵ For those tumors with a

significant risk of recurrence, MMS is a cost-effective treatment compared with surgical excision when considering associated ambulatory surgery center facility fee and a subsequent re-excision procedure. It is also significantly less expensive than radiotherapy and frozen-section–guided excisional surgery.⁶

Curettage and Cautery/Electrodesiccation

Common methods of treatment of uncomplicated skin cancers on the trunk and extremities and certain facial lesions include C&D and cryotherapy using liquid nitrogen. C&D is performed under clean conditions with local anesthesia. The visible tumor is first removed by curettage, which is extended for a margin of 2 to 4 mm beyond the clinical borders of the cancer. Cautery or electrodesiccation is then performed to destroy another 1 mm of tissue at the lateral and deep margins. C&D can yield satisfactory results after a single cycle of C&D for NMSC tumors <1 cm, especially if the tumor is of the superficial subtype. Salasche⁷ recommended that C&D be performed for three cycles to avoid recurrence. The authors believe, based on extensive clinical experience, that if the tumor requires three cycles of C&D, careful consideration should be given to more definitive approaches such as excision or MMS. Detailed reviews of primary BCC treated by C&D revealed 5-year recurrence rates of 8.6% for lesions located on the neck, trunk, and extremities, and between 17.5% and 22% for lesions located on the face.⁸

One potential drawback of C&D is that recurrent tumors following this treatment may be multifocal and develop a more aggressive biologic behavior. C&D is thus reserved for small (<1 cm) superficial or nodular BCCs, AKs, and SCCIS without follicular involvement located on the trunk or extremities.

Cryosurgery

Cryosurgery exposes precancers and NMSCs to destructive sub-zero temperatures. Tissue damage is caused initially by direct effects and subsequently by vascular stasis, ice crystal formation, cell membrane disruption, pH changes, hypertonic damage, and finally thermal shock. Successful cryosurgery requires temperatures reaching -50°C to -60°C at the deep and lateral margins of the tumor. The open-spray technique is used most often and

Figure 92.2 Mohs micrographic surgery. (A–C) After gentle curettage, a tangential specimen of tumor with a minimal margin of clinically normal-appearing tissue is obtained, precisely mapped, and processed immediately by frozen section for microscopic examination. Superior margin control is obtained through examination of the entire perimeter of the specimen. Precise mapping allows for directed extirpation of any remaining tumor, as shown in C. White asterisks in panel B track the 3 o’clock position of the lateral margin as the specimen is transected, inverted, and inked. (Courtesy David J. Leffell, MD, and People’s Medical Publishing House.)

Figure 92.3 (A) Defect resulting from extirpation of basal cell carcinoma by Mohs micrographic surgery. (B) Defect repaired with rhomboid transposition flap.

requires pressurized liquid nitrogen spray delivery from a distance of 1 to 3 cm. With the confined-spray technique, liquid nitrogen is delivered through a cone that allows more precise tissue destruction. With the cryoprobe technique, a prechilled metal probe is applied to the tumor. Immediately following cryosurgery, local erythema and edema are apparent. An exudative phase ensues in 24 to 72 hours and is followed by sloughing at approximately day 7. Complete healing is usually seen at 2 to 3 weeks for facial lesions and up to 6 weeks for lesions on the trunk and extremities.

Temporary complications may include extensive drainage, edema, bulla formation, and hypertrophic scarring. Paresthesia may occur with thermal injury to superficial nerves. Other less common side effects may include headache, syncope, febrile reaction, cold urticaria, pyogenic granuloma, delayed hemorrhage, milia formation, or dyschromia (hypo- and hyperpigmentation). Permanent complications may include tissue contraction, hypopigmentation, and scarring.

The clinical usefulness of cryosurgery and C&D is limited by the inability to evaluate treatment margins and therefore thoroughness of tumor eradication. The absence of margin control and a dense postcryosurgery scar, which might obscure recurrence, makes these methods valuable primarily in the care of histologically superficial NMSC.

TOPICAL THERAPY FOR SKIN CANCER

Imiquimod

Imiquimod, an imidazoquinoline, binds intracellular toll-like receptors 7 and 8 acting as a topical immune-response modifier. Imiquimod promotes a cell-mediated immune response through induction of several cytokines particularly interferon (IFN)- α and IFN- γ and interleukins (IL) 6, 8, and 12 by keratinocytes and peripheral blood mononuclear cells including monocytes, macrophages, and toll-like receptor-7 bearing plasmacytoid dendritic cells.⁹⁻¹² The net effect is a T-helper type 1–dominant inflammatory response driven by CD4 T cells. In addition, IFN- γ stimulates cytotoxic T cells to kill virus-infected and tumor cells, facilitating tumor regression. The use of imiquimod is approved by the US Food and Drug Administration (FDA) for treatment of AKs and superficial BCCs on the trunk, neck, or extremities. Studies with topical imiquimod for nodular BCC, SCCIS, and malignant melanoma in situ have shown variable results.¹³⁻¹⁵ Imiquimod appears to be effective as monotherapy in carefully selected cases and may have a role postoperatively to decrease the rate of recurrence of certain skin cancers. However, long-term data on cure and recurrence remain to be determined. Close monitoring of the treatment site is essential.

Imiquimod-related adverse events include application site reactions (i.e., erythema, pain, edema, ulceration, bleeding), fatigue, myalgias, fever and chills or flu-like symptoms, headache, diarrhea, nausea, and tender lymphadenopathy.

5-Fluorouracil

5-FU, a chemotherapeutic agent that interferes with DNA synthesis by inhibiting thymidylate synthetase, has been used topically since the 1960s for the treatment of AKs. 5-FU is currently approved by the FDA for the treatment of AKs and superficial BCCs. This drug carries a black box warning urging close supervision by a physician experienced with the administration of antimetabolites. Treatment site reactions following topical 5-FU administration include erythema, edema, and pain. In severe cases, ulcerations and bleeding have been reported. Side effects of 5-FU treatment are exacerbated by prolonged UV radiation (UVR). Poor treatment compliance, due to adverse side effects, is associated with significant failure rates.^{11,16}

Diclofenac

Diclofenac is a nonsteroidal anti-inflammatory agent that inhibits cyclooxygenase, the rate-limited enzyme in the synthesis of prostaglandins. Diclofenac has high affinity for cyclooxygenase-2 that is frequently elevated in AKs, melanoma, and NMSC. In addition, diclofenac inhibits prostaglandin-mediated, UV-induced NMSC by decreasing proinflammatory cytokines such as IL-1, tumor necrosis factor- α , and transforming growth factor- β .^{17,18} Diclofenac has a modest effect on treatment of AK but has not been shown to be effective in the treatment of NMSC.

Retinoids

Both topically applied and systemic retinoids have consistently been shown to be effective in the prevention and management of NMSCs. The effect of topical retinoids is at best mild, whereas oral retinoids have a different efficacy profile and side effects that frequently limit its usefulness for cancer treatment and prevention. Retinoids downregulate the expression of AP-1 responsive genes, activate transrepression of AP-1, arrest growth, and induce apoptosis and differentiation.^{19,20} Retinoids also downregulate the UV-induced overexpression of cyclooxygenase-2, reducing prostaglandins that are normally elevated in AKs and NMSC.^{20,21} Isotretinoin at 0.25 to 0.5 mg/kg per day and acitretin at 10 to 20 mg/d are the most common systemic retinoids used for skin cancer chemoprevention, especially in immunocompromised patients.²² Randomized trials of acitretin for secondary prevention of NMSC have shown a significant benefit in patients of renal transplant and modest benefit that did not reach statistical significance in immunocompetent patients.^{23,24} Routine clinical monitoring for signs of retinoid toxicity and laboratory examinations (fasting lipid profile, liver function tests) during systemic therapy are mandatory.

Ingenol Mebutate

Ingenol mebutate is a macrocyclic diterpene ester found in the sap of the *Euphorbia peplus* plant. Ingenol mebutate gel formulations (0.015%, 0.05%) are available for the treatment of AKs. The proposed mechanism of action is induction of apoptosis in proliferating keratinocytes and activation of innate immune effector responses, including rapid release of neutrophil oxidative mediators. Treatment regimens shown to be effective for reduction of AKs include once daily application on three consecutive days to the face or scalp (0.015% gel) or on two consecutive days to the trunk or extremities (0.05% gel).²⁵

Photodynamic Therapy

Topical PDT with 5-aminolevulinic acid (ALA) or methylaminolevulinic acid (MAL) is effective in the treatment of certain NMSCs. Following topical application, ALA or MAL accumulates preferentially in malignant and premalignant cells and is metabolized in the intrinsic intracellular heme biosynthesis pathway to protoporphyrin IX. Preferential accumulation of ALA in malignant and premalignant tissues results from the differences in cellular uptake, differential activities of the heme and porphyrin biosynthetic pathways, iron bioavailability, differential properties of stratum corneum, and variable tissue ALA distribution. Protoporphyrin IX is a photoactive intermediate that facilitates the transfer of singlet oxygen species and the generation of free radicals. The reactive oxygen species induce lipid peroxidation, protein cross-linking, and increased membrane permeability. All these processes contribute to irreversible damage and ultimately cell death of malignant and premalignant cells.^{26,27}

Both lasers and noncoherent light sources (blue and red light) with wavelengths in a range corresponding to absorption peaks of

protoporphyrin IX (from 400 nm to infrared) have been used to activate topically applied ALA and/or MAL.

The use of PDT is currently approved by the FDA for the treatment of AKs. The off-label uses of PDT to treat NMSCs, acne, photodamaged skin, human papillomavirus (HPV)-associated pathologies, lymphocytoma cutis, hidradenitis suppurativa, and other dermatologic conditions are currently under investigation.²⁸ Scarring and postprocedural dyspigmentation are minimal to non-existing following PDT.²⁹ An apparent additional benefit of PDT is photorejuvenation with softening of the appearance of fine lines, rhytids, and acne scars. The mechanism of photorejuvenation is not fully understood, but may relate to increased type I collagen production.³⁰

RADIATION THERAPY FOR SKIN CANCER

RT is a treatment option for certain NMSCs, angiosarcoma, Merkel cell carcinoma (MCC), cutaneous lymphomas, some adnexal carcinomas, and other primary and metastatic cutaneous neoplasms. RT, in properly fractionated doses, is indicated when the patient's overall health status (such as elderly patients who are unwilling or unable to undergo surgery) or size of the tumor precludes surgical extirpation. The procedure is also used as an adjuvant treatment of patients with positive surgical margins, perineural invasion (PNI), or local regional nodal metastasis. The effectiveness of RT, however, is limited by the inability to definitively assess and control the tumor margins. In addition, treatment of an excessively large area of normal skin surrounding the tumor may enhance risk of both postradiation dermatitis and future skin cancers. Two modes of RT delivery are electrons and superficially penetrating photons (X-rays).³¹ Appropriate radiation margins for clinically visible tumors and/or surgical scars should generally be <3 cm. A protracted fractionation scheme using 2 to 2.5 Gy fractions to a total of 50 to 66 Gy for NMSCs is commonly used to achieve the best chance of durable local control and acceptable late effects.³² Nonetheless, treatment may be accelerated to a single large fraction (10 to 20 Gy) or three to five fractions of 6 to 7 Gy for patients with significant comorbidities or for smaller lesions in locations with good perfusion where cosmesis is less critical. Accelerated treatment protocols provide excellent local control but have an increased risk of fibrosis, atrophy, telangiectasias, and poor cosmesis. Although a course of RT may be protracted over several weeks, daily treatments last several minutes.

Local control rates for small (<2 cm) BCCs are 90% to 95% with adequate (>90% rated as excellent or good) cosmesis. For larger tumors with bone or cartilage involvement, local control rates decrease to 50% to 75%. These deeply invasive/destructive lesions are best approached with a combined excision and adjuvant RT. In a randomized trial of patients with incompletely excised recurrent BCCs, adjuvant RT improved the 5-year local control rates from 61% to 91%.³³ The 10-year local control rates were similar for both adjuvant RT and repeat surgery (92% versus 90%). The local control for SCC is lower by 10% to 15% compared with equivalent-sized BCCs with RT. For selected cases of small, superficial BCC and SCC, office-based treatment with superficial X-ray therapy was shown in one series to have a favorable recurrence rate of 5.0% at 5 years.³⁴

The consideration of acute and permanent tissue effects of RT, such as acute and chronic radiation dermatitis, epidermal atrophy, telangiectasias, altered pigmentation, delayed radiation necrosis, alopecia, and secondary cutaneous malignancies, must be anticipated and managed.³⁵ Recurrent SCC after RT may be more resistant to treatment than recurrence after surgery alone.³⁶ The late cosmetic effects are more pronounced with a large dose per fraction (over 3 to 4 Gy), if the total dose is >55 Gy, following treatment to large fields and/or deeply invasive lesions and with continued unprotected sun exposure. RT is most commonly used in the head and neck region,

and treatment of distal extremities should be considered cautiously as poor vascularization and edema increase the risk of posttreatment complications.³³

ACTINIC KERATOSES

AKs are common cutaneous lesions that occur on sun-exposed areas, particularly in blond or red-haired, fair-skinned individuals with green or blue eyes. They, of course, can occur in patients who do not possess these phenotypic features, and relate most directly to cumulative sun exposure. AKs represent the initial intraepidermal manifestation of abnormal proliferation of keratinocytes and harbor the canonical mutations in tumor suppressor genes (such as *p53*) seen in SCC. As such, AK are precursor lesions with the possibility of progression to SCCIS and invasive SCC.³⁷

Clinically, AKs demonstrate one of three behavior patterns: spontaneous regression, persistence, or progression to invasive SCC.³⁸ The risk of progression of AK to SCC has been calculated between 0.025% and 16% per year, and the calculated total risk of malignant transformation for a patient with AKs followed for a period of 10 years ranges from 6.1% to 10.2%.³⁹ Approximately 60% to 65% of SCCs arise from prior AKs. Spontaneous regression has been reported in as high as 25.9% of AKs over a 12-month period, although a 15% recurrence rate was noted at follow-up.³⁷

PATHOGENESIS OF ACTINIC KERATOSIS

Factors linked to pathogenesis of AKs include (1) exposure to UVB light—UVB causes mutations of the tumor suppressor gene (TSG) *p53*; (2) genetic DNA instability (i.e., xeroderma pigmentosum) or melanin deficiency (albinism); (3) older age; (4) male gender; (5) anatomic location—>80% of AKs are located on the head and neck, dorsal forearms, and hands; and (6) history of immunosuppression—solid organ transplant patients are at significantly increased risk.

Studies of the molecular pathogenesis of AK and SCC have revealed a stepwise progression from normal skin to actinically damaged skin to AK to SCC. Global gene profiling has shown similar patterns of abnormal gene expression in AK and SCC, and the identification of expanded clones of *p53*-mutated keratinocytes in precursor AKs confirms that AKs indeed represent an early stage in the molecular carcinogenesis of NMSC.^{40,41} A study of asymptomatic AKs, inflamed AKs, and SCCs similarly showed a stepwise loss of differentiation manifesting as diminishing 27-kD heat-shock protein, an initial increase in lymphocytes suggesting the occurrence of an active inflammatory and immune response, a stepwise increase in the number of cells expressing detectable levels of *p53* suggesting an increase in DNA damage, decreasing levels of Bcl-2, an apoptosis inhibitor, and loss of Fas antigen, suggesting these cells become less sensitive to FasL-mediated apoptosis as they progress.⁴²

CLINICAL FEATURES OF ACTINIC KERATOSIS

AKs are red, pink, or brown papules with a scaly (hyperkeratotic) surface. They occur on sun-exposed areas and are especially common on the balding scalp, forehead, face, dorsal forearms, and hands (Fig. 92.4). Subclinical (nonvisible) AKs are estimated to occur up to 10 times more often than clinically visible AKs, particularly on sun-exposed skin.³⁷ Actinic cheilitis is a clinical subtype of AK on the lower lip marked by diffuse scaling and erythema or hypopigmentation along the vermilion border. More severe cases may have recurrent erosions or fissures. Although the presentation can be subtle, the elevated risk of mucosal SCC development demands clinical vigilance and warrants treatment of actinic

Figure 92.4 Multiple actinic keratoses. Numerous pink thin papules with gritty scale are scattered over the sun-exposed scalp in an elderly man. The lesions are admixed with several tan solar lentigo.

cheilitis, most often with field-directed therapy. Actinic cheilitis is particularly amenable to treatment with PDT, although shorter incubation times must be used on the thin and sensitive skin of the vermilion lip.

The histologic spectrum of AKs includes hyperplastic, atrophic, Bowenoid, acantholytic, and pigmented subtypes.⁴³ Each subtype is characterized by disordered, atypical keratinocytes with nuclear atypia. In the hyperplastic variant, pronounced hyperkeratosis coexists with parakeratosis. Epidermal hyperplasia and downward displacement without dermal invasion can be noted. A thin epidermis devoid of rete ridges is characteristic of the atrophic variant. Atypical cells predominate in the basal layer. The Bowenoid AK is virtually indistinguishable from BD SCCIS. In the Bowenoid variant, considerable epidermal cell disarray and clumping of nuclei gives a windblown appearance. The presence of suprabasal lacunae is characteristic of acantholytic AK. Excessive melanin is present within the basal layer in the pigmented variant of AK.

TREATMENT OF ACTINIC KERATOSIS

Prevention of disease is always superior and preferable to the need for treatment. Effective preventative measures include avoidance of excessive sun exposure (use of broad-brimmed hats, sun-protective clothing, and sunscreen), patient education, and regular self-examinations to detect the earliest signs of malignant transformation. The effectiveness of topical chemoprevention was demonstrated in a double-blind, randomized clinical trial in which 25 patients applied topical all-trans-retinoic acid (tretinoin) 0.05% cream twice daily for 16 weeks, resulting in a 30.3% reduction in the number of AKs compared with baseline.⁴⁴

Because of their low but real potential to develop into invasive SCC, AK therapy is generally recommended. The management of AK should be based on whether a lesion-directed or field-directed therapy is preferred. Lesion-directed therapy, including ablative and surgical procedures, is reserved for selected cases when only a few clinically visible AKs are present. Field-directed therapy, including ablative, nonablative, and topical treatments, offers the advantage of treating both clinically evident and subclinical lesions that may progress to visible AKs and, potentially, SCC.

Lesion-Directed Therapy

Cryotherapy is the most commonly used lesion-directed treatment modality. Clearance rates range from 39% to 98.8%.^{37,45} In a large, multicenter Australian study evaluating the efficacy of cryotherapy for the treatment of AKs on the face and scalp, of the 89 patients and 421 lesions in the intended-to-treat population, there was an average of 67.2% lesion response rate per patient.⁴⁶ As mentioned previously, cryotherapy results in the local side effects of pain, erythema, and potentially blistering or crusting, which are generally transient and well-tolerated. Cryotherapy treatment was associated with “good” and “excellent” cosmetic outcomes in 94% of the lesions.

Other lesion-directed treatment options include C&D and surgical excision. Treatment with C&D may require more than one cycle. High cure rates and good cosmetic outcome have been reported, although this treatment is not commonly used for AK. C&D should be generally avoided in recurrent lesions, lesions that have undergone punch biopsy, and lesions in hair-bearing areas.³⁷

Field-Directed Therapy

Field-directed treatment modalities include topical pharmacologic therapies including imiquimod, 5-FU, and diclofenac, ablative and nonablative laser resurfacing, PDT, dermabrasion, and deep and medium-depth chemical peels.

5-Fluorouracil

Manufacturer-recommended 5-FU treatment protocol for AKs is twice daily for 2 to 4 weeks. Other protocols proposed in the literature include 5% 5-FU once to twice daily for 2 to 7 weeks; 5% 5-FU once daily, 1 day per week for 12 weeks; and 0.5% 5-FU once or twice daily for 1 to 4 weeks.³⁷ The literature reports rates of AK resolution with 5-FU that reach 89% with twice-weekly application for 16 weeks, albeit recurrence rates of up to 55% have been reported.⁴⁷ In addition, low compliance, because of adverse effects of medication, is associated with significant treatment failure rates.

In a phase 3, double-blind randomized study of 117 patients with at least five AKs treated with 0.5% 5-FU cream once daily, complete clearance rates at 1, 2, and 4 weeks were 26%, 20%, and 48%, respectively.⁴⁸ In a large systematic review of 5-FU randomized clinical trials, treatment with 5% 5-FU resulted in an average reduction of 79.5% in the mean number of lesions with clearance rates of 94% and 98% at 2 and 4 weeks, respectively. In comparison, treatment with 0.5% 5-FU resulted in an average reduction in the mean number of lesions of 86.1%. Higher clearance rates with 0.5% 5-FU may represent increased patient medication compliance from lower side effects profile. In the study comparing 0.5% and 5% 5-FU, 85% of patients preferred 0.5% 5-FU.³⁷

Imiquimod (Aldara, Mediceis Pharmaceutical, Scottsdale, AZ)

The FDA-approved imiquimod treatment protocol for AKs is twice weekly for 16 weeks. Other treatment protocols including more frequent dosing for a shorter time period or pulsed treatment

with a 2- to 4-week rest period have been reported with similar efficacy.^{37,49} Clearance rates with imiquimod range from 45% to 85%.⁵⁰ Reported recurrence rates are 10% and 16% within 1 year and 18 months of treatment, respectively.

Imiquimod is effective and well tolerated for the treatment of AKs in posttransplant, immunosuppressed patients. The safety and efficacy of 5% imiquimod cream for the treatment of AKs in posttransplant patients receiving immunosuppressive therapy within the prior 6 months was evaluated in a multicenter, randomized, placebo-controlled study with reported imiquimod clearance rate of 62.1%.⁵¹ Common reported side effects of imiquimod therapy included site reactions (edema, erythema, vesicles, and erosions/ulcerations), fatigue, headache, diarrhea, nausea, and leucopenia. No serious adverse events were reported.⁵¹ Few randomized trials have directly compared the efficacy of the leading topical treatments for AK, 5-FU, and imiquimod. One study compared 5-FU 5% cream applied twice daily for 2 to 4 weeks with imiquimod 5% cream applied twice daily for 16 weeks in 36 patients with AKs on the face and scalp.⁵² At week 24, the total AK count was reduced by 94% and 66% with 5-FU and imiquimod, respectively. Another study randomized patients to either cryotherapy, 5-FU (twice daily for 4 weeks), or imiquimod (three times per week for 4 weeks, repeated if necessary) therapy for multiple AK.⁵³ Cryotherapy resulted in a 68% initial clinical clearance, compared with 96% for 5-FU and 85% for imiquimod. Sustained clearance at 1 year was greatest in the imiquimod group (73%), compared to 54% for 5-FU and 28% for cryotherapy. Overall, the two topical treatments appear to have similar efficacy, although additional studies are needed to assess whether imiquimod has superior long-term clearance rates.

Photodynamic Therapy with 5-Aminolevulinic Acid. PDT with ALA activated by blue light showed reported overall clearance values for AKs between 50% to 80%.³⁷ Response rates vary with duration of ALA incubation and thickness of AK lesions. In a randomized, blinded, placebo-controlled study, 243 patients with a total of 1,403 AKs on the scalp and face were treated with ALA (incubation time 14 to 18 hours) and exposure to blue light.⁵⁴ At 8 weeks, 30% of patients with partial response were retreated. At 12 weeks, 91% lesion clearance rate was reported. Discomfort was the most commonly reported adverse event.

A randomized study of 36 patients with at least four AKs compared efficacy of two sessions of ALA-PDT or ALA-pulsed dye laser (ALA incubation time, 1 hour) with 0.5% 5-FU cream applied once or twice daily for 4 weeks.⁵⁵ At 1 month posttreatment, the overall individual lesion clearance rates for 5-FU, ALA-PDT, and ALA-pulsed dye laser were 70%, 80%, and 50%, respectively. ALA-PDT and ALA-pulsed dye laser were better tolerated than 5-FU. The efficacy of PDT was compared with that of cryotherapy in an open, randomized, controlled study of 202 patients with 732 AKs.⁵⁶ Clearance rates for PDT and cryotherapy were 69% and 75%, respectively. Response rates correlated with the lesion thickness, with thinner lesions having higher response rates. Satisfaction with the cosmetic outcomes for PDT and cryotherapy were 96% and 81%, respectively.

Other Field Treatments. Efficacy of topically applied 3% diclofenac gel in 2.5% hyaluronic acid vehicle gel versus vehicle was addressed in a multicenter, randomized, double-blind, placebo-controlled study of 195 patients. Treatment with 3% diclofenac gel twice daily for 30 to 90 days resulted in an improvement of 59% compared with 31% with placebo.⁵⁷ As described previously, ingenol mebutate is a recently approved therapy for AK with a simplified dosing regimen that was shown to reduce AK counts by 75% to 83% compared to 0% in patients treated with placebo.²⁵ Other treatment modalities primarily used for cosmetic procedures, such as chemical peels and ablative and nonablative laser resurfacing, have been reported to be effective

in the treatment of AKs, but high-quality, well-controlled studies of efficacy are lacking.⁵⁸

BASAL CELL CARCINOMA

BCC is a slow-growing neoplasm of nonkeratinizing cells originating from the basal cell layer of the epidermis. BCC is the most common human cancer, accounting for 25% of all human cancers and 75% of skin malignancies diagnosed in the United States.⁵⁹ Although BCC rarely metastasizes, it is locally invasive and can result in extensive morbidity through local recurrence and tissue destruction. Typically, BCC develops on sun-exposed areas of lighter-skinned individuals. Approximately 30% of lesions of BCC occur on the nose. Nonetheless, BCC can occur anywhere, including non-sun-exposed areas, and has been reported to occur on the vulva, penis, scrotum, and perianal area. Men are affected slightly more often than are women, and although once rare, before the age of 50 years, BCCs are becoming more common in younger individuals.^{1,4}

Intermittent recreational sun exposure, exposure to UVR (UVB confers greater risk than UVA) and sun overexposure (i.e., sunburns), especially in childhood and adolescence, is a significant risk factor for development of BCC. Other factors involved in the pathogenesis include mutations in regulatory TSG, exposure to ionizing radiation, chemicals (e.g., arsenic, polycyclic aromatic hydrocarbons), psoralen plus UVA (PUVA) therapy, and alterations in immune surveillance (i.e., organ transplantation, underlying hematologic malignancy, immunosuppressive medications, or HIV infection).¹

BCC is substantially more common among survivors of childhood cancers, principally due to previous treatment with ionizing radiation therapy alone or in combination with chemotherapy. In affected individuals with a history of childhood cancers, BCC developed between 20 and 39 years of age, with an increased risk of approximately 40-fold in cancer survivors that had received ≥ 35 Gy versus those who did not receive radiation therapy.⁶⁰

BCC can be a feature of inherited conditions. Included among these are the nevoid BCC syndrome (NBCCS), Bazex syndrome (X-linked dominant; characterized clinically by follicular atrophoderma, hypotrichosis, hypohidrosis, milia, epidermoid cysts, and facial BCCs), Rombo syndrome (features similar to those of Bazex syndrome with peripheral vasodilation with cyanosis), xeroderma pigmentosum (autosomal recessive disorder in unscheduled DNA repair, clinically characterized by numerous NMSCs and melanomas), and unilateral basal cell nevus syndrome.

NBCCS is a rare autosomal dominant genetic disorder characterized by a mutation in the human patched (*PTCH1*) gene and predisposition to multiple BCC and other tumors, as well as a wide range of developmental defects. Patients with this syndrome may exhibit a broad nasal root, borderline intelligence, odontogenic keratocysts of the jaw, palmar and plantar pits, calcification of the falx cerebri, medulloblastomas, and multiple skeletal abnormalities in addition to a few to thousands of BCCs.⁶¹ Tumor development in patients with NBCCS is related to sun exposure, as BCCs develop most frequently in sun-exposed areas. The clinical course is commonly benign prior to puberty; nonetheless, after puberty individual lesions may progressively enlarge and ulcerate. Individuals with NBCCS are exceedingly sensitive to ionizing radiation. Hundreds of BCCs were reported in children treated with RT for medulloblastoma.

Genomic analysis of patients with NBCCS has elucidated the molecular pathogenesis of BCC. The behavior of neoplasms occurring in NBCCS confirms a classic two-hit model of carcinogenesis—tumors develop in cells sustaining two genetic alterations.⁶² The first alteration or hit is inheritance of a mutation in a TSG, and the second is inactivation of the normal homologue by environmental mutagenesis or random genetic rearrangement. Sporadic BCCs would arise in cells that underwent two somatic events, resulting in the inactivation of the NBCCS

TSG *PTCH1*. Studies of BCC have indicated an association with mutations in the *PTCH1* regulatory gene, which maps to chromosome 9q22.3.⁶³ Loss of heterozygosity at this site is seen in both sporadic and hereditary BCC. Inactivation of the *PTCH1* gene is probably a necessary step for BCC formation. The *PTCH1* protein is part of a receptor complex that regulates the hedgehog signaling pathway, a key regulator of embryonic development and cellular proliferation. The *PTCH1* protein binds to and inhibits *Smoothened*, a transmembrane receptor for the secreted molecule hedgehog. On hedgehog binding, *Smoothened* is released from the inhibitory effects of *PTCH1* and transduces an activating signal via GLI transcription factors.^{64,65} Loss of function mutations in *PTCH1* thus permit unopposed *Smoothened* activity and cellular proliferation. This understanding of the molecular pathogenesis of BCC has led to the development of targeted medical therapy for BCC with small molecule inhibitors of *Smoothened*, as discussed subsequently. UV-induced mutations in the *p53* gene, such as cyclobutane pyrimidine dimers (CC → TT) have also been reported in up to 60% of BCCs.⁶⁶

CLINICAL BEHAVIOR OF BASAL CELL CARCINOMA

Although the overall prognosis of the vast majority of BCC is excellent, some tumors exhibit infiltrative growth patterns and extensive subclinical spread. Batra and Kelley⁶⁷ looked at risk factors for extensive subclinical spread of more than 1,000 NMSCs treated by MMS. The most significant predictors were anatomic location on the nose of any type of BCC; morpheaform BCC on the cheek; recurrent BCC in men; any tumor located on the neck in men; any tumor located on the ear helix, eyelid, or temple; and increasing preoperative size. Invasive BCC can migrate along the perichondrium, periosteum, fascia, or tarsal plate.^{68,69} This type of spread accounts for higher recurrence rates in tumors involving the eyelid, nose, and scalp. Embryonic fusion planes likely offer little resistance and can lead to deep invasion and tumor spread, with very high rates of recurrence. The most susceptible areas include the inner canthus, philtrum, middle to lower chin, nasolabial groove, preauricular area, and the retroauricular sulcus.

PNI is infrequent in BCC and occurs most often in recurrent, clinically aggressive lesions. In a case series, Niazi and Lamberty⁷⁰ noted PNI in 0.178% of BCC. In all cases, PNI was associated with recurrent tumors that were most often located in the periauricular and malar areas. Clinically, PNI may present with paresthesia, pain, and weakness or, in some cases, paralysis.

Metastatic BCC is rare, with incidence rates varying from 0.0028% to 0.1%.⁷¹ Interestingly, BCC appears to be uniquely dependent upon surrounding stroma, as experimental transplants of tumors devoid of associated stroma are usually unsuccessful.⁷² This concept of stromal dependence may explain the low incidence of metastatic BCC. Metastases, when reported, have involved the lung, lymph nodes, esophagus, oral cavity, and skin. Although long-term survival has been reported, the prognosis for metastatic BCC is generally poor, with an average survival of 8 to 10 months following diagnosis. Platinum-based chemotherapy or molecularly targeted *Smoothened* inhibitors may provide benefit as salvage therapy for metastatic BCC.⁷²⁻⁷⁴

BASAL CELL CARCINOMA SUBTYPES

Clinical variants of BCC include nodular, micronodular, superficial, infiltrative, morpheaform (also termed *aggressive-growth BCC*, *fibrosing BCC*, *sclerosing BCC*), pigmented, cystic BCC, and fibroepithelioma of Pinkus (FEP).^{75,76}

Nodular BCC is the most common BCC subtype, accounting for >60% of all tumors. Clinically, it presents as a raised, translucent pearly, skin-toned to pink papule or nodule with prominent

Figure 92.5 Nodular basal cell carcinoma (BCC). A slightly erythematous, pearly nodule with rolled borders is a classic presentation of nodular BCC. Central ulceration is a common feature of nodular BCC.

telangiectasias (Fig. 92.5). Occasionally, the center of the tumor appears depressed or sunken, leaving a rolled, raised border with the classic pearly appearance so-called rodent ulcer. Not infrequently, history of easy bleeding and/or crusting is obtained. Nodular BCC has a propensity for involving sun-exposed areas of the face in individuals over the age of 60. In patients with severe actinic damage, nodular BCCs may appear in the third decade.

Superficial BCC is the second most common subtype of BCC, comprising of up to 15% of all BCCs. It presents in younger patients at a mean age of 57 years. Superficial BCC presents as well-defined, pink to erythematous scaly or eroded macule or plaque commonly with a thin pearly border. It appears predominately on the trunk and may be difficult to differentiate clinically from AK, SCCIS, or an inflammatory lesion.

Infiltrative BCC comprises approximately 5% of all BCCs and develops predominately in the head and neck region of older adults. Mean age at presentation is 66 years. Clinically, infiltrative BCC most often resembles the nodular form of BCC.

Morpheaform BCC accounts for 3% of all BCCs and commonly develops in the head and neck region of older individuals. It presents as a flat or indurated, slightly firm lesion, without well-demarcated borders, with a white to yellowish hue, and may be difficult to differentiate from a scar. Traction on the skin often highlights the clinical extent of the lesion. Symptoms of bleeding, crusting, and ulceration are often not present in this tumor subtype. The actual size of the cancer is usually much greater than the clinical extent of the tumor. Pigmented BCC is a variant of nodular BCC with clinically visible pigment and may be difficult to differentiate from nodular melanoma. The presence of pigment may be of value in determining adequate excision margins.

FEP, a rare variant of BCC, typically presents on the torso and extremities, but also has been noted on the genitalia, groin, and sole of the foot. Clinically, FEP usually presents as a pink, smooth,

dome-shaped, or pedunculated papule, plaque, or nodule.⁷⁷ It may be difficult to distinguish clinically from amelanotic melanoma.

HISTOLOGY

Histologic features defining BCC are aggregates of neoplastic basaloid cells stemming from the epidermis or the epithelium of adnexal structures.⁷⁵ Aggregates are organized as lobules, islands, nests, or cords of cells that display an orderly arrangement of the basaloid cell nuclei at the periphery, a palisading array. Occasionally, central necrosis or cystic changes are seen within the tumor lobules. Individual tumor cells have uniform, hyperchromatic, round to oval nuclei. Mitotic figures are uncommon, but the presence of apoptotic cells and necrosis is frequently observed. Pleomorphic variant of BCC shows tremendous variability of nuclear size and chromatism, as well as multiple mitoses and multinucleated giant cells. A stromal retraction or clefting around the neoplastic aggregates is commonly seen in the dermis. An accumulation of mucin within and around the tumor lobules may be evident.

Histologic subtypes of BCC include nodular and micronodular, superficial, and infiltrative BCC (Fig. 92.6A,B). Nodular BCC accounts for approximately 50% of all histologic variants of BCCs and exhibits characteristic features as previously described. Superficial multifocal BCC accounts for approximately 15% of BCCs and is a broad lesion characterized by basophilic buds extending from an atrophic epidermis into the papillary dermis. In a two-dimensional view, tumor buds appear to be multifocal, but upon three-dimensional imaging analysis they form a netlike pattern. Retraction artifact is present, as is peripheral palisading within the buds. FEP, which accounts for 1% of BCCs, is characterized by a polypoid lesion in which basaloid cells grow downward from

the surface in a network of anastomoses of cords of cells in loose connective tissue.

The biologic behavior of the micronodular, infiltrating, and morpheaform (sclerosing) subtypes of BCC is more aggressive than that of the nodular and superficial forms. Infiltrative histology is seen in 15% to 20% of BCCs. Individual tumor islands manifest small, irregular outlines with a spiky appearance that invade into and throughout the dermis. Palisading is characteristically absent. The stroma is less myxoid than in the nodular form. In the morpheaform variant, small groups or cords of tumor cells often only one to two cells in thickness infiltrate and dissect a dense, collagenous stroma often parallel to the skin surface. Mixed histology is frequently apparent in BCCs. Areas of follicular, sebaceous, eccrine, or apocrine differentiation may also be seen in some BCCs. BCCs may contain focal areas of squamous differentiation, ranging from individual dyskeratotic cells to keratin pearls. The term *basosquamous (metatypical) carcinoma* denotes BCC with a predominance of mature, atypical keratinizing squamous component. Biologic characteristics of a basosquamous carcinoma are more similar to those of SCC with a possibility for metastasis.

The significance of histologic subtype lies in the correlation with a tumor's biologic aggressiveness. The infiltrative and micronodular types are the most likely to be incompletely removed by conventional wide local excision (WLE). Rates of incomplete excision vary from 5% to 17%.⁷⁸ Incompletely excised infiltrative and micronodular BCCs recur at rates of 33% to 39%. Recurrences after RT show a tendency toward infiltrative histology and squamous transformation, and even recurrent BCC after excision or C&D may become metatypical. Although historical reports in the literature suggested that 60% of incompletely excised BCCs will not recur, none of these studies provided an appraisal of recurrence rates as a function of histologic subtype.^{68,69} In general, incompletely excised BCCs

Figure 92.6 (A) Histology of nodular basal cell carcinoma (BCC). Nodular BCC is characterized by the presence of rounded tumor islands extending from the epidermis into the dermis. Peripheral palisading of nuclei is prominent, and surrounding retraction artifact may be present. (B) Histology of multifocal superficial BCC. Superficial BCC is characterized by basophilic buds extending from an atrophic epidermis into the papillary dermis. Retraction artifact is present, as is peripheral palisading within the buds.

should be removed completely, preferably by MMS, especially if they occur in anatomically critical areas such as the central zone of the face, retroauricular sulcus, or periocular area.

TREATMENT

Excisional surgery, MMS, and C&D have all been used to treat circumscribed, noninfiltrative BCCs. MMS is the treatment method of choice for all recurrent and infiltrative BCCs, particularly if a tumor is located on the face.^{6,79} RT is best suited for poor surgical candidates and patients with extensive lesions not amenable to surgery.^{80,81} RT is not indicated for recurrent or morpheiform lesions and in patients with NBCCS.

C&D is frequently used by dermatologists in the treatment of primary BCC. Knox⁸² noted cure rates as high as 98.3%. Kopf et al.,⁸³ in an earlier study, cited a significant difference in the cure rates obtained between patients treated by private practitioners (94.3%) and those treated by trainees in the New York University Skin and Cancer Unit (81.2%). This supports the premise that C&D, although simple and cost-effective, is highly dependent on operator skill. Traditionally, it was recommended that the procedure be repeated for three cycles, but histology, location, and behavior of the tumor should dictate the number of cycles. C&D should be reserved for small or superficial BCCs, not located on the midface, in patients who may not tolerate more extensive surgery.

Surgical excision offers a unique advantage of histologic evaluation of the excised specimen. It has been demonstrated that 4-mm margins are adequate for removal of BCC in 98% of cases of nonmorpheiform BCC of <2 cm in diameter.⁷⁸ Extending the excision into subcutaneous fat generally is adequate for a small primary BCC.

MMS permits superior histologic verification of complete removal, allows maximum conservation of tissue, and remains cost-effective as compared with traditional excisional surgery for NMSCs including BCCs.^{4,6} In a large study of treatment of primary BCC by Rowe et al.,⁸⁴ MMS demonstrated a recurrence rate (RR) of 1% over 5 years. This was superior to all other modalities, including excision (RR = 10%), C&D (RR = 7.7%), RT (RR = 8.7%), and cryotherapy (RR = 7.5%). In a similar study of recurrent BCC, treatment with MMS demonstrated a long-term RR of 5.6%.⁸⁵ In that treatment group, MMS was superior to all other modalities, including excision (RR = 17.4%), RT (RR = 9.8%), and C&D (RR = 40%). MMS is the preferred treatment for morpheiform, recurrent, poorly delineated, high-risk, and incompletely removed BCC, and for those sites in which tissue conservation for function and cosmesis is imperative. When the surgical approach is contraindicated, RT is a valid option for management of primary BCC. RT may be indicated postoperatively if margins are ambiguous or involved. Disadvantages of RT include lack of margin control, possible poor cosmesis over time, a drawn-out course of therapy, and increased risk of future skin cancers. The RRs for primary BCC treated by RT range from 5% to 10% over 5 years. Wilder et al.⁸⁶ compared local control rates for RT among 85 patients with 115 primary or recurrent biopsy-proven BCCs. A 95% control rate was achieved for primary BCC and a 56% control rate obtained for recurrent BCC at 5 years. Considering cosmesis, RT scars tend to worsen over time, in contrast to surgical scars that tend to improve over time.

Imiquimod is approved by the FDA for the treatment of superficial BCC <2 cm in diameter on the neck, trunk, or extremities. The FDA-recommended regimen is once-daily application 5 days per week for 6 to 12 weeks. Numerous studies evaluated safety and efficacy of imiquimod for superficial BCC.^{11,87} Application schedules varied from 2 days per week to twice daily, and the treatment duration ranged from 5 to 15 weeks. Clinical follow-up ranged from 6 months to 5 years. Reported histologic clearance rates ranged from 52% to 81%, albeit high-risk tumors (within 1 cm of the hairline, eyes, nose, mouth, anogenital region, hands, and feet) or tumors >2 cm in diameter regardless of their location

were excluded. Imiquimod has been used off-label for the treatment of nodular and infiltrative BCC.^{88,89} Although some studies have shown favorable cure rates, imiquimod treatment of these tumors is generally not recommended as subclinical disease may persist and lead to late recurrence.

The FDA-approved protocol for treating superficial BCC with topical 5-FU is twice-daily application for 3 to 6 weeks irrespective of tumor size or location. Longer treatment protocols with an average 11 weeks are reported in the peer-reviewed literature. In a study of 31 tumors treated twice daily for an average of 11 weeks, a 90% clearance rate was observed histologically 3 weeks posttreatment.⁹⁰ Topical PDT has also demonstrated efficacy in the treatment of BCC. Clearance rates for BCC using ALA or MAL PDT range from 76% to 97% for superficial to 64% to 92% for nodular BCC after one to three treatments.^{26,28,91} Many studies of PDT for nodular BCC involve curettage of the lesion prior to treatment, however, and it is unclear if the response rate would be as successful without initial curettage. In a well-designed comparative trial, 601 patients with superficial BCC were randomized to treatment with MAL PDT (two treatments given 1 week apart), imiquimod, or 5-FU according to FDA-approved protocols. Complete clinical remission at 1 year was found to be 72.8% for PDT, 83.4% for imiquimod (superior to PDT), and 80.1% for 5-FU (not statistically different from the other treatments). Patients treated with imiquimod or 5-FU were more likely to report bothersome local side effects of the treatment, however.⁹²

Historically, systemic therapy for BCC was limited to cytotoxic chemotherapy that was marginally effective as salvage therapy for metastatic disease. Elucidation of the critical role of abnormal hedgehog signaling in BCC, however, has led to development of a novel class of molecularly targeted small molecule inhibitors of *Smoothed*, most notably vismodegib.⁷⁴ Based on a seminal trial of 33 patients with metastatic BCC and 63 patients with locally advanced BCC not amenable to surgical therapy, vismodegib was approved (2012) for treatment of advanced BCC (either metastatic or not amenable to surgery or radiation).⁷³ With once daily oral dosing of 150 mg vismodegib, 30% of patients with metastatic BCC and 43% of patients with locally advanced BCC had an objective response (at least 30% decrease in size of tumors), and 21% of patients with locally advanced BCC had complete clinical resolution of tumors. None of the patients with metastatic BCC had a complete response. Adverse events in the trial were common, including serious adverse events in 25% of patients and fatal adverse events in 7% of patients. Most common adverse events in this and other trials were muscle spasms, alopecia, dysgeusia leading to weight loss, fatigue, diarrhea, and hyponatremia, and between 12% and 54% of patients discontinued therapy because of adverse effects.^{73,74,93} Due to the relatively low response rate, the high incidence of adverse events, the potential for resistance with a single mutation,⁹⁴ and reports of rapid recurrence of BCC upon discontinuation of the medication,⁹⁵ *Smoothed* inhibitors remain a limited, albeit important, addition to our treatment options for BCC. Vismodegib may also be an effective suppressive therapy for select patients with NBCCS, where it was shown to decrease the incidence of new tumors by 93% during an 8-month period.⁹³

It is imperative that patients with a history of BCC receive annual full-body skin examinations. Although most recurrences appear within 1 to 5 years, recurrences decades after initial treatment are reported in the literature. Rowe et al.^{96,97} found that 30% of recurrences developed within the first year after therapy, 50% within 2 years, and 66% within 3 years. A separate new primary BCC can present at rates of approximately 40% within 3 years, with 20% to 30% within 1 year of treatment of the original lesion.

SQUAMOUS CELL CARCINOMA

SCC is a neoplasm of keratinizing cells that shows malignant characteristics, including anaplasia, rapid growth, local invasion, and metastatic potential. More than 200,000 cases of SCC are

diagnosed in the United States each year, making it the second most common human cancer after BCC.⁹⁸ People of Celtic descent, individuals with fair complexions, and those with poor tanning ability and predisposition to sunburn are at increased risk for developing SCC. SCC in blacks arises most often on sites of preexisting inflammatory conditions such as burn injuries, scars, or trauma.⁹⁹ Patients treated with PUVA or undergoing immunosuppressive therapy following solid-organ transplantation are at increased risk of SCC (see the following).

PATHOGENESIS OF SQUAMOUS CELL CARCINOMA

Major factors involved in the pathogenesis of SCC include cumulative exposure to UVR, genetic mutations, immunosuppression, and viral infections. UVR acts as both a tumor-initiating and a tumor-promoting factor. Both UVA and UVB (UVB more than UVA) contribute to mutagenesis of DNA by inducing UV landmark mutations (two tandem CC:GG to TT:AA and two C:G to T:A transitions at dipyrimidic sites). UV-induced mutations in TSG lead to uncontrolled cell-cycle progression and subsequent transformation of keratinocytes.¹⁰⁰ In addition to direct mutagenesis, exposure to UVB leads to decreased density and antigen-processing capability of Langerhans cells and may suppress production of the T-helper cell type 1 cytokines IL-2 and INF- γ .¹⁰¹

Alterations in the TSG *p53* are the most common genetic abnormality found in AK, SCCIS, and invasive SCC. Under normal conditions, UVR induces *p53* gene activity. The amount of *p53* protein rapidly increases in keratinocytes after UVR, and drives the expression of downstream genes including *Mdm2*, *GADD45*, and *p21 CIP/WAF1*, leading to cellular arrest in the G1 phase. In cases of squamous dysplasia or SCC, one allele of *p53* contains a missense point mutation with UV signature, while the remaining *p53* allele is often deleted. Based on whole exome sequencing and copy number variation data obtained from cutaneous SCC, it appears that loss of both copies of *p53* is an early event in carcinogenesis, facilitating subsequent clonal expansion and accumulation of many additional point mutations.¹⁰² In this study and in similar studies of SCC of the oropharyngeal mucosa, loss of *p53* was the most common mutation, but inactivating mutations in other TSG were also noted, including *CDKN2A* and *NOTCH1*, which encodes a membrane receptor critical for directing cell fate determination in development.¹⁰²⁻¹⁰⁴ Activating mutations or gene amplifications of oncogenes have also been reported in SCC, most notably involving the epidermal growth factor receptor (EGFR) and its downstream signaling components such as *ras*.^{40,62,102-105} Although these genome-wide studies highlight the mutational complexity and heterogeneity of SCC, two underlying features emerge. First, that both inactivating mutations in TSGs and activating mutations in oncogenes (often multiple) are required for malignant progression, and second, that loss of functional *p53* is a central feature of SCC pathogenesis observed in a majority of tumors.

Other agents associated with development of SCC include (1) chemical agents (e.g., petroleum, coal tar, soot, arsenic); (2) physical agents (e.g., ionizing radiation); (3) exposure to PUVA: calculated adjusted relative risk for a cumulative exposure of between 100 and 337 treatments is 8.6; (4) HPV, especially important for SCC in the anogenital and periungual regions, in the setting of immunosuppression with HIV and solid-organ transplantation, and in patients with epidermodysplasia verruciformis; and (5) smoking. Development of SCC has also been associated with chronic nonhealing wounds, burn scars, and chronic inflammatory dermatoses (discoid lupus, ulcers, osteomyelitis).¹⁰⁶ Certain cervicofacial regions such as the ear and the lower lip are more prone to developing SCC than BCC. Heritable conditions associated with higher incidence of SCC include xeroderma pigmentosum, dystrophic epidermolysis bullosa, and oculocutaneous albinism.

HPV-16 and -18 are frequently implicated in the pathogenesis of subungual and periungual SCC and SCCIS of the digits.

Immunosuppression, including endogenous (underlying lymphoproliferative disorder) and iatrogenic immunosuppression plays a role in pathogenesis of SCC (see the following). In addition to immunosuppressive agents, other medications may also enhance the risk of SCC. Chronic use of photosensitizing drugs, such as the antifungal agent voriconazole, can facilitate actinic damage and have been implicated in accelerated SCC development, particularly in immunosuppressed patients.¹⁰⁷ Vemurafenib, a tyrosine kinase inhibitor recently approved by the FDA for the treatment of metastatic and unresectable melanomas harboring V600E mutations in the *BRAF* gene, appears to increase the risk of keratoacanthoma and SCC development by directly altering signaling through the Ras-Raf mitogen-activated protein kinase pathway known to be involved in SCC pathogenesis.¹⁰⁸

CLINICAL FEATURES OF SQUAMOUS CELL CARCINOMA AND ITS VARIANTS

Clinically, SCCIS appears as a discrete solitary, sharply demarcated, scaly pink to red papule or thin plaque (Fig. 92.7). Erythroplasia of Queyrat (SCCIS on the glans of penis of uncircumcised male related to HPV infection) presents as a verrucous or polypoid papule or plaque, often eroded. Invasive SCC appears as a slightly raised papule plaque or nodule that is skin-colored, pink, or red (Fig. 92.8). The surface of the tumor may be smooth, keratotic, or ulcerated. The lesion may also be exophytic or indurated. Rarely, the tumor is symptomatic with pain or pruritus. Bleeding with minimal trauma is common. It can be clinically difficult to distinguish an invasive SCC from a hypertrophic AK, a benign seborrheic keratosis, or a benign inflammatory lesion. An appropriate biopsy should be performed.

Figure 92.7 Squamous cell carcinoma in situ presents as an erythematous plaque that can be difficult to differentiate from a benign inflammatory process.

Figure 92.8 (A) Clinical differential diagnosis of cutaneous horn includes squamous cell carcinoma (SCC). Biopsy of the pictured lesion confirmed a clinical diagnosis of SCC. (B) Histology of well-differentiated SCC.

Keratoacanthoma (KA) is a variant of SCC defined by a symmetric crateriform architecture and a clinical presentation marked by rapid growth (up to several centimeters) over a period of several weeks. The tumor then typically stabilizes in size and often spontaneously regresses. Although certain KAs may thus behave in a benign fashion, it is impossible to predict which lesions will regress and which will progress. It is thus recommended to treat KAs as a subtype of SCC with appropriate surgical therapy. Verrucous carcinoma, a variant of SCC, includes oral florid papillomatosis, giant condyloma of Buschke-Lowenstein (on the genitalia), and epithelioma cuniculatum (on the plantar foot).¹⁰⁹ Verrucous carcinoma is considered a low-grade carcinoma. It grows slowly and rarely metastasizes, but is frequently deeply invasive into underlying tissue and therefore is difficult to eradicate. Following treatment with RT, verrucous carcinoma may become aggressive or even metastasize.

HISTOLOGY

The histologic criteria defining SCCIS include involvement of the entire thickness of epidermis with pleomorphic keratinocytes and involvement of the adnexal epithelium. The degree of keratinocytes atypia in SCCIS is variable. Marked anaplasia, nuclear crowding, loss of polarity, dysmaturation of the keratinocytes, numerous mitotic figures, including atypical and bizarre forms, and occasional dyskeratotic keratinocytes are seen giving epidermis a “windblown appearance.” The epidermis may also be hyperplastic with psoriasiform appearance and broad rete ridges. A pigmented variant of SCCIS has abundant melanin accumulated within keratinocytes and scattered superficial dermal macrophages. The histologic differential diagnosis of SCCIS includes AK, Bowenoid papulosis, Paget disease, extramammary Paget disease, and malignant melanoma in situ. Immunostaining may be required for proper diagnostic assessment. Bowenoid papulosis is histologically indistinguishable from SCCIS.

SCC is characterized histologically by its relatively large cellular size, nuclear hyperchromatism, lack of maturation, nuclear atypia, and the presence of mitotic figures. Presence of dermal invasion separates invasive SCC from SCCIS. In well-differentiated SCC, cytoplasmic keratinization is manifested by the presence of keratin pearls (horn cysts) and individual cell dyskeratosis. Invading keratinocytes frequently demonstrate minimal cytologic atypia. In contrast, poorly differentiated or undifferentiated SCC shows decreased evidence of keratinization, higher degree of cytologic atypia, and increased number of mitotic figures. Other histologic subtypes include spindle cell, acantholytic, desmoplastic, and adenosquamous (mucin-producing) SCC, which have all been associated with more invasive tumors and increased risk of recurrence.

CLINICAL BEHAVIOR OF SQUAMOUS CELL CARCINOMA

Cutaneous SCCIS is a full-thickness intraepidermal carcinoma. Most lesions are indolent and enlarge slowly over years, seldom progressing to invasive carcinoma. Retrospective studies suggest that the risk of progression to invasive SCC is approximately 3% to 5%. The risk of progression into invasive disease for genital erythroplasia of Queyrat is approximately 10%.¹¹⁰ Bowenoid papulosis classically presents as a reddish brown verrucous papule and is associated with HPV-16 and -18. Bowenoid papulosis usually involves the genitals but may be present elsewhere.

While overall the prognosis of cutaneous SCC is good to excellent, it has been estimated that 3% and 2% of patients, respectively, develop nodal metastasis and die from SCC, leading to >4,000 deaths per year in the United States.⁹⁸ Several studies have attempted to elucidate which factors define patients at highest risk of disease progression. In a pivotal review of studies of SCCs from 1940 to 1992, Rowe et al.⁹⁶ correlated the risk for local recurrence and metastasis with treatment modality, prior treatment, location, size, depth, histologic differentiation, evidence of perineural

involvement, precipitating factors other than UVR, and immunosuppression. Tumors arising in areas of chronic inflammation and at mucocutaneous junctions had a 10% to 30% rate of progression to metastatic disease, whereas the incidence of metastasis from SCC arising on sun-exposed skin in the absence of preexisting inflammatory or degenerative conditions varied widely from 0.05% to 16.0%.⁹⁶ SCC with perineural involvement exhibited a lower 10-year survival (23% versus 88%) and a higher local RR (47% versus 7.3%) than those without perineural disease. For tumors >2 cm in diameter, RRs double from 7.4% to 15.2%, and for tumors >4 mm in depth, metastasis rates dramatically increase from 6.7% to 45.7%. It was also observed that locally recurrent SCC had an elevated metastasis rate of 30%, particularly when located on the lip and ear (31.5 and 45% metastasis rates, respectively).

Based upon these studies and other retrospective case series, the National Comprehensive Cancer Network identified key clinical and histologic risk factors for recurrence of NMSC,¹¹¹ and the American Joint Committee on Cancer (AJCC) developed staging criteria for cutaneous SCC based upon these characteristics in 2011.¹¹² The AJCC criteria specifically identify four high-risk features: depth >2 mm thickness or Clark level IV or greater, perineural invasion, location on ear or nonglabrous lip, and poor histologic differentiation. Tumors ≤2 cm in diameter with less than two of these high-risk features are classified as T1, whereas tumors >2 cm or any tumor with two or more high-risk features are classified as T2. Immunosuppression is not specifically included in the staging criteria, but the authors acknowledged that this feature is correlated with worse prognosis and must be considered in patient management.^{112,113} Tumors with invasion of bone are classified as T3 and T4, depending on whether there is invasion of facial bones (T3) or other skeletal sites (T4).

A critique of the AJCC criteria is that while T3 and T4 are exceedingly rare, T2 tumors comprise a heterogeneous group with anywhere from intermediate to high risk of progression. As such, Schmults and colleagues,¹¹⁴ based on a retrospective, multivariate analysis of 256 high-risk SCC, proposed an alternative staging system with only four risk factors: tumor diameter ≥2 cm, depth of invasion beyond subcutaneous fat, poor histologic differentiation, and perineural invasion. When tumors with one risk factor were classified as T2a, tumors with two to three risk factors were classified as T2b, and tumors with four risk factors or bone invasion were classified as T3, the authors demonstrated improved prognostication of recurrence or nodal metastasis (<1% for T1, 4% for T2a, 37% for T2b, and >75% for T3 at 5 years). While additional studies are needed to define the optimal tumor staging system, the presence of any of the risk factors discussed here should alert clinicians to the elevated risk of disease progression and the need for appropriate treatment and follow-up.

TREATMENT

Many of the treatments for BCC are also appropriate for SCC. The type of therapy should be selected on the basis of size of the lesion, anatomic location, depth of invasion, degree of cellular differentiation, history of previous treatment, and immune status of the host. There are three general approaches to treatment of SCC: (1) destruction by C&D, (2) removal by excisional surgery or MMS, and (3) radiation therapy.

Cautery/Electrodesiccation

C&D is a simple, cost-effective technique for treating low-risk SCCs. Honeycutt and Jansen¹¹⁵ reported a 99% cure rate for 281 SCCs after a 4-year follow-up. In this study, two recurrences were noted in lesions <2 cm in diameter. C&D is frequently used for SCCIS; however, as with all forms of destructive therapy, final pathologic review of the tumor is not obtained and clinically

unrecognized foci of invasive tumor are a concern. Although extension of SCCIS down hair follicles has been reported, this appears to be an uncommon phenomenon that has not been systematically assessed. Nevertheless, C&D is generally not indicated for thicker plaques of SCCIS, for tumors in dense hair-bearing areas, or when tumor extends into the subcutaneous layer.

SCCIS may be treated by cryotherapy. As with BCC, two freeze-thaw cycles with a tissue temperature of -50°C are required to destroy the tumor sufficiently. A margin of normal skin also should be frozen to ensure eradication of subclinical disease. Complications include hypertrophic scarring and postinflammatory pigmentary changes, both hypo- and hyperpigmentation. Concealment of recurrence within dense scar tissue presents a danger. Imiquimod has demonstrated efficacy in the treatment of SCCIS, but it is currently not approved by the FDA for the treatment of this neoplasm.¹¹

Surgical Modalities

Surgical excision is a well-accepted treatment modality for SCC. Brodland and Zitelli¹¹⁶ have demonstrated that lesions of <2 cm in diameter can be safely treated by excision, with a 95% confidence interval using margins of 4 mm and 6 mm for low-risk and high-risk tumors, respectively. These investigators defined high risk as a size of ≥2 cm, histologic grade higher than 2, invasion of the subcutaneous tissue, and location in high-risk areas (primarily periorificial central face). Carcinomas of the penis, vulva, and anus are usually treated by excision or MMS. Surgical excision is the treatment of choice for verrucous carcinoma.

MMS is indicated for high-risk SCCs including invasive, poorly differentiated SCCs, and lesions occurring in high-risk anatomic sites or sites in which conservation of normal tissue is essential for preservation of function and/or cosmesis. Recurrence rates with MMS are superior to those obtained with traditional excisional surgery in primary SCC of the ear (3.1% versus 10.9%), primary SCC of the lip (5.8% versus 18.7%), recurrent SCC (10% versus 23.3%), SCC with PNI (0% versus 47%), SCC >2 cm (25.2% versus 41.7%), and poorly differentiated SCC (32.6% versus 53.6%).¹⁰⁹ MMS has proven useful in SCC involving the nail unit and has been used as a limb-sparing procedure in cases of SCC arising in osteomyelitis.

Radiation Therapy

Indications for RT for patients with SCC are similar to those for patients with BCC. The likelihood of cure for early stage lesions is similar for both surgery and RT. Therefore, the decision on which modality to employ depends on other factors, including a patient's underlying medical status, age, expected posttreatment cosmesis, cost, and treatment availability.

In young patients, surgical treatment is a preferable because the late effects of radiation progress gradually with time and, with long-term follow-up, may be associated with a suboptimal cosmetic result compared with surgical resection and reconstruction. In special sites such as lower lip with advanced (over 30% to 50% of the lip involved) SCC, RT allows for excellent maintenance of oral competency with cure rates similar to those of surgical modalities.³³

Advanced cutaneous cancers may be treated with surgery and adjuvant RT. Adjuvant postoperative RT is added in situations in which the possibility of residual disease is high. In a retrospective study of patients with SCC of the lip, Babington et al.¹¹⁷ reported a 53% local RR in patients who underwent surgery alone (37% of whom had positive, borderline, or unreported surgical margins) compared with a 6% local RR in the minority of patients treated with surgery and adjuvant RT. In the setting of documented clear surgical margins (such as with MMS), no studies to date have shown a benefit of adjuvant RT,¹¹⁸ although it has been used anecdotally for tumors deemed particularly high risk. Indications

for postsurgical RT include positive margins, PNI (especially if symptomatic), multiple recurrences, and underlying tissue invasion. Advanced unresectable cancers, such as those with marked PNI or with gross disease in the cavernous sinus, may be treated with RT alone.

Management of Regional Lymph Node Metastases

Treatment of nodal disease may involve local RT, lymph node dissection, or a combination of both. Skin cancer metastatic to the parotid nodes is commonly managed with superficial or surgical total parotidectomy followed by adjuvant RT (60 Gy in 30 fractions). Extreme care should be taken to preserve the function of the facial nerve. Nonetheless, in certain cases resection is necessary to achieve a gross total resection. With surgery and adjuvant RT, 5-year disease-free survival ranges from 70% to 75%. Although the risk of subclinical disease in the clinically negative nodes is $\geq 20\%$, the ipsilateral neck may be electively irradiated when the parotid is treated postoperatively. RT alone is used for patients with unresectable disease and for those who are medically inoperable. The likelihood of cure is lower with RT-only treatment compared with RT plus surgery, but nodal regression and good palliation are commonly seen. Treatment and palliative doses should be at least 60 to 66 Gy and 40 Gy, respectively.³³

Cervical node metastases may be managed with neck dissection in patients with a solitary node with no extracapsular extension, and with surgery plus adjuvant RT in patients with more advanced disease.¹¹⁹ Similar to parotid node metastasis, surgery with adjuvant RT has shown improved 5-year disease-free survival compared to surgery alone (74% versus 34%).¹²⁰ Depending on the location of the primary tumor, the probability of subclinical disease in the clinically negative parotid may be high and the parotid nodes should be considered for elective treatment.

Medical Therapy for Advanced Subcutaneous Cell Carcinoma

Apart from surgical therapy or RT, treatment options for SCC are limited. Local, intralesional chemotherapy with methotrexate (one to three injections of 5 to 40 mg each) and 5-FU (up to eight injections of 10 to 150 mg each) have been reported to be up to 100% effective for treatment of KA-type SCC in small case series, although these studies were uncontrolled and this is not a commonly utilized therapy.¹²¹ For typical SCC, intralesional treatment with IFN has been found to be an effective treatment, and may be particularly useful as salvage therapy for advanced or multiply recurrent disease.¹²² The largest study to date treated 27 invasive SCC and 7 SCCIS with intralesional IFN- α -2b, 1.5 million units three times a week for 3 weeks, and found a 97% cure rate at 3 months, although long-term follow-up was not reported.¹²³

The long-term prognosis for metastatic SCC is extremely poor. Treatment of metastatic disease may include systemic chemotherapy or treatment with biologic response modifiers. Although the efficacy of these methods has not been established, the recent development of targeted inhibitors of the EGFR holds promise for treatment of advanced SCC, particularly in light of the known aberrations in EGFR signaling in SCC. Cetuximab is a chimeric monoclonal antibody directed against EGFR that inhibits EGFR signaling; it is approved for treatment of head and neck (mucosal) SCC and has been used off label for cutaneous SCC.¹²⁴ The first phase 2 study of monotherapy with weekly cetuximab infusions for unresectable or metastatic cutaneous SCC showed a complete response rate of 6% and a partial response (at least 30% decrease in tumor size) of 22%.¹²⁵ Subsequent case reports have shown improved response rates (up to 50% complete response) when cetuximab was combined with adjuvant RT.¹²⁴ Although the efficacy of

these investigational treatments is clearly inferior to excisional surgery, it compares favorably to the historical prognosis of advanced SCC, in which 10-year survival rates are $< 20\%$ for patients with regional lymph node involvement and $< 10\%$ for patients with distant metastases.¹²⁶ While surgical therapy remains the cornerstone of SCC treatment, it is likely that additional molecularly targeted therapeutics will be incorporated as adjuvant or salvage therapy for advanced SCC.

FOLLOW-UP

Invasive SCC can be a potentially lethal neoplasm and warrants close follow-up. A critical review and meta-analysis has found that for people with fewer than three previous NMSCs, the risk of developing another NMSC within the following 3 years is 38%. In people with three to nine previous NMSCs, this risk rises to 93%.¹²⁷ In another study, approximately 30% of patients with SCC developed a subsequent SCC, with more than half of these occurring within the first year of follow-up.¹²⁸ Thus, it is recommended that patients with SCC be examined every 3 to 6 months during the first 2 years after treatment and at least annually thereafter. Evaluation should include total-body cutaneous examination and palpation of draining lymph nodes. Currently, radiography, magnetic resonance imaging, and computed tomography (CT) play no role in the routine workup of uncomplicated cutaneous SCC.

IMMUNOSUPPRESSION AND NONMELANOMA SKIN CANCER

The role of the immune system in the pathogenesis of skin cancer is still not completely understood. Immunosuppressed patients with lymphoma or leukemia and patients with depressed cellular immunity secondary to HIV infection develop NMSC at a significantly younger age and show a higher frequency of NMSC than the general population.¹²⁹ An Italian study of HIV patients found a three-fold increase in the incidence of NMSC over the general population.¹³⁰ Incidence of clinically aggressive HPV-related anal SCC is significantly increased in this population, requiring serial examinations and anal cytologies for surveillance.¹³¹

Solid-organ transplant recipients (e.g., heart, kidney) have a three- to four-fold increased risk over the general population of developing any cancer.²² These patients experience a marked increase in the incidence of SCCs (40- to 250-fold increase) and BCCs (5- to 10-fold increase). Skin cancers in immunosuppressed patients appear primarily on sun-exposed sites. Incidence of NMSC in renal transplant recipients in Australia increases exponentially over time: 3% within the first year, 25% at 5 years, and 44% at 9 or more years posttransplant.¹³² Similar results were observed in heart transplant patients, with an inverted SCC:BCC ratio of 3:1.¹³³ Furthermore, the SCCs in organ transplant patients occur at a younger age and tend to be more aggressive. There is an increased risk of local recurrence, regional and distant metastasis, and mortality. In case series of renal transplant patients from the United States and Australian heart transplant recipients, SCC-related mortality rates were 5% and 27%, respectively.¹³³ Although organ transplant recipients have an increased incidence of viral warts, HPV infection does not appear to be the primary cause of skin cancer in this population.¹³⁴ Patients who receive hematopoietic transplants do not experience marked increased in skin cancer incidence, presumably because of the shorter duration of immunosuppression.

Cumulative UVR is the primary pathogenic factor for the development of NMSC in solid-organ transplant recipients, but degree, type, duration of immunosuppression, and age at transplantation are also significant.¹³³ Sirolimus (rapamycin), a bacterial macrolide and antitumor agent, is a newer immunosuppressive agent that shows promise in decreasing incidence and severity of

posttransplant NMSCs.¹³⁵ Changing immunosuppressive therapy to sirolimus from a standard regimen of calcineurin inhibitors was shown to be effective for secondary prevention of SCC in renal transplant recipients in a randomized trial, decreasing the risk of subsequent SCC by 44%.¹³⁶ However, because 23% of patients in the sirolimus group discontinued the medication due to adverse effects (including edema, aphthous ulcers, and pneumonitis), sirolimus is often reserved for use in selected patients with particularly elevated risk of SCC complications. As discussed previously, preventative therapy with systemic retinoids is another viable option for minimizing morbidity from SCC in transplant recipients.²³ Prevention, patient education, aggressive sun protection, and timely and aggressive management of skin cancers as well as altering the degree or type of immunosuppression whenever possible are crucial to reduce the significant risk of NMSC complications in this population.

ANGIOSARCOMA

Angiosarcoma (AS; synonyms are malignant hemangioendothelioma, hemangiosarcoma, and lymphangiosarcoma) is an uncommon, aggressive, usually fatal neoplasm of vascular endothelium origin accounting for <2% of all sarcomas.¹³⁷ The overall incidence of this tumor is approximately 0.1 per million per year. Four variants of cutaneous AS currently are recognized and include AS of the “head and neck” (also known as idiopathic AS) accounting for 50% to 60% of all cases, AS in the context of lymphedema (lymphedema-associated AS [LAS]; Stewart-Treves syndrome), radiation-induced AS, and epithelioid AS. Although these variants differ in presentation, they share key features, including clinical appearance of primary lesions, a biologically aggressive nature, and, ultimately, poor outcome.

PATHOGENESIS

Pathogenesis of AS is poorly understood. Approximately 50% of ASs express markers of lymphatic differentiation in addition to vascular endothelium-associated antigens. More recently, AS was found to coexpress podoplanin and podocalyxin, markers of lymphatic and vascular endothelium, respectively.¹³⁸ Human herpesvirus-8 etiologic factor in Kaposi sarcoma appears not to be associated with AS. Cumulative sun exposure has not been shown to be a predisposing factor.

CLINICAL PRESENTATION AND PROGNOSIS

Cutaneous AS of the head and scalp usually affects older adults. Approximately 70% of AS occurs in patients over the age of 40 years and the highest incidence of the disease is reported in those over 70 years of age.¹³⁷ Men are more commonly affected than women with 1.6 to 3:1 ratio.

Clinically, cutaneous AS presents as a violaceous to red, ill-defined patch on the central face, forehead, or scalp, often initially resembling a bruise.¹³⁷ Facial swelling and edema may be present. Differential diagnosis at initial presentation may include benign vascular tumor, hematoma secondary to trauma, or even an inflammatory dermatosis. More advanced lesions are violaceous elevated nodules with propensity to bleed easily. Ulceration may also be present. Satellite lesions are common.

The prognosis of cutaneous AS is poor, with a mortality rate of 50% at 15 months after diagnosis, and the survival rates ranging from 10% to 30% over a 5-year period, with median survival 18 to 28 months.^{139,140} Metastatic potential of AS is high. Metastases to lung, liver, lymph nodes, spleen, and brain are common. Prognosis for metastatic disease is poor. Although prognosis does not

correlate with degree of cellular differentiation, there appears to be a correlation with lesion size at presentation; increased survival has been demonstrated in lesions <5 cm at time of diagnosis. In a clinical univariate analysis of 69 cases, older age, anatomic site, necrosis, and epithelioid features directly correlated with increased mortality.¹⁴¹ Other prognostic factors proposed in the literature include depth of invasion >3 mm, mitotic rate, Ki-67 staining, positive surgical margins, and local recurrence.¹⁴²

LAS accounts for about 10% of all cutaneous AS and was first reported by Stewart and Treves¹⁴³ in six patients with postmastectomy lymphedema. In each case, AS developed in the ipsilateral arm and occurred several years after mastectomy. Subsequently, LAS was reported after axillary node dissection for melanoma and in the context of congenital lymphedema, filarial lymphedema, and chronic idiopathic lymphedema. The risk for developing LAS 5 years after mastectomy is approximately 5%. The most common site is the medial aspect of the upper arm.

LAS presents as a firm, coalescing violaceous plaque or nodule superimposed on brawny, nonpitting edema. Ulceration may develop rapidly. The duration of lymphedema prior to appearance of AS ranges from 4 to 27 years. The pathogenesis of LAS is incompletely understood and may be related to imbalances in local immune regulation or angiogenesis, leading to proliferation of neoplastic cells. The prognosis is poor, and survival rates are comparable to AS involving the scalp and face. Long-term survival has been reported in isolated cases after amputation of the affected limb.

Radiation-induced AS has been reported to occur after RT for benign or malignant conditions.¹³⁷ AS may occur from 4 to 40 years after RT for benign conditions (acne and eczema), or from 4 to 25 years after RT for malignancies. Overall prognosis is poor and comparable to that observed in other forms of AS.

Epithelioid AS is a rare, recently described variant of AS.¹⁴⁴ It tends to involve the lower extremities. On microscopic examination, the tumor may mimic an epithelial neoplasm, with sheets of rounded, epithelioid cells intermingled with irregularly lined vascular channels. Epithelioid AS results in widespread metastases within 1 year of presentation. Prognosis is poor.

HISTOLOGY

Histology of AS, although highly variable in the degree of cellular endothelial differentiation between and within individual tumors, does not vary between individual subtypes.¹³⁷ In well-differentiated lesions, an anastomosing network of sinusoidal irregularly dilated vascular channels lined by a single layer of flattened endothelial cells with mild to moderate nuclear atypia is commonly seen. These exhibit a highly infiltrative pattern, splitting collagen bundles and subcutaneous adipose tissue. Less-differentiated tumors show proliferation of atypical, polygonal, or spindle-shaped, pleomorphic endothelial cells with increased mitotic activity and anastomosing vascular channels. In poorly differentiated AS, luminal formation may be no longer apparent and mitotic activity is high. Poorly differentiated AS may mimic other high-grade sarcomas, carcinoma, or even melanoma. The state of cellular differentiation, however, has not been shown to correlate with prognosis.¹³⁹ Immunohistochemical analysis may be of value in diagnosis of AS, as cells stain positively for *Ulex europaeus* I lectin and factor VIII-related antigen. *Ulex* I is considered to be more sensitive marker for AS. In addition, AS cells express stem cell antigen CD34 and endothelial cell surface antigen CD31. The majority of AS cases stain positively for vimentin, D2-40, and VEGFR-3.

TREATMENT

Because of the clinical aggressiveness, treatment options for AS are limited. Surgical excision with wide margins is the treatment of choice. Nonetheless, the RRs and possibility of metastatic disease

are high even with histologically negative margins and may reflect the tendency for multifocality.¹⁴⁵ Amputation with shoulder disarticulation or hemipelvectomy is recommended for tumors involving the extremities. Because AS tends to extend far beyond clinically appreciated margins, complete surgical removal may be challenging. Several cases of AS have been treated by MMS in an attempt to control margins; however, the difference between AS and normal vasculature may be difficult to interpret on frozen sections, even with the use of immunohistochemical stains.¹⁴⁶ RT and electron beam should be considered postoperatively in an effort to enhance local control.

Patients with isolated lymphatic spread treated with taxol-based chemotherapeutic regimens have a favorable outcome. Both chemotherapy and radical RT are palliative only for metastatic disease and do not improve overall survival.

DERMATOFIBROSARCOMA PROTUBERANS

DFSP is a rare soft tissue sarcoma with aggressive local but low metastatic potential with an annual incidence of approximately 4 per million. DFSP constitutes approximately 1% of all sarcomas and <0.1% of all malignancies.¹⁴⁷ The vast majority, approximately 90% of DFSPs, are low-grade sarcomas, whereas the remainder are classified as intermediate or high grade because of the presence of a high-grade fibrosarcomatous component (DFSP-FS).¹⁴⁸

DFSP most commonly affects patients in their mid- to late 30s; however, the disease can occur at any age. Childhood and congenital cases of DFSP have been reported.¹⁴⁹ Blacks have slightly higher incidence than whites. Both men and women are equally affected.¹⁵⁰

PATHOGENESIS

The pathogenesis of DFSP is incompletely understood but may involve factors as diverse as aberrant TSG or a history of local trauma/scarring.¹⁵¹ More than 90% of DFSP feature a translocation between chromosomes 17 and 22, resulting in the fusion between the collagen type I α 1 gene (*COL1A1*) and the platelet-derived growth factor (PDGF) β -chain gene (*PDGFB*). Thus, the growth of DFSP is a result of the deregulation of PDGF β -chain expression and activation of PDGF receptor (*PDGFR*) protein tyrosine kinase.^{151,152}

DFSP classically presents as a solitary, frequently asymptomatic, plaque with violaceous to blue hue. The tumor exhibits slow growth. Most commonly affected sites include trunk and, less frequently, the extremities, head, and neck, but it may occur anywhere.¹⁵² The Bednar tumor is a rare pigmented variant of DFSP.¹⁵³ Clinically, it may be difficult to differentiate from a dermatofibroma or a keloid.

HISTOLOGY

Histologically, DFSP arises in the dermis and is composed of monomorphous, dense spindle cells arranged in a storiform pattern and embedded in a sparse to moderately dense fibrous stroma.¹⁵⁴ Irregular projections (tentaclelike) of the tumor are common and may account for the high incidence of local recurrence after excision. The distinction between deep penetrating dermatofibroma (DPDF), which involves the subcutis, and DFSP may be challenging. In most instances, attention to the cytologic constituency of the lesions and the overall architecture is sufficient for differentiation. DPDF is typified by cellular heterogeneity. DPDF includes giant cells and lipidized histiocytes and extends deeply, using the interlobular subcuticular fibrous septa as scaffolds, or is in the form of broad fronts. In contrast, DFSP tends to be monomorphous,

surrounding adipocytes diffusely or extending in stratified horizontal plates. This infiltration is characteristically eccentric, often with long, thin extensions in one direction and not another. Immunostaining for factor XIIIa, CD34, and stromelysin 3 may be helpful in distinguishing DPDF from DFSP. Characteristically, DPDF is diffusely factor XIIIa+, CD34-, and stromelysin 3+, whereas DFSP is factor XIIIa-, CD34+, and stromelysin 3-.¹⁵⁵

TREATMENT

Treatment options for DFSP include WLE and MMS. Most authors advocate WLE with a minimal margin of at least 3 cm of surrounding skin, including the underlying fascia, without elective lymph node dissection.¹⁵⁶ The likelihood of local recurrence is directly proportional to the adequacy of surgical margins. Conservative resection can lead to RRs of 33% to 60%, whereas wider excision margins (≥ 2.5 cm) have been reported to reduce the RR to 10%.¹⁵⁷ For well-defined tumors located on trunk or extremities, WLE is likely to achieve tumor clearance with satisfactory cosmetic and functional result. However, extirpation of tumor by MMS, using frozen sections with or without confirmation by examination of paraffin-embedded sections, may be beneficial in sites where maximum conservation of normal tissue is required. Utility of MMS versus WLE was examined in a retrospective review of 48 primary DFSP cases treated at a single institution.¹⁵⁸ Twenty-eight patients underwent WLE and twenty patients underwent MMS. Median WLE margin width was 2 cm. For MMS, the median number of layers required to clear the tumor was two. Positive margins were present in 21.4% (6 of 28) WLE versus 0% MMS. At a median follow-up of 49.9 months for WLE and 40.4 months for MMS, local RRs were 3.6% (1 of 28) and 0%, respectively. The authors concluded that although positive margin resection was more common with WLE, local control was ultimately similar for the two surgical modalities. In a different study, Paradisi et al.¹⁵⁹ compared literature-reported observational data on 41 patients who underwent MMS and 38 who underwent WLE. Recurrence rates were 13.2% and 0% for WLE and MMS at 4.8 and 5.4 years follow-up, respectively. The relative risk of recurrence for WLE versus MMS was 15.9.

In the cases of congenital DFSP treated with MMS, the reported clearance rate was 100% during an average follow-up period of 4.3 years.¹⁶⁰ The clearance rate seen with WLE was 89% with an average follow-up period of 1.9 years. The average margins taken during MMS (1.7 cm) were smaller than those taken with WLE (2.8 cm). Based on superior cure rates and smaller surgical margins, MMS was proposed as first-line treatment for congenital DFSP.

Alternative treatment options for DFSP include RT and chemotherapy. RT was used selectively in a number of cases if surgical resection was not possible or would result in major cosmetic or functional deficit, with good local response.^{161,162} A PDGF receptor inhibitor, imatinib, has been used with clinical success in advanced disease.^{163,164} In a case series of 10 patients with locally advanced or metastatic disease treated with imatinib, 9 patients showed therapy response.¹⁶⁵ Limited clinical data are available on the use of chemotherapeutic agents such as vinblastine and methotrexate.¹⁶¹

RECURRENCE AND METASTATIC POTENTIAL

Patients with DFSP should be followed closely for evidence of local or regional recurrence or metastatic disease. DFSP has a tendency to recur locally. The average time for recurrence is within the first 3 years. DFSP of the head and neck has been reported to have a higher local RR (50% to 75%) than DFSP in other locations and might be related to smaller surgical margins used in cosmetically sensitive areas.¹⁶⁶ Although metastases are rare, multiple local recurrences appear to predispose to distant metastases.¹⁶⁷

Lymph node metastases occur in approximately 1% of cases, and distant metastases, principally to lung, occur in approximately 4% of DFSP cases. DFSP-associated mortality is low. In a series of 218 patients, the 5- and 10-year mortality rates were 1.5% and 2.8%, respectively.¹⁶¹

A fibrosarcomatous variant, DFSP-FS, represents an uncommon form of DFSP that tends to follow a more aggressive clinical course.¹⁶⁸ In a series of 41 patients with DFSP-FS, a mean follow-up period of 90 months revealed a local RR of 58%. Metastatic rate was 14.7%.

MERKEL CELL CARCINOMA

MCC is a rare and aggressive tumor of neuroendocrine cell origin with an estimated annual incidence in the United States of 3 per million people.¹⁶⁹ Incidence of MCC is estimated in men at more than twice that in women, and whites are more than 20 times more likely to develop disease than blacks. The average age at diagnosis is 70 years.¹⁷⁰

Merkel cells derive from the neural crest and differentiate as a part of the amine precursor uptake and decarboxylation system. Merkel cells function as slowly adapting type I mechanoreceptors.¹⁷⁰

PATHOGENESIS

The pathogenesis of MCC is incompletely characterized. Given the increased incidence of MCC with increasing age, it is likely that accumulation of oncogenic events plays a role. UVR has been indirectly implicated in the development of MCC. The risk is higher among whites of European ancestry, incidence is inversely related to latitude, and the majority of tumors present on the face (36%), head, extremities, and trunk.¹⁷⁰

The risk of MCC is particularly high with prior PUVA treatment. A multicenter study of 1,380 patients with psoriasis who were treated with PUVA showed that the incidence of MCC was 100 times higher than expected in the general population.¹⁷¹ Immunosuppression, whether through iatrogenic means, HIV infection, or neoplasia, may play a role in the development of MCC. Patients with MCC have increased incidence of multiple myeloma, non-Hodgkin lymphoma, and in particular chronic lymphocytic leukemia.^{172,173} Rapid progression has been reported in the setting of immunosuppressive therapy after organ transplantation.¹⁷⁴ Numerous chromosomal abnormalities have been described in MCC, but a definite causal relationship has not been established.

Recently, a double-stranded DNA virus, Merkel cell polyomavirus (MCPyV) was elegantly implicated in the pathogenesis of MCC.¹⁷⁵⁻¹⁷⁷ Viral genome was detected in 8 of 10 MCCs and at low levels in 16% of unaffected skin and 8% of tissues from other body sites of patients without MCC. Within MCC substantial variation in the relative number of MCPyV, DNA was noted. Virus-positive MCCs contain between 1 viral DNA copy per 10,000 tumor cells to 10 viral DNA copies per tumor cell. MCPyV was integrated at various locations in the MCC tumor genome in a clonal pattern, suggesting that infection of the cells occurred before their clonal expansion.¹⁷⁷ Increased detection techniques reveal that virtually all MCC contain MCPyV¹⁷⁸ and that both CD4+ and CD8+ antiviral T cells are detectable within tumors and the blood of patients with MCC.¹⁷⁹

CLINICAL PRESENTATION

Clinically, MCC usually presents as a rapidly growing, firm, flesh-colored or red-violaceous, dome-shaped papule or plaque on sun-exposed skin. Most lesions are <2 cm in diameter at the time of diagnosis. Clinical differential diagnosis often includes leukemia cutis, amelanotic melanoma, metastatic carcinoma, pyogenic granuloma, BCC, and SCC. Regional lymph nodes are involved in up to 30% of patients, and approximately 50% of patients develop systemic disease. Secondary sites of MCC spread include skin (28%), lymph nodes (27%), liver (13%), lung (10%), bone (10%), and brain (6%).^{147,180}

HISTOLOGY

Histologic examination of MCC reveals sheets and cords of atypical cells in the dermis extending to the subcutaneous layer that sometimes form an interlacing trabecular or pseudoglandular pattern (Fig. 92.9). Three histologic subtypes have been described: intermediate, trabecular, and small cell. No clinically significant differences between subtypes have been described. A grenz zone separating tumor from epidermis is often present. Individual cell membranes often are indistinct, giving a syncytial appearance. Cells are round to oval and generally noncohesive. Cytoplasm tends to be scant, with round to oval nuclei containing two to three nucleoli. Special stains may prove useful in the histological evaluation of MCC. Cytokeratin-20 staining gives a characteristic paranuclear dot pattern. MCC also stains positively for chromogranin neuron-specific enolase and synaptophysin, and may be weakly

Figure 92.9 (A and B) Histologic examination of cutaneous Merkel cell carcinoma reveals sheets and cords of atypical cells in the dermis extending to the subcutaneous layer that sometimes form an interlacing trabecular or pseudoglandular pattern. Cells are round to oval and generally noncohesive. Cytoplasm tends to be scant, with round to oval nuclei containing two to three nucleoli.

positive for S100 protein.¹⁸¹ In 2002, it was shown that MCC also stains for the KIT receptor tyrosine kinase (CD117), and perhaps abnormal functioning of the KIT receptor could be involved in the malignant transformation of this tumor.¹⁸²

Histologic differential diagnosis of MCC includes lymphoma, BCC, metastatic oat cell carcinoma, or noncutaneous neuroendocrine tumors. In contrast to MCC, lymphoma cells are CD45-positive and cytokeratin-20 negative. Melanoma can be differentiated from MCC by strong S100 positivity of melanocytes.

TREATMENT

MCC warrants aggressive therapy. It has a high propensity for local recurrence (20% to 75%), regional (31% to 80%), and distant metastases (26% to 75%). Approximately one-third of patients with MCC eventually die of the disease. Age older than 65 years, male sex, size of primary lesion >2 cm, truncal site, nodal/distant disease at presentation, and duration of disease before presentation (≤ 3 months) appear to be poor prognostic factors. All patients with histologically confirmed MCC should undergo imaging and laboratory examination to evaluate the full extent of disease. Evaluation must include full-body skin examination with lymph node evaluation, a complete blood cell count, and liver function tests. CT scanning of the chest, pelvis, and abdomen may be indicated to detect distal metastasis.¹⁸³ CT scanning of the head and neck may prove valuable in detection of nodal disease. Octreotide scans may be more sensitive than CT scans in diagnosing primary and metastatic MCC.¹⁸⁴ Perianal and vulvar sites have the worst prognosis of all primary sites. Metastases have been noted most commonly in skin and lymph nodes but also in the lung, liver, brain, intestine, bladder, stomach, and abdominal wall.

STAGING

Five competing staging systems have been used to describe MCC. However, these staging systems are highly inconsistent. To address these concerns, a new MCC-specific consensus staging system was developed by the AJCC. Patients with primary MCC with no evidence of regional or distant metastases (either clinically or pathologically) are divided into two stages: stage I for primary tumors no >2 cm in size and stage II for primary tumors >2 cm in size. Stage I and stage II are further divided into A and B substages based on method of nodal evaluation. Patients who have pathologically proven node-negative disease (by microscopic evaluation of their draining lymph nodes) have improved survival (substaged as IIA) compared with those who are evaluated only clinically (substaged as IIB). Stage II has an additional substage (IIC) for tumors with extracutaneous invasion (T4) and negative node status, regardless of whether the negative node status was established microscopically or clinically. Stage III includes patient with nodal disease, either microscopically positive and clinically occult nodes (IIIA) or macroscopic nodes (IIIB). Distant metastases are classified as stage IV MCC.¹⁸⁵

Before the new AJCC consensus staging system was published, the recent Memorial Sloan Kettering Cancer Center (MSKCC) four-stage system was favored as it was based on the largest number of patients and was the best validated. The stages in the MSKCC system include stage I (primary tumor alone, <2 cm in diameter), stage II (primary tumor alone, >2 cm in diameter), stage III (regional nodal disease), and stage IV (distant metastatic disease).¹⁸⁶

RECURRENCE AND METASTATIC RISK

MCC has a propensity to recur locally (sometimes with satellite lesions and/or in-transit metastases) following surgical excision. In a review of 18 case series, 279 of 926 patients (30.1%) developed

local recurrence during follow-up. These recurrences have been typically attributed to inadequate surgical margins or possibly a lack of adjuvant radiation therapy.¹⁸⁷ WLE to reduce the risk of local recurrence has been recommended for patients with clinical stage I or stage II disease.

Recommendations about the optimal minimum width and depth of normal tissue margin that should be excised around the primary tumor differ among the various retrospective case series, but this question has not been studied systematically.^{180,186,188} No definitive data suggest that extremely wide margins improve overall survival, although some reports suggest that wider margins appear to improve local control.¹⁸⁹

Recommended management has usually been WLE with 1- to 3-cm margins; however, treatment guidelines are not well defined, owing to the rarity of the tumor, which precludes randomized clinical trials. Recurrence rates after primary therapy for MCC with surgery alone are reported to be within the range of 0% to 50% to 70%. In a single-institution case series of 95 patients with early-stage MCC, a total of 45 (47%) patients relapsed, with 80% of the recurrences occurring within 2 years and 96% within 5 years.¹⁹⁰ Patients with MCC in the head and neck region had a 5-year local-recurrence cumulative incidence of 19% and no distant recurrences, and patients with MCC in the extremity and trunk region had a 5-year local-recurrence cumulative incidence of 2% and a 5-year distant-recurrence cumulative incidence of 22%.¹⁹⁰ MMS has been proposed as being more successful in controlling local disease than WLE, especially in cosmetically sensitive anatomic locations. The relapse rate has been reported to be similar to or better than that of wide excision, but comparatively few cases have been treated in this manner and none in randomized, controlled trials.^{188,191,192} In a retrospective review of 38 consecutive patients with MCC of the extremities, WLE and MMS showed similar local RR.¹⁸⁸

MCC spreads to regional lymph nodes within 2 years in up to 70% of cases. Because of the propensity for early nodal spread and the significant negative impact that nodal disease has on outcome, regional lymph node dissection or sentinel lymph node (SLN) dissection may be advisable. Surgical nodal staging in clinically negative patients has identified positive nodes in at least 25% to 35% of patients.¹⁸⁶ At present, it is questionable whether lymph node dissection has an impact on survival, but it seems to benefit local and regional control. Clinically or radiographically positive nodes should be resected but it is unclear whether elective lymph node dissection provides benefit.

SLN biopsy is a preferred initial alternative to complete elective lymph node dissection for the proper staging of MCC. SLN biopsy is associated with lower morbidity, and in the sites with indeterminate lymphatic drainage, SNL technique can be used to identify the pertinent lymphatic basins. Several reports support the use of SLN biopsy techniques in MCC staging and management.¹⁹³⁻¹⁹⁵ One meta-analysis of 10 case series found that SLN positivity strongly predicted a high short-term risk of recurrence and that subsequent therapeutic lymph node dissection was effective in preventing short-term regional nodal recurrence.¹⁹⁵ Another meta-analysis of 12 retrospective case series found that (1) SLN biopsy detected MCC spread in one-third of patients whose tumors would have otherwise been clinically and radiologically understaged, (2) the RR was three times higher in patients with a positive SLN biopsy than in those with a negative SLN biopsy, and (3) the relapse-free survival rate in patients with positive SLN biopsy who did or did not receive additional treatment to the nodes was 51% and 0% at 3 years, respectively.¹⁹⁶ Whether complete dissection of regional nodes following positive SLN biopsy improves definitively survival remains unresolved, however.

Radiation to the primary site has been considered for patients with larger (>2 cm) tumors and locally unresectable tumors, while adjuvant nodal radiation is considered for those with positive regional nodes (stage II).^{169,192} Several small retrospective series have shown that radiation plus adequate surgery improves

local-regional control compared with surgery alone,^{180,196} whereas other series did not show similar results.^{186,191} Adjuvant RT offers a substantial benefit in both time to recurrence and disease-free survival, but a survival benefit is yet to be proven.¹⁹⁷ The controversy regarding the utility of adjuvant RT following excision remains.

Chemotherapy is used for nodal, metastatic, and recurrent MCC, but an optimal treatment regimen is yet to be established. From 1997 to 2001, the Trans-Tasman Radiation Oncology Group performed a phase 2 evaluation of 53 patients with MCC with high-risk, local-regional disease. Given the heterogeneity of the population and the nonstandardized surgery, it is difficult to infer a clear treatment benefit of the chemotherapy.¹⁹⁸ Regimens are similar to those used for small cell lung carcinoma. The most commonly used agents are cyclophosphamide, anthracyclines, and cisplatin. In a study by Voog et al.,¹⁹⁹ overall response to first-line chemotherapy for MCC was 61%, with a 57% response in metastatic disease and a 69% response in locally advanced disease. Reported 3-year survival rate was 17% in metastatic disease and 35% in locally advanced disease. Forty-two different regimens were used to treat these 107 reported cases.

PROGNOSIS

The prognosis of MCC is directly correlated with the stage of disease. Reported 5-year survival according to MSKCC classification is 81% for stage I, 67% for stage II, 52% for stage III, and 11% for stage IV.¹⁴⁷ More than 50% of patients experience recurrence with the median time to recurrence of 9 months (range, 2 to 70 months). Ninety-one percent of recurrences occurred within 2 years of diagnosis.¹⁸⁶ Overall survival of head and neck MCC at 5 years postoperatively ranges between 40% and 68%.²⁰⁰

MICROCYSTIC ADNEXAL CARCINOMA

Microcystic adnexal carcinoma (MAC) was first described as a distinct entity in 1982 by Goldstein et al.²⁰¹ Synonyms quoted in the literature to describe MAC include sclerosing sweat duct carcinoma, malignant syringoma, sweat gland carcinoma with syringomatous features, aggressive trichofolliculoma, and combined adnexal tumor of the skin. MAC originates from pluripotent adnexal keratinocytes capable of both eccrine and follicular differentiation. The pathogenesis of MAC is not completely understood but may involve exposure to ionizing and UVR that may precede development of MAC by as long as 40 years.²⁰² MAC is an aggressive, locally destructive cutaneous appendageal neoplasm with a high rate of local recurrence but low rate of metastasis. It primarily affects white, middle-aged individuals, although it has been reported in children and blacks. Unlike the other primary cutaneous malignancies, MAC has slight female predominance.

CLINICAL AND HISTOLOGIC FEATURES

MAC classically presents as a smooth-surfaced, nonulcerated, flesh-colored to yellowish asymptomatic nodule, papule, or plaque. When symptomatic, common findings include numbness, tenderness, anesthesia, paresthesia, burning, discomfort, and/or rarely pruritus of the affected site. These symptoms can relate to the frequent PNI of the tumor. MAC is locally aggressive with common perineural invasion and extension to muscle, vascular adventitia, perichondrium, periosteum, and bone marrow. MAC has a clear predilection for the head and neck (86% to 88%), particularly the central face (73%). Other sites include eyelid, scalp, breast/chest, axillae, buttocks, vulva, extremities, and tongue. This tumor is often misdiagnosed clinically and histologically.^{202,203}

Histologically, MAC is a tumor of pilar and eccrine differentiation. It may be misdiagnosed as a benign adnexal process. The

Figure 92.10 Histology of microcystic adnexal carcinoma. The tumor frequently exhibits a stratified appearance with larger keratin horn cysts and epithelial nests, strands, or cords in the superficial dermis and desmoplastic deeper dermis with smaller cysts and more pronounced ductal structures. Horn cysts may contain laminated keratin and/or small vellus hairs. Cysts may be also calcified. Ducts may be well differentiated, with two rows of cuboidal cells, or less differentiated, with single strands without lumina.

tumor frequently exhibits a stratified appearance with larger keratin horn cysts and epithelial nests, strands, or cords in the superficial dermis and desmoplastic features in the deeper dermis with smaller cysts and more pronounced ductal structures (Fig. 92.10). Ducts may be well differentiated, with two rows of cuboidal cells, or less differentiated, with single strands without lumina. Mitotic figures and cytologic atypia are rare. Histologic differential diagnosis of MAC includes desmoplastic trichoepithelioma, benign syringoma, papillary eccrine adenoma, morpheaform BCC, SCC, and metastatic breast carcinoma. Adequately deep biopsy is crucial for correct diagnostic assessment.

TREATMENT AND PROGNOSIS

Current standard of care for MAC is to surgically remove the tumor in its entirety whenever feasible. This task can be challenging in clinical practice because the tumor often extends microscopically centimeters beyond the clinically apparent margins. Margins reported in the literature for WLE vary from a few millimeters to 3 to 5 cm. Extirpation of tumor by MMS may prove beneficial in the management of MAC. Recurrence rates vary significantly between the two surgical techniques with rates after WLE and MMS ranging from 40% to 60%²⁰⁴ and 0 to 12%,²⁰⁵ respectively. To date, seven cases of metastases have been reported for a cumulative metastatic rate of <2.1%, although this is likely an overestimate. RT has been used as mono- or adjuvant therapy for MAC with reported success in only one of six case reports, highlighting the tumor's resistance to RT. Patients with MAC should have ongoing examination of the skin and lymph nodes for the remainder of their lifespan, given the potential for late recurrence decades after initial presentation.

SEBACEOUS CARCINOMA

Sebaceous carcinoma (SC) is a malignant adnexal tumor with variable sites of origin, histologic growth patterns, and clinical presentations. About 75% of SCs are periorcular in location.²⁰⁶ Periorcular SC may arise from Meibomian glands and, less frequently, from the glands of Zeis. The upper eyelids are most frequently involved.

Approximately 25% of cases of SC involve extraocular sites, which may include head and neck, trunk, salivary glands, and external genitalia.²⁰⁷ Worldwide, SC affects all races, but Asians are particularly prone to the disease. Women are affected more commonly than men, at a ratio of approximately 2:1. SC classically presents in the seventh to ninth decades.²⁰⁸ SC is associated with sebaceous adenomas, radiation exposure, and Muir Torre syndrome. Because of the strong association of SC with Muir Torre syndrome, patients presenting with SC should be referred for colonoscopy to assess for occult colon cancer. Routine genetic screening for Muir Torre in the absence of colon lesions is not currently indicated.

CLINICAL AND HISTOLOGIC FEATURES

The most frequent clinical presentation is a slowly growing, painless, subcutaneous nodule. Other presentations include diffuse thickening of the skin, pedunculated papules, or an irregular subcutaneous mass. On the eyelid, SC is most often misdiagnosed as chalazion. It may present as chronic diffuse blepharconjunctivitis or keratoconjunctivitis, particularly with pagetoid or intraepithelial spread of tumor onto the conjunctival epithelium.²⁰⁹ SC is the second most common eyelid malignancy after BCC and is the second most lethal after melanoma. Histologically, SCs are classified as well, moderately, or poorly differentiated. Most commonly, lesions have an irregular lobular growth pattern with sebaceous and undifferentiated cells. SC cells exhibit varying degrees of differentiation, nuclear pleomorphism, hyperchromatism, basaloid appearance, and high mitotic activity. Local infiltration of the surrounding tissues and neurovascular spaces can be seen. A known feature of the SC is pagetoid spread, the spread of tumor cells into the overlying epithelium. Special stains, including lipid stains as Oil-Red-O or Sudan IV for fresh tissue, and immunohistochemical stains such as EMA or LeuM1 are also helpful.²¹⁰

TREATMENT AND PROGNOSIS

Treatment options for SC include WLE with 5- to 6-mm margins and extirpation by MMS. The local RR after WLE has been reported to be as high as 36% at 5 years and associated 5-year mortality rate of 18%.²¹¹ In one study of 14 cases of SC excised with frozen-section margin control, five recurrences were observed in cases with surgical margins of 1 to 3 mm, whereas no recurrences were seen with margins of 5 mm.²¹² Potential difficulties arise because tumors are often multicentric with discontinuous foci of tumor, and pagetoid spread is difficult to determine even on high-quality, paraffin-embedded sections. Extirpation of SC by MMS has compared favorably to WLE, with local RRs of $\leq 12\%$ in reported series.²¹³ A series of poorly differentiated SC successfully treated with RT has also been reported.²¹⁴

SCs have high rates of local recurrence and metastasis, particularly when occurring on the eyelid. SC can spread by lymphatic or hematogenous routes or by direct extension. Distant metastases are reported in up to 20% of cases and may involve the lungs, liver, brain, bones, and lymph nodes. Mortality of SC ranges from 9% to 50%. Extraocular SC has a reported local RR of 29% and metastatic rate of 21%, although there appears to be a reporting bias in the literature for more advanced disease. Small primary lesions < 1 cm in diameter may exhibit a more favorable prognosis.

EXTRAMAMMARY PAGET DISEASE

Extramammary Paget disease (EMPD) is a rare cutaneous malignancy of older adults, often on the genitalia, with a mean age of onset of approximately 70 years. While there is a slight female predominance in Caucasian patients, there is a strong 4:1 male predominance in Asians.²¹⁵ Although histologically similar to

Paget disease of the breast, EMPD is a separate entity with a distinct prognosis and is not related to breast cancer. EMPD is most often a primary intraepidermal malignancy thought to derive from eccrine or apocrine glands. EMPD has been associated with internal malignancy in 15% to 30% of cases, usually colon, bladder, or prostate cancer.²¹⁶ These cases of secondary EMPD have a worse prognosis than primary EMPD.

CLINICAL AND HISTOLOGIC FEATURES

EMPD most often presents as a pink to bright red plaque of the genitalia. Scaling, erosion, and maceration are common features. It is usually asymmetric and may extend to the perianal region, inguinal fold, suprapubic region, and medial thigh, but it is classically seen on the scrotum of men or the labia majora of women. Rare cases of primary EMPD have also been described in the axillae.²¹⁷ While most cases present as large flat plaques, nodular presentations have been described that portend a worse prognosis, as does clinical lymphadenopathy. Because of its innocuous appearance, EMPD is often misdiagnosed as benign inflammatory conditions such as psoriasis, dermatitis, or superficial fungal infections, and clinicians should have a low threshold for biopsy of suspected inflammatory conditions that do not respond to routine treatment.

Biopsy of EMPD reveals acanthosis with an intraepidermal proliferation of large, pale staining cells with prominent vesicular nuclei. These cells are spread throughout all layers of the epidermis, often forming large clusters just above the basal layer. Mitotic figures may be present. A minority of patients may have extension of EMPD into the superficial or deep dermis, which is associated with decreased survival.²¹⁷ Immunohistochemical stains may be helpful in the diagnosis of EMPD. Most cases of EMPD stain with CK7 and GCDFP-15, while CK20 staining may be more common in secondary EMPD.²¹⁸

TREATMENT AND PROGNOSIS

To rule out internal malignancy and secondary EMPD, patients should undergo a colonoscopy and appropriate screening for genitourinary malignancy prior to initiating treatment. Complete surgical excision of EMPD has classically been the standard of care, although local RRs may be as high as 30% to 40%. MMS may be a superior option, with local RRs of 12% to 18% reported in small case series.^{215,219} Because of its primarily superficial nature, nonsurgical treatment of primary EMPD has been proposed, with several case reports documenting success (and a few reporting failure) with topical imiquimod therapy.^{220,221} In the authors' experience, topical therapy with imiquimod at a variable frequency for up to 12 weeks, titrated to the local inflammatory response, is an effective first-line therapy for primary EMPD. Surgical treatment may be employed for recalcitrant cases, and radiation therapy has also been reported for EMPD with some success.²²² Overall, the prognosis for primary EMPD is good, with a reported 85% overall survival at 5 years.²¹⁷ For the majority of patients that present with in situ disease, the prognosis is excellent, while the 14% of patients presenting with deep dermal invasion exhibit a 20-fold increased risk of disease-specific death.

ATYPICAL FIBROXANTHOMA AND MALIGNANT FIBROUS HISTIOCYTOMA

Until recently, atypical fibroxanthoma (AFX) and malignant fibrous histiocytoma were thought to be two distinct presentations of the same malignancy. However, following reclassification of soft tissue sarcomas by the World Health Organization in 2002 that mandated identification of cell line origin in classification of tumors, most cases of malignant fibrous histiocytoma, as previously considered,

were found to be merely a morphologic pattern rather than a defined pathologic entity.²²³ In a majority of cases, ultrastructural and immunohistochemical examination allowed for reclassification into defined histologic subtypes of sarcomas. Under the new classification, the term *malignant fibrous histiocytoma* is a synonym for undifferentiated pleomorphic sarcoma (UPS) not otherwise specified. UPS is a deep-seated subcutaneous nodule rarely encountered in the skin; it is most often seen on the limbs of elderly patients. UPS is an aggressive tumor with a poor prognosis. Although complete surgical excision is the preferred treatment (often with adjuvant RT), up to 50% of patients may have distant metastasis at the time of initial presentation, with the lung being the most common site.

ATYPICAL FIBROXANTHOMA

AFX is a spindle cell tumor that occurs on the head and neck of sun-exposed individuals and on the trunk and extremities of younger patients. Tumors of the head and neck characteristically present during the eighth decade, whereas tumors involving the extremities often present during the fourth decade. The ratio of affected men to women appears to be equal. A few cases have been reported in children with xeroderma pigmentosum. The pathogenesis of AFX involves exposure to UVR, ionizing radiation, and/or aberrant immune host response. In a series of 10 cases of AFX, 7 cases showed mutation in TSG *p53*, often with UVR signature mutations.²²⁴ Tumors may occur 10 to 15 years after local ionizing radiation. An increased incidence of AFX has been observed in renal transplant patients, and metastatic AFX has been reported in a patient with chronic lymphocytic leukemia.

CLINICAL AND HISTOLOGIC FEATURES

AFX usually presents as an asymptomatic, often rapidly growing, dome-shaped papule or nodule covered by thin epidermis on actinically damaged skin of individuals with a fair complexion. Average size at presentation is 1 to 2 cm. Secondary changes such as serosanguinous crust or ulceration may be present. The clinical appearance is not distinctive, and the clinical differential diagnosis of the lesion often includes pyogenic granuloma, SCC, BCC, amelanotic melanoma, MCC, and cutaneous metastasis. AFX may be found in the setting of other NMSCs.

On microscopic examination, AFX is a dermal or partially exophytic nodule composed of a proliferation of atypical spindle-shaped cells with moderate amounts of cytoplasm and large histiocyte-like atypical cells with abundant pale-staining vacuolated cytoplasm

arranged in haphazard fashion in a collagenous or occasionally myxoid stroma.²²⁵ The neoplastic cells have large, pleomorphic, and heterochromatic “bizarre-looking” nuclei, and some of them are multinucleated. There are numerous typical and atypical mitotic figures. Some cells may contain droplets of lipid. The epidermis overlying the dermal proliferation is commonly ulcerated. Both the spindle-shaped and the histiocyte-like cells stain positively for vimentin, while CD68 and CD10 are often, but not universally, positive in AFX. Stains for HMB-45 and S100, as well as cytokeratin stains, are negative, distinguishing this lesion from spindle cell melanoma and SCC, respectively.^{225,226}

TREATMENT AND PROGNOSIS

Treatment of AFX is surgical removal by WLE or MMS. In a large retrospective series of 45 patients comparing WLE with MMS, recurrences were observed during a mean follow-up period of 73.6 months in 12% of 25 cases treated by WLE.²²⁷ Metastatic involvement of the parotid gland occurred in one of these patients, for an overall regional metastatic rate of 4%. In contrast, no recurrences or metastases were observed over a mean follow-up period of 29.6 months in patients treated by MMS. Others have reported similarly favorable outcomes after treatment of AFX by MMS.^{228,229} The authors favor the use of MMS for AFX because of the superior margin control and conservation of normal tissue.

Although AFX rarely metastasizes, it is a locally aggressive tumor with metastatic potential. Metastases to the parotid gland, lymph nodes, and lung have been reported. In a series of eight cases of metastatic AFX, poor prognostic indicators included vascular invasion, recurrence, deep-tissue penetration, necrosis, and impaired host resistance.^{229,230} Because AFX is often found in the setting of diffuse actinic damage and other NMSCs, close follow-up after complete tumor extirpation is critical.

CARCINOMA METASTATIC TO SKIN

The most frequently observed cutaneous metastatic cancers are breast, colon, and melanoma in women, and lung, colon, and melanoma in men. Cutaneous involvement is also seen in the leukemias, with a wide variation in the morphology of lesions. The scalp is a common site for cutaneous metastatic disease. Immunohistochemical stains may be helpful in determining the site of the primary tumor. The discovery of cutaneous metastatic disease should prompt consultation with an oncologist for staging and management.

93 Molecular Biology of Cutaneous Melanoma

Michael A. Davies and Levi A. Garraway

INTRODUCTION

The most common forms of skin cancer are basal cell carcinoma, squamous cell carcinoma, and melanoma. While melanoma represents <5% of the cases diagnosed, it is the cause of >70% of the deaths attributable to skin cancer each year. In 2013, an estimated 76,690 new cases of melanoma will be diagnosed, and 9,840 patients will die from this disease.¹ Although the annual incidence and mortality for most major cancers (i.e., lung, colorectal, breast, prostate) are decreasing, the public health burden of melanoma continues to rise. The annual incidence of melanoma has risen steadily at a rate of ~3% per year over the past 25 years.²⁻⁴ As melanoma often strikes individuals who are young and otherwise healthy, it is also a significant financial burden, with an annual estimated cost of \$3.5 billion in lost productivity in the United States due to melanoma mortality.⁵

Cutaneous melanoma arises from pigment-producing epidermal melanocytes. Clinically, melanomas are staged using the guidelines established by the American Joint Committee on Cancer.⁶ For patients who present with primary tumors only (stage I, stage II), the vertical tumor (Breslow) thickness (in millimeters) and ulceration status are the most powerful indicators of prognosis. Melanoma usually spreads first regionally to draining lymph nodes. For patients with regional disease (stage III), the prognosis is determined by the number of lymph nodes involved, the size of the lymph node metastases (micro-metastases versus macrometastases), the pattern of lymph node involvement (lymph nodes, in-transit metastases, or both), and the ulceration status of the primary tumor. Melanoma is also infamous for its ability to metastasize to virtually any distant organ. For patients with distant metastases (stage IV), prognosis is defined by the organ sites involved and the presence or absence of elevated serum lactate dehydrogenase levels. For patients who present with thin primary tumors without high-risk features (stage I), the long-term disease-specific survival is >95%. In contrast, for patients with distant metastases (stage IV), the median survival is 6 to 8 months, and <10% of patients are alive 5 years after diagnosis.

A number of epidemiologic studies have identified a strong link between the risk of cutaneous melanoma and exposure to ultraviolet (UV) radiation.^{7,8} This initial insight into the molecular basis of this aggressive disease has expanded tremendously over the last two decades through focused molecular analyses and mechanistic studies in preclinical models. More recently, the development of high-throughput sequencing approaches that allow for exome- and genome-wide assessment of molecular changes have led to a rapid increase in the understanding of the molecular heterogeneity and pathogenesis of melanomas. Notably, these studies have demonstrated that melanomas have one of the highest rates of somatic mutations of all solid tumors (Fig. 93.1). The preponderance of the observed mutations consist of CT or GA substitutions, which are strongly associated with UV radiation-induced DNA damage, and thus confirm at the molecular level the important role of this environmental exposure in this disease.⁹ The patterns of somatic

aberrations have also identified a number of key functional pathways that likely contribute to the pathogenesis of this disease. Importantly, many of these findings are rapidly being translated into molecular tests and therapies that are impacting the clinical management and outcomes of patients with this highly aggressive disease.

THE RAS-RAF-MAP KINASE PATHWAY

The RAS-RAF-mitogen-activated protein kinase (MAPK) signaling pathway is a cascade of molecules that is activated by multiple cellular signals and pathways (Fig. 93.2). Signaling through RAS and RAF leads to activation of the ERK1/2 kinases, which regulate a variety of proteins through serine-threonine phosphorylation events and ultimately the transcription of many genes governing cell proliferation, survival, and other critical cellular processes. Examples of transcription factors operant in melanocytes that are regulated by ERK signaling include the microphthalmia-associated transcription factor (MITF, described in detail in the following), various ETS transcription factors, the FOS and JUN immediate early genes, among others.

Extensive genetic and mechanistic studies have unearthed a prevalence of activating MAPK pathway mutations across many tumor types. In particular, activation of this pathway appears to be one of the most frequent and important molecular events in cutaneous melanoma (Fig. 93.3). Toward this end, several MAPK signaling proteins (e.g., RAS and RAF isoforms) are encoded by “classic” oncogenes, and key transcriptional effectors downstream of MAPK also undergo oncogenic dysregulation in melanoma and other cancers. Key MAPK effectors have also been shown to regulate differentiation and senescence in non-transformed melanocytes.

RAS Family GTPases

RAS proteins (H-, K-, and NRAS) are small GTPases that comprise an initial signaling node of the RAS-RAF-MAPK cascade. The discovery of activating mutations in HRAS and KRAS led to investigations that identified mutations in this gene family in multiple cancer types, and thus the significance of this pathway in the pathogenesis of cancer. Activating mutations in NRAS are detected in 20% to 25% of cutaneous melanomas (see Fig. 93.3).¹⁰⁻¹² NRAS mutations are also detected in nevi, particularly congenital nevi.¹³ HRAS mutations are uncommon in cutaneous melanomas, but they are detected in Spitz nevi, which are rare, benign lesions most often diagnosed in children and young adults.¹⁴ Despite their high incidence in other cancer types, KRAS mutations are extremely rare in melanocytic lesions.

In mouse models, overexpression of activated HRAS or NRAS on an Ink4a/Arf-null background results in spontaneous melanoma formation.^{15,16} However, while HRAS-induced melanomas rarely, if ever, metastasize, NRAS tumors frequently metastasize to draining lymph nodes and distal organs, in line with the apparent selection for NRAS over HRAS mutations in human melanomas.

Figure 93.1 The rate of somatic mutations in whole exome sequencing analysis of various types of cancer. Each dot represents the total frequency of mutations (in mutations/Mb) in each exome of the indicated tumor types. Among the 27 tumor types analyzed, melanomas demonstrate the highest median frequency of somatic mutations. AML, acute myeloid leukemia; CLL, chronic lymphocytic leukemia; DLBCL, diffuse large B-cell lymphoma. (Reprinted from Lawrence MS, Stojanov P, Polak P, et al. *Nature*. Vol. 499. London: Nature Publishing Group; 2013:215, with permission.)

Knockdown of *NRAS* in human melanoma cell lines inhibits their viability, indicating dependency on this oncogene for tumorigenicity.¹⁷ Furthermore, shutting off transgene expression in an inducible *NRAS* model caused regression of melanomas that arose following transgene induction, thereby confirming the *RAS* oncogene dependency in these tumors.¹⁸

RAF Kinases

The RAF proteins (*ARAF*, *BRAF*, and *CRAF*) are serine-threonine kinases that comprise critical signaling effectors through the *RAS*-*RAF*-*MAPK* pathway (see Fig. 93.2). While each of these proteins likely plays a role in physiologic signaling, *BRAF* has a central role in the pathogenesis of melanoma. Somatic hotspot mutations in *BRAF* are detected in 40% to 45% of cutaneous melanoma, making them the most common oncogenic aberration detected in this disease to date.¹⁰ Approximately 95% of these mutations result in substitutions of the valine at the 600 position in the protein. The most common mutation (~70% of *BRAF* mutations) is a T→A transversion, resulting in a valine to glutamate amino acid substitution (V600E). Although the T→A transversion is not classically associated with UV-induced damage, *BRAF* V600E mutations appear are more common in melanomas arising at sites with intermittent exposure to UV.¹⁹ Other substitutions, particularly the V600K mutation that represents ~20% of *BRAF* mutations in melanoma, are more common in melanomas with evidence of chronic sun damage (CSD), although the overall rate of *BRAF* mutations in those melanomas is lower compared to tumors without CSD.^{19–22} *BRAF* V600 mutations are an early event in melanomas, as they are also present in the majority (~80%) of benign and dysplastic nevi.²³ In addition to mutations affecting V600, somatic events affecting >20 other sites in *BRAF* have been detected in patients, but overall they are quite rare (total ~5% prevalence).²⁴

BRAF is an immediate downstream target of *RAS* (see Fig. 93.3) in the *MAPK* pathway. The *BRAF*(V600E) mutation and other substitutions at the V600 site confer more than 200-fold induction of kinase activity in vitro.²⁵ Mutations affecting other sites in *BRAF* can have high, intermediate, or low catalytic activity. However, all

of these mutations cause increased activation of *MEK* and *ERK* signaling. This likely occurs in low-activity mutants due to conformational changes that promote heterodimer formation with other *RAF* isoforms, such as *CRAF*, in a multiprotein complex with *RAS* proteins.²⁴ Notably, while *BRAF*(V600) mutations and *NRAS* mutations are mutually exclusive in newly diagnosed melanomas, frequent co-occurrence of *NRAS* mutations with nonactivating *BRAF* mutations has been observed.^{26,27}

Extensive data suggest that wild-type *BRAF* operates on a senescence pathway in benign human nevi. Transgenic expression of *BRAF*(V600E) targeted to melanocytes in zebrafish produced benign nevus-like lesions, whereas invasive melanomas were produced (after extended latency) when crossed into p53-deficient zebrafish.²⁸ Inducible expression of *BRAF*(V600E) alone in murine melanocytes resulted in excessive skin pigmentation and the appearance of nevi containing hallmarks of senescence.²⁹ Human congenital nevi with activating *BRAF* mutations were shown to express senescence-associated acidic β -galactosidase, the classical senescence-associated marker.³⁰ This implied that activated *BRAF* alone is insufficient to induce tumor progression beyond the nevus stage in patients. Interestingly, immunohistochemical staining of nevus tissues found heterogeneous patterns of *INK4A* that only partially overlapped with senescence-associated acidic β -galactosidase, suggesting the presence of *INK4A*-independent pathway(s) operative in oncogene-induced senescence. Expression of *BRAF*(V600E) in murine melanocytes, in the setting of inactivation of *INK4A*, caused melanocyte hyperplasia, but no invasive lesions.³¹ However, concurrent loss of phosphatase and tensin homolog (*PTEN*), a negative regulator of the phosphatidylinositol kinase (*PI3K*) signaling pathway, resulted in 100% penetrance of invasive melanomas that formed spontaneous metastases.

The significance of *BRAF* mutations is now also supported by the functional and clinical effects of inhibiting this target. Early experiments demonstrated that RNAi knockdown of *BRAF* in human melanoma cells with *BRAF*(V600E) mutations inhibits *ERK* activation, induces cell cycle arrest and/or apoptosis, and blunts cell growth.^{32,33} These initial results led to the development and testing of potent and selective inhibitors of the *BRAF*(V600E) protein. Two of these agents (vemurafenib, dabrafenib) have dem-

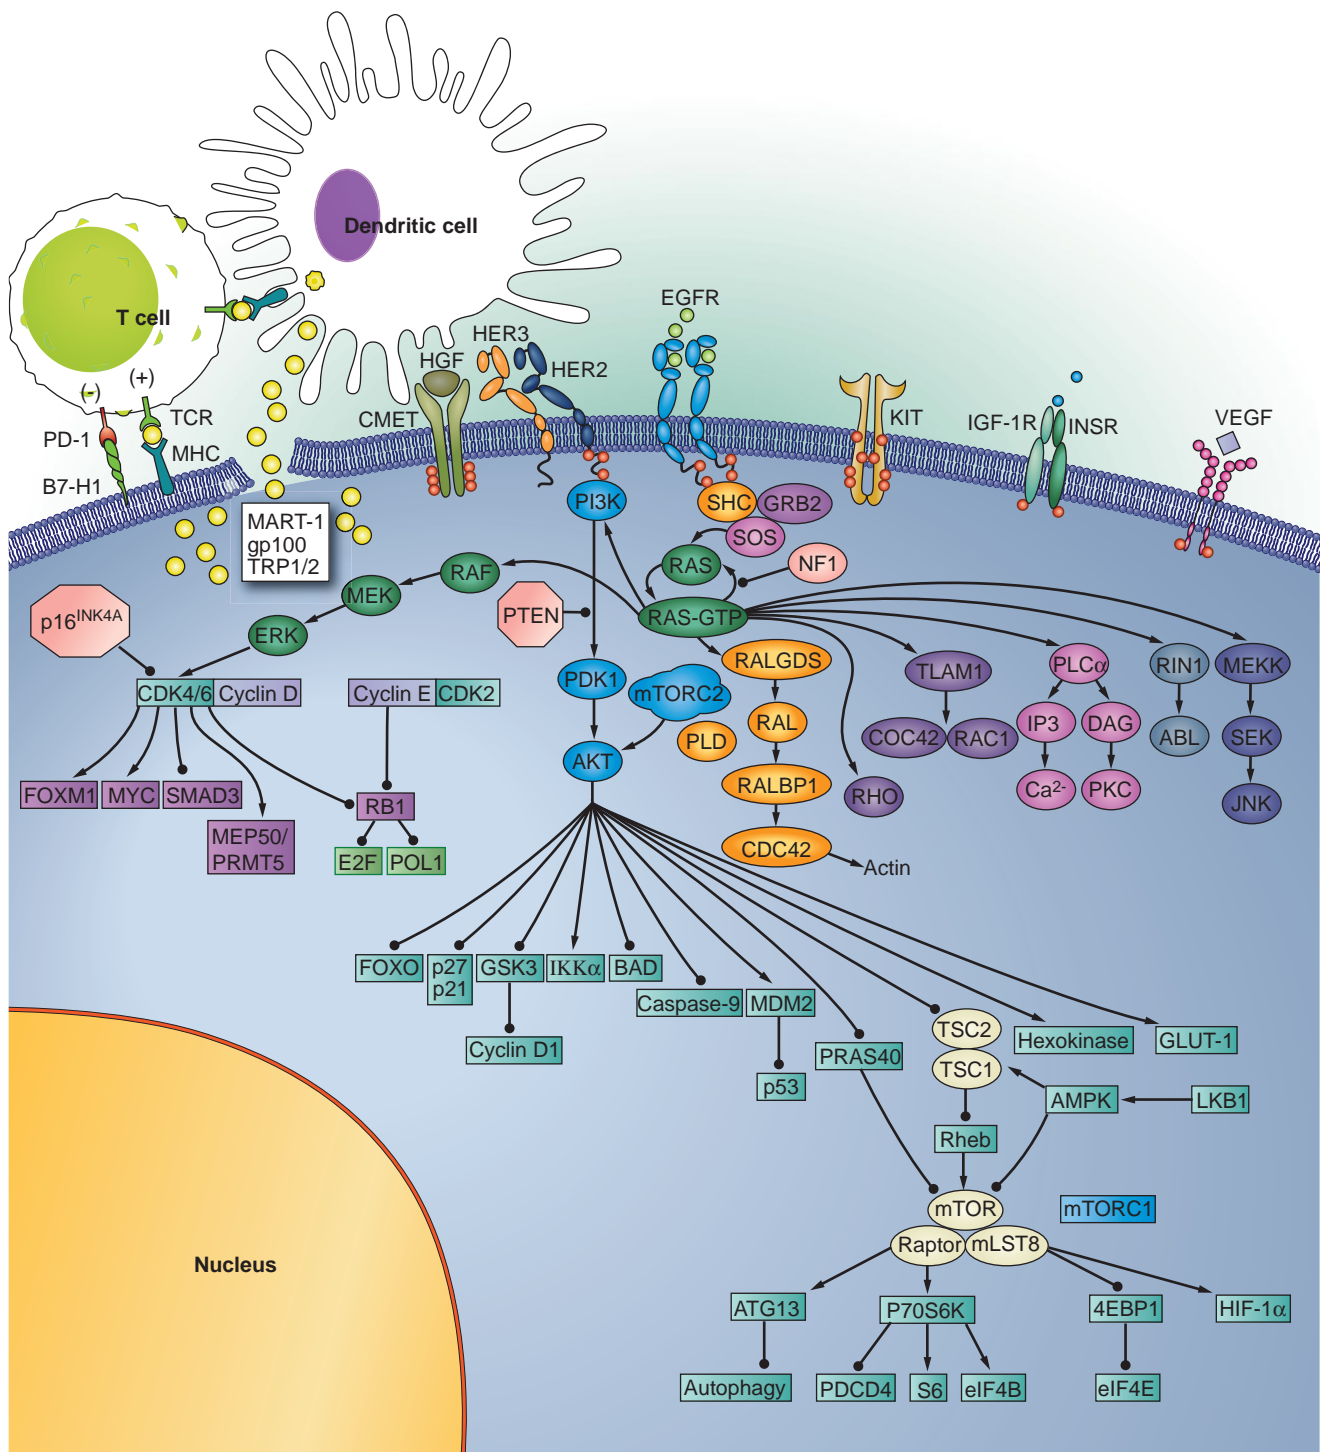

Figure 93.2 Molecular signaling pathways in melanoma. (Reprinted from Sullivan RJ, Lorusso PM, Flaherty KT. *Clinical Cancer Research*. Vol. 19. Philadelphia, PA: American Association for Cancer Research; 2013:5286, with permission.)

onstrated significant improvements in patient outcomes in phase 3 clinical trials, leading to their regulatory approval, while other agents have shown promising results in early testing.^{34,35}

Interestingly, use of these selective inhibitors of BRAF(V600E) causes paradoxical activation of the MAPK pathway in melanomas with a wild-type BRAF, particularly in those tumors that have an activating NRAS mutation.^{36,37} This pathway activation causes increased tumor growth in cell lines and xenograft models, and supports the restricted use of these inhibitors to patients with melanoma with activating BRAF mutations. This paradoxical signaling

effect also appears to be the underlying mechanism of the proliferative cutaneous lesions (keratoacanthomas and squamous cell carcinomas) that are among the most common toxicities of the selective BRAF inhibitors.^{38,39}

While only rarely mutated in melanoma, preclinical studies support the premise that CRAF can also have functional significance in this malignancy. Cells with activating NRAS mutations appear to utilize CRAF predominantly to transmit signals to MEK and ERK.²⁶ While CRAF appears to be largely dispensable in melanomas with BRAF(V600) mutations, it is likely critical for

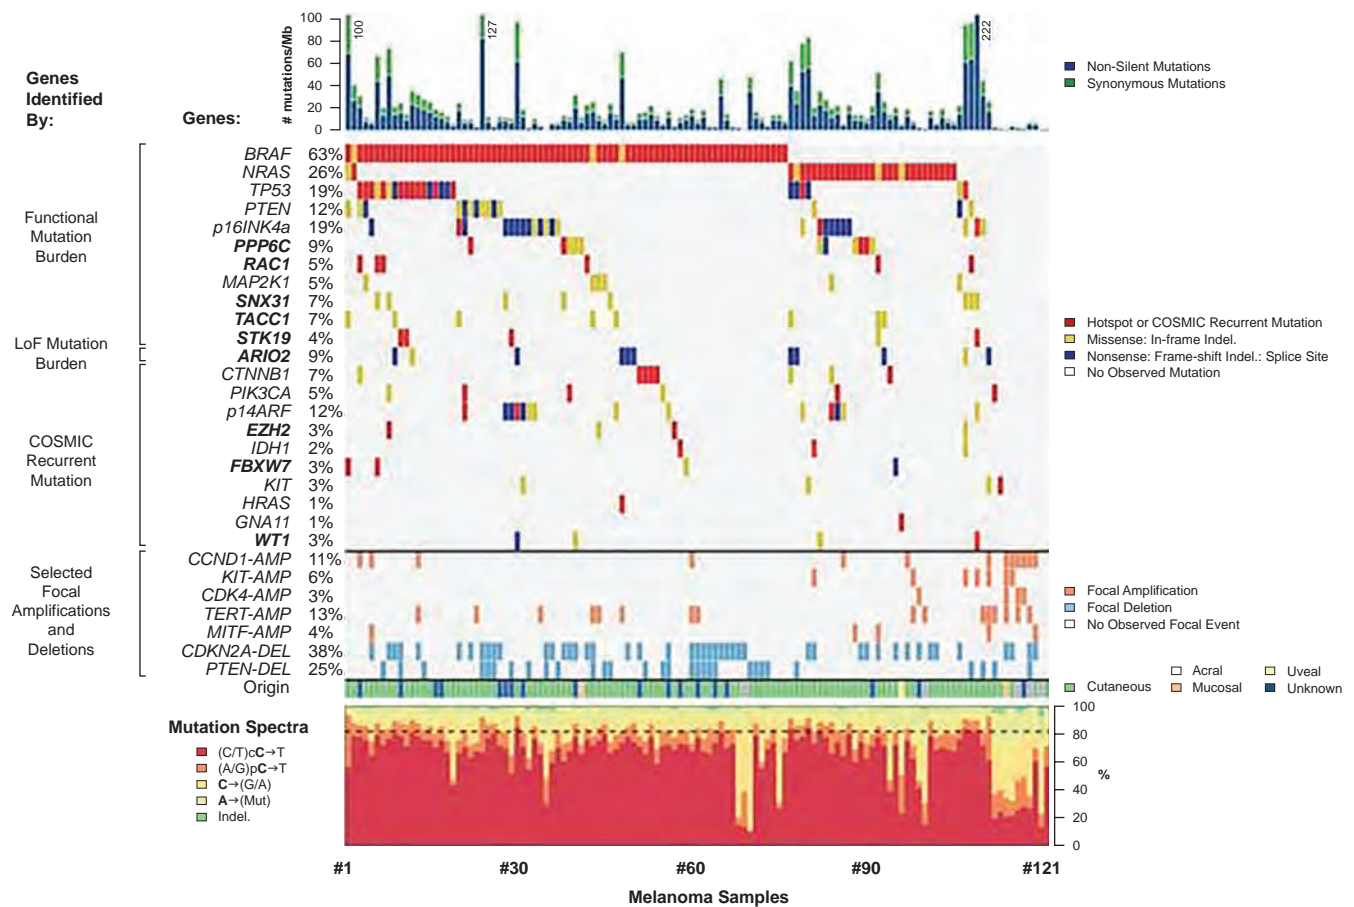

Figure 93.3 A landscape of driver mutations in melanoma. Each row indicates the prevalence of somatic mutations, amplifications, or deletions in each indicated gene in the cohort of 121 melanomas. Each column indicates the somatic events present in that tumor. The mutation spectra for each tumor is illustrated at the bottom of the figure. (Modified from Hodis E, Watson IR, Kryukov GV, et al. *Cell*. Vol. 150. Cambridge, MA: Cell Press; 2012:259, with permission.)

pathway activation through heterodimer formation with nonactivating BRAF mutations, and it may be a therapeutic target in such tumors.⁴⁰ Increased expression and/or signaling by CRAF has also been implicated as a mechanism of resistance to mutant-selective BRAF inhibitors in melanomas with BRAF(V600E) mutations.^{41–43}

MEK1/2

Because the MEK1/2 serine-threonine kinases transmit the critical MAPK signal downstream of RAS and RAF, considerable interest has also emerged regarding these kinases in melanoma biology and therapeutics. MEK1/2 mutations are rare in melanoma, and in cancer in general, in contrast to RAS and BRAF mutations.^{11,12,44} Nonetheless, pharmacologic MEK inhibition presents another possible therapeutic strategy for BRAF- or NRAS-mutant melanomas. Robust preclinical evidence favoring this notion derived from a genetic and pharmacologic analysis showing that various MEK inhibitory compounds demonstrated markedly enhanced potency against BRAF(V600E) cancer cells compared to cell lines lacking oncogenic MAPK pathway mutations.⁴⁵ Treatment with the MEK1/2 inhibitor trametinib as a single agent in patients with metastatic melanoma with BRAF(V600E) or BRAF(V600K) mutations resulted in significant improvements in clinical response rates, progression-free survival, and overall survival compared to chemotherapy, leading to its regulatory approval in 2013.⁴⁶ In addition, combined treatment with selective RAF inhibitors (i.e., dabrafenib) and MEK inhibitors (i.e., trametinib) significantly improves both the rate and duration of clinical responses.⁴⁷ This pivotal observation led to the approval of combined RAF/MEK inhibition for use in BRAF(V600E)-mutant

melanoma. Interestingly, this combination also has less cutaneous toxicity than is observed with single-agent BRAF inhibitors, likely due to blockade of the paradoxical activation of RAS-RAF-MAPK pathway signaling in keratinocytes with RAS mutations.³⁹

While mutant-selective BRAF inhibitors are contraindicated for patients with activating NRAS mutations, preclinical studies have demonstrated that at least some NRAS-mutant melanoma cells were also sensitive to MEK inhibitors.⁴⁵ Recently the MEK1/2 inhibitor MEK162 has demonstrated promising results in patients with metastatic melanoma with NRAS mutations, leading to randomized clinical studies versus chemotherapy.⁴⁸ MEK inhibitors have also demonstrated efficacy in NRAS-mutant melanomas as a part of combinatorial strategies (i.e., with PI3K inhibitors, CDK4 inhibitors, etc.). The safety and efficacy of several of these combinations in patients are currently being investigated in clinical trials.⁴⁹

NF1

A small percentage of melanomas lack BRAF or NRAS mutations; however, MAPK signaling is often still operant in this setting. Recent genome characterization efforts have revealed that the tumor suppressor gene *NF1* undergoes inactivating mutations in a substantial proportion of “BRAF/NRAS wild-type” melanomas.^{11,12} *NF1* encodes neurofibromin, a so-called RAS-GAP whose normal physiologic role involves negative regulation of RAS signaling effected through cleavage of the RAS-GTP. Consequently, loss of *NF1* leads to dysregulated RAS signaling. *NF1* loss is sufficient to drive melanoma genesis together with other known cancer genes in genetically engineered mouse models of melanoma.⁵⁰ More-

over, *NF1* loss has been observed in BRAF-mutant clinical specimens that exhibit resistance to RAF inhibition.^{50,51}

THE MEK PATHWAY AND THERAPEUTIC RESISTANCE

Unfortunately, the impressive clinical effects of RAF and MEK inhibition in BRAF(V600)-mutant melanoma are transient: the vast majority of patients will experience disease progression within one year of treatment (although a subset of patients may enjoy prolonged clinical benefit). Multiple mechanisms of resistance to RAF/MEK inhibition have been described, most of which restore MEK/ERK signaling as the key downstream mechanism. Resistance mechanisms such as *NRAS* mutations⁵² or *NF1* inactivation⁵¹ accomplish this by signaling through C-RAF, which is normally inactive in BRAF-mutant melanoma but can be engaged through homo- or heterodimerization in the setting of upstream RAS signaling. An alternative splice isoform of BRAF also acts through RAF-mediated dimerization.⁴⁵ Certain receptor tyrosine kinase-driven resistance mechanisms may also work in part by augmenting A- and/or C-RAF activity in a RAS-dependent manner.^{42,53} Other resistance effectors may bypass RAF proteins altogether yet still converge on MEK/ERK activation—the kinase COT (encoded by the *MAP3K8* gene) comprises an example of this mechanism.⁵⁴ Alternatively, MEK/ERK signaling may be restored through activating somatic mutations in *MAP2K1* or *MAP2K2*, which encode MEK1 and MEK2 kinases, respectively.^{55,56} Interestingly, *NRAS* and *MAPK2* mutations have been observed in the setting of resistance to both single-agent RAF inhibition and combined RAF/MEK inhibition,⁵⁷ underscoring the importance of sustained ERK signaling as a resistance mechanism to this therapeutic modality.

Although MEK/ERK-independent resistance mechanisms are less well understood, recent data suggest that such effectors may also prove important. For example, a large-scale functional screen for open reading frames whose overexpression produces resistance to MAPK inhibitors identified several dozen genes that can confer resistance to RAF, MEK, and ERK inhibition.⁵⁸ Several of these genes encode proteins that may bypass MEK/ERK signaling altogether, whereas others encode transcription factors known to operate downstream of ERK (such as MITF) or that can otherwise substitute for the ERK-driven transcriptional output. As combinatorial MAPK-directed therapy gains traction in BRAF(V600)-mutant melanoma, such ERK-independent resistance mechanisms are likely to become increasingly manifest.

Cell Cycle Regulators

The RB signaling pathway regulates the entry in and progression through the cell cycle. A significant role for this pathway in melanoma was initially implicated by the finding that germline mutations in this pathway (*CDKN2A*, *CDK4*) are the most frequently detected events in familial melanomas (more than three affected family members). Subsequent studies have demonstrated that somatic aberrations in this pathway are ubiquitous in cutaneous melanoma. Functional studies support that dysregulation of cell cycle entry and progression is critical to the pathogenesis of this disease, and potentially contributes to resistance to RAS-RAF-MAPK pathway inhibitors.

The *CDKN2A* Locus

Germline deletions and activating mutations in the *CDKN2A* locus on chromosome 9p21 are the most common event (~40%) prevalent in familial melanoma. Somatic mutations and deletions, or epigenetic silencing, are detected in as many as 70% of cutaneous melanomas.^{59,60} Thus, disruption of *CDKN2A* function

likely plays a central role in melanoma pathogenesis. The *CDKN2A* locus contains an unusual gene organization, which allows for two separate transcripts and corresponding tumor suppressor gene products to be produced: p16^{INK4A} and p19^{ARF} (see Fig. 93.2). Loss of p16^{INK4A} results in the suppression of retinoblastoma (RB) tumor suppressor activity via increased activation of the CDK4/6-cyclin D1 complex; loss of ARF (p14^{ARF} in human and p19^{ARF} in mouse) downmodulates p53 activity through increased activation of MDM2. Thus, deletion of the entire locus accomplishes the inactivation of two critical tumor suppressor pathways: RB and p53. Homozygous deletion of exons 2 and 3 of the mouse *Cdkn2a* homolog predisposed to a high incidence of melanomas when combined with an activated *HRAS* transgene in melanocytes.¹⁵ Thus, *CDKN2A* lesions may “prime” melanocytic tissue for neoplasia.

INK4A

The specific significance of INK4A function is supported by the clinical identification of intragenic mutations of *INK4A* that do not affect the *ARF* coding region that sensitize germline carriers to the development of melanomas.⁶¹ In addition, in familial melanomas that lack *CDKN2A* aberrations, the most commonly identified genetic event is a point mutation in *CDK4* that disrupts the interaction of that protein with INK4A.⁶² In a mouse model engineered to be deficient only for Ink4a (with intact ARF), melanoma formation was observed in cooperation with an oncogenic initiating event (activated *HRAS*), albeit with a longer latency than in mice with deletions affecting the entire locus.⁶³ Notably, the tumors in these mice were also found to harbor either deletion of ARF or mutation of p53. Therefore, while INK4A is a bona fide tumor suppressor, additional genetic dysregulation of the p53 pathway seems obligatory for melanoma genesis, at least in the mouse.

CDK4

CDK4 is a direct target of inhibition by p16^{INK4A} (see Fig. 93.2) and is a primary regulator of RB activation. As noted previously, germline mutations of *CDK4* that render the protein insensitive to inhibition by INK4A (e.g., Arg24Cys) have been identified in a melanoma-prone kindreds.⁶¹ These tumors retain wild-type INK4A function, suggesting that INK4A is epistatic to *CDK4* and that RB pathway deregulation is central to melanoma genesis. Somatic focal amplifications of *CDK4* are also observed (albeit rarely) in sporadic melanomas.⁶⁴ Carcinogen treatment induced melanomas in the animals without somatic Ink4a inactivation, similar to the mutual exclusivity observed in familial melanoma.⁶⁵ *CDK4* interacts with cyclin D proteins (see the following) to drive progression through the G1/S cell cycle checkpoint. Recently, small molecule inhibitors of *CDK4* and other CDKs have entered clinical trials in several tumor types, including melanomas. In particular, both tumor genetic data and recent results from genetically engineered mouse models provide a rational basis for combining CDK and MAPK pathway inhibition in *NRAS*-mutant melanoma.¹⁸

CCND1

CCND1 encodes the CyclinD1 kinase, which forms a complex with *CDK4* or *CDK6* to inactivate RB1 (see Fig. 93.2). Amplification of the *CCND1* locus has been identified in relatively rare event in cutaneous melanomas (5% to 10%).^{11,66} However, this molecular event is enriched in cutaneous melanomas that do not have mutations in BRAF or *NRAS*.^{11,19} Although it is rare in melanomas with BRAF(V600) mutations, amplification of CyclinD1 has been implicated as predictor of resistance to BRAF inhibitors in preclinical models, and increased copy number of *CCND1* correlated with shorter progression-free survival in one study of patients with metastatic melanoma treated with the BRAF inhibitor dabrafenib.^{67,68}

RB1

Germline mutations in *RB1* confer predisposition to melanoma in patients who have survived bilateral RB.⁶⁹ These melanomas exhibit loss of heterozygosity of the remaining wild-type *RB1* allele. In such patients, estimates of increased lifetime risk of melanoma range from 4- to 80-fold. The *RB1* gene locus has been found deleted in some primary cutaneous melanomas,¹³ and *RB1* may also be subject to genomic rearrangement in rare instances.¹⁴

The p53 Pathway

The p53 pathway is critical for maintenance of the normal genome by regulating a multiplicity of mechanisms, including cell cycle checkpoints, DNA damage repair activation, and the appropriate induction of apoptosis. Mutations in the *TP53* gene occur in >50% of all tumors. While initial studies suggested that the *TP53* locus is rarely mutated in human melanomas, whole exome studies have identified mutations in ~20% of tumors, generally in tumors without mutations or deletions affecting *CDKN2A* and *P14^{ARF}*.¹¹ Amplification of *MDM2*, which inhibits P53 function, has also been detected in melanomas with intact *CDKN2A*.⁶⁴ Functionally, loss of p53 cooperates with activated BRAF in zebrafish, and with activated HRAS in mice, to induce melanomas.^{28,70} Thus, while *TP53* is rarely deleted in human melanomas, inactivation of its pathway appears critical for melanomagenesis.

The Phosphatidylinositol 3-Kinase Pathway

The PI3K-AKT pathway is affected by activating oncogenic events more frequently than any other pathway in cancer.⁷¹ PI3K phosphorylates lipids in the cell membrane, causing the recruitment of proteins that have a pleckstrin homology domain. One of the key proteins regulated by PI3K is the serine-threonine kinase AKT. AKT is phosphorylated at two key residues (Ser473 and Thr308) at the cell membrane, activating its catalytic activity. Activated AKT phosphorylates multiple effector proteins, including GSK3, P70S6K, PRAS40, BAD, and more, which regulate cellular processes including proliferation, survival, motility, angiogenesis, and metabolism (see Fig. 93.3). The pathway can be activated genetically in cancer both by activating mutations (i.e., in *PIK3CA*, *AKT1*) and loss of function events (i.e., *PTEN*, *TSC2*) in components of the pathway. The PI3K-AKT pathway is also a critical effector pathway of RAS proteins and many growth factors and their receptors, which are also frequently aberrant in cancer.

As described previously, activation of the RAS-RAF-MAPK pathway is a nearly ubiquitous event in cutaneous melanoma. Overall, genetic events in the PI3K-AKT pathway are less common.¹¹ However, multiple lines of evidence support that PI3K-AKT signaling functionally complements RAS-RAF-MAPK activation in at least a subset of melanomas. Moreover, recent data indicates that PI3K pathway mutations may arise in the setting of resistance to RAF inhibition.^{56,72}

Phosphatase and Tensin Homolog

Of the PI3K pathway mutations that do occur, losses of chromosome 10q encompassing *PTEN* tumor suppressor is the most frequent, the caveat being that additional tumor suppressor(s) may reside in this region (see the following). *PTEN* normally downregulates phosphorylated AKT via suppression of the second messenger PIP₃ (see Fig. 93.3). Loss of *PTEN* has been shown to result in increased AKT activity in multiple cancer types, including melanoma. In melanoma, somatic point mutations and homozygous deletions of *PTEN* are relatively rare. However, although allelic loss of *PTEN* is observed only in about 20% of melanoma, loss of expression of *PTEN* is reported to be in the range of 30% to

40% of melanoma tumors.^{27,73} In multiple studies, loss of *PTEN* has shown to occur in melanomas with activating BRAF mutations and in melanomas with wild-type BRAF and NRAS, but it is extremely rare in tumors with NRAS mutations.⁷⁴

As mentioned previously, in a mouse model the presence of simultaneous *PTEN* loss and oncogenic BRAF induction in melanocytes resulted in 100% penetrance of invasive, metastatic melanomas.³¹ Notably, loss of *PTEN* alone did not cause a melanocytic phenotype. While this complementation of BRAF and *PTEN* supports the overlap of these alterations that is observed clinically, preclinical models have also demonstrated that loss of *PTEN* can promote melanoma motility, invasion, and metastasis in the setting of NRAS mutations.⁷⁵ However, the significance of this finding is unclear due to the very low prevalence of this occurring naturally. The functional significance of *PTEN* loss in BRAF/NRAS wild-type melanomas also remains to be elucidated. Functionally, ectopic expression of *PTEN* in *PTEN*-deficient melanoma cells can abolish phospho-AKT activity, induce apoptosis, and suppress growth, tumorigenicity, and metastasis.⁷⁶ Many different inhibitors of the PI3K-AKT pathway have been developed and are undergoing clinical testing. Previous data suggest that the presence of different molecular mechanisms of PI3K-AKT pathway activation may correlate with activation and functional dependence on different pathway effectors.⁷⁷ Preclinical studies support that AKT and PI3K are attractive targets for melanomas with loss of *PTEN*.⁷⁸

AKT

Loss of *PTEN* in melanoma tumors and cell lines correlates with markedly increased expression of phospho-AKT (indicative of activation).⁷³ In addition to loss of *PTEN*, AKT can be activated by point mutations that affect the pleckstrin homology domain of the proteins. Such mutations of *AKT1* have been detected in multiple tumor types.⁷⁹ Analysis of melanoma tumors and cell lines identified the same mutation as a rare event in melanoma (~1% prevalence), but also discovered the analogous mutation in *AKT3*, which has not been reported in other cancers.⁸⁰ Each tumor with a mutation in *AKT1/3* had a concurrent BRAF(V600) mutation. Copy number gain of the *AKT3* locus has also been detected in melanomas, and functional studies support that metastatic melanomas specifically demonstrate phosphorylation of and functional dependence upon that AKT isoform.^{76,81}

Phosphatidylinositol Kinase

Hotspot mutations in *PIK3CA*, which encodes the predominant catalytic subunit of PI3K, are common in multiple cancer types, including breast, colon, and lung tumors.⁸² Mutations in *PIK3CA* are very rare (<2%) in melanomas, and often affect residues of unknown functional significance.⁸³ Despite this clinical observation, preclinical studies have shown that the presence of simultaneous activating PI3K and BRAF mutations in melanocytes can induce melanomas in mouse models.⁸⁴

Receptor Tyrosine Kinases

Receptor tyrosine kinases (RTK) are a diverse family of transmembrane kinases that have been implicated in many neoplasms. Several RTKs map to known regions of recurrent melanoma DNA copy number gain or amplification, with corresponding alterations in their expression levels.

The RTK c-KIT and its ligand (stem cell factor) were both initially shown to play essential roles in melanocyte development. Mutation of either KIT or RTK results in pigmentation deficiencies, and injection of c-Kit blocking antibody in mice was used to identify the presence of melanocyte stem cells within hair follicles.⁸⁵ However, numerous immunohistochemical studies linked progres-

sive loss of c-KIT expression with the transition from benign to primary and metastatic melanomas.⁸⁶ Thus, at first glance, KIT appeared to be inactivated during melanoma genesis and progression. However, more recently activating mutations and amplification of the *KIT* gene have been identified in cutaneous melanomas with evidence of CSD or that arise on acral surfaces (palms, soles, nail beds).⁸⁷ The point mutations in the *KIT* gene generally occur in the same regions affected in gastrointestinal stromal tumors, where the functional significance of these mutations has been proven by the clinical efficacy of KIT inhibitors for that disease.⁸⁶ Functional studies support that KIT mutations can activate multiple signaling pathways, particularly the PI3K-AKT pathway.⁸⁸ Inhibition of KIT in melanoma cell lines with recurrent point mutations results in growth inhibition and/or apoptosis.⁸⁹ In patients, initial clinical trials of the KIT inhibitor imatinib in populations of patients with KIT mutations and/or amplifications have reported clinical response rates of 10% to 30%.^{90,91} This is a much higher response rate than was observed in three previous clinical trials of imatinib in patients with unselected melanoma (~1% response rate), but is much lower than the activity observed in patients with gastrointestinal stromal tumor (>70%).⁸⁶ Thus, although many of the clinical responses in patients with KIT mutations have been dramatic and durable, research is ongoing to further understand the significance of KIT mutations, and to develop more effective clinical strategies for patients with melanoma patients with KIT mutations.

Overexpression of the RTK c-MET and its ligand, HGF, is correlated with melanoma progression. Copy gains involving the c-MET locus at 7q33-qter are associated with invasive and metastatic cancers in humans,⁹² and elevated MET/HGF expression is correlated with metastatic ability in murine melanoma explants.⁴⁷ HGF/SF overexpression in a transgenic mouse model triggered spontaneous melanoma formation after a long latency (up to 2 years); however, time to tumor onset was greatly reduced by exposure to UVB or *Ink4a/Arf* deficiency.⁹³ More recently, independent groups of investigators demonstrated that c-MET may be activated by HGF produced by supporting cells in the tumor microenvironment of melanomas.^{53,94} This paracrine effect resulted in activation of the PI3K-AKT pathway in the tumor cells and caused resistance to MAPK pathway inhibitors. The clinical utility of c-MET inhibition in melanoma is being tested in ongoing clinical trials.

A sequencing-based study of the tyrosine kinome in melanoma found that *ERBB4* mutations may affect as many as 20% of melanomas.⁹⁵ Unlike other well-known oncogene mutations, the *ERBB4* mutations identified in this study were mostly nonrecurrent (e.g., the same amino acid or conserved region was rarely affected). However, *ERBB4* mutations produced increased activation of the receptor itself and PI3K-AKT pathway signaling, as well as dependence upon the corresponding protein for viability. Despite these promising initial findings, the clinical significance of *ERBB4* inhibitors in melanoma remains unclear.

MELANIN SYNTHESIS PATHWAY

MITF

MITF encodes a lineage transcription factor whose function is critical to the survival of normal melanocytes. The identification of *MITF* amplification in melanoma defined this transcription factor as a central modifier of melanoma.⁹⁶ In so doing, this discovery identified a novel class of oncogenes termed *lineage survival* oncogenes.⁹⁷ That is, a tumor may “hijack” extant lineage survival mechanisms in the presence of selective pressures to ensure its own propagation. The elucidation of *MITF* as an oncogene took a cross-tissue approach, wherein the NCI-60 cell line panel representing nine tumor types was subjected to both gene expression and high-density single-nucleotide polymorphism array analysis.⁹⁶ A recurrent gain of 3p13–14 significantly segregated

melanoma from other tumor classes, with *MITF* as the only gene in the region showing maximal amplification and overexpression. *MITF* amplification was subsequently detected in 10% of primary cutaneous and 15% to 20% of metastatic melanomas by fluorescence in situ hybridization, correlating with decreased survival in Kaplan-Meier analyses of 5-year patient survival. Exogenous *MITF* showed transforming capabilities in immortalized primary human melanocytes in combination with activated BRAF. Additionally, inhibition of *MITF* in cell lines showing 3p13–14 amplification reduced growth and survival and conferred sensitivity to certain anticancer drugs. *MITF* gene disruption leads to coat color defects in mice and pigmentation defects in humans, due to diminished viability of melanocytes. This suggested that *MITF* was essential for the lineage survival of melanocytes, supporting the contention that it is also critical for the survival of melanomas. More recently, a germline variant (E318K) of *MITF* has been identified that confers an increased risk of developing melanoma.^{98,99}

The downstream elements of the *MITF* pathway include both pigment enzyme genes as well as genes involved in proliferation, survival, and metabolism.^{100,101} *MITF* intersects with a number of established melanoma pathways, including the transcriptional activation of *INK4A*, *c-Met*, and *CDK2*.¹⁰² Moreover, *MITF* is regulated by both MAPK signaling and c-KIT.^{100,103} Recently, the ETS transcription factor *ETV1* was found to positively regulate *MITF* expression in melanoma, and *ETV1* may function as an amplified melanoma oncogene in its own right.¹⁰⁴ Collectively, these observations place *MITF* in a central role of melanoma signal integration.

The MC1R Pathway

Pigmentation exerts a major influence on skin tumor susceptibility, as it is well documented that fair skin is more sensitive to UV radiation and melanoma genesis. The mechanism underlying this observation is partially explained by the protective effects of melanin, which is produced by melanocytes and distributed to interfollicular keratinocytes. Genetically, the red hair color/pale skin (RHC) phenotype is linked to variant alleles of the melanocyte-specific melanocortin 1 receptor gene (*MC1R*), which is central to melanin synthesis.¹⁰⁵ The ligand for the G-protein-coupled *MC1R* is the MSH peptide, which activates downstream signaling consisting of a cAMP-CREB/ATF1 cascade, culminating in the induced expression of *MITF*. Not all individuals carrying RHC alleles have identical melanin production, yet increased risk for melanoma genesis remains notable regardless,¹⁰⁶ implying that melanin-independent mechanisms might impact the susceptibility of RHC carriers. One possible node is cAMP, the *MC1R* as second messenger, which may activate pathways incompletely understood at present, such as MAPK and PI3K.¹⁰⁷

Experiments have implicated the MSH/*MC1R* pathway in the normal UV pigmentation (tanning) response in skin, a response that is linked to skin cancer (and melanoma) risk in humans. A “redhead” mouse model (frameshift mutation in *MC1R*) was used to demonstrate that the UV tanning response is dependent on *MC1R* signaling, because keratinocytes respond to UV by strongly upregulating expression of MSH. The “fairskin” phenotype was rescued by topical administration of a small molecule cAMP agonist.¹⁰⁸ The resulting dark pigmentation in genetically redhead mice was protective against UV-induced skin carcinogenesis. Subsequent analyses revealed that the p53 tumor suppressor protein may function as a “UV sensor” in keratinocytes, translating UV damage into direct transcriptional stimulation of MSH expression.¹⁰⁹

RAC1

RAC1 is a member of the Rho family of small GTPases that are regulators of cytoskeletal reorganization and cell motility. Re-

cently, two whole exome sequencing studies of >100 melanomas each identified hotspot mutations in *RAC1* that result in a P29S substitution.^{11,12} Overall, the mutation was detected in 5% to 10% of samples, making it the third most common gene, after *BRAF* and *NRAS*, to be affected by hotspot mutations in the coding region. Initial characterization of the mutation confirmed that it conferred increased activity to the *RAC1* protein, and promoted cell proliferation and motility *in vitro*. The overall clinical significance of the *RAC1* P29S mutation awaits studies determining its clinical associations and functional evaluation of its inhibition.

Telomerase

Telomere stabilization through telomerase dysregulation has long been recognized as a hallmark of carcinogenesis in many cancers. However, the molecular basis for altered telomerase regulation in cancer has remained obscure. Analysis of whole genome sequencing data from a collection of melanoma tumors led to the unexpected discovery of two highly recurrent mutations affecting the promoter of *TERT*, which encodes a key catalytic component of the telomerase enzyme complex.^{110,111} Both mutations generate consensus ETS transcription factor binding motifs in the setting of an identical 11-nucleotide stretch, suggesting a gain-of-function effect. Since this index observation, multiple studies have confirmed the high frequency of *TERT* promoter mutations in melanoma and other tumor types, and that the presence of these mutations is associated with enhanced *TERT* expression. Thus, melanoma genetic studies produced the first example of a highly recurrent functional mutation that falls within the regulatory region of a gene.

MOLECULAR GENETICS OF MELANOMA: LOOKING AHEAD

The genetic and molecular understanding of melanoma, and its impact on therapy, is currently in the midst of a transformative era. The last decade witnessed an almost exponential increase in our understanding of the pathogenesis of this disease. Massively parallel sequencing technology has made it possible to obtain the complete sequence of entire cancer genomes or “exomes” (protein coding region of the genome) at ever diminishing costs. Together with developments in computational biology, these advances are rapidly bringing forth new understanding of cancer genome alterations and the tumorigenic mechanisms that result. One of the first cancer genomes to be sequenced was that of a cell line (and its paired normal counterpart) derived from a patient with metastatic melanoma.¹¹² This effort uncovered more than 33,000 somatic base substitutions, of which 187 were nonsynonymous coding mutations. As expected, most base mutations were C→T transitions indicative of UV exposure.

This initial discovery provided a glimpse into one of the central challenges of melanoma research: to identify which somatic changes are meaningful. The high UV-associated base mutation rate in melanoma suggests that nearly 2% of all genes may harbor nonsynonymous coding mutations in a typical cutaneous melanoma, most of which are likely to be “passenger” events with little biologic consequence to melanoma genesis or progression. Thus, cataloging all significant genomic alterations that might represent “driver” events will require not only sequencing hundreds of tumor specimens but also the principled application of increasingly sophisticated analytical methods for data deconvolution. Initial insights toward this end emerged from a whole-exome sequencing study of melanoma, which utilized a computational algorithm designed to model the effects of evolutionary selection on the cancer genome.¹¹ This approach facilitated the discovery of several new melanoma genes that might otherwise have been obscured by the high UV-associated mutation rates pervasive in melanoma genomes. Concomitantly, large-scale US (Cancer

Genome Atlas) and international efforts (International Cancer Genomic Consortium) have taken on the ambitious goal of comprehensively characterizing the genomes of diverse human tumors including melanomas.¹¹³ Thus, it seems certain that the next decade will witness additional major breakthroughs in melanoma genome characterization that inform the biology and treatment of this malignancy.

While sequencing of large numbers of melanomas will help to identify which mutations are statistically significant, additional approaches are needed to distinguish the complete spectrum of functional “drivers” of melanoma genesis, progression, and maintenance. Such genetic events may confer transforming activity, dictate prognosis, or correlate with responsiveness (or resistance) to emerging targeted therapeutics. While the initial exome sequencing efforts in melanoma have been very informative, they have not included parallel characterization of other molecular characteristics, such as DNA methylation, mRNA and miRNA expression, protein expression and activation, and clinical characteristics and outcomes. The availability of all of these types of data will allow for integrated analysis approaches that will help to elucidate key molecular events and pathways. In addition, hypotheses about critical drivers of melanoma biology will benefit from functional testing. Increasingly, such testing is being performed, at least initially, through the use of high-throughput screening methods using RNAi libraries, collections of small molecules, and/or expression libraries of open reading frames of genes of interest. These approaches allow not only for evaluation of individual genes/targets, but also for more global approaches for data analysis to identify key networks and pathway. Such approaches can help to tailor investigations to focus on individual genes which may be most important functionally or most exploitable clinically.

One challenge in characterizing the molecular biology of melanoma is the recognition that it can be impacted by increasingly effective therapeutics. As noted earlier, multiple studies have been undertaken to characterize the molecular basis of resistance. To date, all studies that have been reported have identified the continued presence of the same mutation in the *BRAF* gene at the time of disease progression that was present before treatment was started.¹¹⁴ At the same time, a variety of new genomic features have been identified in the progressing lesions that confirm certain longstanding assumptions while challenging others. As noted earlier, *NRAS* mutations arise alongside mutated *BRAF* in the progressing lesions of ~25% of patients.⁵² This stands in marked contrast to the mutual exclusivity of these mutations in treatment-naïve tumors, and highlights how such studies must not be constrained by assumptions based on previous observations about the molecular biology of this disease. On the other hand, while some mutations in *MEK1/2* cause marked resistance to both *BRAF* and *MEK* inhibitors, in other cases the presence of *MEK1* mutations does not preclude clinical response to *RAF* inhibition.^{55,115} Thus, not all *MEK1* mutations are equivalent, similar to prior findings involving distinct *BRAF* mutations.²⁴ The characterization of progressing lesions has also confirmed the molecular heterogeneity of melanoma. Such heterogeneity has been demonstrated by the finding of independent resistance mechanisms within different progressing tumors of individual patients, and within different regions of individual tumors.^{72,115,116}

In addition to the aforementioned advances in the field of targeted therapy, melanoma treatment is being revolutionized by improved understanding and targeting of the antitumor immune response. Ipilimumab, an antibody that blocks the inhibitory *CTLA4* molecule on the surface of T-cells, was the first therapy to ever demonstrate a survival benefit in a randomized clinical trial in patients with metastatic melanoma, and it gained regulatory approval in 2011.¹¹⁷ Agents that target other inhibitory molecules, including *PD-1* and *PD-L1*, have recently demonstrated very promising clinical safety and activity in early phase clinical trials.^{118,119} While the resistance studies described previously focused on the molecular biology of resistance to *MAPK* pathway inhibitors, there is also growing evidence that somatic mutations

may be critical to the effectiveness of immunotherapy.¹²⁰ In addition to creating new antigens that may be recognized by the immune systems, oncogenic signaling pathways in tumors can also influence the antitumor immune response.^{121,122}

In the future, integration of melanoma molecular biology with a growing knowledge of the tumor microenvironment and the im-

mune system will likely be needed to propel additional discoveries. While this presently stands as a daunting task, the remarkable progress of the last decade provides a proof-of-concept that advancing our understanding of the molecular basis of this disease will have a tremendous positive impact on the quality of life and survival of patients with this highly aggressive disease.

94 Cutaneous Melanoma

Antoni Ribas, Craig L. Slingluff, Jr., and Steven A. Rosenberg

INTRODUCTION

Melanoma arises from the malignant transformation of the melanocyte, the cell responsible for the production of the pigment melanin. Precursor melanocytes arise in the neural crest and, as the fetus develops, migrate to multiple areas in the body including the skin, meninges, mucous membranes, upper esophagus, and eyes. Melanomas can arise from any of these locations through the malignant transformation of the resident melanocytes. By far the most common location is the hair follicle-bearing skin arising from melanocytes at the dermal/epidermal junction. In the National Cancer Database, 91.2% of melanomas are cutaneous, 5.3% are ocular, 1.3% are mucosal, and 2.2% are of unknown primary site.¹ Each of these types has significant differences in the etiology and genetic makeup, in particular related to the degree of ultraviolet (UV) radiation exposure and their frequency of driver oncogenic mutations. The current understanding of melanoma biology comes from studies of genetic analyses of melanomas correlated with clinicopathologic presentations, which have elucidated two key features of this cancer: (1) cutaneous melanoma, as opposed to mucosal or uveal melanoma, is usually a carcinogen-induced cancer with a high mutational load, demonstrated by the molecular fingerprinting of UV light damage, and (2) the majority of melanomas are dependent on a particular oncogenic signaling pathway, the mitogen-activated protein kinase (MAPK) pathway, through usually mutually exclusive driver mutations in cKit, NRAS, BRAF, GNAQ or GNA11.²⁻⁶ Cutaneous melanomas arising from the trunk and extremities, which are associated with intermittent UV radiation exposure, have high rates of BRAF (50%) or NRAS (20%) mutations.^{2,7,8} Mucosal and acrolentiginous melanomas, with low rates of UV radiation exposure, have lower rates of BRAF mutations (5% to 20%) and higher rates of KIT mutations (5% to 10%).² The great majority of uveal melanomas have mutually exclusive mutations in the alpha subunits of G-protein-coupled receptors GNAQ and GNA11.^{3,4}

The primary focus of this chapter is on cutaneous melanoma, but summary information is presented for the other forms of melanoma, as well as on the subtypes of cutaneous melanoma.

MOLECULAR BIOLOGY OF MELANOMA

Mutational Landscape in Melanoma

Studies of whole exome sequencing (sequencing of the approximately 1.6% of the genome that encodes for expressed proteins) and whole genome sequencing of melanomas compared to matched normal DNA of the same patients are leading to a greatly improved understanding of the genomic alterations in melanoma. The studies of the mutational load of cutaneous melanomas by next generation sequencing demonstrate that melanoma has significantly more sequence variations per megabase of DNA compared to most other cancers. For example, melanomas have 15 times more mutations per megabase of DNA than colorectal cancer and 4 times more than lung cancer.⁹ As a high proportion

of these mutations are cytosine to thymine (C>T) substitutions, typical of UV radiation-induced thymine dimmers, it is highly likely that the high rate of sequence variants in melanoma is due to the role of UV as the principal carcinogen in the disease.¹⁰⁻¹²

Two studies have reported on exome sequencing of relative large series of melanomas compared to normal matched DNA. After sequencing the exomes of 147 melanomas, it became evident that sun-exposed melanomas had markedly more UV-like C>T somatic mutations compared to sun-shielded acral, mucosal, and uveal melanomas. These studies confirmed the recurrent mutations in BRAF, NRAS, and cKit. Newly identified recurrently mutated cancer genes included PPP6C, encoding a serine/threonine phosphatase in 12% of sun-exposed melanomas, and were mutually exclusively in tumors with mutations in BRAF or NRAS. Furthermore, an activating mutation in RAC1(P29S) was noted in 9.2% of sun-exposed melanomas.¹¹ In a similar study, analysis of large-scale melanoma exomes from 121 paired samples¹² also confirmed the recurrent BRAF, NRAS, and cKIT mutations, and discovered six recurrently mutated melanoma genes (PPP6C, RAC1, SNX31, TACC1, STK19, and ARID2), two of which are the same as in the other study. Integration with chromosomal copy number data contextualized the landscape of driver mutations, providing oncogenic insights in BRAF- and NRAS-driven melanoma as well as those without known NRAS/BRAF mutations. In this study, the authors found a higher than expected number of genetic events dysregulating the RB and p53 pathways, which had previously thought to be mostly intact in melanoma.¹²

The first fully sequenced whole genome of any cancer was a melanoma cell line compared to a lymphoblastoid cell line generated from the same patient to provide the comparing source of normal DNA.¹⁰ This study provided the first comprehensive catalogue of somatic mutations from an individual cancer. The dominant mutational signature reflects DNA damage due to UV light exposure. It also revealed an uneven distribution of mutations across the genome, with a lower prevalence in gene footprints, which indicated that DNA repair preferentially functioned in areas with transcribed regions. There are ongoing efforts to perform whole exome sequencing in large panels of melanomas. The largest effort is The Cancer Genome Atlas. It will report on whole exome sequencing in over 500 melanoma samples compared to normal exomes, with a subset of cases additionally undergoing whole genome sequencing, DNA methylation studies, RNA sequencing, microRNA sequencing, and reverse phase protein array analysis of phosphorylated proteins.

The studies of whole genome sequencing will be important to understand melanoma genetic alterations in nontranscribed genes since there can also be recurrent mutations in them. This is exemplified by the demonstration of two very common mutations in the promoter of telomerase reverse transcriptase (TERT) by two independent research groups. TERT is the gene coding for the catalytic subunit of telomerase. In one of the studies,¹³ mutations in the TERT promoter were reported in 71% of melanomas examined. The mutations increased the transcriptional activity from the TERT promoter by two- to four-fold. This information may be of high relevance beyond melanoma, since examination of 150 cancer cell lines derived from diverse tumor types revealed the same mutations

in 24 cases (16%). The other group reached the same conclusion by investigated a melanoma-prone family through linkage analysis and high-throughput sequencing.¹⁴ They identified the same TERT promoter mutations as disease-segregating germline mutations. When they screened TERT promoter mutations in sporadic melanoma, they found them in 74% of human cell lines derived from metastatic melanomas and in 33% of primary melanomas.

Driver Mutations in Melanoma

Melanoma has become a notable example of a cancer histology dependent upon driver oncogenic mutations in the MAPK pathway, with additional genetic alterations in other pathways leading to uncontrolled cell growth and avoidance of apoptosis (Fig. 94.1). There is evidence of MAPK activation by defined point mutations in at least 70% of melanomas, resulting in constitutive signaling leading to oncogenic cell proliferation and escape from apoptosis.¹⁵ The aberrations that lead to MAPK pathway activation in most cutaneous and mucosal melanomas consist in usually mutually exclusive activating mutations in the receptor tyrosine kinase KIT (2% to 3%), the G-protein neuroblastoma RAS viral oncogene homolog (NRAS) (15% to 20%), and the serine-threonine kinase BRAF (40% to 50%).³⁻⁶ Uveal melanomas have a distinct set of driver mutations in GNAQ and GNA11, which are the alpha subunits of G-protein-coupled receptors.^{3,4}

Mutations in KIT are found in exons 9, 11, 13, and 17, and there is no one predominant point mutation.⁶ Because of this, molecular

testing for KIT mutations must evaluate multiple regions of the gene by extended sequencing or multiplexed polymerase chain reaction (PCR) tests. Emerging evidence suggests that not all KIT mutations activate its function, resulting in some mutations being insensitive to KIT inhibitors used for patient treatment.¹⁶ NRAS mutations cluster in the RAS hotspot mutation site Q61, usually Q61L and less frequently Q61R and Q61H. NRAS mutations are more frequent in older individuals and are equally common in melanomas arising from the skin with chronic or intermittent sun damage.^{2,17} The vast majority of BRAF mutations in melanoma involve a substitution for valine at the 600th amino acid position to glutamine (V600E).^{5,18} The frequency of the BRAF V600E mutation is inversely correlated with age since it is most frequent in melanomas that appear on the skin without chronic sun damage in young adults. BRAF V600K is the second most common variant, which increases in incidence with age. V600D or V600R mutations are much less frequent.⁸ Overall, up to 90 different point mutations have been described in BRAF in different cancers, some of which are activating and others are inhibiting its enzymatic activity.¹⁸

Aberrations in the phosphoinositide 3-kinase (PI3K)/protein kinase B (AKT)/mammalian target of rapamycin pathway, including the phosphatase and tensin homolog (PTEN), are also noted in a significant number of melanomas, but these do not seem to function as true drivers of the malignant phenotype. PTEN alterations include missense mutations, deletions, and insertions, as well as loss of heterozygosity and epigenetic silencing, making interrogation for mutations and genomic rearrangements in PTEN necessary.^{19,20} The pathogenesis of melanoma, like most

Figure 94.1 Signaling pathways disrupted by genetic alterations and their relationship to the hallmarks of melanoma. Proteins boxed in red are affected by gain-of-function mutations; those boxed in blue are affected by loss-of-function mutations. (Source: Bastian BC. The molecular pathology of melanoma: an integrated taxonomy of melanocytic neoplasia. *Ann Rev Pathol Mech Dis* 2014;9:239-271.)

other cancers, requires the presence of a driver oncogene and the dysregulation of cell cycle control and apoptosis to provide the full oncogenic signaling and ability to grow autonomously. These happen with the frequent mutations or genetic deletions of CDKN2A, cyclin D1, or the amplification cyclin-dependent kinase 4.²¹

Progression of Melanocytes to Cutaneous Melanoma

Genetic Events in Melanocyte to Melanoma Progression and Oncogene-Induced Senescence

BRAF and NRAS are founding mutations of cutaneous melanoma that are frequently present in benign nevi.²² Despite of the presence BRAF and NRAS mutations, nevi have an exceedingly low proliferative activity and infrequently progress to melanoma. This is explained because of the phenomenon of oncogene-induced senescence preventing malignant progression to melanoma, where these mutations require functioning with additional genetic events that lead to dysregulation of cell cycle control to result in the development of a progressive melanoma.^{15,23} The model for oncogene-induced senescence in melanoma is based on the identity of the main driver mutations (BRAF and RAS) in nevi, the initial phase of proliferative activity they spark, the

formation of a benign nevus in association with the induction of senescence markers (cell cycle arrest, induction of the tumor suppressor p16^{INK4a}, endoplasmic reticulum stress markers and increased SA-βGal activity, and possibly additional senescence biomarkers), and the subsequent cessation of expansion, which is typically maintained for decades.²⁴

Cellular Changes in Melanocyte to Melanoma Progression

The transition from melanocyte to metastatic melanoma involves several histologic intermediates, including melanocytic atypia, atypical melanocytic hyperplasia, radial growth phase melanoma, vertical growth phase melanoma, and metastatic melanoma. Atypical melanocytes arising in a preexisting nevus or de novo are very common but rarely progress to melanoma. However, some patients develop confluent atypical melanocytic hyperplasia at the dermal/epidermal junction or nests of atypical melanocytes in the epidermis or at the dermal/epidermal junction. As this process progresses, it reaches a point at which a diagnosis of melanoma is warranted.

Early cutaneous melanomas usually proceed to grow radially, and this is called the *radial growth phase* (RGP) of melanoma, which may continue for years before progressing to the vertical growth phase (VGP) (Figs. 94.2 and 94.3). The RGP of a cutaneous melanoma may include either melanoma in situ or superficial

Figure 94.2 Biologic events and molecular changes in the progression of melanoma. (From Miller AJ, Mihm MC Jr. Melanoma. *N Engl J Med* 2006;355:51–65.)

Figure 94.3 (A) A nodule of vertical growth phase melanoma arising from a radial growth phase pigmented macule on the right cheek. (B) Superficial spreading melanoma, 2.9 mm thick, arising on the temple of a young woman. There were microscopic satellites, and the patient died of disease within several years. (C) Superficial spreading melanoma with all the classic features of the ABCD mnemonic (asymmetry, border irregularity, color variation, and diameter >6 mm). (D) Large, ulcerated 2.5 mm superficial spreading melanoma with regression in elderly man.

invasion into the papillary dermis, or both. Melanomas in RGP present clinically as enlarging macules or very minimally raised papular lesions, which are typically (but not always) pigmented. These lesions are rarely symptomatic. If not recognized, these lesions typically progress to the VGP, manifest clinically by a nodular growth of the lesion, often described by the patient as a lesion that began to “raise up.” This vertical growth usually arises as a nodule within the RGP component and encompassing only part of the RGP (see Fig. 94.3A,C). Thus, the VGP appears to represent further steps in the process of malignant transformation due to clonal changes in the cells of the RGP.

Some melanomas present as metastatic melanoma in lymph nodes, skin, subcutaneous tissue, or visceral sites without an apparent primary cutaneous site. In some cases, these have been associated with a history of a regressed primary melanocytic lesion. In other cases, such an explanation is less clear. In all of these cases, the prospect of early diagnosis of melanoma is compromised, and the risk of melanoma-associated mortality is increased.

EPIDEMIOLOGY

Malignant melanoma is the sixth most common US cancer diagnosis. The actual incidence of melanoma is increasing more rapidly than that of any other malignancy. It was estimated that 76,690 men and women (45,060 men and 31,630 women) will be diagnosed with and 9,480 men and women will die of melanoma of the skin in 2013.²⁵ This amounts to 4% of new cancer diagnoses and 1.5% of cancer deaths. In the early part of the 20th century, the lifetime

risk of a white person developing melanoma was approximately 1 in 1,500. Currently, 1 in 49 men and women will be diagnosed with melanoma of the skin during their lifetime. Its incidence is second only to breast cancer for women from birth to age 39 years; similarly, it is the second most common cancer diagnosis for men through age 39 years, slightly less common than leukemia.²⁶ Overall 5-year survival rates for melanoma have increased from 82% in the late 1970s (1975 to 1977) to 91% in the more recent era (2002 to 2006).²⁶

This is a disease that disproportionately affects whites over African Americans, Asians, or Hispanics. In the United States, whites account for 98.2% of cutaneous melanomas reported in the National Cancer Database, with African Americans accounting for 0.7% and Hispanics accounting for 1.1%.¹ This is best explained by a combined effect of UV sunlight exposure and fair skin. It is most striking that the highest per capita incidence of melanoma worldwide is in Australia, and that this high incidence afflicts primarily the Australians of Western European descent who have fair skin, and not the darker-skinned aboriginal population. It is also notable that these fair-skinned European descendants who moved to Australia have much higher incidences of melanoma than the Western European populations that remain in the higher latitudes of Europe. In migrant populations, individuals who move during childhood to areas with greater sun exposure develop melanoma at rates higher than those of their country of origin and similar to those of their adopted country.²⁷

In nonwhite populations, there is a much higher proportion of melanomas in acral (subungual, palmar, plantar) and mucosal locations. However, the incidences of those types of melanoma are similar across races. Their higher relative proportion in Asians and African Americans can be best explained by the disproportionate

increase in nonacral cutaneous melanomas in fair-skinned whites rather than by an absolute increase in risk of acral and mucosal melanomas in nonwhite populations.

Ocular and nonacral cutaneous melanomas are 50- to 200-fold more likely in white populations than in nonwhite populations, but melanomas in acral and mucosal sites are within twofold of each other across racial groups. Similarly, the increased incidence of melanoma over the last few decades can be explained primarily by increased incidence in white populations, not in nonwhite populations.²⁸ These observations support the hypothesis that most cutaneous melanomas in white populations are etiologically related to sun exposure but that there may be a baseline risk of melanoma in other locations that is unrelated to sun damage. There are significant molecular differences between acral melanomas and melanomas arising on the skin associated with chronic sun damage, with *B-RAF* and *N-RAS* mutations in approximately 80% of melanomas on chronically sun-damaged skin, whereas those mutations were uncommon in melanomas from acral or mucosal sites or from skin without chronic sun damage.²

CHANGES IN INCIDENCE

Data from the Surveillance, Epidemiology, and End Results program reveal an increase in age-adjusted melanoma incidence rates from 8.2 per 100,000 in the 1970s (1974 to 1978) to 18.7 per 100,000 in more recent years (1999 to 2003).²⁹ From 1990 to 2003, during which there was a 16% decrease in male cancer deaths overall for all cancers, there was a 2% increase in mortality rate from melanoma. From 1991 to 2003, during which there was an 8% decrease in cancer deaths overall for women, there was only a 4% decrease in mortality rate associated with melanoma.²⁶

In Australia, and to a lesser extent in the United States, there has been a substantial increase in awareness about melanoma and the value of screening by total-body skin examinations. There also has been a greater proportion of patients diagnosed at earlier and noninvasive stages of disease. Thus, part of the increase in incidence may be explained by increased early diagnosis of lesions with low metastatic potential. However, there has also been a significant increase in mortality from melanoma over the last few decades.²⁹

GENDER AND AGE DISTRIBUTION

In the United States and Australia, the gender ratio of melanoma at diagnosis is 2 male to 1 female, but it depends on the age group. Analysis of incidence data for invasive melanoma diagnosed from 1992 to 2006 from 12 cancer registries that participate in the Surveillance, Epidemiology, and End Results program of the National Cancer

Institute revealed that, by age, the men-to-women rate ratio ranged from 1.3 (95% confidence interval [CI], 1.2 to 1.3) for ages 40 to 64 years for incidence to 2.6 (2.5 to 2.7) for older than 65 years for both incidence and mortality. However, between the age of 15 and 39 years old, melanoma is more common in females (rate ratio = 0.6).²⁵ The median age of melanoma patients has increased from 51 years in the 1970s (1974 to 1978) to 57 years in a more recent time period (1999 to 2003). Nonetheless, the median age for diagnosis of melanoma is approximately 10 years lower than the current median age of diagnosis for the more common solid tumors, such as colon, lung, or prostate cancer. The large majority (approximately 80%) of patients with melanoma are diagnosed in the productive years from age 25 to 65 as shown for a representative population from the state of Virginia (Fig. 94.4). Melanoma is common in patients in their 20s and older, but it also is observed in teenagers, and occasionally even in infants and neonates. For women aged 25 to 35 years, melanoma is the leading cause of cancer-related death.

MELANOMA IN CHILDREN, INFANTS, AND NEONATES

Diagnosis and management of melanoma in children, infants, and neonates is complicated by several factors: (1) excisional biopsy of skin lesions often is not feasible under local anesthesia in young children, and (2) pigmented skin lesions with substantial cellular atypia but with structural symmetry may be Spitz nevi, which typically have benign behavior. Thus, some young patients with changing pigmented skin lesions are observed longer than would be advisable because biopsy is more problematic than in most adults. In addition, young patients may undergo incomplete shave biopsy to avoid a full-thickness excision, and information is lost about the architecture of the lesion, leaving a diagnostic dilemma between melanoma and Spitz nevus. Even in the best of circumstances, some melanocytic tumors are difficult to diagnose with certainty. This has led to a formal definition of melanocytic tumors of uncertain malignant potential.³⁰

Melanoma deaths in children and young adults have a large effect on total years of life lost because of melanoma. Current recommendations for management of melanoma in children and infants are the same as for adults, and outcomes are generally believed to be comparable.³¹

ANATOMIC DISTRIBUTION

Cutaneous melanoma can occur at any skin site in the body. The most common sites in males are on the back and in the head and neck regions. In women, the most common sites are in the lower

Figure 94.4 Age-related incidence of melanoma in Virginia, 1970 to 1996 (total of 9,018 cases).

Trunk M:F = 1.8; lower limb M:F = 1/3; head and neck M:F = 1.9

Figure 94.5 Incidence of melanoma in Virginia, 1970 to 1996, by gender.

extremities, commonly below the knee (Fig. 94.5). Lentigo maligna melanoma (LMM) most commonly arises on sun-damaged surfaces of the head and neck in older patients. Acral lentiginous melanoma (ALM) is most common on subungual and other acral locations.

ETIOLOGY AND RISK FACTORS

Ultraviolet Light Exposure

The demographic features of cutaneous melanoma have implicated UV light exposure as a major etiologic factor in the development of melanoma. Multiple studies continue to support an etiologic association between UV irradiation and melanoma.³² UVC radiation (290 to 320 nm) is associated with sunburn and induction of tanning by melanin pigment production. There are substantial data to support its etiologic role in melanoma.³² There is also some evidence implicating UVA radiation (320 to 400 nm), although UVA is more associated with chronic sun damage changes.³³ However, the relative role of each type of UV irradiation in melanoma etiology is debated. Animal data suggests that sun exposure early in life increases the risk of melanoma. Human skin grafted on mice will develop nevi and melanomas in the presence of UVB irradiation, further supporting the role of UVB irradiation in melanoma.³⁴ Similar to the animal modeling, sunburns early in life have been implicated in melanoma incidence.³⁵ However, chronic sun exposure in individuals who tan well may even be protected against melanoma. The role of sunlight intensity and frequency is debated, but both chronic and intermittent exposure may be relevant.³² Current data suggest that UV radiation causes melanoma by a combination of DNA damage, inflammation, and immune suppression.³⁶

Tanning bed use has been implicated in the etiology of melanoma, in particular tanning bed use in adolescence or early adulthood.³⁷ Tanning bed use has been formally classified as a carcinogen, and increased awareness of the harmful effects of UV exposure promise to control the increase in melanoma incidence.

Physical Traits

Several physical traits have been linked to increased incidence of cutaneous melanoma. These include blond or red hair, green or blue eyes, presence of multiple (>100) melanocytic nevi, and five or more atypical nevi. A prior diagnosis of melanoma is associated with an eight-fold increased risk of developing a secondary melanoma.

Familial Predisposition

It has been estimated that 5% of melanomas occur in high-risk families with an autosomal dominant inheritance with incomplete penetrance.³⁸ The most frequent and highest penetrance melanoma susceptibility gene is a germline mutation in CDKN2A, a tumor suppressor gene that encodes for two different proteins, p16INK4A and p14 ARF.³⁹ These proteins control cell cycle progression and apoptosis, and have roles in correcting DNA damage and cellular senescence. CDKN2A mutations have been reported in approximately 25% of melanoma-prone families, but this frequency varies highly on the selection criteria used and the region of the world where it is studied. The rare autosomal dominant inherited familial atypical multiple mole melanoma-pancreatic cancer syndrome is associated with CDKN2A mutations, and less frequently to BRCA2 mutations.⁴⁰ Another germline mutation linked to familial melanoma is cyclin-dependent kinase 4, which is linked to the function and p16INK4A and controls the retinoblastoma pathway. A germline mutation in microphthalmia-associated transcription factor (*MITF* E318K) represents a medium-penetrance susceptibility gene predisposing to familial melanoma, as well as to sporadic melanoma and renal cell carcinoma.^{41,42} The E318K mutation in *MITF* disrupts sumoylation and enhances transcription of *MITF*-responsive genes. Other common risk factors include dysplastic nevus syndrome, xeroderma pigmentosum, and a family history of melanoma even without the known genetic traits. The association of melanoma with Li-Fraumeni syndrome, with germline mutations in p53, is currently unclear.⁴³

Pregnancy and Estrogen Use

Older literature suggested anecdotally that the incidence of melanoma was higher in pregnant females and that they had a particularly bad outcome. However, multiple systematic and larger studies have shown no evidence of any negative (or positive) impact of prior, concurrent, or subsequent pregnancy on clinical outcome.^{44,45} Similarly, there is no clear prognostic relevance for birth control pills or estrogen replacement therapy.⁴⁶ The prior sense of an apparent association of pregnancy and melanoma may be due to melanoma being the second most frequent cancer in females of childbearing age. The general recommendation for treatment of women with melanoma diagnosed during pregnancy is to manage them in the same fashion as patients who are not pregnant. Depending on the time during pregnancy at which a melanoma is diagnosed, there can be circumstances in which radiologic imaging may be limited because of concern for the fetus, and major surgery may be delayed until the fetus is at an age when it can

survive independently. However, the excision of a primary melanoma certainly can be done in almost any circumstance, under local anesthesia.

The other related question often asked by patients is whether it is advisable to become pregnant and to bear a child after treatment for melanoma. As just stated, there is no evidence that a subsequent pregnancy adversely impacts outcome. However, the more interesting and challenging question is the more personal or social issue of the potential for premature parental death due to melanoma. Thus, it is helpful for patients to understand their risk of future recurrence and melanoma-related mortality because that translates into the risk that the child will grow up losing a parent. Measures of the risk of future disease progression can be defined based on the initial prognosis and the subsequent elapsed time without recurrence, and such information may help to guide patients with this challenging question.⁴⁷

PREVENTION AND SCREENING

Melanomas diagnosed and treated during the RGP have an excellent prognosis. Thus, prevention and early diagnosis can have a great impact on decreasing melanoma morbidity and mortality. The apparent leveling off of melanoma-related mortality rates in Australia and the United States likely is the result of better screening and prevention.

Sun Protection

UV exposure and sunburns, in particular, appear to be etiologic in most melanomas. Thus, protection from UV light, especially in fair-skinned individuals, is believed to have substantial benefit in preventing melanoma.

A clinical trial has provided evidence that regular sunscreen use helps prevent melanoma.⁴⁸ This was a randomized trial from March 1992 to August 1996 of 1,621 randomly selected adult residents of a Queensland township in Australia with an initial primary end point testing the prevention of squamous cell and basal cell carcinomas, which the study did demonstrate.⁴⁹ Prevention of the development of melanoma was a prespecified secondary end point. Participants were randomly assigned to either a planned sunscreen intervention group or a control group using sunscreen at their discretion. The intervention group received broad-spectrum, sun protection factor (SPF) 16 sunscreen every morning, and was instructed to reapply the sunscreen after a long sun exposure, heavy sweating, or after bathing. After a 10-year follow-up, regular sunscreen use decreased by half the rate of developing new melanomas. This conclusion was based on 11 participants in the intervention group and 22 in the control group being newly diagnosed with either invasive or in situ melanoma ($p = 0.051$). The incidence of invasive melanoma decreased by 73% in the intervention group compared with the control group (3 versus 11 patients, respectively; $p = 0.045$). Therefore, this study provides evidence that use of sunscreen can decrease the incidence of melanoma development.

There are limitations inherent in sunscreen use as the primary means to protecting from UV light damage. One is that certain body sites are not easily covered with sunscreen, such as the scalp. More important, even "waterproof" sunscreens wash off or become less effective with time. Most people also forget to reapply sunscreens frequently enough and may still get burns. There are also sociologic issues, which may differ for different populations and are arguable. However, it is worth considering the provocative findings of a study performed on young adults from Western Europe, who were randomized to receive either SPF10 or SPF30 sunscreen. In a blinded fashion, they were asked to report sun exposure times and sunburns. The number of sunburns was the same in both groups, and sun exposure was greater in the SPF30

group, suggesting that some populations may stay in the sun until they get a burn, and that sunscreen simply helps them to stay in the sun longer.⁵⁰ The sun-seeking behavior has been related to an evolutionary need that favored UV exposure to make vitamin D in the skin in populations that migrated to areas of the world with lower sun exposure. In mouse models, the exposure to UV light was linked to increased production of beta-endorphins and recurrent seeking of UV exposure.⁵¹

It is safe to say that the best protection from the sun is a building, the next best is protective clothing, and the third best is sunscreen. Patients should be advised to use all three. Avoiding midday sun from about 11 a.m. to 3 p.m. by staying indoors is advised, as well as wearing clothing with a thick enough weave that it blocks sunlight, or a formal SPF rating, when possible. Hats are particularly helpful for the face and scalp, which often are highly exposed to sunlight and not so readily covered fully with sunscreen. Otherwise, sunscreen can provide protection to sun-exposed areas when outside.

Screening for Early Diagnosis

Self-Examination

For many patients, they, their spouses, or other family members may be able to screen effectively for new suspicious skin lesions, and this should be encouraged. It is more common for women to detect melanomas than for men to do so, either for themselves or for their partners. In any case, there is value in educating patients about how to detect melanomas if they are at high risk. As many as half of melanomas are identified by the patient or family,⁵² and patient self-examination has been associated with diagnosis of thinner melanomas.⁵³ Teaching aids for patients on how to perform skin self-examination are available from the American Cancer Society and the American Academy of Dermatology. Patients with melanoma or at high risk should be seen regularly by a dermatologist. It is reasonable to suggest that patients perform skin self-examinations more often than their dermatology visits, although there are no proven guidelines. Doing a self-examination once a month may be the easiest for the patient to remember.

The role of skin cancer screening to decrease incidence and mortality from cutaneous melanoma has been prospectively studied in the Schleswig-Holstein project.⁵⁴ This was an observational study comparing trends in melanoma mortality in a population-based skin cancer screening project conducted in the northern German region of Schleswig-Holstein, compared to neighboring regions in Germany and Denmark where no such screening was conducted. From July 1, 2003, to June 30, 2004, 360,288 individuals aged 20 years were screened by whole-body examination. They reported that mortality in Schleswig-Holstein melanoma declined by 48% when analyzed using log-linear regression to assess mortality trends. No such change in melanoma mortality rates was noted in the studied adjacent regions. This study provides strong evidence that skin cancer screening programs may reduce melanoma mortality.⁵⁴

Management of the Patient with Numerous Atypical Moles

Some patients have numerous atypical moles. This presentation is commonly described as atypical mole syndrome, dysplastic nevus syndrome, or B-K mole syndrome.⁵⁵ These patients have a heightened risk of melanoma, and this is commonly a familial feature. When associated with a family history of melanoma, patients with dysplastic nevus syndrome have a risk of melanoma that may approach 100%. These patients deserve particular attention to melanoma prevention through sun protection and to early diagnosis through aggressive screening. However, the optimal approach for screening is not defined. At a minimum, routine skin examinations by a dermatologist are usually recommended, as often as every 3 months. Visual inspection of the atypical nevi

may be augmented by routine digital photography to facilitate detection of subtle changes in radial growth or other changes over time. Although these approaches commonly permit identification of melanomas when they are in situ or thin, it is not known whether they improve survival. In addition, concern remains that visual inspection alone, even for very experienced dermatologists, is inadequate to diagnose all melanomas when they are still curable. Thus, substantial effort is in progress to develop more sensitive and specific diagnostic tools than visual inspection alone. One that is employed routinely in many practices is dermoscopy, also known as epiluminescent microscopy. This involves use of a handheld microscope at the bedside to examine skin lesions in an oil immersion setting. This appears to improve diagnostic accuracy in experienced hands, and increasing experience has made its use more feasible in general practice, especially with considerations for standardization.^{56,57} When coupled with the use of a digital camera, the images can be stored and compared over time as well. Computer-assisted digital analysis of these images is also being studied but remains investigational.

Evaluation and management of patients with dysplastic nevus syndrome is complicated by the fact that very few dysplastic nevi will develop into melanoma. Estimates range from a risk of 1 per 1,000 nevi examined in a pigmented lesion clinic being melanoma to 1 per 10,000 nevi becoming melanoma per year.^{56,57} Recommendations for management of dysplastic nevi include those from the Melanoma Working Group in the Netherlands and by a National Institutes of Health Consensus Conference.⁵⁸

It is tempting to consider excision of all dysplastic nevi. Although that remains an option, there is no proof that this will decrease risk. Melanomas may arise de novo in 30% to 70% of cases, and so it is not clear that removal of all suspicious nevi will lead to a meaningful improvement in survival. However, it is certainly appropriate to biopsy any nevus that is suspicious, especially one that is changing.

Testing for Genomic Changes in Melanoma

Understanding the genetic makeup of melanoma has become the cornerstone of advances in the management of advanced disease, and it is likely to have an increasing role in the management of earlier stage melanoma. Genetic analyses can be focused on driver oncogenic events or can provide a broader understanding of the genomic aberrations in the cancer. Their study is becoming a standard of care practice in melanoma.

Commercially available tests identifying the BRAF V600E/K mutation have been approved by the U.S. Food and Drug Administration (FDA) and other regulatory bodies as companion diagnostics for the use of novel BRAF and MEK inhibitors. These assays are frequently based on specific PCR probes labeled with fluorescent tags that bind to wild-type and V600E or V600K mutant BRAF sequences. These assays are performed in sections of formalin-fixed paraffin embedded tissue blocks routinely used for pathologic analyses. As with all techniques used to detect somatic mutations, they are limited by the amount of mutant sequence in the initial sample as well as DNA integrity in the sample, and their ability to detect non-V600E BRAF mutations since the primers used are usually restricted to this particular BRAF mutation. Multiplexed single nucleotide extension assays (i.e., Sequenom [San Diego, CA] or SNaPshot [Vanderbilt-Ingram Cancer Center, Nashville, TN]) evaluate a list of specific base mutations of interest, but do not identify mutations outside the interrogated bases. These techniques are designed for simultaneous interrogation of different point mutations. They are particularly suited for the targeted interrogation of known oncogenes that contain mutation hotspots, such as NRAS, BRAF, and GNAQ/GNA11, being relevant for melanoma.⁵⁹

Traditional Sanger sequencing has been the gold standard for the detection of point mutations, but it has been shown to have lower sensitivity than the PCR-based assays, thereby leading to a

higher frequency of false negative results. Pyrosequencing provides information from the sequencing 300 and 500 nucleotides at a time, resulting useful for the analysis of mutations clustered in a small gene region. It is a highly sensitive technique, being able to detect mutant DNA when only 5% of the total sample is from the cancer tissue.

Copy number analyses have been very useful in the discovery and description of genes and pathways involved in melanoma pathogenesis. Initially, probe sequences were derived from bacterial artificial chromosomes using array comparative genomic hybridization. More recently, single nucleotide polymorphism-based arrays have been introduced. But currently the approach of choice for the analysis of the DNA alterations in melanoma at the genome level is massively parallel sequencing techniques. These techniques enable the sequencing of exomes and entire genomes of tumor samples (compared to normal DNA from the same patient), with the simultaneous sequencing of a large number of genes and determination of mutations, genetic alterations, and copy number changes. The price and complexity of this type of analysis has rapidly improved, making it feasible to use beyond research studies. Limited panels performing next generation sequencing in what have been called “actionable” genes have been implemented for clinical use. These provide information based on sequencing data of 200 or so genes for which the available literature suggests that they could provide information which may be interpretable to decide on treatment options, in particular in terms of clinical trial participation with new targeted agents.⁶⁰

A clinically applicable approach to genetic testing of melanomas is first performing a targeted testing for the mutation status of BRAF, NRAS, and KIT in cutaneous and mucosal melanoma samples before pursuing alternative mutation interrogation with higher throughput approaches. Next-generation sequencing may be applicable in situations where known mutations are not identified, and the identification of additional genetic mutations is needed.

DIAGNOSIS OF PRIMARY MELANOMA

Characteristics of Primary Melanoma

The classic appearance of primary cutaneous melanoma is summarized by the mnemonic ABCD for *asymmetry*, *border irregularity*, *color variation*, and *diameter* >6 mm (see Fig. 94.3). Because melanomas arise from melanocytes, which contain the melanin-synthetic pathway, melanomas classically are distinguished by their pigmentation. Melanomas may have shades of brown, black, blue, red, and white. However, there is a wide range in the appearance of melanomas. Some melanomas are pitch black. Others are shades of brown. Some have no visible pigment and appear skin-colored. Still others have a red color only. When melanomas have all of the classic ABCD features, they are typically easy to diagnose. However, those melanomas that lack some of these features can be difficult to diagnose. In addition, in patients with large numbers of atypical nevi, which may also have ABCD features, this mnemonic is often inadequate to aid in early diagnosis. The other important findings that may aid in early diagnosis are a change in a lesion over time or new development of a skin lesion. These warrant evaluation, and in high-risk patients there should be a low threshold for biopsy. In addition, some dermatologists recommend considering the “ugly duckling” sign: A lesion that stands out as different from the patient’s other nevi should be evaluated and possibly biopsied.⁶¹ This can be particularly helpful in a patient with a large number of clinically atypical nevi. Both of these approaches may help to identify amelanotic (nonpigmented) melanomas, which often do not meet the ABCD criteria. Some melanomas are not diagnosed until they become symptomatic, and whereas awareness of the symptoms of bleeding, itching, pain, and ulceration are worth noting, these usually connote deep vertical growth and are hallmarks of a late diagnosis, not an early one.

Biopsy

Biopsy of a suspicious skin lesion is necessary for an accurate diagnosis and for optimal staging. The correct way to perform such a biopsy is to make a full-thickness biopsy of the entire lesion, with a narrow (1 to 2 mm) margin of grossly normal skin. The depth of excision should include the full thickness of dermis and thus should extend into the subcutaneous tissue, but it does not need to include all of the subcutaneous tissue except in very thin patients or patients with very thick polypoid lesions that may go deep into the subcutis. This allows assessment of the architecture of the lesion, which is critical for differentiation of melanoma from Spitz nevus, and it permits an accurate measure of tumor thickness, which is critical for prognosis and affects the surgical treatment recommendations. Of importance, desmoplastic melanoma often arises from LMM and is difficult to diagnose both clinically and histologically. Shave biopsies of these lesions can often lead to failure to appreciate the desmoplastic melanoma in the dermis and may substantially delay diagnosis.

For some large lesions (e.g., >2 cm diameter) in cosmetically sensitive locations (e.g., face or genitalia), there may be a rationale for an incisional biopsy, but that also should be performed as a full-thickness skin biopsy. Ideally, it should include the most suspicious area of the lesion and also should include, if possible, a portion of the edge of the lesion where it transitions to normal skin to enable assessment of the junctional change. The incisional biopsy may be an elliptical incision or it may be a full-thickness 4- to 6-mm punch biopsy. Punch biopsies are problematic if too small, if they do not include full-thickness skin, if they are crushed during removal, if they are oriented inaccurately in the paraffin block, or if they are too small to include both the edge of the lesion and the most suspicious or most raised part of the lesion.

Orientation of the incision used for an excisional biopsy should be considered in the context of the prospect for the future need for a wider re-excision. On extremities, the incision and scar should be oriented longitudinally rather than transversely, although some exceptions may be considered near joints to avoid crossing a joint. When in doubt about the optimal orientation, it is very reasonable to perform the excisional biopsy as a simple circular excision, leaving the wound open for secondary or delayed primary closure.

Biopsy of subungual lesions is more challenging. The pigmentary changes seen in patients with subungual melanoma usually extend along the length of the nail, but the lesions usually arise at the proximal end of the nail bed. Access to that location often requires removal of all or a large part of the nail. One or more punch biopsies of the base of the nail bed often constitute the most realistic method for obtaining a biopsy of such lesions, and it may need to be repeated to be diagnostic. A punch biopsy tool can remove a circle of the nail, providing access to the nail bed for punch biopsy of the suspicious area.

Melanoma Subtypes: Histologic Growth Patterns

Classically, four main histologic growth patterns are described for melanomas, but two others are also worth mentioning.

Superficial Spreading Melanoma

The most common type is superficial spreading melanoma, which accounts for about 70% of primary cutaneous melanomas (see Fig. 94.3C). It is typical for the trunk and extremities, except on acral sites. It is associated with pagetoid growth of atypical melanocytes in the epidermis. Superficial spreading melanoma is commonly associated with sun exposure.

Nodular Melanoma

Nodular melanomas lack an RGP, may be nonpigmented, and commonly are diagnosed when relatively thick. Thus, these carry

the worst prognosis of the various subtypes of melanoma. They account for about 20% of cutaneous melanomas. By definition, nodular melanomas are in VGP when recognized.

Acral Lentiginous Melanoma

ALMs account for <5% of melanomas.⁶² They are typically found on acral sites (subungual, palmar, plantar) and on mucosal surfaces (anorectal, nasopharyngeal, female genital tract). ALM occurs across all races and ethnicities. Its etiology is likely independent of UV light exposure. Because other cutaneous melanomas are uncommon in African, Asian, and Hispanic populations, ALMs on acral sites are proportionately more common in these populations than in fair-skinned whites. ALM is typically associated with a prolonged RGP before vertical growth; however, its locations make it harder to diagnose than other forms of melanoma. Subungual lesions can be detected by linear pigment streaks arising from the base of the nail, but these are not always evident. They can be confused with subungual hematomas, which can lead to diagnostic delay. When there is a question of whether a pigmented subungual lesion may be melanoma or a hematoma, the location of the pigment can be marked and then followed over a short interval (e.g., 3 weeks), during which time a hematoma should move toward the end of the nail, but a melanoma should not.

Subungual melanomas can also present with breakage of the nail or a nonpigmented thickening or drainage, and these are often confused with chronic fungal infections. Any concerning pigmented subungual lesion should be biopsied, but it is sometimes challenging and requires splitting or removing part of the nail. A punch biopsy near the nail bed matrix is often appropriate. In addition, when there is spontaneous chronic inflammation or breakage of the nail, biopsy for melanoma should be considered, even in the absence of pigmentation.

Lentigo Maligna Melanoma

LMMs typically occur in older individuals, in chronically sun-damaged skin, and commonly on the face. They tend to have shades of brown or black, whereas the red and blue colors seen in other melanomas are not typical of LMM. They may also develop areas of regression manifested by depigmentation of part of the lesion. Overall, LMMs account for about 10% to 20% of melanomas in the National Cancer Database experience,¹ 47% of melanomas of the head and neck, and only 2% of melanomas of other regions.⁶² LMMs usually have an extensive RGP that extends for many years before developing invasion. When melanoma is just in situ, this RGP portion is called *lentigo maligna* or Hutchinsonian freckle, as opposed to LMM. These are not to be confused with the benign pigmented macule, lentigo. Lentigo malignas evolve a VGP to become invasive LMMs at a rate estimated to be between 5% and 33%.⁶³ LMMs are commonly diagnosed as thin lesions. However, more substantial vertical growth can occur, as seen in Figure 94.3A.

Lentiginous Melanoma

Early RGP melanomas sometimes are difficult to classify into the typical patterns of lentigo maligna, superficial spreading melanoma, or ALM. A report defined a distinct entity of lentiginous melanoma. Its features include diameter ≥ 1 cm, elongated and irregular rete ridges, confluent melanocytic nests and single cells over a broad area of the dermal/epidermal junction, focal pagetoid spread, cytologic atypia, and possible focal dermal fibrosis.⁶⁴ Over time, this may represent a growing proportion of melanomas that have traditionally been grouped as superficial spreading melanoma, lentigo maligna, ALM, or unclassified melanomas.

Desmoplastic Melanoma

Desmoplastic melanoma is an uncommon form of melanoma, histologically manifest by dermal melanocytes in a dense stromal

response. These lesions are usually nonpigmented and usually have lost the melanin production pathway. They usually stain negative for MART-1/MelanA, gp100, and tyrosinase, but they do stain for S100. The lack of pigmentation and the dense stromal response often interfere with clinical and histologic diagnosis. It occurs most commonly in the head and neck, but it may occur in other body sites.⁶⁵ Desmoplastic melanoma may appear de novo as a nonpigmented skin papule or as a dermal/VGP component arising from a preexisting lentigo maligna or other pigmented junctional lesion. Desmoplastic melanomas may have neurotropic features and have been associated with a high rate of local recurrence.⁶⁶ However, recent reports suggest that if adequate margins are taken, the risk of local recurrence is low.

The overall mortality risk for desmoplastic melanomas is comparable to that of other invasive melanomas of similar depth of invasion.⁶⁷ Multiple studies support the contention that desmoplastic melanomas have a significantly lower risk of nodal metastases than other melanomas,⁶⁸⁻⁷² with only 1.4% sentinel node positivity among 155 patients with pure desmoplastic melanoma, compared with 18.5% in those with mixed desmoplastic melanoma.^{67,68,71,72} There has been a debate about whether to abandon histologic staging of regional nodes in patients with desmoplastic melanoma.⁶⁹ It may be appropriate to consider a higher threshold for performing sentinel node biopsy (SNBx) in patients with pure desmoplastic melanoma, but there is no consensus on this question.

Prognostic Factors for Primary Melanomas

The best predictor of metastatic risk is the depth of invasion, measured with an ocular micrometer, from the granular layer of the skin to the base of the primary lesion. This was originally described by Breslow⁷³ and remains an important factor in staging and prognostic stratification. However, many other histologic and clinical features have relevance for estimating the risk of future metastasis and mortality. These include age, angiolymphatic invasion, mitotic rate, gender, and body site.

Depth of Invasion

Breslow thickness is the depth of invasion measured from the granular layer of the epidermis to the base of the lesion. Melanoma cells involving adnexal structures are considered junctional and are not included in the Breslow depth. The current melanoma staging system of the American Joint Committee on Cancer (AJCC) identifies tumor (T) stage based on Breslow thickness such that T1 lesions are <1 mm thick, T2 lesions are 1 to 2 mm thick, T3 lesions are 2 to 4 mm thick, and T4 lesions are >4 mm thick.⁷⁴

Clark et al.⁷⁵ defined depth based on the layer of skin to which the melanoma has invaded. Clark level I melanomas are melanomas in situ, limited to the epidermis or dermal/epidermal junction. Clark level II melanomas invade into the superficial (papillary) dermis, and these are usually RGP lesions. Clark level III melanomas fill the papillary dermis. Clark level IV melanomas invade into the deep (reticular) dermis and have significant metastatic risk. Clark level V melanomas are uncommon and contain invasion into the subcutaneous fat.

It has become apparent that Clark level does not add much additional prognostic value to Breslow thickness and has been removed from the 2010 version of the AJCC staging system.⁷⁴ Breslow thickness has an effect on survival, local, regional, and systemic recurrence rates, and that association is continuous, without any apparent breakpoints. Although the staging system requires categorization of thickness ranges, the continuous nature of the risk association should be kept in mind. Thickness is considered in defining the margins of excision for primary melanomas.^{76,77}

Ulceration

Ulceration of the primary lesion has been identified as an important negative prognostic feature⁷⁶ and is incorporated in the current

staging system such that T1a, T2a, T3a, and T4a melanomas are nonulcerated, and T1b, T2b, T3b, and T4b melanomas are ulcerated. In an analysis of prognostic features in a large multicenter database, the prognosis of an ulcerated lesion was comparable to that of a nonulcerated lesion one T level higher. Thus, the overall stage assignment groups ulcerated lesions with nonulcerated lesions one T level higher (e.g., T2b and T3a are both stage IIA). The staging system is summarized in Tables 94.1 and 94.2 and is described in detail elsewhere.⁷⁴

Patient Gender and Skin Location of Primary Melanoma

The incidence of melanoma is higher for men than women overall, but in adolescents and young adults it is more common in women.²⁵ Furthermore, for essentially all patient subgroups, the prognosis is better for women than men. Thus, among patients with stage III and IV melanoma, men outnumber women approximately 1.5:1. Women are more likely to have melanomas on the extremities, whereas men are more likely to have melanomas on the trunk and head and neck. The clinical outcome for patients with melanomas on extremities is better than that for patients with truncal or head-and-neck melanomas; thus, the prognostic impact of gender is difficult to distinguish from the impact of tumor location. There may still be, however, a prognostic benefit for female gender independent of tumor location.^{76,78} In addition, location of tumors has prognostic relevance in that head-and-neck melanomas have poorer prognosis than trunk or extremity melanomas, and melanomas on acral sites have poorer prognosis than other extremity melanomas.^{78,79} A particular location associated with poor prognosis is the mucosal melanoma. Anorectal, female genital, and head-and-neck melanomas of mucosal origin have a mortality risk of 68% to 89% over 5 years.^{1,79,80}

Patient Age

The impact of age on prognosis is confusing. There is a greater risk of lymph node metastasis in young patients at the time of SNBx,⁸¹ especially for patients younger than age 35 years, but the melanoma-associated mortality risk increases with age for all thickness ranges.^{1,76} This paradox has not been explained. It suggests a possible age-specific curative potential for patients with micro-metastatic nodal disease. Alternatively, it is worth considering that the attribution of mortality to melanoma progression is not always straightforward. Older patients have other competing causes for death that could lead to earlier mortality in the presence of metastatic disease. Nonetheless, age does appear to have independent prognostic significance for patients with melanoma.

Growth Pattern

Overall, nodular melanomas have the worst prognosis, associated with their diagnosis at a thicker stage. Lesser risk is associated with ALM, superficial spreading melanoma, and LMM, in that order, all associated with decreasing average Breslow thickness. Generally, the histologic growth pattern of melanoma has little prognostic relevance when Breslow thickness is taken into account. The VGP component appears to be the component of melanoma that determines metastatic risk, and these VGP components are similar, independent of the growth phase in the RGP component. LMMs are a possible exception, in that they appear to have a better prognosis than other histologic types, independent of thickness. Desmoplastic melanoma, superficial spreading melanoma, LMM, and ALM have comparable prognosis, for distant metastases and survival, when stratified by thickness.^{68,81}

Mitotic Rate

It is reasonable to expect that the growth rate of melanomas is linked to the rate of tumor cell division. Accordingly, mitotic rate in the dermal component has been identified as a negative

TABLE 94.1

Melanoma Tumor, Node, Metastasis Classification

T Classification	Thickness (mm)	Ulceration Status	Mitotic Rate
TX	Unknown	—	—
T0	No evidence of primary tumor	—	—
Tis	Melanoma in situ	—	—
T1a	≤1.0	No	<1/mm ²
T1b	≤1.0	Yes	≥1/mm ²
T2a	1.01–2.0	No	Any
T2b	1.01–2.0	Yes	Any
T3a	2.01–4.0	No	Any
T3b	2.01–4.0	Yes	Any
T4a	>4.0	No	Any
T4b	>4.0	Yes	Any
N Classification	No. Nodes with Metastasis	Presentation	In Transit or Satellite Metastasis(es)
NX	Not assessable	—	—
N0	0	—	No
N1a	1	Clinically undetectable ^a	No
N1b	1	Clinically detectable ^b	No
N2a	2–3	Clinically undetectable ^a	No
N2b	2–3	Clinically detectable ^b	No
N2c	0	—	Yes
N3	≥4 or matted	—	—
N3	≥1	Any	Yes
M Classification	Metastatic Site	Serum LDH Level	
M0	None detected	—	
M1a	Distant skin, subcutaneous or node	Normal	
M1b	Lung	Normal	
M1c	All other visceral	Normal	
M1c	Any	Elevated	

LDH, lactate dehydrogenase.

^a Clinically undetectable nodes are those diagnosed only with sentinel node biopsy or elective lymphadenectomy, and lacking gross extracapsular extension. They are referred to also as micrometastases, but this definition differs from the pathologist's definition of a micrometastasis as one that is <2 mm in diameter.

^b Clinically detectable nodes are also referred to as macrometastases, but this is a different definition than the pathologist's definition based on a diameter >2 mm. Patients with gross extracapsular extension are also considered to have macrometastases.

Modified from Edge S, Byrd DR, Compton CC, et al., (eds.). *AJCC Cancer Staging Manual*. 7th ed. New York: Springer; 2010.

prognostic feature, especially with six or more mitoses per square millimeter.^{81,82} Similarly, dermal expression of Ki67, a molecular marker of proliferation, is associated with greater risk of metastasis.⁸³ For thin melanomas, the presence of any mitotic figures has been associated with metastatic risk, whereas the absence of dermal mitoses is associated with an excellent prognosis.⁸⁴ The current staging system incorporates mitotic rate of ≥1/mm² in differentiating low-risk thin melanomas (T1a) from higher-risk thin melanomas (T1b), and data used to define the current staging system identify increasing risk with increasing mitotic rate for all thicknesses.⁷⁴ Increased mitotic rate is associated with a poorer prognosis across all thickness ranges, but is not yet incorporated formally in the staging system beyond the current cutoff of 1/mm² for thin lesions.^{74,85,86}

Other Prognostic Factors

There is also evidence, and biologic rationale, that angiolymphatic invasion has negative prognostic significance,⁸¹ and that microscopic satellites are associated with poorer prognosis. Satellites is incorporated in the current staging system⁷⁴ but will be considered separately because it defines the patient as stage III and thus goes beyond assessment of risk factors of the primary lesion alone.

Unresolved Issues in Melanoma Staging

The AJCC staging system is evidence-based and accounts for several important clinical and histopathologic findings. However,

TABLE 94.2

N/A, not available.

^a Clinical staging includes microstaging of the primary melanoma and clinical-radiologic evaluation for metastases.

By convention, it should be done after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

^b Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage IA tumors are the exception; they do not require pathological evaluation of the lymph nodes.

Modified from Edge S, Byrd DR, Compton CC, et al., (eds.). *AJCC Cancer Staging Manual*. 7th ed. New York: Springer; 2010.

several clinical settings are not fully addressed by the AJCC staging system. These include the following.

Positive Deep Margin on Biopsy

When a primary melanoma is diagnosed by shave biopsy, and the tumor extends to the deep margin, it is presumed that the melanoma was deeper than the original measured biopsy depth. Sometimes, on wide local excision there is residual melanoma with a greater depth than on the original biopsy. In that setting, it is appropriate to define the T stage based on the latter depth of invasion. However, in many cases, the wide excision does not reveal any more melanoma, or may reveal tumor that is more superficial. It is generally assumed that in those cases, any residual melanoma at the deep margin may have been destroyed by inflammatory changes after the biopsy. One approach for defining T stage in that setting is to call it TX. The other is to use the T stage of the original depth, even though that is incomplete. The latter has the advantage of distinguishing thin melanomas (e.g., a clinically thin melanoma with thickness <1 mm) from a thick melanoma (e.g., a 5-mm melanoma on shave biopsy, with positive deep margin). Thus, use of TX results in substantial loss of information for patients and their clinicians.

Local Recurrence After Original Incomplete Excision

Some patients present with melanoma after excisional biopsy or destruction (e.g., cryotherapy) of a pigmented skin lesion that was believed to be benign (clinically or histologically) on initial review. When such a lesion recurs and is found to contain melanoma, re-review of the original biopsy is appropriate, if available. Staging of such recurrent melanomas, when the original lesion was not known to be melanoma, is not well addressed.

Skin or Subcutaneous Lesion Without Junctional Involvement and Without Known Primary Melanoma

This is addressed later in this chapter. Cutaneous or subcutaneous nodules that occur in the absence of junctional melanocytic change, and in the absence of any other known primary, are among the most interesting presentations of melanoma. They may be in-transit metastases from primary melanomas that spontaneously regressed (stage IIIB), primary melanomas that arose from dermal nevi or that persisted in the dermis after arising from a partially regressed primary melanoma (stage IIB), or a distant metastasis

from an unknown primary melanoma (stage IV, M1a). A review of experience with these lesions at the University of Michigan suggests that they behave more like primary tumors arising in the dermis or subcutaneous tissue.⁷⁶ In the current staging system, these are considered stage III.

GENERAL CONSIDERATIONS IN CLINICAL MANAGEMENT OF A NEWLY DIAGNOSED CUTANEOUS MELANOMA (STAGE I–II)

Most melanomas present as clinically localized lesions without clinical or radiologic evidence of metastatic disease. Nonetheless, some of these patients have occult metastases, and the definitive surgical management includes both therapeutic resection and pathologic staging evaluation for regional metastases. The vast majority of primary melanomas are diagnosed on histologic assessment of skin biopsy performed by a dermatologist or a primary care practitioner. The patient then presents to a surgeon or other physician for definitive treatment.

Clinical Evaluation and Radiologic Studies for Patients with Clinical Stage I–II Melanoma

In patients with clinically localized melanoma, there is a wide range of clinical practice in the appropriate radiologic staging studies to be performed. Certainly all patients with such disease should have a complete history and physical examination, with attention to symptoms that may represent metastatic melanoma, including headaches, bone pain, weight loss, gastrointestinal symptoms, and any new physical complaints. Physical examination should carefully assess the site of the primary melanoma for clinical evidence of persistent disease and should evaluate the skin of the entire region (e.g., whole extremity or quadrant of torso, or side of the face) for dermal or subcutaneous nodules that could represent satellite or in-transit metastases. Biopsy should be done for any suspicious lesions and with a very low threshold for biopsy. In addition, physical examination should include thorough evaluation of both the major regional nodal basins (e.g., epitrochlear and axillary for a forearm melanoma) and also any atypical lymph node locations, such as the triangular intermuscular space on the back for upper back primaries.

There is a great deal of uncertainty and debate about appropriate initial staging studies. NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines[®]) from 2013 recommend no staging radiographs or blood work for melanoma in situ, and recommend imaging for low-risk thin melanomas (stage IA) “only to evaluate specific signs or symptoms.” For clinical stage I–II, no other imaging is recommended. For stage III melanoma, consideration of imaging is recommended, to include chest radiograph (CXR), computed tomography (CT) scans, or positron emission tomography (PET)/CT scans, with consideration of magnetic resonance imaging (MRI) of the brain, and other imaging is suggested only as clinically indicated. More complete staging studies are suggested for stage III melanoma.⁸⁷

CXR for asymptomatic patients with a new diagnosis of clinically localized melanoma yielded suspicious findings in 15% of patients, of whom only 0.1% had a true unsuspected lung metastasis.⁸⁸ In a similar study, the yield of true positive CXR was 0% of 248 patients.⁸⁹ In patients with stage IIB melanoma, initial staging CT scans identified occult metastasis that changed management in 0.7% of patients.⁹⁰ Even in patients with positive SNBx, staging PET scan identified no melanoma metastases in 30 patients, even though there were lymph node metastases in 16% of cases.⁹¹ In patients with clinical T1b–T3b melanomas, true positive rates for all imaging studies was 0.3%, and false-positive rates were 50% to 100% for CXR, 88% for CT and PET/CT scans.⁹² Thus, there is a large body of data that argues that

CXR, CT, and PET/CT are all of little or no value in initial staging of melanoma stage 0–IIIA.

PET with fluorodeoxyglucose (FDG) has a role in staging patients with advanced melanoma,⁹³ but its role in earlier-stage disease is less clear both because it is expensive and because it is associated with substantial radiation exposure. In one study, patients with clinically localized melanomas >1 mm thick, with local recurrence, or solitary in-transit metastases, FDG-PET scanning was performed prior to sentinel node biopsy. Sensitivity for detection of sentinel nodes was only 21%, although specificity was high (97%). In addition, 21% of patients had PET evidence of metastases, but none was confirmed by conventional imaging at that time, and the sensitivity for predicting sites of future disease recurrence was only 11%. Overall sensitivity for detecting occult stage IV disease was only 4%, and this is not recommended for initial staging.⁹⁴ These findings are similar to other experiences with PET imaging for intermediate-thickness melanomas.^{95,96}

Also, some clinicians send blood for a complete blood count, for serum chemistries, including liver function tests, and for a lactate dehydrogenase (LDH) level, especially as they may be useful prior to surgery under general anesthesia. These also are of low clinical yield in terms of the melanoma but may detect unappreciated concurrent illness that may affect therapeutic decisions, including preoperative assessment. Specifically, if there is microcytic anemia, it should be worked up, with the differential diagnosis to include gastrointestinal metastasis of melanoma. Elevated LDH should prompt a more extensive staging workup, and elevated liver function tests should prompt a hepatobiliary ultrasound or CT scan unless there is another known explanation.

Wide Local Excision for Clinical Stage I–II Melanoma: General Considerations

Wide excision of the primary melanoma is performed to provide local control. Multiple randomized, prospective clinical trials support current recommendations for the extent of the margins of resection. The wide excision also provides an opportunity to evaluate the tissue adjacent to the primary lesion for microscopic satellites, which, if present, have clinical and prognostic significance.

There has been considerable debate about the appropriate margins of excision for primary melanomas, and it is helpful to understand the evolution of thought and data about this topic. In the early 1900s, melanoma was a rare disease, and when it was diagnosed, it was often locally advanced. Surgical resection was often associated with recurrence disease, and there were no guidelines for appropriate and successful surgical management of the primary lesion. In 1907, Handley reported a study that involved histologic examination of tissue sections taken at varied distances from the primary melanoma in a human tissue specimen that he obtained from a patient with a large primary melanoma. In that study, he found microscopic evidence of melanoma cells as far as 5 cm from the primary tumor. He recommended wide re-excision of melanomas with a measured margin of 5 cm from the primary lesion. This recommendation became standard management for melanoma for many decades, with patients typically undergoing radical resections requiring skin grafts ≥ 10 cm in diameter.

As melanoma became a more frequent diagnosis, there was greater awareness of it, and lesions were often diagnosed at an earlier (thinner) stage. In addition, these large re-excisions usually contained no detectable melanoma cells separate from the primary lesion. These observations, and concern for the morbidity of large resections and skin grafts, led to a questioning of the need for 5-cm margins of resection. It is ironic that the origin of this aggressive resection practice was based on data from a single patient in a single study; however, limiting the margins of excision has required multiple large, randomized, prospective trials. These trials are summarized in Table 94.3 and are detailed in the follow sections.

TABLE 94.3

Prospective Randomized Clinical Trials of Melanoma Excision Margins

Clinical Trial	N	Thickness Ranges (mm)	Margins–Study Groups (cm)	Local Recurrence	Disease-Free Survival	Overall Survival
World Health Organization Melanoma Program Trial No. 10	612	0–2	1 vs. 3–5	None for 0–1 mm with 1 cm margins; for 1–2 mm, more local recurrences with 1 cm margins (NS)	—	No difference
French Cooperative Surgical trial	337	0–2	2 vs. 5		No difference; 10-y DFS 85% and 83%, respectively	No difference; 10-y survival 87% and 86%, respectively
Swedish Cooperative Surgical Trial	989	0.8–2	2 vs. 5	<1% overall	No difference; relative hazard rate for 2 cm margin 1.02 (0.8, 1.3)	No difference; relative hazard rate for 2 cm margin 0.96 (0.75, 1.24)
Intergroup Melanoma trial	740	1–4	2 vs. 4	0.4% (first, recurrence) 0.9% (first recurrence), 2.1% ever for 2 cm margins; 2.6% ever for 4 cm margins	—	10-y disease-specific survival 70% for 2 cm margins; 77% for 4 cm margins ($p = 0.074$, NS)
British Cooperative Group trial	900	≥ 2	1 vs. 3	(Locoregional = local + in-transit + nodal) Increase with 1 cm margin (hazard ratio 1.26, $p = 0.05$)	—	Similar; trend to better survival with 3 cm margins, $p > 0.1$ (NS)

DFS, disease-free survival; NS, not significant.

CLINICAL TRIALS TO DEFINE MARGINS OF EXCISION FOR PRIMARY CUTANEOUS MELANOMAS

The World Health Organization (WHO) Melanoma Program Trial No. 10 randomized 612 melanoma patients with melanomas ≤ 2 mm in thickness to excision margins of 1 cm versus 3 to 5 cm.^{97,98} Patients were stratified into two subgroups: Breslow depth < 1 mm versus 1 to 2 mm. There were no differences in survival rates or in rates of distant recurrences with 1-cm margins versus 3- to 5-cm margins with follow-up beyond 15 years.⁹⁹ There were more local recurrences for the group with 1-cm margin (eight versus three patients), but this was not a significant difference. There were no local recurrences for melanomas < 1 mm thick treated with 1-cm margins. The lack of local recurrences with thin melanomas (< 1 mm) after 1-cm margins of excision support this as a standard excision margin for T1 melanomas. The numerically slightly higher (but statistically insignificant) local recurrence risk with thinner margins for T2 melanomas has left questions about the appropriate margin for thicker lesions.

French and Swedish Cooperative Surgical Trials

The French Cooperative Group randomized 337 patients with melanomas up to 2 mm in thickness to 2- or 5-cm margins.¹⁰⁰ Ten-year disease-free survival rates were 85% and 83%, respectively, and ten-year overall survival (OS) rates were 87% and 86%, respectively.¹⁰⁰ The Swedish Melanoma Study Group randomized 989 patients with primary melanoma 0.8 to 2 mm thick on the trunk or extremities to 2- or 5-cm margins. Local recurrences were observed in only eight patients overall ($< 1\%$). In a multivariate Cox analysis, estimated hazard rates for OS and recurrence-free survival for those with 2-cm margin were 0.96 (95% CI, 0.75 to 1.24) and 1.02 (95% CI,

0.8 to 1.3), respectively, compared with the 5-cm margins.¹⁰¹ Both of these studies support 2-cm margins as adequate for melanomas up to 2 mm thick and find no added benefit to 5-cm margins.

Intergroup Melanoma Trial

The Intergroup Melanoma Surgical Trial addressed the question of surgical margins in 740 patients with intermediate-thickness melanomas (1.0 to 4.0 mm thick) randomized to either 2- or 4-cm margins.¹⁰² Patients were stratified by tumor thickness (1 to 2 mm, 2 to 3 mm, and 3 to 4 mm), anatomic site (trunk, head and neck, and extremity), and ulceration (present or absent). Patients with melanomas on the head and neck or distal extremity were not randomized for margin of excision because 4-cm margins are not readily performed in such locations. Thus, 468 patients (group A) were actually randomized for margin of excision. All patients were also randomly assigned to undergo either an elective lymph node dissection (ELND) or observation after wide local excision, and this component of that study is discussed separately.¹⁰²

Among the 468 patients in group A (randomly assigned to excision with 2- versus 4-cm margins), only 3 (0.6%) experienced a local recurrence as the first site of failure, and 11 (2.3%) had local recurrence overall.¹⁰² Among the 272 patients in group B (nonrandomly assigned to excision with a 2-cm margin), a higher rate of local recurrence was observed, with 3.7% having a local recurrence as a first recurrence and 6.2% overall experiencing a local recurrence during the course of their disease.¹⁰² Among these 468 patients in group A, the incidences of local recurrence as first relapse were 0.4% versus 0.9% for 2- and 4-cm margins, respectively, and the incidences of local recurrence at any time were 2.1% versus 2.6%, respectively. In addition, the time to local recurrence and the median survival after local recurrence were unaffected by the extent of the margin. Ten-year disease-specific survival rates for the two groups were 70% and 77% for 2- and 4-cm margins, respectively ($p = 0.074$, not significant). Thus, this study supports a 2-cm margin as adequate

for melanomas 1 to 4 cm thick, and this was associated with rates of local recurrence (as first recurrence) well <1%. Multivariate analysis of data from this study further supported the lack of benefit of wider margin of excision for local control and identified ulceration of the tumor and head-and-neck location only as significant negative prognostic features.

British Cooperative Group Trial

The British randomized trial compared 1- versus 3-cm margins of excision in patients who had cutaneous melanomas ≥ 2 mm thick (T3, T4).¹⁰⁵ Nine hundred patients with T3 and T4 melanomas were accrued, of whom 25% had T4 melanomas. It is the only randomized trial evaluating margins of excision that included patients with T4 melanomas. Patients with melanoma on head and neck, hands, or feet were excluded. No patients had any surgical procedure to stage the regional nodal basins (sentinel node biopsy or ELND) or systemic adjuvant therapy. The trial was stratified according to tumor thickness (2 to 4 mm versus >4 mm). There were few local recurrences; local recurrences and in-transit metastases were not statistically more frequent in the 1-cm margin group. Locoregional recurrences were defined broadly to include local, in-transit, or regional nodal recurrences. Using that definition, a 1-cm margin of excision was associated with a significantly increased risk of locoregional recurrence (hazard ratio [HR], 1.26; $p = 0.05$). Overall survival was comparable for the two groups ($p = 0.6$); there was a nonsignificant trend toward higher death rate in the group with 1-cm margins (128 versus 105 deaths; HR 1.24, $p = 0.1$). This study has been controversial, and its relevance to current practice is questioned because of the lack of surgical staging of the regional nodes, but it does challenge the safety of 1-cm margins for melanomas >2 mm thick.¹⁰⁵ These results support excision >1 cm for thicker melanomas. The data from the Melanoma Intergroup study support 2-cm margins for melanomas 2 to 4 mm thick. No data have formally compared 2-cm margins with 3-cm margins for T4 melanomas.

SURGICAL STAGING OF REGIONAL NODES

Thin and RGP melanomas are commonly cured by excision alone; however, thicker melanomas may have metastatic potential. Initial management includes an assessment for metastases and consideration of treatment options that may be beneficial in providing regional control and systemic control. Melanoma may metastasize by lymphatic or hematogenous routes. Usually, lymphatic dissemination presents earlier than hematogenous dissemination. Thus, emphasis is placed on staging the regional nodes in patients with melanoma. The finding of lymphatic metastases is associated with a higher risk of systemic disease. Another potential benefit of staging the regional nodes is to select patients for curative resection. There are substantial data on this issue that bear on the current recommendations for surgical staging of nodes, and these are summarized here.

Lymphatic anatomy is variable and is poorly understood in comparison to venous and arterial anatomy. Classic work by Sappey defined aspects of lymphatic drainage patterns from skin and defined the skin regions that typically have lymphatic drainage to major nodal basins. More recently, lymphoscintigraphy has permitted mapping the actual lymphatic drainage patterns from the skin at the site of the primary melanoma. This sometimes identifies lymphatic drainage that differs from Sappey's predictions.

In the past, the standard recommendation was to perform ELNDs for melanomas of intermediate thickness (1 to 4 mm). Despite some retrospective data supporting this approach,¹⁰⁴ subsequent retrospective and prospective studies have failed to show a significant survival advantage to routine ELND.¹⁰⁵⁻¹⁰⁷ In the early 1990s, a new procedure was developed and popularized for

surgical staging of node-negative primary melanomas, which is called *intraoperative lymphatic mapping and sentinel lymph node biopsy*. This approach has become routine practice for melanoma management.

The concept and method for SNBx was originally developed by Cabanas¹⁰⁸ for management of penile carcinomas, but it was not pursued extensively. The initial experience with lymphatic mapping and SNBx for melanoma was the work of Morton et al.¹⁰⁹ at the University of California Los Angeles and the John Wayne Cancer Institute. They injected a vital blue dye (isosulfan blue) intradermally and found that this stained the draining lymphatics and stained, in turn, the first node(s) into which these lymphatics empty. This was validated in human clinical experience and it was rapidly adopted as an effective way to identify the first lymph node(s) to which the melanoma drains.¹¹⁰ The sentinel node(s) serve as sentinels for the remainder of the node basin. Lymphatic mapping permits identification of the specific nodes that drain the relevant area of skin, and so these nodes (typically one or two nodes) can be excised for detailed histopathologic assessment while sparing the remaining nodes in that basin, which are critical for drainage of other skin areas, thus minimizing morbidity, in particular lymphedema.

Lymphoscintigraphy has been coupled with the blue dye injection to support identification of the sentinel node(s), using handheld probes for detection of γ radiation emitted by technetium-99 (⁹⁹Tc), the radionuclide commonly used in lymphoscintigraphy. Most surgical oncologists performing SNBx use a combination of radionuclide injection several hours preoperatively (in the nuclear medicine suite, up to 1 mCi of ⁹⁹Tc) and intraoperative intradermal injection of isosulfan blue dye (up to 1 ml) a few minutes prior to the incision. The injection of radiocolloid is shown in Figure 94.6. The sentinel node(s) should be both blue and radioactive ("hot"). However, sometimes the blue dye may fail to enter the node in the short interval before the dissection. Alternatively, if the dissection takes longer than anticipated, the blue dye may transit through the node by the time the node is identified. In addition, technical issues may result in the blue dye and radiocolloid being injected in slightly different areas, such that they identify different nodes. The gamma probe is used to guide the dissection to the sentinel node(s), as suggested in Figure 94.7.

Lymphatic mapping and SNBx using both blue dye and radiocolloid increases sentinel lymph node identification rates to 99% compared with 87% with blue dye ($p < 0.0001$).¹¹¹ However, radiocolloid alone has not been formally compared with radiocolloid plus blue dye. There is substantial multicenter and single-center experience with use of radiocolloid alone, which is associated with successful identification of the sentinel node(s) in >99% of patients and with a mean of approximately two sentinel nodes per

Figure 94.6 Injection of technetium-99 sulfur colloid intradermally near primary melanoma.

Figure 94.7 Schematic of a way to identify and remove the sentinel node using a handheld gamma camera.

patient.¹¹² The effectiveness of blue dye alone is limited because some patients have drainage to lymph node basins that may not be predicted (e.g., drainage from the right upper back to the left axilla) or drainage to atypical nodal basins (e.g., the triangular intermuscular space on the back, epitrochlear or popliteal nodes, or subcutaneous “in-transit” nodes that are outside a traditional nodal basin).^{113,114} Examples of unusual lymph node locations mapped by lymphoscintigraphy are shown in Figure 94.8. Thus, in the large majority of clinical settings, it is most appropriate to perform radiocolloid lymphoscintigraphy in lymphatic mapping for SNBx of melanoma.

In experienced hands, lymphatic mapping should identify a sentinel node in 98% to 100% of cases, and it should be feasible to perform the SNBx with minimal morbidity, on an outpatient basis, and in many cases under local anesthesia with sedation. The early reports of SNBx stress a long learning curve, but as the technology of gamma probes has improved, the technique is less operator dependent. In addition, lymphatic mapping has now been performed long enough that surgical residents trained since the mid-1990s typically have had experience with it for melanoma and for breast cancer. The standard evaluation of a sentinel node includes evaluation of multiple sections of the node, often combined with immunohistochemical staining for melanoma markers (e.g., S100, HMB45, tyrosinase, and/or MART-1/MelanA).

Typical results of SNBx reveal that the rate of positive nodes increases with increasing tumor thickness, as would be expected, from <5% for the thin melanomas that undergo SNBx (e.g., T1b lesions) to approximately 40% for thick melanomas. Current experience with SNBx in most series supports the prognostic value of SNBx in thick melanomas (>4 mm)¹¹⁵ as well as in thinner lesions. When ELND was performed, it was typically recommended only for melanomas 1.5 to 4 mm thick. However, in the Duke experience, the relative risk of distant versus regional metastases is not dramatically higher for thick melanomas, and this supports a clinical approach that includes the potential for curative resection of regional metastases in these cases.¹⁰⁵ In addition, the low morbidity of SNBx supports a threshold for SNBx in thinner mel-

nomas than the 1.5-mm criterion that was used for performance of ELND.

The overall rate of positive SNBx in most series (typically for melanomas >1 mm) is in the range of 15% to 25%. The percentage of patients with false-negative SNBx in experienced hands and with use of radiocolloid and the handheld gamma probe, with or without blue dye, is typically in the range of 1.9% to 4%.¹¹¹ The most rigorous definition of false-negative rate is false negative/(false negative + true positive), and 3% false negative in the setting of 20% true positive represents 13% false-negative rate. False-negative rates have been estimated by seeking nodes containing metastases in the remaining nodal basin after a negative SNBx. In other settings, it is done by defining patients who return with clinically evident nodal metastases after a prior negative SNBx in the same node basin. These may or may not be equivalent. Nonetheless, there is a small percentage of patients who have negative SNBx who later return with nodal metastases in the same nodal basin. Although the procedure is very accurate and does identify the large majority of nodal metastases, it is prudent to follow patients for nodal recurrence even after a negative SNBx.

Lymphatic mapping and SNBx has been applied generally for all cutaneous sites and may also be useful for melanomas of mucous membranes.¹¹⁶ A challenging area for SNBx is the head and neck. In particular, melanomas of the scalp and of the face may drain to parotid nodes or periparotid nodes, for which SNBx is more complex, more technically challenging, and associated with greater potential morbidity. In addition, false-negative SNBx are more common than in trunk and extremity melanomas, occurring in approximately 10% of patients, for a true false-negative rate that may approach 30%. However, in many cases, it can be performed reliably and still has a place in management.

More recent technology that offers promise for improving sentinel node localization are the development of mobile gamma cameras that can replace the single gamma detector of the gamma probe with an array of hundreds of detectors that permit real-time imaging that rivals that of the fixed gamma camera. This approach has the potential to improve identification of nodes in atypical loca-

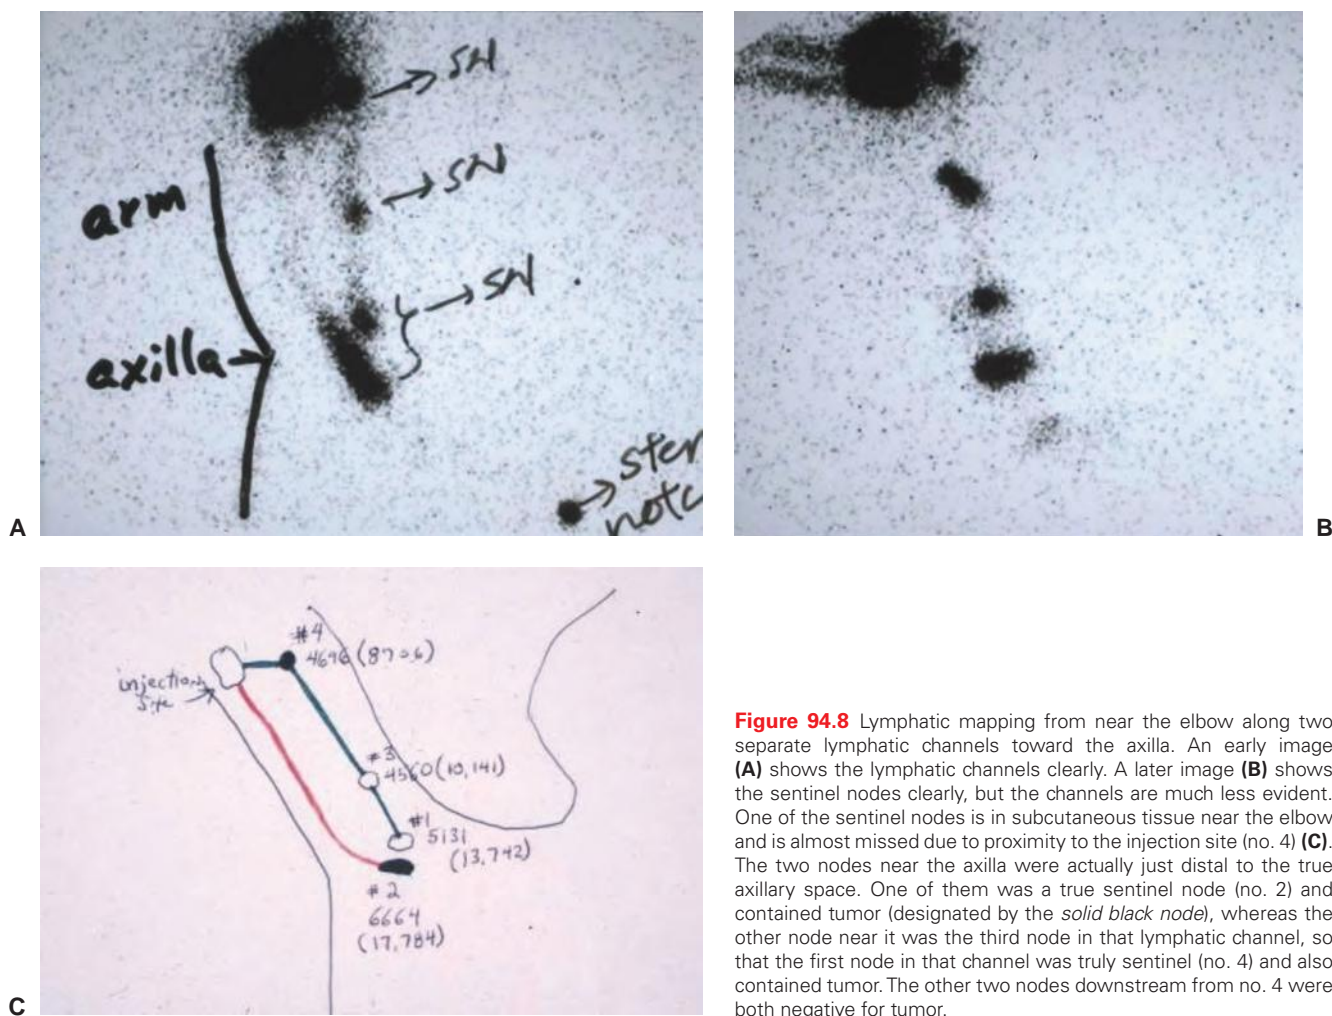

Figure 94.8 Lymphatic mapping from near the elbow along two separate lymphatic channels toward the axilla. An early image (A) shows the lymphatic channels clearly. A later image (B) shows the sentinel nodes clearly, but the channels are much less evident. One of the sentinel nodes is in subcutaneous tissue near the elbow and is almost missed due to proximity to the injection site (no. 4) (C). The two nodes near the axilla were actually just distal to the true axillary space. One of them was a true sentinel node (no. 2) and contained tumor (designated by the *solid black node*), whereas the other node near it was the third node in that lymphatic channel, so that the first node in that channel was truly sentinel (no. 4) and also contained tumor. The other two nodes downstream from no. 4 were both negative for tumor.

tions and for ensuring adequate clearance of the sentinel nodes.¹¹⁷ Also promising is single photon-emission computed tomographic/CT imaging, which can provide very discrete localization of sentinel nodes, which may be helpful in selected challenging locations. Despite the high accuracy of SNBx for nodal staging, the false-negative rate may be as high as 10% to 20%,¹¹⁸ and these new technologies offer a possibility to reduce that false-negative rate.

In performing SNBx, melanoma metastases are sometimes clinically evident in the operating room as small pigmented spots just under the capsule of the node. When these are present, the hottest part of the node is usually precisely at that location (unpublished clinical observations). This may be particularly relevant for some large nodes, where the pathologist can be guided to the portion most at risk of metastasis for detailed histologic assessment (Fig. 94.9). Morton et al.¹¹⁹ have formalized a technique that may identify the part of the node that is most likely to contain metastases, based on injecting carbon black dye and isosulfan blue dye. This has not yet become standard, but this or other refinements may further increase the accuracy of staging by this procedure.

The Multicenter Sentinel Lymphadenectomy Trial 1 was initially reported in 2006, and updated in 2014, as a randomized, prospective trial of 1,269 patients with melanomas 1 to 4 mm thick who were randomized to SNBx or observation in addition to wide local excision of the primary lesion.^{110,120,121} The finding was that there was no difference in 5-year disease-specific survival (87.1% versus 86.6%).¹²⁰ Patients who developed clinically positive nodes during follow-up after initial observation of the node basins had worse survival than those with positive nodes found at the time of SNBx; however, this posthoc analysis carries inher-

ent weaknesses.¹²⁰ In this trial, patients were randomized 3:2 to wide excision plus SNBx, or wide excision only, respectively. In the group receiving SNBx, 225 of 814 (27.6%) patients underwent early completion lymph node dissection (CLND), compared to 132 of 533 (24.7%) in the control group having delayed CLND. Lymphedema was significantly greater (20.4% versus 12.4%, $p = 0.04$) for those in the observation group who underwent delayed CLND, and hospitalization was longer for delayed

Figure 94.9 Immunohistochemical detection of isolated melanoma cells in a sentinel node when stained for the melanoma marker S100.

CLND.¹²² The follow-up results in 2014 supported the conclusion that biopsy-based staging of intermediate-thickness or thick primary melanomas provides important prognostic information and identifies patients with nodal metastases who may benefit from immediate CLND. In this series, SNBx-based management prolonged disease-free survival for all patients and prolonged distant disease-free survival and melanoma-specific survival for patients with nodal metastases from intermediate-thickness melanomas.¹²¹

One important consideration should be kept in mind, which is often overlooked in considering the potential value of SNBx and subsequent CLND. That consideration is the value to patients of regional control of their tumor, even in the absence of survival benefit. A study evaluating patients' perception of their own utilities for health states suggested that the development of recurrent disease markedly decreases patient perception of their health state, even if it does not impact survival.¹²³ This study thus suggests that regional tumor control may have value to patients, even in the absence of a survival benefit.

The rationale for performing SNBx for melanoma includes the following: (1) A negative SNBx is a good prognostic indicator that may provide comfort to low-risk patients. (2) A positive SNBx for patients with T1–T3a clinically N0 melanomas (clinical stage I–IIA) renders them candidates for adjuvant high-dose interferon (HDI) therapy, which offers some clinical benefit. (3) Patients with T4 melanomas or with microscopic satellites (N2c, stage IIIB) are further upstaged by the finding of a positive sentinel node, which helps these patients in risk assessment and may make them candidates for selected clinical trials. (4) Many clinical trials require surgical staging of regional nodes, and, thus, sentinel node mapping makes patients candidates for trials that may prove to be of benefit. (5) Identification of melanoma in a sentinel node permits selection of patients for CLND to increase the chance of regional tumor control. (6) Excision of the sentinel node may be curative if there is no tumor beyond the node, even if CLND is not feasible. This hypothesis is being explored explicitly in the Multicenter Selective Lymphadenectomy Trial 2 (MSLT2).

Selection of Patients for Sentinel Node Biopsy

SNBx is generally recommended for patients with melanomas at least 1 mm thick. For thinner melanomas, there is debate about the appropriate criteria for performing SNBx.⁸¹ A common practice is to offer SNBx for thin melanomas with adverse prognostic features, including ulceration. The 2010 staging system also identifies a mitotic rate of ≥ 1 as an adverse prognostic feature, and this is associated with higher risk of sentinel node metastasis. Earlier data also support the relevance of mitotic rate as a prognostic factor in primary melanomas⁸² or Clark level IV.⁷⁸ There is debate about performing SNBx for thin melanomas that are in VGP, that have dermal mitoses, or that occur in young patients.^{81,84} Also, there is rationale for offering SNBx for melanomas <1 mm thick that have a positive deep margin on biopsy and thus are not fully evaluable for depth.

Pure desmoplastic melanomas have a similar overall metastatic and mortality risk as other melanomas, but their risk of regional nodal metastases appears to be lower than that of other melanomas.^{67,124} Thus, it may be reasonable to limit SNBx for pure desmoplastic melanomas. However, there is limited experience with managing regional nodes in desmoplastic melanoma, and some desmoplastic melanomas can metastasize to regional nodes.⁶⁵

Sentinel Node Biopsy Subsequent to a Prior Wide Local Excision

SNBx should be performed at the same procedure as wide local excision. However, there are some circumstances in which wide local excision may be performed without SNBx, and there is then a question of whether SNBx can be performed reliably after

a prior wide local excision. Such circumstances include a thin melanoma on original biopsy, found to be deeper on re-excision or on second-opinion pathology review. A multicenter experience with 76 patients having SNBx performed after a prior wide local excision revealed a 99% success rate in SNBx, a mean yield of two sentinel nodes per patient, with a 15% overall sentinel node-positive rate, a 4% rate of melanoma recurrence in a negative mapped basin, and only a 1% rate of isolated first recurrence in a node. These and other data support performing SNBx after prior wide local excision, although performing it concurrently with the original wide local excision is preferred.¹²⁵

MANAGEMENT

Clinically Localized Melanoma

Melanoma In Situ (Clinical TISN0M0, Stage 0)

For melanomas confined to the epidermis and epidermal/dermal junction that are diagnosed as melanoma in situ, this is a lesion that is curable in the vast majority of cases by wide excision alone. On initial evaluation, the regional nodes should be examined, as should the skin and subcutaneous tissue between the primary site and these regional node basins. Melanoma in situ by definition is not invasive or metastatic; however, metastatic melanoma to regional nodes has been observed occasionally from melanoma in situ with histologic evidence of regression.¹²⁶ Thus, it is prudent to examine the nodes clinically. However, in the absence of clinical evidence of metastasis, there is no need to perform radiologic staging studies. Definitive management involves re-excision with a margin of 5 mm. The standard recommendation is to perform a full-thickness re-excision including underlying subcutaneous tissue, although there are no formal data that a full-thickness skin excision is less adequate for melanoma in situ. However, variation in thickness within the original biopsy specimen may lead to occult invasion that is not observed on the evaluated sections. Thus, it is prudent to perform a full-thickness excision of skin and subcutaneous tissue to the underlying deep fascia. A 5-mm margin is the standard recommendation, but melanoma in situ can extend beyond its visible extent. Thus, if cosmetically acceptable, it is reasonable to obtain a margin of as much as 1 cm, especially if the original biopsy was incomplete. If the margins are positive or close, re-excision to a widely clear margin is recommended. SNBx is not indicated. No adjuvant therapy is needed if the margins are widely clear.

Clinical Follow-Up After Surgical Treatment

Melanomas in situ are curable in the vast majority of cases with surgery alone. However, they rarely may be associated with metastasis, probably attributable either to an invasive component that was not detected because of sampling error, or to an associated regressed invasive component.¹²⁶

Thus, in accord with the NCCN Guidelines[®], it is appropriate to follow these patients for local recurrence, in-transit metastasis, or regional node metastasis on an annual basis. The risk of recurrence is not high enough to require specialty follow-up, but a focused physical examination of the patient by the primary care physician is appropriate. More important, patients with melanoma in situ are at increased risk of subsequent primary melanomas, and so close dermatologic follow-up with full-body skin examinations is recommended.

Thin Primary Melanoma (Clinical T1A)

The classic definition of a thin melanoma was based on the original report of Breslow⁷³ of the association between depth of invasion (Breslow thickness) and subsequent risk of metastasis and death. In that report, patients with melanomas <0.76 mm thick had no

subsequent metastasis. Thus, the definition of a thin melanoma had been a melanoma <0.76 mm thick. However, subsequent studies have shown a continuous risk association with increasing thickness, without an absolute “cutoff” at 0.76 mm,⁷³ and melanomas <0.76 mm in thickness do have approximately a 5% risk of subsequent metastasis.¹²⁷ Additional studies have defined additional histopathologic features that affect the prognosis of thin melanomas. The current AJCC staging system addresses several prognostic features of thin melanomas such that T1a melanomas are those <1 mm thick, with less than one mitosis per square millimeter, and without ulceration. In the absence of any clinical evidence of metastasis, these are clinical stage IA melanomas and have a 5-year survival rate of 94%.^{74,78}

In most centers, the surgical management of patients with T1a melanomas includes wide excision with a 1-cm margin (including skin and all underlying subcutaneous tissue, to the deep muscle fascia). The margin should be measured from the visible edge of the pigmented lesion or from the biopsy scar, whichever is larger. Excisions of this size can almost always be closed primarily, with exceptions being on the face, palms, and feet, where skin grafts or rotation flaps may be needed.

Surgical Methods in Wide Local Excision (Applies for All Primary Melanoma Thicknesses)

For melanomas of the trunk and proximal extremities, wide local excisions should involve measuring the appropriate margin (usually 1 to 2 cm) around the entire scar from the biopsy, or from the visible edge of residual melanoma, and extending the incision to make an ellipse that is approximately three times as long as it is wide. Ideally, the direction of the scar should be longitudinal on the extremities, occasionally with some modification at joints, and should be along skin lines on the trunk and neck. On the upper back, it is usually best for the scar to run transversely, to minimize tension on it. When the initial biopsy scar is not in the direction that is desired for the final excision, an effective approach is first to mark out the oval shape that is required for the appropri-

ate margins, then rather than extending that to an ellipse that is in the same direction, the ends of that oval can be extended in the desired direction, resulting in a sigmoid-shaped oval, which has two advantages: The closure results in a scar that is more in the desired direction, and the sigmoid shape allows the tension to be distributed in two directions. The excision should include all skin and subcutaneous tissue to the deep fascia, but not including the fascia. When a major cutaneous nerve runs along the deep fascia to innervate distal cutaneous structures, it is appropriate to preserve that nerve. Wide excisions can almost always be performed under local anesthesia, with or without intravenous sedation, in the patient who is thus motivated.

Clinical Follow-Up for Thin Melanomas (Stage IA)

There are no definitive data showing a survival advantage for close follow-up after surgical management of primary or metastatic melanoma; however, there is an expectation from patients for follow-up, and there are treatable recurrences and metastases that can be identified best by physician follow-up. The National Comprehensive Cancer Network[®] (NCCN[®]) has issued useful guidelines for treatment and follow-up of melanoma.¹²⁸ The risk of metastasis for thin melanomas is in the 5% to 10% range, and less for RGP lesions. In the uncommon case of recurrent thin melanomas, the recurrences usually occur late, often beyond 5 years from diagnosis; the annual risk of recurrence is fairly constant over a long time,⁴⁷ so annual follow-up for many years is recommended rather than frequent follow-up in the first few years. Follow-up suggestions are listed in Table 94.7.

Clinical T2A, T2B Melanomas

Melanomas 1 to 2 mm thick, with or without ulceration, should be managed with an initial history and physical examination to elucidate signs or symptoms that could suggest metastatic disease. In the absence of such findings, there is very low yield of additional staging studies, and they are not recommended. In those patients without evidence of metastasis, definitive management includes

wide excision with a 1- to 2-cm margin and SNBx. There are definitive data from the Melanoma Intergroup trial that a 2-cm margin is adequate for these patients,¹⁰⁷ and even a 1-cm margin was associated with the same survival as a 3- to 5-cm margin in long follow-up of the WHO Trial 10 (see Table 94.3).⁹⁹ However, there has been a slight increase in local recurrence in patients with 1- to 2-mm lesions who had 1-cm margins (versus 3- to 5-cm margins). This is not statistically significant in the patients studied, but it may signal a slight increase in local recurrence risk. When it is feasible to take a 2-cm margin without a skin graft (trunk and proximal extremities in most cases), this is recommended to minimize the chance of local recurrence. However, when the lesion is located on the face or distal extremities, where such a margin may be difficult to achieve without a skin graft, a 1- to 1.5-cm margin is acceptable. If a skin graft will be necessary even to close a 1-cm margin (rare), it is recommended that a 2-cm margin be taken because the morbidity and cost of the skin graft will already be needed. In addition, for lesions that are barely above 1 mm in depth (e.g., 1.03 mm), it certainly is reasonable to use a 1-cm margin.

SNBx is routinely recommended for patients with melanomas 1 to 2 mm thick.¹²⁹ If the SNBx is positive, then subsequent management should follow recommendations given later for stage IIIA melanoma (T2a with positive SNBx involving one to three nodes) or stage IIIB melanoma (T2b with positive SNBx involving one to three nodes). However, if the SNBx is negative, then the patient is considered to have been pathologically staged as T2aN0M0 (stage IB) or T2bN0M0 (stage IIA), and no additional surgical management is required and no adjuvant systemic therapy is indicated, other than clinical trials.

Clinical T3A Melanomas (Clinical Stage IIA)

Melanomas 2 to 4 mm thick, without ulceration, represent T3a lesions, and in the absence of metastases, these are clinical stage IIA lesions. They should be managed clinically with a history and physical examination as detailed previously and may be considered for a staging studies and serum LDH level. Definitive management includes wide excision with a 2-cm margin and SNBx for histologic staging of the regional nodes. If the SNBx is negative, then no additional surgical or systemic therapy is indicated other than possible clinical trials. If the SNBx is positive, then management for stage IIIA melanoma should be followed.

Clinical T3B Melanomas (Clinical Stage IIB)

Melanomas 2 to 4 mm thick with ulceration represent T3b lesions and thus are clinical stage IIB melanomas. These are high-risk localized melanomas. Initial management should include a careful history and physical examination. Staging studies are generally of low yield, but in selected high risk cases may be considered, and if there are symptoms suspicious for metastatic disease, there is value in performing indicated imaging studies.¹³⁰ Given the higher risk of synchronous metastases that may be detected at diagnosis, systemic staging with CT scans of the chest, abdomen, and pelvis (or PET/CT scan) plus MRI scan of the brain may be indicated if there are symptoms or signs suggestive of systemic metastasis.

In the absence of clinical evidence of metastasis, definitive management is wide excision with a 2-cm margin and an SNBx. If the nodes are negative, the summary stage is IIB (T3bN0M0). For these patients, no additional surgical therapy is needed. However, HDI and pegylated-interferon therapies have been approved for use as postsurgical adjuvant therapy for patients with resected stage IIB-III melanoma. It is worth noting that the randomized clinical trials of adjuvant interferon were performed before the recent revision of the AJCC staging system, when ulceration was not incorporated in the staging system. Thus, the patients with stage IIB in whom interferon was tested did not include the current patients with stage T3bN0. Nonetheless, it is available for such patients,

whose risk is comparable to that of patients with nonulcerated thick melanomas (T4aN0).

Thick Melanomas (T4A, T4B, Greater than 4 mm Thick)

Thick melanomas have been commonly associated with a risk of metastasis and mortality in the range of 50% over 5 to 10 years. Ulceration increases this risk: T4a melanomas are clinical stage IIB, and T4b melanomas are clinical stage IIC. Initial workup should include a history and physical examination, and serum LDH plus more aggressive radiologic imaging as indicated by signs and symptoms. For these high-risk patients, consideration should be given to more complete staging with CT scans of the chest, abdomen, and pelvis plus MRI of the head. Definitive management includes wide excision with at least a 2-cm margin plus SNBx. There are no definitive prospective, randomized data regarding margins for melanomas thicker than 4 mm, but margins of at least 2 cm are recommended. The general experience is that 2-cm margins provide adequate local control for these lesions, suggesting that the strong data supporting the adequacy of 2-cm margins in 1- to 4-mm melanomas may be extrapolated to thicker lesions.¹³¹

As SNBx has been employed routinely since the early 1990s, most studies show that sentinel node status has independent prognostic value for patients with thick melanomas.¹³¹ Because these patients have a high risk of sentinel node positivity (approximately 35% to 40%), there is a high chance of regional nodal recurrence, and SNBx, followed by CLND, offers the prospect of increasing the chance of regional control. In patients with negative sentinel nodes, adjuvant interferon should be considered because it is approved by the FDA for these patients. This should be discussed in detail with patients.

SPECIAL CONSIDERATIONS IN MANAGEMENT OF PRIMARY MELANOMAS

Primary Melanomas of the Head and Neck

For melanomas on the head and neck, there are important anatomic constraints, and there are times when the optimal margins are not feasible (e.g., a 2-cm margin for a lesion 1 cm below the eye), but to the extent possible, the optimal margins should be obtained and closed with an advancement flap, skin graft, or limited rotation flap. In the unusual circumstance of a large-diameter lentigo maligna on the face that is not amenable to surgical resection because of cosmetic results or comorbid patient conditions, it may be treated with superficial or Grenz X-rays with local control rates reported above 90%.¹³² Anecdotal reports of off-label topical treatment with imiquimod ointment have also resulted in effective local control of superficial melanomas.^{133,134} This is being used increasingly, with good results in reported experience, but recurrence may occur.¹³⁵ Initial experience suggests that imiquimod is not effective at eradicating dysplastic nevi.¹³⁶ Desmoplastic melanomas commonly occur in the head and neck region and may have reported local recurrence rates up to 40% to 60% after resection.¹³⁷ Other series vary substantially in local recurrence rates of desmoplastic melanomas. One reports local recurrences as first recurrences in 14% of patients, which exceeds that of other histologic types,⁶⁹ and another reports no difference in local recurrence rates compared to other melanomas, although the presence of neurotropism was associated with higher risks of local recurrence.⁷⁰ An explanation for the high local recurrence rates in some series of desmoplastic melanoma may include inadequate margins of excision because of anatomic constraints in the head and neck. In addition, because desmoplastic melanomas are usually amelanotic, the surgical margins may be underestimated, and the his-

tologic appearance of desmoplastic melanoma can interfere with accurate detection of microscopically positive margins, especially in fibrotic skin. Thus, in patients with desmoplastic melanoma, every effort should be made to obtain adequate margins.¹³⁷ If that is not possible, postoperative adjuvant radiation should be considered with 2- to 3-cm margins around the resected lesion because this may reduce subsequent local recurrences.

Neurotropic melanomas of the head and neck have a propensity to recur at the skull base by tracking along cranial nerves, and postoperative adjuvant radiation including the resection bed and the cranial nerve pathway should be considered for this variant.

Primary Melanomas of the Mucous Membranes

Mucosal melanomas of the head and neck, anorectal region, and female genital tract are usually diagnosed when they are thick. They are associated with higher risks of distant metastases and death compared to cutaneous melanoma. They are also associated with higher risks of local recurrence and regional nodal metastases. Staging of these lesions is not addressed completely in the AJCC staging system for cutaneous melanomas, but there are general similarities that can be applied to mucosal melanomas. The depth of invasion is difficult to measure because they are often biopsied in a fragmented way, but they usually are deep lesions, with depths often of ≥ 1 cm. They should be resected with wide margins if possible. Resection of melanomas of the nasopharynx, oropharynx, and sinuses is limited by the bony structures of the skull and the base of the brain. Vulvovaginal melanomas may be widely resected in many cases but may also be constrained by efforts to preserve urinary and sexual function. They may also be associated with extensive radial growth in addition to the invasive lesion, which can lead to multifocal local recurrences. Anorectal melanoma may usually be resected widely by an abdominoperineal resection, but this morbid operation is not associated with higher survival rates than local excision only.¹³⁸ Adjuvant local radiation therapy may be of value when widely clear margins are not feasible.¹³⁹ However, no randomized, prospective trials of radiation have been performed in this setting. SNBx has been performed for vulvovaginal melanomas, but its impact on ultimate clinical outcome is not known.¹⁴⁰ It may also be performed for anorectal melanomas,¹⁴¹ but pelvic and systemic metastases are more concerning for ultimate outcome than the risk of groin metastases. SNBx is not generally feasible for mucous membrane melanomas of the head and neck because of technical considerations.

Mucosal melanomas have not specifically been tested for their response to interferon therapy, but they are considered eligible for interferon, which is reasonable to consider after resection of thick mucosal melanomas with or without lymph node involvement. These patients may also be eligible for clinical trials in the adjuvant setting.

Primary Melanomas of the Fingers and Toes

For melanomas of the plantar aspect of the foot, especially on the anterior weight-bearing surface or on the heel, skin grafts are inadequate for bearing the weight of walking. Thus, it is often effective to rotate the skin of the instep of the foot to cover defects in those areas, with skin grafting of the instep area if needed.

For subungual melanomas of any finger or toe, the appropriate management is amputation at the interphalangeal joint of the toe or just proximal to the distal interphalangeal joint of the finger. Even for subungual melanomas in situ, such an amputation is indicated. These lesions often are found to contain invasion on the final specimen that is not evident on original biopsy, and it is not feasible to resect the entire nail bed with any margin without taking the bone of the distal phalanx because the two are intimately associated. It is important for amputations of the fingers, especially the

thumb, to attach the severed deep flexor tendon to the remaining proximal phalangeal bone, to retain adequate flexor strength after surgery. This can be done by passing a braided multifilament suture through the phalangeal bone and the ligament via holes drilled in the bone in two places. The skin incision for these amputations can be designed by measuring 1 to 2 cm (depending on thickness) from the nail bed and including at least that amount of skin with the amputation. This almost always leaves some skin on the plantar or palmar surface (except when the subungual melanoma has extended well out onto the plantar/palmar surface) that can be used to close the surgical defect and provides a sturdy skin surface.

For melanomas of the proximal toe or finger, the considerations are similar to those for distal and subungual digital melanomas. For melanoma of the toe, amputation of the toe is usually the best choice because the functional morbidity of losing a toe is small. The exception is the great toe, but even amputation of that toe is feasible, although retention of the first metatarsal head is valuable for gait and balance. For small-diameter, thin melanomas proximally located on the fingers, and for toes when appropriate, it occasionally may be feasible to perform a wide excision and skin grafting (rarely primary closure) with preservation of the digit.

SNBx can be performed accurately from these lesions and should usually be performed for melanomas of the fingers or toes if they are at least T1b lesions.

THE ROLE OF RADIATION THERAPY IN THE MANAGEMENT OF PRIMARY MELANOMA LESIONS

The general management of primary melanoma lesions is surgical resection. However, there is a role for definitive or adjuvant radiation therapy in certain histologic variants including lentigo maligna, desmoplastic melanoma, or neurotropic melanoma, and for palliation of unresectable primary disease. Lentigo maligna commonly occurs as a large lesion in the head and neck region of elderly patients. If the patient is medically inoperable or if the proposed resection would result in a poor cosmetic outcome, he or she can be treated with superficial or Grenz X-rays with local control rates above 90%.¹³² Desmoplastic melanomas also commonly occur in the head and neck region and have high local recurrence rates. Postoperative adjuvant radiation may be delivered with 2- to 3-cm margins around the resected lesion if margins are inadequate, or following resection of a locally recurrent lesion, and thus as this can substantially reduce subsequent local recurrences.¹³⁷ Neurotropic melanomas of the head and neck have a propensity to recur at the skull base by tracking along cranial nerves, and postoperative adjuvant radiation including the resection bed and the cranial nerve pathway should be considered for this variant. Large unresectable primary lesions should be considered for palliative radiation therapy or be enrolled in clinical trials. Of note, the concurrent use of interferon- $\alpha 2b$ with radiation or its use 1 month following radiation has been reported to cause increased radiation toxicity and should be used cautiously.¹⁴²

CLINICAL FOLLOW-UP FOR INTERMEDIATE-THICKNESS AND THICK MELANOMAS (STAGE IB–IIC)

Suggestions for follow-up are listed in Table 94.4. For intermediate-thickness melanomas, history and focused physical examination may be done as often as every 3 months and as infrequently as annually, with LDH, and complete blood count at least annually, and other scans done as indicated for symptoms. CT or PET/CT is not likely to have much yield if the other studies and clinical examination are all unremarkable. However, there are circumstances in which they may be useful. Especially for the high-risk

primary (e.g., T4b) on the lower extremity, pelvic CT scan or PET/CT may be helpful in identifying iliac nodal recurrences that are difficult to detect on examination. In addition, for high-risk melanomas, brain MRI may be helpful in detecting small brain metastases when they are asymptomatic and amenable to treatment with gamma knife radiation therapy.

Most first recurrences will be in local skin, in-transit skin, or lymph nodes, which can be detected on physical examination and can be treated surgically with some chance of cure. The most common first sites of visceral metastasis are lung and liver. Other frequent sites of metastasis include the gastrointestinal tract, brain, bone, distant skin or nodes, and adrenal glands. Clinical follow-up should elicit any information on headaches, weight loss, change in appetite, bone pain, or other symptoms that could be associated with these metastatic sites. There should be a low threshold for performing radiologic studies to work up such symptoms. However, routine extensive scans have not been shown to improve clinical outcome. In a study of follow-up for patients with stage II-III melanoma, melanoma recurrences were detected based on symptoms in 68%, physical examination findings in 26%, and CXR in 6%.¹⁴³ In another study of patients with stage I-II melanoma followed with physical examination, blood tests, and CXR, recurrences were detected by physical examination (72%), patient symptoms (17%), and CXR (11%).¹⁴⁴ The diagnostic yield of laboratory tests is low, but elevations of LDH or other liver function tests may signal a liver metastasis or other new metastasis. New microcytic anemia can be a first sign of gastrointestinal blood loss due to a small bowel metastasis.

REGIONALLY METASTATIC MELANOMA (STAGE III): LYMPH NODE METASTASIS, SATELLITE LESIONS, AND IN-TRANSIT METASTASES

Melanoma has a high propensity to regional metastasis in any of several presentations, all presumably via intralymphatic dissemination. These are the most common first metastases. The presence of regional metastasis is a negative prognostic finding; however, there is some chance of long-term disease-free survival and cure for patients with regional metastases, and they should be managed with curative intent whenever feasible.

There is a wide range of outcomes for patients who develop regional (stage III) metastases. Prognostic features of the primary melanoma have been associated with clinical outcome even after the development of metastases.¹⁴⁵ However, in the assessment of

prognosis of patients with stage III melanoma performed for the current AJCC staging system, only ulceration of the primary lesion had independent prognostic impact,^{74,76} and this has been incorporated in the staging system.

Regional metastases are defined as follows:

- **Local recurrence** is best defined as recurrence of melanoma in the scar from the original excision or at the edge of the skin graft if that was used for closure.
- **Satellites metastases** may occur either simultaneously with the original diagnosis or arise subsequent to original excision. Typically, recurrences that are separate from the scar but within 2 to 5 cm of it are considered satellite metastases (Fig. 94.10).
- Regional recurrences beyond 5 cm of the scar but proximal to regional nodes are considered *in-transit metastases* (Fig. 94.11).
- **Regional node metastases** are typically in a draining nodal basin that is near the lesion.

Thus, for example, melanomas of the forearm usually drain to an axillary node. However, the most proximal regional node may be an epitrochlear node or simply a subcutaneous node in an atypical location. With the use of lymphoscintigraphy and SNBx routinely in melanoma, such atypical nodal locations are increasingly defined.¹⁴⁶ It is occasionally difficult to distinguish whether an in-transit metastasis is a regional skin metastasis or a true nodal metastasis.

Management of Local Recurrence

Local recurrence is common after a primary lesion is inadequately excised. This type of local recurrence thus represents a failure of initial surgical management and may not represent the same high risk of distant metastasis and mortality that is associated with local recurrence after what is otherwise considered adequate surgical resection. However, local recurrences after adequate wide excision are associated with a very poor prognosis. In the Inter-group Melanoma trial, local recurrences were associated with 9% to 11% overall 5-year survival rate, as compared with 86% for those without local recurrence.¹⁰²

Despite the bad prognosis associated with local recurrences, some patients either may be cured or may have extended tumor control by surgical resection. It is best to re-resect the entire scar down to the level of fascia, and perhaps including fascia, because there may be more tumor in the scar than is clinically evident, and this type of resection can generally be performed with minimal morbidity. Excision with a 1- to 2-cm margin is reasonable if the recurrences are limited to the scar. In the setting of associated

Figure 94.10 Local and satellite metastases after wide excision of melanoma on the chest.

Figure 94.11 Close-up view of in-transit metastases involving the dermis, along the skin of the leg.

satellite metastases, more extensive resection may be appropriate with a skin graft. In patients with concurrent distant disease, a less aggressive approach to the local recurrence may be justified, and simple excision to a clear margin may be acceptable. In addition, it is appropriate to consider SNBx by mapping from the site of the local recurrence.¹⁴⁷ This is usually successful even if there has been a prior SNBx or a prior CLND. This may enable regional control in such high-risk patients in whom the sentinel nodes may be positive in up to 50% of cases.¹⁴⁷ Unresectable recurrent lesions should be considered for palliative radiation therapy.

Management of Satellite and In-Transit Metastases

The presence of in-transit or satellite metastases is a negative prognostic feature, with clinical outcomes similar to those observed for patients with palpable nodal metastases. Satellite and in-transit metastases have comparable biologic and prognostic significance.¹⁴⁸ When a patient presents with a solitary in-transit metastasis or a localized cluster of in-transit metastases, it is reasonable to perform excision of this along with SNBx. The margin of excision should be adequate to obtain free margins. This usually requires a 5- to 10-mm margin. A fairly frequent clinical scenario that is difficult to manage is the patient with multiple in-transit metastases. This most commonly occurs in the lower extremity from primary lesions below the knee, but it may occur in other locations. There is no ideal management for such patients because the natural history almost always involves systemic dissemination of disease, which may occur simultaneously, within a few months, or many years after the in-transit metastases. The large majority of such patients will continue to develop new in-transit metastases over time, and so true control of this process is uncommon. However, there is no reliable systemic therapy for this process; thus, surgery remains the best first option for regional control, when feasible. In some scenarios, surgical management of a symptomatic lesion may be valuable for palliation while addressing the appropriate management of other in-transit disease.

Because these patients typically continue to progress with more in-transit metastases and shorter intervals between metastases, other options for management are needed. Radiation therapy may be considered after surgical resection in this setting. Other regional options include intralesional therapy with interferon- α , interleukin (IL)-2, bacillus Calmette-Guérin (BCG), oncolytic replication competent virus injections and dyes like Rose Bengal¹⁴⁹ or application of diphencyprone,¹⁵⁰ or topical treatment of superficial metastases with imiquimod, all of which can induce responses in the treated lesions and occasionally in untreated lesions.

With the marked improvements in systemic treatments for advanced melanoma the indication for surgical excision of satellite lesions and in-transit melanoma decreases. The presence of these lesions is a hallmark of a melanoma that has ability to metastasize. Therefore, an early systemic intervention with the existing locoregional skin lesions being used as indicators for the effectiveness of the treatment has the potential to change the natural course of that melanoma as opposed to serving as a temporary local therapy. Systemic treatments that could be used in this setting are anti-cytotoxic T-lymphocyte antigen (CTLA4), anti-programmed death 1 PD-1 or anti-PD-L1 antibodies, and the neoadjuvant use of BRAF and other targeted inhibitors.¹⁵¹

Isolated Limb Perfusion and Infusion

An option for management of some patients with extensive regional recurrences in an extremity is hyperthermic isolated limb perfusion (ILP) with melphalan or isolated limb infusion. ILP can lead to complete responses in 60% to 90% of patients, with complete responses reported in 25% to 69% of patients.^{152,153} Some patients will fail to respond and others may have short-duration responses, but a

subset of patients may have durable complete responses and long-term survival.¹⁵³ Retreatment with ILP or isolated limb infusion is feasible with some benefit. There also is some morbidity associated with ILP, including a low risk of limb loss. ILP may also shrink an unresectable recurrence, rendering it resectable. Tumor necrosis factor- α has been explored as a regional therapy agent for use in combination with melphalan in ILP for melanoma, with some encouraging findings in initial assessments. However, a randomized, prospective clinical trial performed through the American College of Surgeons Oncology Group, Z0020, showed no improvement in response rates or clinical outcome with melphalan plus tumor necrosis factor- α compared with melphalan alone.¹⁵²

ILP has also been studied in the adjuvant setting after surgical treatment of a primary melanoma on the extremity, but no benefit was seen with this therapy in the adjuvant setting.¹⁵⁴

Intratumoral Therapies with Potential Systemic Effects

Intratumoral therapies have been studied to induce regression of injected lesions in patients who are not good candidates for aggressive surgery or in patients with many cutaneous in-transit metastases. Intralesional BCG has been used successfully and occasionally with regression of uninjected lesions as well as injected lesions.¹⁵⁵ A recent randomized phase 3 trial reported clinical responses after intralesional injection of melanoma metastases with an oncolytic herpes virus encoding granulocyte macrophage-colony-stimulating factor (GM-CSF), called talimogene laherparepvec, with improved clinical response rates compared to control patients receiving GM-CSF alone.¹⁵⁶ In that study, there were regressions of treated and untreated lesions, with a 26% response rate (11% complete response) versus 6% with GM-CSF control (1% complete response), with durable response rate of 16% versus 2% ($p < 0.0001$), with a trend to better survival at interim analysis.¹⁵⁶ Review of the literature reveals a range of outcomes with intratumoral injection therapies or topical treatments of cutaneous metastases (see Table 94.4). A general finding is that noninjected lesions regress in some patients, but only if the injected lesions regress.

Other approaches studied for direct treatment of individual metastases, but not included in Table 94.4, include focused radiation therapy, pulsed dye laser therapy, intralesional GM-CSF, electrochemotherapy with cisplatin, or any of several oncolytic viruses administered intralesionally.¹⁵⁷ The German S3 guidelines for melanoma management discuss intralesional medical therapy of local and regional recurrences for melanoma, based on a summary of the literature, and specify that “patients with satellite and in-transit metastases should be treated within the context of clinical studies if possible,” and that the highest response rates to intralesional therapy have included intratumoral IL-2, intratumoral electrochemotherapy with bleomycin or cisplatin, or local therapy with diphencyprone. All of these warrant investigation alone or in combination with other active therapies.

Management of Regional Lymph Node Metastases

In patients with metastases to regional nodes, prognosis is related to tumor burden in the nodes and the number of nodes involved with tumor. In numerous studies, the number of metastatic nodes is the dominant prognostic factor in stage III melanoma.^{76,158} The extent of lymph node involvement has been studied in various ways. For the current staging system, differentiation was made between clinically occult metastases (sentinel node positive, clinically negative) and clinically positive (palpable) metastatic nodes. This was a significant prognostic distinction.^{74,76} Patients with non-ulcerated primary melanomas and one to three positive sentinel nodes are stage IIIA, and 5-year survival probability is significantly

better than 50%. However, a palpable node represents stage IIIB disease. Prognosis also is worse for patients with four or more tumor-involved nodes or with satellite or in-transit metastases in addition to nodal metastases (stage IIIC).

Management of Patients After a Positive Sentinel Node Biopsy (Stage IIIa if Nonulcerated Primary Lesion, One to Three Positive Nodes)

The rationale for performing SNBx, when first developed, was to avoid the morbidity of CLND in the 80% to 85% of patients with negative regional nodes, but simultaneously to stage patients accurately and to select those patients with regional nodal metastasis for CLND. However, experience with SNBx for melanoma has been that most patients with positive sentinel nodes have only one positive node, and only about 15% of patients have melanoma metastases identified in CLND specimens.¹⁵⁹ This finding has prompted consideration of abandoning CLND for some patients after positive SNBx. Review of data from the National Cancer Database showed that only about 50% of patients with positive sentinel nodes in the United States undergo CLND.¹⁶⁰ Thus, there is a wide range of practice without clear consensus. Several studies have identified features of the positive sentinel node that predict a low risk of a positive CLND, with the suggestion that CLND may not be necessary in such situations. Features such as the number of positive sentinel nodes, the tumor burden, and the location of tumor in the node plus features of the primary melanoma all are associated with greater risk of positive nonsentinel nodes.¹⁶¹ However, most clinical experience with SNBx and evaluation of nonsentinel nodes is complicated by the fact that sentinel nodes are evaluated by a much more rigorous histopathologic approach than nonsentinel nodes, and thus the incidence of positive nonsentinel nodes may be greater than the reported 15%. One study used multiantigen reverse transcriptase-PCR to evaluate nonsentinel nodes from patients whose formal pathology report was negative for melanoma and found molecular evidence of melanoma metastases in 54% of these patients.¹⁶² This PCR approach is typically more sensitive than standard histology and may detect positive nodes that have such a low tumor burden as to be clinically insignificant. However, the current limited data suggest that the true rate of positive nonsentinel nodes after a positive SNBx may be somewhere between 15% and 50%.

The standard recommendation has been to perform CLND of any lymph node basin with a positive sentinel node for melanoma.¹⁶³ However, some patients refuse to have CLND or are not eligible for it because of medical contraindications. A recent article summarized the combined experience from 16 institutions and reported on the clinical outcome of 134 patients who had positive SNBx but who did not undergo CLND.¹⁶⁴ Their outcomes were compared with a cohort of patients with positive sentinel nodes who did undergo CLND. At a median follow-up of 20 months, 15% of patients had developed recurrent melanoma in lymph nodes as a component of a first recurrence. This was not significantly different from the outcome in patients who underwent CLND.¹⁶⁴ Thus, there is now justification for reconsidering the best surgical management after positive SNBx. Morton and colleagues initiated the MSLT2, which is randomizing patients with positive SNBx to (1) CLND or (2) close observation with lymph node basin ultrasound.¹⁶⁴ This trial will take several years to accrue and additional years for mature data. Until then, there will likely be evolution of perspectives about CLND after SNBx. There is support both for CLND and for close observation after positive SNBx, and thus equipoise exists for the MSLT2 trial. In the midst of this debate, the 2012 joint guidelines from the Society of Surgical Oncology and the American Society of Clinical Oncology recommend CLND for all patients with positive sentinel lymph nodes.¹²⁹

Management of Palpable Metastatic Melanoma in Regional Nodes: Therapeutic or Completion Lymphadenectomy

The other clinical settings for lymphadenectomy include various presentations with clinically evident regional nodes: after a negative SNBx, after observation of a nodal basin, or from an unknown primary melanoma. If lymph node recurrence appears after a prior complete dissection in the same basin, the surgical management may include a repeat node dissection, but if there is confidence that the original dissection was thorough, the repeat procedure may be more limited to the site of evident tumor recurrence.

Metastasis to a regional node represents stage III (A, B, or C) disease and is associated with a subsequent risk of distant metastasis in the range of 40% to 80%. Nonetheless, there is a significant chance of cure after complete lymphadenectomy for stage III melanoma^{105,158} with overall 25-year survival rates of 35%.¹⁶⁵ Thus, lymphadenectomy for stage III melanoma is performed with curative intent. However, even if the patient develops distant disease in the future, there is benefit in achieving regional control, which is obtained in about 90% of patients.¹⁰⁵ When regional nodal disease is left in place, it can become extensive, with skin involvement, even ulceration, and with extension to involve major neurovascular structures. An example of extensive axillary recurrence with skin involvement is shown in Figure 94.12. Aggressive surgical management of less extensive disease can avoid these changes in most patients.

There are some specific considerations related to lymph node dissections in different node basins. These are summarized as follows.

Axillary Dissection

Axillary dissection should include all node-bearing tissue in levels I, II, and III. The long thoracic nerve and thoracodorsal neurovascular bundle should be identified and preserved unless involved with tumor. The superior border of dissection should be the axillary vein, anteriorly, which should be skeletonized. However, deep to the axillary vein and plexus, the axillary space extends superiorly and medially substantially above the level of the axillary vein, and that region should be cleared surgically, with careful attention to preservation of the long thoracic nerve, which runs along the chest wall to its origin from spinal nerves. The intercostobrachial nerve and lower intercostal nerves that run through the axillary space may usually be sacrificed. The pectoralis major and minor muscles are usually preserved along with the medial pectoral nerve and vessels, but in reoperative cases or cases with involvement of one or both of

Figure 94.12 Extensive axillary adenopathy before resection.

these muscles, part of all of them may be sacrificed. It is rare for the long thoracic node to be involved with tumor, and it should be preserved because denervation of the serratus anterior muscle leads to “winged scapula” and can be associated with chronic pain related to destabilization of the shoulder. When there is bulky axillary disease, though, it is not uncommon for the thoracodorsal nerve to be involved, and patients usually tolerate sacrifice of that nerve when necessary. However, the possibility of resection of it should be discussed with patients preoperatively, especially when there is bulky adenopathy. In addition, if there is bulky axillary disease, the tumor often abuts or involves the axillary vein. The axillary vein usually consists of more than one vessel running in parallel; thus, sacrifice of the lowest limb of the axillary vein often is accomplished without evident morbidity. Even sacrifice of the entire axillary vein (one or several trunks) is usually tolerated well and can be considered in cases of advanced disease when necessary to enable complete resection of recurrent tumor. A troublesome finding is tumor involvement of the brachial plexus. Definitive therapy of that may require forequarter amputation, which is usually an unappealing option when the risk of systemic recurrence is also likely to be high, as it is in such cases. One alternative is to resect as much as possible while preserving the plexus, followed by adjuvant radiation therapy to the axilla. Another is to resect part of the brachial plexus, which has been reported, and in experienced hands can be done with reasonable outcomes.

In the vast majority of cases, even with some bulky disease, axillary dissection can be performed with minimal morbidity, with full expectation of full range of motion and function after recovery from the surgery over approximately 8 to 12 weeks. Lymphedema is an expected long-term complication, but it is usually a significant clinical issue in only about 10% of patients, and it can often be treated well with compression sleeve and/or manual lymphatic drainage therapy.

Inguinal and Iliac Dissection

For patients with metastatic melanoma to inguinal nodes, complete groin dissection is indicated. The nomenclature and clinical practice patterns vary for this procedure. As described by Spratt et al.,¹⁶⁶ the inguinal region can be defined as including the superficial inguinal region, which is superficial to the fascia that lies immediately superficial to the femoral vessels, and the deep inguinal region, which is deep to that fascia and includes the femoral vessels. The saphenous vein enters the femoral vein in the upper third of the inguinal region and passes through a foramen in the deep fascia. Cloquet node is the deep inguinal node that is classically considered to be the transitional node between the inguinal region and the iliac region. Although it is variable in its location, presence, and size, a superficial groin dissection should include removal of that node and identification of it for histologic evaluation. If that node contains metastatic melanoma, an iliac and obturator dissection is usually indicated. When patients have extensive nodal disease in the inguinal region, a complete inguinal dissection is appropriate, with skeletonization of the femoral artery and vein, often with a Sartorius flap to cover these vessels. However, for completion node dissection after a positive SNBx, a superficial inguinal dissection with excision of Cloquet node may be performed. Cloquet node is accessible through the foramen in which the saphenous bulb is found and is located lateral to the saphenous bulb.

Some surgeons describe the iliac region as the deep groin, but this terminology can lead to ambiguity. An iliac node dissection involves skeletonizing the external iliac vessels and is generally combined with removal of the iliac node-bearing tissue and obturator fat pad (obturator dissection). This dissection extends from the inguinal ligament to the takeoff of the internal iliac vessels and can be performed in continuity with the inguinal dissection or through a separate lower-quadrant abdominal wall incision and a retroperitoneal approach.

Patients with known inguinal metastases should undergo CT scan of the pelvis or PET/CT scan. Clinical evidence of iliac adenopathy or a positive Cloquet node at the time of groin dissection is an indication for iliac and obturator dissection. There is a range of clinical practice; some surgeons perform iliac dissections routinely for patients with extensive inguinal adenopathy.

The risk of lymphedema with inguinal or ilioinguinal dissection is greater than for axillary or cervical node dissections. Although most patients recover well, some degree of lymphedema probably occurs in most patients with this procedure. It may require a fitted compression stocking or massage therapy approaches.

Cervical Dissection

Metastatic melanoma to a cervical node is appropriately managed by complete neck dissection. A modified radical neck dissection should be performed, with preservation of the internal jugular vein, sternocleidomastoid muscle, and spinal accessory nerve. However, if these structures are invaded by tumor or involved with tumor, they can be resected. Sacrifice of the spinal accessory nerve can cause significant morbidity but is occasionally necessary. Melanomas of the face, ear, or anterior scalp often drain to parotid or periparotid nodes. In such cases, superficial parotidectomy is indicated as part of a modified radical neck dissection. In some situations, such as metastases to submental nodes near the midline or very low cervical nodes from a medial shoulder primary, there may be rationale for a neck dissection that is limited based on lymphatic anatomy.

MANAGEMENT OF REGIONAL METASTASES IN PATIENTS WITH VISCERAL OR OTHER DISTANT DISEASE

Regional metastases are common also in patients with advanced distant disease. Management of regional metastases can be important for clinical management even in the setting of distant disease, especially when painful or presenting with skin invasion and impending ulceration.

Melanoma Radiation Therapy

Data exist to support the use of adjuvant radiation to reduce primary and regional nodal recurrences in selected patient populations and for its use for palliation of unresectable primary and nodal recurrences or distant metastases. There is no current consensus regarding the optimal dose fractionation schedule for melanoma. Controversy surrounding the radiosensitivity of melanoma began in the early 1970s when cell survival curves for several human melanoma cell lines were published showing a broad shoulder indicative of high levels of potentially lethal damage repair. This fosters the hypothesis that melanomas were less likely to respond to conventionally fractionated radiation at 2 to 2.5 Gy per fraction and that higher dose per fraction schedules might result in superior clinical outcomes.¹⁶⁷ These studies caused many investigators to adopt high-dose (≥ 4 Gy per fraction) fractionation schedules for melanoma, and several investigators published improved clinical outcomes with these large fractional doses compared to conventional fractionation.¹⁶⁸ This led the Radiation Therapy Oncology Group (RTOG) to initiate RTOG 83-05, which was a prospective randomized trial comparing the effectiveness of high dose per fraction radiation and conventionally fractionated radiation in the treatment of melanoma. RTOG 83-05 randomized 126 patients with measurable lesions to 8.0 Gy \times 4 fractions (32 Gy total) in 21 days delivered once weekly or 2.5 Gy \times 20 fractions (50 Gy total) in 26 to 28 days delivered 5 days a week. The study was closed early when interim statistical analysis suggested that further accrual would not reveal a statistical difference between the arms. The 8.0 Gy \times 4 fraction arm had a complete remission of 24% and

partial remission of 36%, and the 20 × 2.5 Gy arm had a complete remission of 23% and partial remission of 34%.¹⁶⁸ This randomized trial demonstrated that melanoma is a radioresponsive tumor, and conventional and high dose per fraction schedules are equally effective clinically.

Despite the results of this study, many investigators still report that melanoma is a radioresistant histology and most current retrospective clinical reports regarding radiation for melanoma have used a high dose per fraction schedule. Although high dose per fraction treatments can result in increased risk of late radiation toxicity, there are little data to suggest that high dose per fraction schedules such as 30 Gy in five fractions over 2.5 weeks, which is currently commonly used in the adjuvant treatment of nodal basins following lymph node dissection,¹⁶⁹ results in increased late toxicity compared to conventionally fractionated regimens to 50 to 70 Gy. High-dose fractionation schedules are more convenient for the patient, less expensive, allow patients to proceed with systemic therapy sooner, and should be considered as a reasonable option unless critical structures are in the irradiated volume that would be treated above their radiation tolerance or the volume has previously been irradiated. They are particularly appropriate for patients with widespread disease and short life expectancies as they can provide rapid palliation, and late-radiation toxicity is not a concern for this patient population.

The Role of Radiation Therapy in the Management of Regional Nodal Disease

Patients with positive SNBx or palpable regional nodal metastases (stage III disease) are treated with therapeutic inguinal, axillary, or cervical lymph node dissections. Several large retrospective studies have identified lymph node extracapsular extension, large lymph nodes (≥ 3 cm in diameter), four or more involved lymph nodes, or recurrent disease after previous lymph node dissection as adverse risk factors that increase the risk for nodal basin recurrence following therapeutic nodal dissection to 30% to 50%.^{76,170,171} Given the potential morbidity of recurrent unresectable nodal disease with pain, ulceration, bleeding, and lymphedema, these high-risk patients have been treated with high dose per fraction or conventionally fractionated postoperative adjuvant radiation delivered to nodal basins. Retrospective reports from several centers report 5-year locoregional control rates after radiation ranging from 80% to 93%.^{169,171} There are no prospective randomized data comparing high dose per fraction schedules to conventional fractionation schedules to compare efficacy or toxicity between these treatment techniques; however, locoregional control rates appear to be equivalent with both schedules, resulting in 87% 5-year locoregional control rate in at least one report.¹⁷¹

Despite the improvement in locoregional control, postoperative adjuvant nodal irradiation has not shown a survival benefit. Most reports quote 5-year survival rates of 33% to 0%, which is similar to historic rates of patients not undergoing radiation or patients undergoing radiation following a re-excision of nodal failures, because of high rates of distant metastatic spread in this patient population.^{169,171,172} Radiation complication rates in these retrospective studies vary depending on the site irradiated and include lymphedema, fibrosis, nerve plexopathies, and osteonecrosis, with lymphedema of the arm and leg being the major toxicity reported in most series.^{169,171,172} Given the retrospective nature of these studies, it is not clear if some of these toxicities are solely attributable to radiation or are related to surgical morbidity or tumor recurrence.

In a multi-institutional report, the outcomes of 615 patients from MD Anderson and Roswell Park Cancer Centers with advanced regional nodal metastatic disease who underwent lymphadenectomy with and without adjuvant radiation were reported retrospectively.¹⁷³ On multivariate analysis, the number of positive lymph nodes, the number of lymph nodes removed,

and the use of adjuvant radiation were associated with improved regional control. At a median follow-up of 60 months, regional failure occurred in 10% of patients with adjuvant radiation and 41% without adjuvant radiation. Distant metastatic disease developed in 55% of patients treated with adjuvant radiation and 74% of patients treated without adjuvant radiation. On multivariate analysis, disease-specific survival was reported to be significantly improved by the addition of adjuvant radiation.¹⁷³ In summary, retrospective data suggest that postoperative adjuvant radiation for patients with stage III disease results in improved locoregional control with reasonable complication rates but with no obvious survival benefit in most reports.

The Trans Tasman Radiation Oncology Group (Study 96.06) is the first prospective single-arm phase 2 study of adjuvant postoperative radiation therapy following lymphadenectomy in malignant melanoma with sufficient statistical power to answer its primary end points of regional in field relapse and late toxicity rates and secondary end points of adjacent relapse, distant relapse, OS, progression-free survival (PFS), and time to in-field recurrence. A total of 234 patients were treated with CLND followed by 48 Gy delivered in 20 fractions with 2.4 Gy per fraction over 4 weeks to the nodal basin using specified treatment guidelines. The reported overall pattern of first relapse showed a regional in-field recurrence rate of 6.8% and a distant relapse rate of 63%. The 5-year OS was 36% and the 5-year regional control rate was 91%. Grade 3 toxicity from axillary and inguinal lymphedema was 9% and 19%, respectively.¹⁷⁴ Burmeister et al.¹⁷⁵ reported results of the first multicenter prospective randomized trial (Trans Tasman Radiation Oncology Group 02.01/ANZMTG 01.02) comparing postoperative adjuvant radiation (48 Gy in 20 fractions) versus observation of patients with high-risk nodal metastatic melanoma (one or more parotid node, two or more cervical or axillary, or three or more groin-positive nodes, extracapsular spread, or ≥ 3 cm diameter cervical or axillary node or ≥ 4 cm groin node) following lymphadenectomy. A total of 250 patients were randomized and 217 were eligible for analysis; with a median follow-up of 27 months, the regional nodal failure rates were 19% for the radiation arm and 31% for the observation arm ($p = 0.041$) and median disease-free survival times and OS times were not significantly different ($p = 0.56$ and 0.12, respectively).¹⁷⁵ This study also found that the extent of extranodal extension (ENE) of melanoma independently predicted in-basin lymph node recurrences (14% for those without ENE, 17% with limited ENE, and 32% with extensive ENE, $p = 0.001$, multivariate).¹⁷⁵ Therefore, adjuvant radiation therapy to a nodal basin in patients with high risk of relapse after surgery improved local control at the expense of increased toxicities, but since the main risk in these patients is systemic relapse, then its use needs to be carefully evaluated in the setting of lack of improvement in PFS and OS.

ADJUVANT SYSTEMIC THERAPY (STAGES IIB, IIC, AND III)

Adjuvant Interferon Therapy

After over 50 years and in excess of 100 randomized clinical trials aimed at decreasing the relapse rate of melanomas at a high risk of relapse after surgery, only interferon- α (in two different formulations) has gained regulatory approval by either the FDA and/or the European Medicines Agency. Interferon- α -based adjuvant therapy has been administered in several variations: (1) HDI- α for 1 month followed by 1 year of intermediate dosing, (2) interferon- α at an intermediate dose administered for 1 or 2 years, (3) interferon- α at a low dose administered for 1 or 3 years, or (4) pegylated interferon administered for a target period of 5 years (Table 94.5). The multiple randomized clinical trials testing the benefits of interferon- α using these different regimens in the adjuvant setting have been subject of metanalysis.¹⁷⁶

TABLE 94.6

Summary of Ongoing Phase 2 Adjuvant Trials in High-Risk Melanoma

Study Reference	No. of Patients	TNM Stage	Therapy	Dose and Schedule—Treatment Arm	Primary Endpoint	ClinicalTrials.gov Identifier
EORTC 18071	950	III (T _{any} , N+ except in transit, M0)	Ipilimumab vs. placebo	IV, 10 mg/kg, 4× every 21 d, then starting from week 24 every 12 wk until week 156 or progression, 3 y	RFS	NCT00636168
US Intergroup E1609	1,500	III (IIIB, IIIC), IV (M1a, M1b)	Ipilimumab at 10 mg/kg (Arm A) or 3 mg/kg (Arm C) vs. high-dose interferon-alpha (Arm B)	IV, 10 mg/kg (A) or 3 mg/kg (C), 4× every 21 d, then starting from week 24 every 12 wk, 4× Vs. IV 20 MU/m ² 5×/wk for 4 wk, then SC 10 MU/m ² 3×/wk for 48 wk	RFS and OS	NCT01274338
COMBI-AD	852	III BRAF V600E/K mutation-positive	Dabrafenib + trametinib vs. placebo	Dabrafenib (150 mg twice daily) and trametinib (2 mg once daily) orally for 12 mo	RFS	NCT01682083
BRIM 8	725	IIC, III BRAF V600 mutation positive by Cobas (Roche, Basel, Switzerland)	Vemurafenib vs. placebo	Vemurafenib 960 mg orally twice daily for 52 wk	DFS	NCT01667419
DERMA	1349	IIIB or IIIC (tumor expression of MAGE-A3 gene)	GSK 2132231A (D1/3-MAGE-3-His fusion protein) vs. placebo	GSK 2132231A IM solution, 13 injections over 27 mo	DFS	NCT00796445

TNM, tumor, node, metastasis; EORTC, European Organisation for Research and Treatment of Cancer; IV, intravenous; RFS, relapse-free survival; OS, overall survival; SC, subcutaneous; DFS, disease-free survival; IM, intramuscular.

Provided by Ahmad Tarhini (Adapted from Davar D, Tarhini AA, Kirkwood JM. Adjuvant immunotherapy of melanoma and development of new approaches using the neoadjuvant approach. *Clin Dermatol* 2013;31:237–250).

Data from a total of 10,499 participants enrolled in 18 randomized clinical trials were reviewed, allowing the evaluation of the therapeutic efficacy of interferon in terms of disease-free survival (17 trials) and OS (15 trials). Adjuvant interferon was associated with significantly improved disease-free survival (HR = 0.83; 95% CI, 0.78 to 0.87, $p < 0.00001$) and OS (HR = 0.91; 95% CI, 0.85 to 0.97; $p = 0.003$). Subgroup analyses failed to detect a significant impact of different regimens of interferon- α administration or patient subgroups with different benefit to this mode of therapy. The use of adjuvant interferon-based therapy has become the standard of care therapy in most melanoma centers and in the community, and it is the basis of most comparator arms in ongoing adjuvant therapy clinical trials (Table 94.6).

High-Dose Interferon- α 2B

Adjuvant HDI- α 2b was approved by the FDA in 1996 for the treatment of resected stage IIB and stage III melanoma based on the results of the Eastern Cooperative Oncology Group (ECOG) trial E1684.¹⁷⁷ Interferon- α was administered by intravenous infusion, 20 million U/m², for 5 consecutive days every 7 days for 4 weeks during the “induction” phase. For the subsequent 48 weeks, 10 million U/m² were administered by subcutaneous injection on alternate days for a total of three doses every 7 days in the “maintenance” phase. The control arm was observation, which was the standard at the time that the trial was conducted. A total of 287 patients were enrolled, 80% of whom had stage III melanoma; 20% had stage IIB melanoma. Pathologic staging was performed with regional lymph node dissection because SNBx had not yet been introduced. Overall survival was the primary end point, and the trial was designed to detect a 33% improvement. A protocol-specified analysis with median follow-up of 6.9 years revealed a statistically significant 33% improvement

by HR in OS compared to the observation arm after adjusting for other prognostic factors in a multivariate model ($p = 0.012$). Relapse-free survival was also significantly improved (39% improvement by HR compared to observation after adjusting for other prognostic factors; $p = 0.001$). Approximately three-fourths of the interferon-treated patients experiencing grade 3 or 4 toxicities by National Cancer Institute Common Toxicity Criteria. The most common were fatigue, asthenia, fever, depression, and elevated liver transaminases. A subsequent quality-of-life analysis of this trial population suggested that the toxicity associated with this regimen was largely compensated for by the psychological benefit derived from prevention of disease relapse.¹⁷⁸

Since the reporting of E1684, several other studies of HDI have been conducted. Overall, nearly 2,000 patients with stage IIB and III melanoma have participated in four multicenter, randomized trials, conducted by the US Intergroup, investigating adjuvant HDI- α 2b therapy. Data from these E1684, E1690, E1694, and E2696 clinical trials was updated to April 2001.¹⁷⁹ Analysis of treatment effects versus observation was based on data from 713 patients randomized to HDI or observation in trials E1684 and E1690. Overall, this updated analysis confirmed the original conclusions with the extended median follow-up intervals of 2.1 to 12.6 years. Relapse-free survival, but not OS, was significantly prolonged (two-sided log-rank $p = 0.006$) for patients treated with HDI versus observation. Among all patients, ulceration, recurrent disease at entry, enrollment in E1684, and age >49 years significantly negatively impacted relapse-free survival.

The North Central Cancer Treatment Group trial tested a regimen of 20 MU/m² dose of interferon- α 2a administered intramuscularly three times per week for 12 weeks for stage II and III disease. This clinical trial demonstrated improvements in median disease-free survival and OS that were nonsignificant, with higher-risk patients appearing to benefit disproportionately.¹⁸⁰

Several clinical trials have tested a variety of regimens using lower doses of interferon, which have been conducted with the goal of decreasing toxicities while maintain efficacy. EORTC 18871 used a very-low-dose regimen (1 MU subcutaneously every other day), while the low-dose regimen of 3 MU subcutaneously thrice weekly was tested in WHO Melanoma Program Trial 16¹⁸¹ (stage III), Scottish Melanoma Cooperative Group trial¹⁸² (stage IIB/III), UK Co-ordinating Committee on Cancer Research AIM-High trial¹⁸³ (stage IIB/III), E169020 (T4, N1), and the 2010 German Dermatologic Cooperative Oncology Group (DeCOG) study¹⁸⁴ (T3Nx). None of these clinical trials showed a benefit in terms of OS. The 2008 German DeCOG study demonstrated a survival benefit for low-dose interferon but was powered primarily to assess the benefit of combination low-dose irradiation with dacarbazine and not designed to evaluate the low-dose regimen per se.¹⁸⁵ A number of trials have tested intermediate-dose interferon. EORTC 18952 demonstrated a 7.2% increase in distant metastases-free survival in patients with stage IIB/III, which was not statistically significant and no OS benefit was observed.¹⁸⁶

Shortening the duration of therapy with HDI has also been a focus of clinical testing. The Italian Melanoma Intergroup enrolled 336 patients with stage III disease to receive either standard HDI or an intensified regimen (20 MU/m² intravenously 5 days/week for 4 weeks every other month for four cycles). At the 5-year mark, there were no statistically significant differences in either relapse-free survival or OS while toxicities did not increase.¹⁸⁷

It had been postulated that the first month of intravenous HDI- α 2b may be the main component providing benefit in HDI regimens. To test this concept, the ECOG E1697 randomized patients to 4 weeks of intravenous HDI with no maintenance therapy compared to observation. However, the interim analysis of E1697 after 1,150 of an originally planned 1,420 patients led to closing the study for futility.¹⁸⁸

Pegylated Interferon- α

Pegylated interferon- α 2b was approved by the FDA in 2011 for the adjuvant treatment of melanoma with microscopic or gross nodal involvement (stage III) within 84 days of definitive surgical resection including complete lymphadenectomy based on the results of EORTC 18991.¹⁸⁹ This was a randomized clinical trial comparing pegylated interferon- α 2b with observation. Pegylation results in substantially slower clearance of interferon after administration. This allows for more stable drug exposure than can be achieved with the shorter-lived conventional interferon- α administered on alternating days by subcutaneous injection. Pegylated interferon can be administered less frequently and at a lower dose per injection but maintaining drug exposure over the course of several days. This results in a lower peak concentration after each dose while increasing the interval during which interferon is at biologically active concentrations in blood. Short-term¹⁸⁹ and long-term follow-up data has been provided on the EORTC 18991 clinical trial.¹⁹⁰ In this study, 1,256 patients with resected stage III melanoma were randomly assigned to observation ($n = 629$) or pegylated interferon 6 mcg/kg per week for 8 weeks by subcutaneous injection, followed by maintenance at 3 mcg/kg weekly ($n = 627$) for an intended duration of 5 years. Patients were prospectively stratified according to microscopic (N1) versus macroscopic (N2) nodal involvement, number of positive nodes, ulceration and tumor thickness, sex, and center. The primary end point was recurrence-free survival, and OS was a secondary end point. At 7.6 years of median follow-up, 384 recurrences or deaths had occurred with pegylated interferon versus 406 in the observation group (HR = 0.87; 95% CI, 0.76 to 1.00; $p = 0.055$); 7-year recurrence-free survival rate was 39% versus 35%. There was no difference in OS ($p = 0.57$). In stage III-N1 ulcerated melanoma, recurrence-free survival (HR = 0.72; 99% CI, 0.46 to 1.13; $p = 0.06$), and OS (HR = 0.59; 99% CI, 0.35 to 0.97; $p = 0.006$) were prolonged with pegylated interferon. Despite the anticipation that

pegylated interferon would be better tolerated than HDI, pegylated interferon was discontinued for toxicity in 37% of patients.

Cytotoxic Chemotherapy and Biochemotherapy in Adjuvant Therapy of Melanoma

There has been a long list of prospective randomized clinical trials testing single-agent or combination-agent chemotherapy in the adjuvant setting, which have been nearly universally negative in terms of providing a clear clinical advantage over the control arm. For example, dacarbazine was not effective in the postoperative setting, whether administered alone or combined with BCG.⁹⁹ The only clearly positive clinical trial has been US intergroup study led by SWOG S0008, a phase 3 clinical trial of a biochemotherapy combination compared to standard HDI- α in patients with high-risk melanoma.¹⁹¹ The investigators sought to determine whether a short course of biochemotherapy would be more effective than HDI as adjuvant treatment in patients with high-risk melanoma. S0008 enrolled patients with stage IIIA-N2a through stage IIIC-N3, who were randomized to either HDI following the E1684 schedule, or biochemotherapy consisting of dacarbazine 800 mg/m² on day 1, cisplatin 20 mg/m² on days 1 to 4; vinblastine 1.2 mg/m² on days 1 to 4; IL-2 9 MU/m² per day continuous intravenous administration on days 1 to 4; interferon 5 MU/m² per day subcutaneously on days 1 to 4, 8, 10, and 12; and granulocyte-colony-stimulating factor 5 ug/kg per day subcutaneously on days 7 to 16. Biochemotherapy cycles were given every 21 days for three cycles (9 weeks total). Patients were stratified for number of involved nodes (one to three versus four or more), micro- versus macrometastasis, and ulceration of the primary. Coprimary end points were relapse-free survival and OS. Between 2000 and 2007, 432 patients were enrolled. Grade 3-4 adverse events occurred in 64% of patients receiving HDI and 76% of patients randomized to biochemotherapy. At a median follow-up of 7.2 years, biochemotherapy improved relapse-free survival ($p = 0.015$; HR = 0.75; 95% CI, 0.58 to 0.97), with median relapse-free survival for biochemotherapy of 4.0 years (95% CI, 1.9 years— not reached) versus 1.9 years for HDI (95% CI, 1.2 to 2.8 years), and a 5-year relapse-free survival of 48% versus 39%. However, the OS was not different between the two arms ($p = 0.55$; HR = 0.98; 95% CI, 0.74 to 1.31), with median OS of 9.9 years (95% CI, 4.62 years— not reached) for biochemotherapy versus 6.7 years (95% CI, 4.5 years— not reached) for HDI, and 5-year OS of 56% for both arms. It was concluded that biochemotherapy could be considered as a shorter alternative to HDI for patients with high-risk melanoma.

Experimental Adjuvant Immunotherapy

There has been a long list of large adjuvant clinical trials with a variety of immunotherapy approaches for melanoma with negative results. The studies used whole tumor cell vaccines like Melacine (Corixa Corporation, Seattle, WA) or Cancervax (Marina del Ray, CA), MAGE-A3 (GlaxoSmithKline, Brentford, UK), ganglioside-based vaccines like GMK (Progenics Pharmaceuticals, Inc., Tarrytown, NY), and smaller studies with melanosomal antigen peptide vaccines. Furthermore, uncontrolled studies in patients with completely surgically resected stage IV (stage IV with no evidence of disease) led to the testing of adjuvant GM-CSF and a multi-peptide vaccine in a placebo-controlled, randomized, prospective trial (ECOG E4697). That trial accrued approximately 800 patients but showed no significant beneficial impact of GM-CSF on clinical outcomes.¹⁹² Recent data highlight the critical nature of vaccine adjuvants. Murine and human data suggest that use of incomplete Freund adjuvant with short peptide vaccines may interfere with protective antitumor T-cell responses by recruiting T cells selectively back to the vaccine site rather than to the tumor.¹⁹³ On the other hand, vaccines may be

made much more effective at inducing T-cell responses in patients by incorporating a toll-like receptor 9 agonist CpG.¹⁹⁴ Thus, new vaccine approaches will explore the value of more optimal adjuvants. Also, the availability now of clinically effective immune therapies for advanced melanoma promises to open the door to new combination immune therapies in the adjuvant setting that will be explored in clinical trials over the next few years (see Table 94.6).

Cytotoxic T-Lymphocyte Antigen 4 and PD-1 Blockade in Adjuvant Therapy

Ipilimumab is a fully human immunoglobulin G1 monoclonal antibody that blocks CTLA4, which has demonstrated improvement in OS in the treatment of metastatic melanoma in two randomized clinical trials.^{195,196} This has led to clinical trials investigating the potential for ipilimumab in the adjuvant setting (see Table 94.6). EORTC 18071 is comparing ipilimumab at 10 mg/kg with maintenance therapy against placebo. Accrual is complete and results are pending. E1609 is an accruing clinical trial randomizing patients to ipilimumab at 10 mg/kg or 3 mg/kg for four doses, compared to a control arm receiving standard high-dose adjuvant interferon therapy. Enrollment on the 10 mg/kg arm was put on hold in 2013. Results are not anticipated until 2015. Early evaluation of clinical trials testing anti-PD-1 and anti-PD-L1 antibodies in patients with metastatic melanoma suggest that this class of immune modulating antibodies is likely to provide a high rate of durable tumor responses. S1404 is a planned clinical trial testing the anti-PD-1 IgG4 monoclonal antibody MK-3475 (lambrolizumab) compared to HDI. Results of this trial will take 3 to 4 years.

Neoadjuvant Therapy for Resectable Stage III or IV Melanoma

Neoadjuvant therapy for resectable stage III or stage IV melanoma remains an investigational approach. A study of neoadjuvant interferon for patients with palpable regional lymph node metastases was associated with an objective tumor response rate of 55%.¹⁹⁷ Further studies of this or other neoadjuvant therapies provide opportunities to investigate tumor biology in the tumor microenvironment and may lead to better understanding of the mechanism of antitumor effects of novel therapies.

Clinical Follow-Up for Patients with Regionally Metastatic Melanomas (Stage III)

There is no agreed follow-up plan for surgically resected melanoma. Most studies conducted to date were retrospective analyses of patients diagnosed and relapsing in the era when there were very limited truly active treatment options. Therefore, diagnosing patients at an earlier time point had very little chance of improving outcomes other than resulting in a lead time bias in the assessment of survival. This situation has led to a series of guidelines for follow-up of patients. Such guidelines have been proposed based on an analysis of the site and timing of first relapse in patients with surgically excised stage III melanoma at a single institution.¹⁹⁸ This was based on a review of the clinical records at Memorial Sloan-Kettering Cancer Center between 1992 and 2004 of patients who ultimately relapsed after surgical resection of stage III melanoma. In this group of patients, the overall 5-year relapse-free survival for patients with stage IIIA, IIIB, and IIIC disease was 63%, 32%, and 11%, respectively. Site of first relapse was local/in-transit (28%), regional nodal (21%), or systemic (51%). First relapses were detected by the patient or family in 47% of cases, by the physician in 21%, and by screening radiologic tests in 32%. Based on these observations, the authors proposed that routine physical examinations beyond 3 years for stage IIIA, 2 years for stage IIIB, and 1 year for stage

IIIC; radiologic imaging beyond 3 years for stages IIIA and IIIB; and 2 years for stage IIIC would be expected to detect few first systemic relapses.

National/International Guidelines for Follow-Up

Recommendations for patient follow-up are largely based on the time-dependent risk of recurrence, the likely sites of metastasis, and historical experience with whether recurrences are commonly identified by the patient, the physician, or by imaging or laboratory studies. However, there is also evidence that follow-up is comforting to patients and decreases psychological stress associated with the diagnosis.¹⁹⁹ No studies have shown a clear benefit in terms of survival with closer follow-up, but this could change as there are now effective therapies for advanced melanoma, so that diagnosis of patients when they are well enough to tolerate those therapies may be of clinical value. Thus, routine clinical follow-up continues to be a part of management, but studies of follow-up have mostly been retrospective, and there is a need for more rigorous studies of the global benefit, risk, and cost of follow-up visits, imaging, and serum markers. Two comprehensive guidelines on melanoma management provide guidance on follow-up based on systematic review of the literature, and expert opinion. The NCCN[®] has been reported in their 2013-14 guidelines,¹²⁸ summarized in Table 94.7. Also, evidence-based guidelines were published in 2013 from Germany, from the German Dermatological Society and the DeCOG.²⁰⁰ These German S3 guidelines are also summarized in the Table 94.6. These two guidelines are very similar, but differ in the extent of cross-sectional imaging recommended, and the use of ultrasound for evaluation of the node basins. The German guidelines also recommend serum S100B levels in follow-up, whereas these are not recommended by the NCCN. Other minor differences are also evident. The NCCN Guidelines also recommend self-exam by patients on a regular basis as well as annual body skin exams for life, for all patients with a history of stage 0-IV melanoma in addition to the recommendations in the table.

Follow-up visits should include history and physical exam, which should focus on skin exam of the primary site, regional nodes, and in-transit sites. Self-examination by the patient is also recommended, which depends on education of the patient and/or family about what findings may signal recurrence. Chest X-rays were not recommended, but there was lower consensus (77%) for this than for most other German S3 recommendations.

MANAGEMENT OF DISTANT METASTASES OF MELANOMA (STAGE IV)

Any patient with distant metastases is considered stage IV. Distant metastases may include skin or soft tissue metastases distant from a known primary site or visceral, bone, or brain metastases. The prognosis is better for skin and subcutaneous tissue metastases, which are considered M1a, than for lung metastases (M1b) or other distant metastases (M1c). In addition, an elevated serum LDH in the setting of distant metastases is associated with a poor prognosis and also is considered M1c disease.⁷⁴

Timing of Distant Metastases

It is uncommon for patients with melanoma to present initially with stage IV disease. Most patients who develop distant metastases do so after an interval from their original management for clinically localized disease or after management for regionally metastatic disease. Often, metastases become evident within 2 to 3 years of diagnosis, but delayed metastasis is also common, and for melanoma, regional and distant metastases have occurred after

TABLE 94.7

Recommendations for Melanoma Follow-Up Adapted from the National Comprehensive Cancer Network V2.2014 and German S3 Guidelines

NCCN, National Comprehensive Cancer Network; H&P, history and physical exam; U/S, ultrasound exam of draining node basins; S100B = serum S100B level; MRI, magnetic resonance imaging.

^a In addition, NCCN Guidelines recommend annual physical exams and history on an annual basis, as indicated, after 5 years. The German S3 guidelines extend to 10 years.

^b Unless no SNBx, then like IIC.

^c Image = consider chest X-ray, computed tomography, and positron emission tomography/computed tomography.

^d For imaging in this stage, the NCCN Guidelines specify that imaging should be considered but is not mandatory.

disease-free intervals measured in decades.²⁰¹ In general, the interval to detection of distant metastases is shorter for patients who initially present with high-stage disease (e.g., stage IIB–III) and is longest for patients who present with clinically localized thin melanomas (e.g., stage IA).

Patterns of Metastases

Approximately 60% to 80% of first metastases are at local or regional sites including regional nodes. The most common first sites of visceral metastasis are lung and liver (about 10% each), and metastases to distant skin sites are also common. After an initial metastasis, subsequent metastases are more commonly visceral or distant and increasingly become multiple. Common visceral sites of metastasis are lung, liver, brain, gastrointestinal tract (especially small bowel), bone, and adrenal gland.

Prognostic Factors in Distant Metastatic Melanoma (Stage IV)

The new active systemic therapies for advanced melanoma are changing the prognosis of patients. However, no long-term follow-up is available for the most recent trials. Without treatment, or with mostly ineffective therapies, patients with stage IV melanoma were reported to have a median survival of 12 months, with 6 to 9 months for those who presented with visceral metastatic disease (M1c), as long as 15 months for those who presented with skin and lymph node metastases only (M1a), and patients with lung metastases as their only site of visceral organ involvement (M1b) had an intermediate prognosis.⁷⁶ Negative prognostic factors in stage IV melanoma also include a large number of metastatic sites, elevated LDH level, and poor performance status.²⁰²

Clinical Evaluation of Patients with Distant Metastasis (Stage IV)

When a patient is found to have a distant metastasis, the initial steps are to perform full staging studies. This typically should include MRI scan of the brain and either total-body PET/CT scan or CT scans of the chest, abdomen, and pelvis. Other scans or imaging studies (bone scan, soft tissue MRI, ultrasound, or plain films) may be indicated to evaluate known areas of metastasis (e.g., soft tissue masses in extremities) or to evaluate symptoms (e.g., plain films or bone scans for bony symptoms). Melanoma is usually highly avid for FDG uptake due to the strong Warburg effect (aerobic glycolysis even in the presence of sufficient glucose), and therefore metastatic lesions >5 mm are efficiently imaged by PET scans. An exception is uveal melanoma, which has variable FDG uptake even when metastatic. PET/CT scans are helpful in distinguishing tumor from scar in areas of prior surgery, although surgical sites may remain FDG-avid for up to 3 months after surgery. PET is substantially more sensitive for detection of small bowel metastases and lymph node metastases that are borderline in size.²⁰³ PET/CT scan may also be helpful in assessing patients for resectability when there is limited disease on initial assessment.

Histologic or Cytologic Diagnosis

Patients being followed for a history of melanoma may develop new evidence of metastatic disease. In such patients, a new and growing mass in the chest or abdomen is likely to be metastatic melanoma, but tissue confirmation of metastatic melanoma is usually recommended. New masses can represent new primary lung cancers, lymphoma, sarcoid, inflammatory masses, or other changes, and the management and prognosis of these lesions usually differs dramatically from the management and prognosis of stage IV melanoma.

If the lesion is in an accessible area of the lung and is about 1 cm in diameter or greater, a CT-guided transthoracic needle biopsy is usually feasible and appropriate for making the diagnosis. If there is a solitary lung mass, and especially if the mass is <1 cm in diameter, then thoracoscopic resection with preoperative localization can be performed with great success and with low morbidity.²⁰⁴ In the event that the lesion is malignant, then the biopsy may also have some therapeutic value.

Fine needle aspiration biopsy of soft tissue masses or lymph nodes can be rapid and accurate diagnostic approaches either at the bedside or with radiologic localization. Similarly, biopsies of many other tissue lesions can be accomplished by minimally invasive techniques. A fine needle aspirate will be diagnostic in most cases, but a core needle biopsy, when feasible, can improve diagnostic accuracy further. Immunohistochemical stains for S100, HMB45, tyrosinase, and MART-1/MelanA can all be helpful in confirming a diagnosis of melanoma.

Testing for BRAF and Other Genetic Analyses

A major decision point in the management of advanced melanoma is the determination of BRAF mutational status. The clinical development and approval of BRAF and MEK inhibitors has been based on the treatment of a patient population selected based on the expression of mutant BRAF at position V600. This is because pre-clinical studies predict that BRAF inhibitors are ineffective when BRAF mutations are not present, and there is even data that they may be detrimental by inducing paradoxical MAPK activation (see the following) and increased cancer progression.^{205–208} Therefore, the decision to use BRAF inhibitors should be based on a positive testing for a BRAF V600 mutation (either V600E or V600K, with currently less clear benefits in other BRAF mutations).

BRAF mutation needs to be tested from DNA obtained from a melanoma biopsy or resection. It is best to test a metastatic lesion than an archival primary lesion as it cannot be assured that the metastases come from that particular primary lesion. The tumor DNA is usually obtained from formalin-fixed paraffin-embedded tissue blocks, and the assay laboratories usually isolate the genomic DNA from this fixed tissue. The actual BRAF mutation test can be performed using the mutation-specific PCR tests, such as the FDA-approved companion diagnostic assays for the use of vemurafenib, dabrafenib, or trametinib, or by less sensitive Sanger sequencing. In addition, assay panels that provide results from multiple hot-spot single nucleotide mutations have been developed, as well as assays based on next generation sequencing of a panel of several hundred genes that are commonly associated with cancer.⁶⁰

Surgery for Distant Metastases (Stage IV)

Patient Selection and Prognostic Factors

Selected patients may benefit from surgery for distant metastatic (stage IV) melanoma. The benefit can be palliative in some patients and may be curative in rare cases. There are numerous clinical scenarios in which surgery may be considered, and it is not possible to address all of them here. However, it is useful to consider some of them.

Cases in Which the Benefit of Surgery Is Clear

- Anemia due to occult bleeding from intestinal metastasis
- Bowel obstruction due to small bowel metastasis
- Cutaneous or subcutaneous metastasis with ulceration, pain, or impending ulceration
- Lymph node metastasis with neurologic symptoms
- Symptomatic brain metastasis
- Life-threatening hemorrhage from metastasis

Melanoma frequently metastasizes to the gastrointestinal tract. It usually originates as an intramural lesion but grows into the lumen and through the serosa with time. These usually present as anemia due to occult gastrointestinal bleeding or as intermittent small bowel obstruction due to intussusception (Fig. 94.13). They are difficult to diagnose by CT scan in the absence of symptoms. PET/CT is probably the best study now available. However, it may miss small lesions. Nonetheless, when a patient presents with gastrointestinal blood loss or obstruction associated with a small bowel (or other gastrointestinal) metastasis of melanoma, operation is usually indicated. If the tumor involves the mesenteric nodes and is matted, then it may not be feasible or appropriate to resect the entire tumor, but enteroenteric bypass of the obstruction will be palliative. Resection of most or all small bowel metastases can manage bleeding and obstruction effectively. If there is a single small bowel metastasis, then a simple resection and reanastomosis is appropriate (Fig. 94.14). However, if there are numerous small bowel metastases, then excision of large lesions with reanastomosis is appropriate, but small lesions may be excised by partial-diameter excision and stapled (or sewn) closure. If the patient can be rendered surgically free of disease, then there may be long-term survival >5 years in as many as 25% of patients and mean survival >2 years.²⁰⁹

Cutaneous, subcutaneous, and nodal metastases are not usually a cause of death, but they can be a cause of substantial morbidity. As they grow, they develop substantial inflammation in the overlying skin (see Fig. 94.12) and without resection may often ulcerate. Because such lesions usually can be resected under local anesthesia with minimal morbidity, it is reasonable to offer resection.

Extensive lymph node metastasis with neurologic symptoms is commonly an issue in the axilla, where tumor growth may compress or invade the brachial plexus and axillary vein. Patients with extensive axillary recurrence with neurologic symptoms and patients with other nodal disease and neurologic symptoms should be considered for radical resection of the involved nodal basin. The morbidity of surgery usually is much less than the morbidity of the tumor left untreated. Major risks of tumor growth include paralysis or major neurologic dysfunction of the extremity, intractable lymphedema, disabling pain, and unresectability.

Brain metastasis is a particularly ominous sign in terms of future survival, which can usually be measured in months. However, some patients with isolated brain metastasis can have long-term control after surgical resection or stereotactic radiation therapy. For patients with symptomatic brain metastases, the presentation with acute cognitive deficits can be dramatic. Steroid therapy should be instituted immediately (4 mg orally every 6 hours per day initially). However, if this fails, or if the presentation is particularly acute with impending herniation, then surgical resection of the brain metastasis can be therapeutic.

Melanoma can metastasize to nodes, adrenal glands, or other sites and then develop spontaneous hemorrhage. Sometimes such bleeding can be trivial, but in some cases, there can be massive hemorrhage into the tissues, with associated hypovolemia. In such cases, resection of the hemorrhagic mass may diminish future risk of bleeding, decrease pain, and delay death.

New effective systemic therapies,¹⁵¹ including CTLA4 blockade or mutant BRAF inhibition, as well as blockade of PD-1/PD-L1, may be alternatives for managing patients with metastases that are too extensive to resect, but a multidisciplinary team assessment is advised to weigh the short-term risks of delaying surgery against the possibility of major systemic tumor regression with those therapies. In cases where systemic therapy induces partial responses, surgical resection of residual gastrointestinal disease may be feasible to render the patient clinically free of disease.

Cases in Which the Benefit of Surgery Is Likely

- Solitary asymptomatic visceral metastasis resectable with minimal morbidity

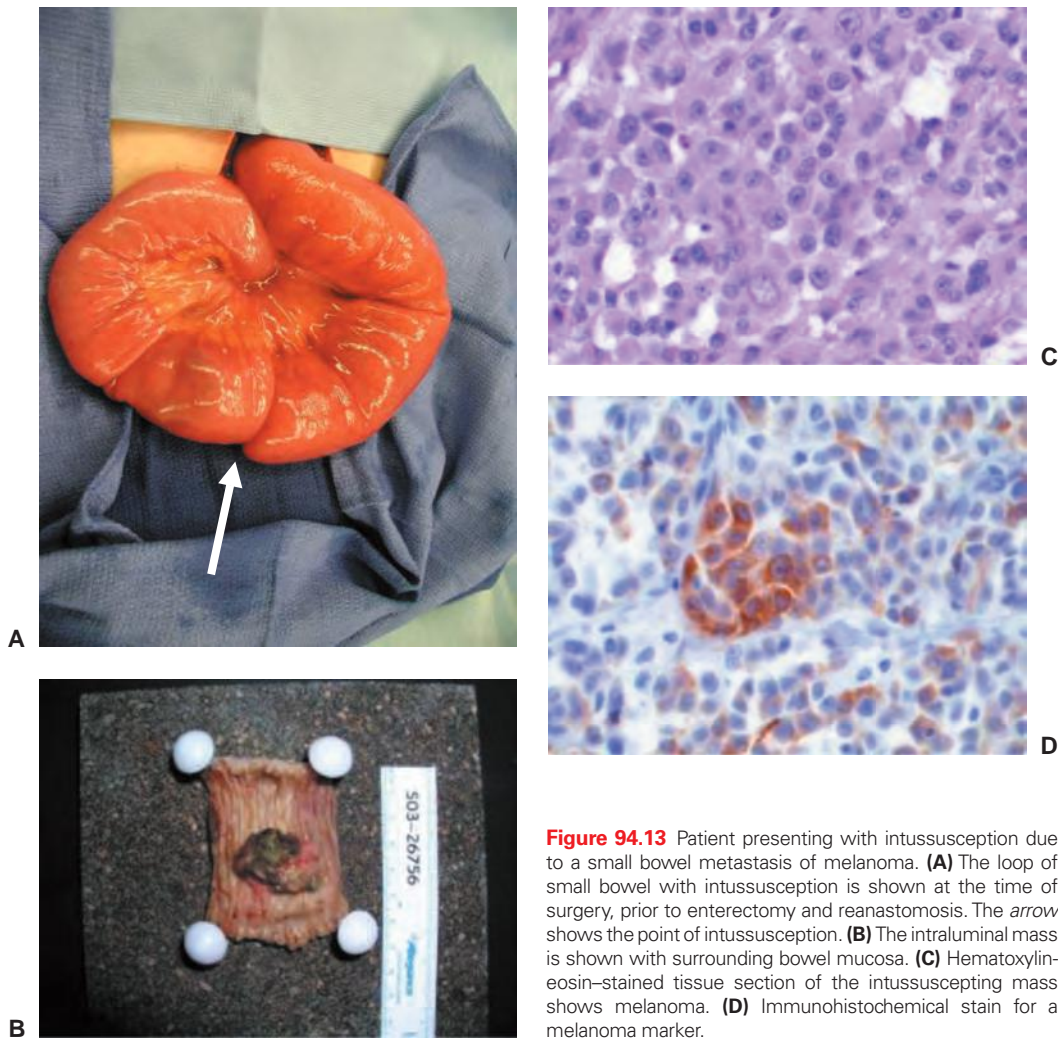

Figure 94.13 Patient presenting with intussusception due to a small bowel metastasis of melanoma. **(A)** The loop of small bowel with intussusception is shown at the time of surgery, prior to enterectomy and reanastomosis. The *arrow* shows the point of intussusception. **(B)** The intraluminal mass is shown with surrounding bowel mucosa. **(C)** Hematoxylin-eosin-stained tissue section of the intussuscepting mass shows melanoma. **(D)** Immunohistochemical stain for a melanoma marker.

- Bony metastasis with pain or joint involvement, unresponsive to radiation
- Solitary brain metastasis without symptoms
- Large, asymptomatic nodal metastasis with concurrent low-volume systemic disease

Figure 94.14 Small bowel metastasis of melanoma with extension through the bowel wall and with extensive neovascularity.

- Extensive skin and soft tissue metastases in the absence of visceral metastases
- Isolated growing metastasis in the setting of stable or regressing metastases after therapy

In general, in a patient with solitary visceral metastasis, if excision can be accomplished with minimal morbidity, the excision can be both therapeutic and diagnostic. The OS for patients with one or several distant metastases resected coupled with experimental melanoma vaccine therapy has been associated with 5-year survival rates in the 40% to 60% range.²¹⁰ Another reasonable option for the patient with a single (or few) resectable distant and/or visceral metastases is to enroll in an experimental therapeutic trial or to take an approved systemic therapy in the hope of clinical response but with the additional benefit of having about 3 months of observation time to be sure that no other new visceral lesions appear prior to resection of the lesion in question.

Bone metastases can cause pain and fracture. Radiation therapy is usually the first choice for therapeutic intervention if significant pain exists. If patients are at risk of impending fracture, orthopedic stabilization should be considered before radiation. However, if the lesion does not respond to radiation or is solitary, resection with bone grafting or joint replacement can be considered. Current success rates with such therapy are high, but the period of postoperative recovery can be extended, and so careful patient selection is indicated.

An asymptomatic solitary brain metastasis that is amenable to resection can often be removed surgically with minimal morbidity and often with approximately a 3-day hospital stay. Stereotactic

radiosurgery (e.g., gamma knife) is often the first choice for treatment of such lesions, but surgery is another reasonable option and probably will have benefit, especially if the solitary brain lesion is >2 to 3 cm diameter, in which case stereotactic radiosurgery may be less effective and surgery may be a preferred option.

In patients with multiple metastases, systemic therapy may be associated with partial clinical responses with progressive growth of one or more lesions while the remainder are stable or shrinking and asymptomatic. In that case, patients may benefit from resecting the one or several tumor deposits that are progressing. This will not be curative, but it may lead to a more prolonged period of good quality of life, with minimal perioperative morbidity.

Cases in Which Some Patients May Benefit from Surgery but Risk and Benefit Are Closely Balanced

- More than one visceral metastasis, without symptoms
- Multiple lung nodules
- Bilateral adrenal metastases
- Extensive skin and soft tissue metastases in the setting of visceral disease

A more difficult decision is whether to treat patients with surgery when they have multiple asymptomatic visceral metastases, such as multiple lung nodules, bilateral adrenal metastases, or extensive skin metastases in the presence of visceral disease. These are generally situations in which surgery is not recommended as the treatment of choice, but there are anecdotes of such patients enjoying prolonged disease-free survival after such surgery, and so it is worth considering in very selected patients. Situations that may push the patient and the clinician toward such an aggressive surgical approach include (1) prior failure of systemic therapy, (2) a young patient for whom perioperative morbidity is not a major concern, and (3) disease sites that are particularly amenable to surgery through limited surgery (e.g., multiple lung nodules amenable to thoracoscopic lobectomy).

Adjuvant Therapy for Resected Stage IV Melanoma

There is no standard adjuvant therapy after resection of metastatic melanoma (stage IV). Interferon has not been thoroughly evaluated in this setting. Therefore, observation remains the standard management of patients in this setting. Investigational vaccines, GM-CSF, CTLA4 blockade, PD-1 blockade, and other experimental therapies are being evaluated for these patients. ECOG 4697, a US intergroup clinical trial testing the potential benefit of GM-CSF as an adjuvant therapy for resected stage IIIB-IV melanoma, demonstrated no impact on survival overall.¹⁹² Several ongoing adjuvant therapy clinical trials for stage III melanoma are open to enrollment to this patient population and are testing the potential benefits of adjuvant therapy with ipilimumab (ECOG 1609), vemurafenib single agent, or dabrafenib and trametinib in combination.

Treatment of Unresectable Metastatic (Stage IV) Melanoma

Progress in Treatment for Metastatic Melanoma

Clinical translation of preclinical scientific knowledge has resulted in the rapid advancement of new therapies active in patients with metastatic melanoma. This contrasts sharply with the lack of significant progress for many years when attempting to treat melanoma with nonspecific agents, in particular chemotherapy, and performing combination studies with low active components. In this context, the OS and PFS was analyzed in 70 US cooperative group single-arm phase 2 clinical trials performed between 1975 and 2005 (termed the Korn meta-analysis) that had been deemed to not be

TABLE 94.8

Summary of Best Clinical Endpoints with Selected Therapies for the Treatment of Advanced Melanoma

Improved overall survival	Ipilimumab (vs. gp100 peptide vaccine) Vemurafenib (vs. dacarbazine) Trametinib (vs. dacarbazine)
Improved progression-free survival	Dabrafenib (vs. dacarbazine) Nab-paclitaxel (vs. dacarbazine) Dabrafenib + trametinib (vs. dabrafenib)
Improved response duration	T-Vec (vs. granulocyte macrophage-colony-stimulating factor)
Validated antitumor activity	High dose interleukin-2 TIL ACT Carboplatin-paclitaxel Dacarbazine Fotemustine
Promising new agents and combinations	Anti-PD-1 antibodies: nivolumab, MK3475, MEDI Anti-PD-L1: BMS559, MPDL8032A BRAF and MEK inhibitor combination Anti-PD-1 and anti-CTLA4 combination
Agents and combinations not supported by data	Nistosurea combination chemotherapy: CVD, biochemotherapy Darmuth regimen and tamoxifen-chemotherapy combinations Thalidomide and thalidomide-chemotherapy combinations Sorafenib and sorafenib-chemotherapy combinations Elesclomol-chemotherapy combinations Peptide vaccines

TIL ACT, tumor infiltrating lymphocyte adoptive cell transfer therapy; PD, programmed death; CTLA, cytotoxic T lymphocyte associated-antigen; CVD, cisplatin-vinblastin-dacarbazine.

promising for further development.²¹¹ From this meta-analysis, individual-level and trial-level data were obtained for patients enrolled onto 42 phase 2 trials. Prognostic factors for OS were performance status, presence of visceral disease, sex, and whether the trial excluded patients with brain metastases. The Korn meta-analysis has provided the minimum benchmarks of OS and PFS at defined time points to compare to new clinical trials in patients with metastatic melanoma. The recent clinical trials with immune checkpoint inhibitors and BRAF inhibitor-based targeted therapies have improved this grim panorama (Table 94.8), and there are reasons to anticipate that treatment options for advanced melanoma will continue to improve. The ability to understand mechanisms of response and resistance to BRAF inhibitor-based therapies and immune checkpoint blockade at a molecular level, and the rapid advancement of the knowledge brought through by the scientific community's renewed interest in melanoma, predicts further improvements in the development of effective therapies for this disease.

Anti-Cytotoxic T-Lymphocyte Antigen 4 Blocking Antibodies

Approaches such as inactivated tumor vaccines, dendritic cell vaccines, or immune-stimulating cytokines like interferon- α and IL-2 are aimed at turning on T cells against cancer. This has led to tumor responses in a minority of patients, but with the remarkable feature that these tumor responses tend to be durable (counted in years) in most cases. This feature, together with the lack of significant activity of standard therapy approaches for melanoma, has maintained the interest in this mode of therapy for advanced

Figure 94.15 Schematic representation of the mechanism of action of anti-cytotoxic T lymphocyte-associated protein 4 (CTLA-4) and anti-programmed cell death protein (PD)-1 monoclonal antibodies. Cytotoxic T lymphocyte-associated protein 4 is a negative regulatory signal that limits activation of T cells upon ligation with cluster of differentiation 80 or cluster of differentiation 86 costimulatory molecules expressed by antigen-presenting cells, within the priming phase of a T-cell response in lymph nodes. PD-1 is expressed by T cells upon chronic antigen exposure and results in negative regulation on T cells upon ligation with PD-L1, which is primarily expressed by peripheral tissues including in the tumor microenvironment. The PD-1/PD-L1 interaction happens in the effector phase of a T-cell response. Its blockade with antibodies to PD-1 or PD-L1 results in the preferential activation of T cells with specificity for the cancer. MHC, major histocompatibility complex; TCR, T-cell receptor. (From Ribas A. Tumor immunotherapy directed at PD-1. *N Engl J Med* 2012;366:2517–2519.)

melanoma. Immune responses against cancer are usually kept under negative regulatory control by a series of physiological breaks (checkpoints; Fig. 94.15). Negative immune regulatory checkpoints are induced after T-cell activation. These include CTLA4, which when engaged by the costimulatory molecules B7.1 (CD80) or B7.2 (CD86) results in a dominant negative regulation of T cells by competing with the CD28-positive costimulatory receptor. When an activated T cell arrives to the peripheral tissues, including melanoma metastases, it can be turned off by the PD-1/PD-L1 interaction. PD-1 is a negative regulatory checkpoint receptor that is expressed by T cells upon activation and chronic antigen exposure, as in cancer. Its main peripheral ligand, PD-L1, is expressed by cancer and stromal cells mainly upon exposure to T cell-produced interferons. Therefore, it represents a mechanism of acquired immune resistance that allows melanoma to hide from activated T cells.²¹² Release of both the CTLA4 and PD-1 checkpoints has resulted in objective and durable immune-mediated tumor responses in patients with advanced melanoma, and it is an area of active clinical research and drug development.

Ipilimumab (Yervoy, Bristol-Myers Squibb, New York, NY) is a fully human monoclonal antibody (IgG1) that blocks CTLA4. The FDA approved ipilimumab at a dose of 3 mg/kg administered at 3-week intervals for four doses for the treatment of unresectable or metastatic melanoma in 2011. This approval was based on a randomized clinical trial of ipilimumab compared to a gp100 peptide vaccine, or in combination, in patients with previously treated metastatic melanoma.¹⁹⁵ 676 HLA-A*0201-positive patients with unresectable stage III or IV melanoma who had been previously treated with systemic therapy for metastatic disease were randomly assigned, in a 3:1:1 ratio, to ipilimumab plus gp100 (403 patients), ipilimumab alone (137 patients), or gp100 alone (136 patients). Ipilimumab was administered at a dose of 3 mg per kilogram every 3 weeks for up to four treatments (induction). Eligible patients could receive re-induction therapy. The primary end point of median OS with ipilimumab alone was 10.1 months as compared with 6.4 months among patients receiving gp100 alone (HR = 0.66; $p = 0.003$). No difference in OS was detected between the ipilimumab groups (HR with ipilimumab plus gp100 = 1.04; $p = 0.76$),

and the median OS was 10.0 months among patients receiving ipilimumab plus gp100 (HR for death = 0.68; $p < 0.001$). Grade 3-4 immune-related adverse events occurred in 10% to 15% of patients treated with ipilimumab, the most common being colitis, skin rash, and endocrinopathies (Table 94.9). There were 14 deaths related to ipilimumab (2.1%), and 7 were associated with immune-related adverse events. This was the first randomized clinical trial demonstrating an improvement in OS in patients with metastatic melanoma (Table 94.10).

There was a second randomized clinical trial with OS improvement using ipilimumab.¹⁹⁶ This was a frontline trial comparing

ipilimumab (10 mg/kg) plus dacarbazine (850 mg/m² of body surface area), or dacarbazine (850 mg/m²) plus placebo, in patients with previously untreated metastatic melanoma. A total of 502 patients were randomized in a 1:1 ratio, with the study drugs given at weeks 1, 4, 7, and 10. Patients with stable disease or an objective response and no dose-limiting toxic effects were eligible to receive ipilimumab every 12 weeks thereafter as maintenance therapy. The primary end point of OS was significantly improved in the group receiving ipilimumab plus dacarbazine compared to dacarbazine plus placebo (11.2 months versus 9.1 months). Survival rates at 1 year (47.3% versus 36.3%), 2 years (28.5% versus

17.9%), and 3 years (20.8% versus 12.2%) were significantly improved (HR for death = 0.72; $p < 0.001$). Grade 3 or 4 adverse events occurred in 56.3% of patients treated with ipilimumab plus dacarbazine, as compared with 27.5% treated with dacarbazine and placebo ($p < 0.001$). The most frequent toxicities in the experimental combination group were increases in transaminases. No drug-related deaths or gastrointestinal perforations occurred in the ipilimumab–dacarbazine group.

The FDA approval of ipilimumab comes with a black box warning due to the potential for severe and occasionally fatal immune-mediated adverse reactions. The most common are enterocolitis, hepatitis, dermatitis (including toxic epidermal necrolysis), neuropathy, and endocrinopathies like hypophysitis and thyroiditis. The recommendation is to permanently discontinue ipilimumab infusions and initiate systemic high-dose corticosteroid therapy for severe immune-mediated reactions.

Re-induction with ipilimumab after the first four infusions without serious side effects is an option for patients with stable disease sustained for at least 3 months or a prior confirmed partial or complete response. Among 31 patients given re-induction with ipilimumab, a complete or partial response or stable disease was achieved in 13%, 37.5%, and 65.2%, respectively.²¹³

Several studies are testing the effects of combinations based on ipilimumab. E1608 is a phase 2 randomized trial that tested the combination of ipilimumab with GM-CSF with the goal of analyzing if this combination improved OS.²¹⁴ A total of 245 patients were randomized to ipilimumab (10 mg/kg every 3 weeks intravenously for four courses, then every 12 weeks) plus GM-CSF (250 µg subcutaneously on days 1 to 14 of 21-day cycles) or ipilimumab alone. With a median follow-up of 13.3 months, the response rate and PFS was not different between both arms. In a planned interim analysis, the primary end point of median OS was improved with the combination. One-year OS with the combination was 67.9% (59%, 76%), while it was 51.2% (42.6%, 61.3%) for ipilimumab alone (stratified log rank $p_1 = 0.016$, $p_2 = 0.033$; HR = 0.65). Grade 3–5 toxicities were lower with the combination compared to ipilimumab alone (45% compared to 57%, $p_2 = 0.078$). Therefore, ipilimumab plus GM-CSF may increase OS and decrease toxicities compared to ipilimumab alone. However, this combination remains investigational unless the benefit is confirmed in further clinical trials.

Another anti-CTLA4 antibody has been developed clinically in patients with metastatic melanoma, tremelimumab (by Pfizer and MedImmune-Astra-Zeneca, New York, NY). This fully human IgG2 monoclonal antibody went through phase 1, 2, and 3 testing in melanoma,^{215–217} but failed to demonstrate improvement in OS compared to dacarbazine.²¹⁶ Potential contributing factors were the study design, the treated population, the dosing regimen, and the postrandomization use of ipilimumab in the control arm.²¹⁸

The main feature of therapy with anti-CTLA4 antibodies is the long durability of tumor responses in patients with an objective tumor response, as exemplified by a patient with metastasis to the lung and liver who initially received ipilimumab and then tremelimumab in May of 2001²¹⁹ and continues in response over a decade later. In many instances, it is difficult to assess objective responses as these may appear late after the therapy and go through a process of apparent clinical progression when using standard response evaluation criteria. This has led to the proposal of alternate response evaluation criteria tailored to this mechanism of action, termed the immune-related response criteria.^{220,221}

Interleukin-2

The intravenous administration of high-dose IL-2 (aldesleukin) was approved for the treatment of patients with metastatic melanoma in 1998 mainly thanks to its ability to mediate durable complete responses in patients with widespread metastatic disease. The administration of IL-2 represented the first demonstration that purely immunotherapeutic maneuvers could mediate the regression of metastatic cancer.^{222,223} IL-2 has no direct effect on cancer

cells, and all of its antitumor activity is a function of its ability to modulate immunologic responses in the host.

The FDA-approved regimen for the treatment of patients with metastatic melanoma using IL-2 involves the use of an intravenous bolus infusion of 600,000 to 720,000 IU/kg every 8 hours to tolerance using two cycles separated by approximately 10 days (maximum of 15 doses per cycle). Results of this treatment are evaluated at 2 months after the first dose, and if tumor is regressing or stable, a second course is then administered.

In the report of the original 270 patients treated at 22 different institutions that was the basis of the approval of IL-2 by the FDA, a 16% objective response rate was obtained, with 17 complete responses (6%) and 26 partial responses (10%).²²⁴ At the last full analysis of these 270 patients, the median duration of response for complete responders had not been reached but exceeded 59 months, and disease progression was not observed in any patient who responded for more than 30 months. An analysis of patients treated from 1988 to 2006 in the Surgery Branch, National Cancer Institute, reported 13 complete responders, only 2 of which had recurred with the remainder ongoing at 1 to 21 years.²²⁵ Thus, IL-2 appears to be one of a very small group of systemic treatments capable of curing patients with a metastatic solid cancer.

Because of the side effects associated with high-dose bolus IL-2 administration, this treatment is generally restricted to patients younger than the age of 70 years with an ECOG performance status of ≤ 2 and in patients who do not have active systemic infections or other major medical illness of the cardiovascular respiratory or immune system. Because IL-2 often causes transient renal and hepatic toxicity, eligibility criteria generally require normal serum creatinine and serum bilirubin levels. Patients with any history of systemic ischemic heart disease or pulmonary dysfunction should undergo stress testing and pulmonary function tests before initiating therapy, and patients with significant abnormalities should not be included.

The administration of high-dose bolus IL-2 is different than the administration of most cancer therapeutics in that dosing is continued every 8 hours until patients reach grade 3 or 4 toxicity that is not easily reversible by supportive measures. The toxicities of IL-2 administration are transient, with virtually all returning to baseline after IL-2 administration is stopped. Thus, patients are often treated despite creatinine levels that increase to the 2- to 3-mg/dL range because of confidence that renal function will return to normal after cessation of IL-2 administration. Thus, there are no set doses that patients receive, and there is no correlation between the number of doses seen and the likelihood of achieving a response as long as patients receive dosing to tolerance based on physical findings and laboratory measurements.

Administration of Interleukin-2 Plus Vaccine

In 1998, Rosenberg et al.²²⁶ reported an increase in objective response to IL-2 when administered in conjunction with a heteroclitic gp100:209–217(210M) melanoma peptide vaccine. An updated analysis showed a response rate of 12.8% to IL-2 alone compared to a 25.0% response rate to IL-2 plus immunization with this peptide ($p = 0.01$). A prospective randomized trial in patients with metastatic melanoma of IL-2 alone or in conjunction with this peptide in 185 patients²²⁷ reported centrally reviewed response rates of 6% and 16%, respectively ($p = 0.02$), with an increase in PFS in the vaccine arm ($p = 0.008$) and a strong trend toward an increase in survival (17.8 versus 11.1 months, $p = 0.06$).

BRAF Inhibitors

Vemurafenib (Zelboraf, Roche, Basel, Switzerland) and dabrafenib (Tafinlar, GlaxoSmithKline) are two BRAF inhibitors approved by the FDA, European Medicines Agency, and other regulatory bodies with high antitumor activity in patients with BRAF^{V600} mutant metastatic melanoma mediated by the inhibition of oncogenic MAPK signaling.^{151,228} They are both classified as type I BRAF kinase inhibitors because they block the enzymatic activity of BRAF in the activated, mutated conformation, as opposed to

type II RAF inhibitors that work only in the inactive conformation, such as sorafenib.²²⁸ In a phase 3 trial in which patients with BRAF^{V600E} metastatic melanoma were treated with vemurafenib versus dacarbazine, there was a large early improvement in OS, leading to an early closure of the clinical trial.²²⁹ This was a phase 3 randomized clinical trial comparing vemurafenib (960 mg orally twice daily) with dacarbazine (1,000 mg/m² of body surface area intravenously every 3 weeks) in 675 patients with previously untreated, metastatic melanoma with the BRAF^{V600E} mutation. A planned interim analysis after 98 deaths led to the closing of this trial. In this interim analysis, vemurafenib was associated with a relative reduction of 63% in the risk of death and 74% in the risk of either death or disease progression, as compared with dacarbazine ($p < 0.001$ for both comparisons). The independent data and safety monitoring board recommended crossover from dacarbazine to vemurafenib for patients under study. Response rates were 48% for vemurafenib and 5% for dacarbazine. At 6 months, OS was 84% (95% CI, 78 to 89) in the vemurafenib group and 64% (95% CI, 56 to 73) in the dacarbazine group. Common adverse events associated with vemurafenib were arthralgia, rash, fatigue, alopecia, keratoacanthoma or squamous cell carcinoma, photosensitivity, nausea, and diarrhea (see Table 94.9); 38% of patients required dose modification because of toxic effects.

Secondary cutaneous squamous cell carcinomas and keratoacanthomas are the most common grade 3-4 toxicities with vemurafenib, which occur in 20% of the patients treated, often with RAS mutations and usually the first 2 to 3 months of therapy.²³⁰ The pathogenesis of their development is due to the inhibition of wild-type BRAF within a dimer with CRAF, which results in increased MAPK signaling through the paradoxical transactivation of CRAF in the setting of strong RAS-GTP signaling in that cell.^{208,231} This is the so-called paradoxical activation of the MAPK pathway with BRAF inhibitors. These skin squamoepithelial proliferative lesions are usually treated with local excision and do not require changing the doses of the BRAF inhibitor.

Dabrafenib was tested in a phase 3 trial in patients with previously untreated stage IV or unresectable stage III BRAF^{V600E} mutation-positive metastatic melanoma.²³² Patients were randomly assigned (3:1) to receive dabrafenib (150 mg twice daily, orally) or dacarbazine (1,000 mg/m² intravenously every 3 weeks). A total of 250 patients were randomized either to dabrafenib (187 patients) or dacarbazine (63 patients). The primary end point of median PFS was 5.1 months for dabrafenib and 2.7 months for dacarbazine (HR = 0.30; 95% CI, 0.18 to 0.51; $p < 0.0001$) (see Table 94.10). Treatment-related adverse events (grade 2 or higher) occurred in 100 (53%) of the 187 patients who received dabrafenib and in 26 (44%) of the 59 patients who received dacarbazine. The most common adverse events with dabrafenib were skin-related toxic effects, fever, fatigue, arthralgia, and headache (see Table 94.9). An update reported of this phase 3 trial with a longer follow-up showed a median OS in the dabrafenib arm of 18 months compared to 15 months with dacarbazine.²³³

Overall, both vemurafenib and dabrafenib used as single agents showed similar effects in terms of objective response rate and PFS. The incidence of clinically significant photosensitivity is higher with vemurafenib compared to dabrafenib, and the incidence of clinically significant pyrexia is higher with dabrafenib compared to vemurafenib (see Table 94.8).

MEK Inhibitors

MEK inhibitors block signaling in the MAPK pathway downstream from BRAF. These agents effectively inhibit cellular proliferation and tumor growth in BRAF mutant melanoma, although they may also have some activity in NRAS mutant disease.^{234,235} Trametinib (Mekinist, GlaxoSmithKline) was approved by the FDA and other regulatory bodies in 2013 based on the results of a phase 3 trial in patients who had metastatic melanoma with a V600E or V600K BRAF mutations.²³⁶ A total of 322 patients were randomly assigned to either trametinib (2 mg orally once daily)

or intravenous dacarbazine (1,000 mg/m² of body surface area) or paclitaxel (175 mg/m²) every 3 weeks. The primary end point of median PFS was 4.8 months in the trametinib group and 1.5 months in the chemotherapy group (HR = 0.45; 95% CI, 0.33 to 0.63; $p < 0.001$) (see Table 94.10). At 6 months, OS was 81% in the trametinib group and 67% in the chemotherapy group despite crossover (HR = 0.54; 95% CI, 0.32 to 0.92; $p = 0.01$). Rash, diarrhea, and peripheral edema were the most common toxic effects in the trametinib group (see Table 94.9) and were managed with dose interruption and dose reduction; asymptomatic and reversible reduction in the cardiac ejection fraction and ocular toxic effects occurred infrequently. Due to the higher incidence of side effects and lower efficacy (see Tables 94.9 and 94.10), the use of BRAF inhibitors is usually preferred over the use of MEK inhibitors for the treatment of patients with BRAF mutant advanced melanoma.

Mechanisms of Resistance to BRAF Inhibitors

Progression on therapy with no evidence of tumor response (innate resistance) to BRAF inhibitors is rare, present in approximately 15% of patients. However, progressive growth after a period of tumor response (acquired resistance) is common with a median PFS of 6 to 7 months. Mechanisms of acquired resistance are diverse and can be categorized between the ones that reactivate the MAPK pathway and the mechanisms that lead to a MAPK pathway-independent signaling that substitutes for the blocked driver oncogenic signal. MAPK reactivating mechanisms are more common and have the common theme of reactivating oncogenic signaling through MEK and ERK. Specific mechanisms reported to date in patient-derived samples include truncations in the BRAF protein resulting in increased kinase activity,²³⁷ amplifications of the mutant BRAF gene,²³⁸ secondary mutations in NRAS or MEK,²³⁹⁻²⁴¹ or overexpression of COT.²⁴² The mechanisms leading to MAPK-redundant pathway activation are less well characterized and most may represent mechanisms of adaptive resistance to provide an alternative survival pathway. These include the overexpression or overactivation of receptor tyrosine kinases like the platelet-derived growth factor receptor beta^{239,243} or the insulin-like growth factor receptor 1,²⁴⁴ leading oncogenic signaling through the PI3K-AKT pathway.

In a study of 100 biopsies taken from patients receiving BRAF inhibitors,^{245,246} MAPK reactivation mechanisms were detected among disease progression tissues in 64% of samples; among these, RAS mutations (37%), mutant BRAF amplification (30%), and alternative splicing (20%) were most common. This study also detected genetic alterations in the PI3K-AKT pathway among progressive tissues in 26% of samples. Furthermore, increasing evidence suggests that multiple mechanisms of resistance may develop in the same patient when melanoma relapses after therapy with BRAF inhibitors. In 20% of patients, at least two mechanisms of resistance were detected in the same melanoma in the same or different progressive tumor sites. When studying the genetic features of multiple temporally and geographically distinct baseline and progressive metastatic lesions from an individual patient, it revealed distinct drivers of resistance via both divergent and convergent evolution and evidence of genomic diversification associated with an altered mutational spectra. Therefore, BRAF mutant melanomas acquire BRAF inhibitor resistance via diverse molecular alterations, which indicate MAPK and PI3K-AKT pathway addiction.²⁴⁶ The finding of multiple genetic mechanisms of escape in the same patient implies that the use of upfront, co-targeting of the escape pathways may be an essential strategy for durable responses.

Combination of Targeted Therapies for BRAF Mutant Melanoma

As the most common core pathway mechanism of resistance to single-agent BRAF inhibitor therapy is mediated by the reactivation of the MAPK pathway through MEK,^{246,247} combined therapy with a BRAF and a MEK inhibitor may result in a greater initial tumor response and prevent MAPK-driven acquired resistance mecha-

nisms. A randomized phase 2 trial tested two dosing regimens of combined dabrafenib and trametinib, or dabrafenib alone.²⁴⁸ The rate of complete or partial response with combination therapy was 76%, as compared with 54% with monotherapy ($p = 0.03$). Median PFS in the combination was 9.4 months, as compared with 5.8 months in the monotherapy group (HR = 0.39; 95% CI, 0.25 to 0.62; $P < 0.001$). Pyrexia was the most common toxicity in the combined therapy group compared with the monotherapy group (71% versus 26%). The combination had the additional benefit of blocking the paradoxical activation of the MAPK pathway induced by BRAF inhibitors, and thus decreasing toxicities compared with BRAF inhibitor monotherapy such as squamous cell carcinomas and hyperkeratotic skin lesions. Other BRAF and MEK inhibitor combinations are being evaluated in clinical trials with promising activity and a distinct safety profile, including the combination of the BRAF inhibitor vemurafenib with the MEK inhibitor cobimetinib, and the BRAF inhibitor LGX818 with the MEK inhibitor MEK162. Several phase 3 trials that compare the BRAF/MEK inhibitor combination with a BRAF inhibitor as monotherapy are ongoing. Therefore, the combination of BRAF and MEK inhibitors is likely to result in improved initial responses through better oncogenic BRAF inhibition, more durable responses by preventing mechanisms of acquired resistance, and decreased toxicities by inhibiting paradoxical MAPK activation with BRAF inhibitors. But the final results of the phase 3 trials will be needed to fully evaluate the benefits of combined therapy compared to single-agent BRAF inhibitors.

When acquired resistance to a BRAF inhibitor has been established, the sequential use of a MEK inhibitor after stopping therapy with the BRAF inhibitor does not result in secondary tumor responses.²⁴⁹ However, in agreement with preclinical models, there are secondary responses when adding a MEK inhibitor to continued therapy with a BRAF inhibitor in patients progressing on single-agent BRAF inhibitors. In some instances, a secondary response can be achieved with the reintroduction of therapy with a BRAF inhibitor in patients who previously progressed on this therapy and had been off therapy for a period of time.²⁵⁰

KIT Inhibitors

Mutations in the KIT receptor occur infrequently (2% to 3% of unselected cases of metastatic melanoma) and are more prevalent in mucosal and acral melanomas.⁴⁸ Expression of Kit protein by immunohistochemical staining for CD117 is not sufficient to select for sensitivity to Kit inhibitors, and testing for KIT alterations needs to be performed by DNA sequencing. Imatinib (Gleevec, Novartis, Basel, Switzerland) has modest activity in patients with metastatic melanoma, and KIT mutations in the juxtamembrane domain (L596, V559), as well as K642E, are present.^{50,51} The overall durable response rate was 16% (95% CI, 2 to 30) among 51 patients with KIT mutations or genetic amplification, with a median time to progression of 12 weeks.¹⁶ Other drugs such as dasatinib (Sprycel, Bristol-Myer Squibb) and sunitinib (Sutent, Pfizer) also appear to have activity in KIT mutant melanoma.⁵²⁻⁵⁴ Therefore, KIT inhibitors have modest activity in patients with KIT mutant metastatic melanoma.

Single-Agent Chemotherapy

Melanoma is regarded as a relatively chemotherapy-refractory tumor. The specific mechanisms underlying resistance are not well known, but likely derive from the inherent resilience of melanocytes, which have to be naturally resistant to apoptotic death when exposed to UV radiation from the sun. In particular, DNA repair enzymes as well as the expression of efflux pumps for xenobiotics are more highly expressed in melanoma compared with many other cancers.

Dacarbazine, an imidazole carboxamide [5-(3,3-dimethyl-1-triazeno)-imidazole-4-carboxamide], is a classic alkylating agent. It was first evaluated in clinical trials in melanoma in the late 1960s and approved by the FDA for the treatment of metastatic melanoma

in 1974 on the basis of a response rate of approximately 20%,²⁵¹ but this response assessment predates modern stringent response evaluation criteria. In the majority of trials, dacarbazine was administered intravenously at daily doses of 200 mg/m² for 5 days every 3 or 4 weeks; however, 1,000 mg/m² given once every 3 or 4 weeks has been the standard regimen in recent trials. The most common toxicities are myelosuppression and nausea. The severity of myelosuppression rarely requires the use of growth factor support, and the advent of potent antiemetics has significantly improved the tolerability of this agent. Of note, an adequately powered randomized trial of dacarbazine or any other systemic therapy compared with best supportive care has never been undertaken in advanced melanoma.

Temozolomide is an orally available prodrug that is metabolized into the active form MTIC [5-(3-methyltriazene-1-yl)imidazole-4-carboxamide], which is closely related to dacarbazine.²⁵² MTIC penetrates into the cerebrospinal fluid.²⁵³ Because it is an oral therapy, temozolomide is also more amenable to protracted dosing schedules than dacarbazine, particularly an advantage when combined with fractionated radiation therapy. Single-arm phase 2 trials demonstrated activity in patients with metastatic melanoma, but more modest activity was noted for patients with brain metastases treated with this agent.²⁵⁴ EORTC 18032 was a phase 3 randomized clinical trial in which a dose-intense schedule of temozolomide was administered (150 mg/m² daily for 7 of every 14 days), compared with dacarbazine (1,000 mg/m² intravenously every 28 days). This trial randomized 859 patients and sought a 23% improvement in OS as the primary end point. However, OS was not significantly different between the two arms (HR = 1.0; $p = 1.0$). Response rate was superior in the temozolomide group (14.4% versus 9.8%, $p = 0.05$), but PFS was not (HR = 0.92 in favor of temozolomide; $p = 0.092$).²⁵⁵ Therefore, there is little evidence for the use of temozolomide compared to using dacarbazine in patients with metastatic melanoma.

Fotemustine is a nitrosourea approved by European regulatory bodies for the treatment of advanced melanoma. It is administered by intravenous infusion (100 mg/m² weekly for 3 weeks followed by a 4- to 5-week break, with continued administration every 3 weeks for stable or responding patients.²⁵⁶ A total of 229 patients were randomized to fotemustine or dacarbazine, seeking to demonstrate a 17% absolute difference in objective response rate. The observed difference in response rate (13% for fotemustine versus 6% for dacarbazine) was not statistically significant. Median time to progression was similar for the two arms. Overall survival, a secondary end point, was not significantly improved with fotemustine compared to dacarbazine (median, 7.3 versus 5.6 months).

Nab-paclitaxel is an albumin nanoparticle-bound paclitaxel that was demonstrated to have an improved PFS over dacarbazine in a phase 3 randomized open-label trial in chemotherapy-naïve patients with stage IV metastatic melanoma with no brain metastasis and LDH ≤ 2 upper limit of normal. Patients received either nab-paclitaxel 150 mg/m² on days 1, 8, and 15 every 4 weeks, or dacarbazine 1,000 mg/m² every 3 weeks. A total of 529 patients were randomized to nab-paclitaxel ($n = 264$) or dacarbazine ($n = 265$) between April 2009 and June 2011. In the intent-to-treat population, the primary end point of PFS was improved in favor of the nab-paclitaxel group (4.8 and 2.5 median months in the nab-paclitaxel and DTIC arm, respectively; HR = 0.792; 95.1% CI, 0.631 to 0.992; $p = 0.044$). Interim OS was 12.8 with nab-paclitaxel and 10.7 months with dacarbazine (HR = 0.831; 99.9% CI, 0.578 to 1.196; $p = 0.094$). The most common grade 3 or higher treatment-related adverse events was neuropathy with nab-paclitaxel and neutropenia with dacarbazine. The median time to neuropathy improvement was 28 days. Further follow-up to assess potential effects in OS will be needed to determine the role of nab-paclitaxel in patients with advanced melanoma.

Combination Chemotherapy

Over the past 20 years, several uncontrolled clinical trials suggested the benefits of combination chemotherapy regimens, such

as cisplatin, vinblastine, and dacarbazine (CVD) and the so-called Dartmouth regimen (cisplatin, carmustine, dacarbazine, and tamoxifen). A phase 3 trial was conducted among 240 patients comparing the Dartmouth regimen with single-agent dacarbazine with the goal of detecting a 50% improvement in OS.²⁵⁷ The median OS was similar between the two arms (7.7 months for Dartmouth versus 6.3 months for dacarbazine; $p = 0.52$), and 1-year survival rates were also very similar (23% for Dartmouth versus 28% for dacarbazine; $p = 0.38$). The response rate was not significantly higher for the combination regimen (17% for Dartmouth versus 10% for dacarbazine; $p = 0.09$) and was substantially lower than the reported response rate in the smaller, single-institution studies. The Dartmouth regimen was associated with significantly more severe neutropenia, anemia, nausea, and vomiting. In addition, several randomized trials refuted the concept that tamoxifen substantially modulates the efficacy of chemotherapy in metastatic melanoma. CVD was tested in the context of ECOG 3695, in which CVD was the control-arm therapy for 201 patients with metastatic melanoma. The response rate was 12% and median PFS was 3.1 months, suggesting a very low activity.²⁵⁸ Overall, there is little evidence of benefit with these combination chemotherapy regimens for the treatment of patients with metastatic melanoma.

The combination of carboplatin and paclitaxel has been tested in melanoma, initially as a combination chemotherapy with sorafenib that was then shown to have benefits as a chemotherapy combination without sorafenib. This was based on the results of two randomized clinical trials. E2603 was a US intergroup double-blind, randomized, placebo-controlled phase 3 study that enrolled 823 patients to carboplatin-paclitaxel or the same combination with the addition of sorafenib.²⁵⁹ At final analysis, the median OS was 11.3 months (95% CI, 9.8 to 12.2 months) for carboplatin-paclitaxel and 11.1 months (95% CI, 10.3 to 12.3 months) for carboplatin-paclitaxel-sorafenib. Median PFS was 4.9 months for carboplatin-paclitaxel-sorafenib and 4.2 months for carboplatin-paclitaxel. Response rate was 20% for carboplatin-paclitaxel-sorafenib and 18% for carboplatin-paclitaxel. This study established a benchmark for the carboplatin-paclitaxel regimen in first-line therapy of metastatic melanoma.

The PRISM study randomized 270 patients with previously treated metastatic melanoma to the same two regimens.²⁶⁰ The median PFS was 17.9 weeks for carboplatin-paclitaxel and 17.4 weeks for the sorafenib plus carboplatin-paclitaxel arm. Response rate was 11% with carboplatin-paclitaxel versus 12% with the addition of sorafenib. Together, these studies demonstrate that sorafenib has no role in this combination and that carboplatin-paclitaxel has activity in patients with metastatic melanoma.

Biochemotherapy

For most of the 1990s and 2000s, biochemotherapy was considered by many melanoma clinicians as a treatment option due to the lack of other alternatives and the reported high response rates in uncontrolled, mostly single-institution clinical trials. However, over 20 randomized clinical trials have failed to demonstrate an improvement in OS when administering biochemotherapy compared to a control arm, although many have suggested some benefit in terms of PFS or response rate. A meta-analysis of 18 trials involving 2,621 patients provided evidence that biochemotherapy improves response rates over single-agent chemotherapy or cytokine therapy, but this does not appear to translate into a survival benefit.²⁶¹ The definitive testing of biochemotherapy has come from two large cooperative group trials.

In E3695, the combination of CVD with interferon and IL-2 administered concurrently was compared with CVD in patients with metastatic melanoma.²⁵⁸ Accrual was stopped after 416 patients were enrolled because of a preplanned futility analysis. OS was not improved (8.4-month median for biochemotherapy versus 9.1 months for CVD). PFS was superior (5-month median for biochemotherapy versus 3.1 months for CVD) but not significantly

so. Response rate was not significantly higher in the biochemotherapy arm (17% versus 12%).

In EORTC 18951, cisplatin, dacarbazine, and interferon- α were administered to all patients, with “decrecendo” IL-2 administered only to one cohort.²⁶² A total of 363 patients were accrued, with all receiving dacarbazine 250 mg/m² daily for 3 days, cisplatin 30 mg/m² daily for 3 days, and interferon- α 2b, 10 MU/m² daily for 5 days. The experimental arm also received IL-2 for 4 days after completion of the chemotherapy. The dose per day was fixed, but the duration of the infusion was lengthened each day. Survival rate at 2 years was the primary end point, and an improvement from 10% to 20% was sought. The observed difference in 2-year survival (18% for the IL-2-containing arm versus 13% for the arm without IL-2) was not statistically significant. PFS and response rates were not significantly different between the two treatments. In conclusion, there is little supportive evidence to justify the use of biochemotherapy in the management of patients with metastatic melanoma.

EXPERIMENTAL IMMUNOLOGIC THERAPIES FOR METASTATIC MELANOMA

Anti-PD-1 and Anti-PD-L1

Early clinical testing of antibodies blocking PD-1, an inhibitory T-cell receptor belonging to the CD28 superfamily of immune-regulatory receptors, or blocking its main ligand PD-L1 (also known as B7-H1 or CD274), demonstrate a high rate of durable tumor responses.^{263–265} PD-1 downregulates T-cell function by blocking T-cell receptor signaling upon binding to its ligands, PD-L1 or PD-L2 (also known as B7-DC or CD273). PD-L1 is expressed by inflamed tissues and cancer mainly in response to interferons, and confers peripheral tolerance from endogenous antigens. PD-L2 is expressed primarily by antigen-presenting cells.²¹²

In a phase 1 trial, patients with advanced melanoma, non-small-cell lung cancer, castration-resistant prostate cancer, or renal cell or colorectal cancer were treated with the anti-PD-1 antibody nivolumab at a dose of 0.1 to 10.0 mg/kg of body weight every 2 weeks.²⁶⁴ Response rate was 28% among patients with melanoma (26 of 94 patients). A maximum tolerated dose was not defined at the range of dosing levels tested. Common treatment-related adverse events included fatigue, rash, diarrhea, pruritus, decreased appetite, and nausea. Overall, grade 3 or 4 treatment-related adverse events were observed in 41 of 296 patients (14%). Drug-related serious adverse events occurred in 32 of 296 patients (11%). Drug-related adverse events of special interest included pneumonitis, vitiligo, colitis, hepatitis, hypophysitis, and thyroiditis. An update analysis of the nivolumab phase 1 clinical trial reported a median OS over 16 months, with more than 40% of patients alive after 3 years of treatment with a long-term favorable safety profile.²⁶⁶

In another phase 1 clinical trial, patients with advanced melanoma, with and without prior treatment with ipilimumab, received the anti-PD-1 antibody MK-3475 (transiently known as lambrolizumab) intravenously at 10 mg/kg every 2 or 3 weeks or at 2 mg/kg every 3 weeks.²⁶⁵ A total of 135 patients with advanced melanoma were treated. The confirmed response rate evaluated by central radiologic review per response evaluation criteria in solid tumors (RECIST) 1.1, across all dose cohorts, was 38% (95% CI, 25 to 44), with the highest confirmed response rate observed in the 10 mg/kg every 2 weeks cohort (52%; 95% CI, 38 to 66). Response rate was not different between patients with and without prior ipilimumab treatment. Responses were durable in the majority of patients. Most adverse events were low grade, and common adverse events attributed to treatment were fatigue, skin rash, pruritus, and diarrhea.

A phase 1 trial has tested the combination of anti-PD-1 therapy with nivolumab with the CTLA4-blocking antibody ipilimumab.²⁶⁷ Nivolumab and ipilimumab was administered every 3 weeks for four doses followed by nivolumab alone every 3 weeks for four doses to 53 patients with metastatic melanoma. The objective response rate

(according to modified WHO criteria) was 40%. At the maximum doses that were associated with an acceptable level of adverse events (nivolumab at a dose of 1 mg/kg of body weight and ipilimumab at a dose of 3 mg/kg), 53% of patients had an objective response. Grade 3 or 4 adverse events related to therapy occurred in 53% of patients, but were qualitatively similar to previous experience with monotherapy and were generally reversible.

Adoptive Cell Transfer Therapy

Adoptive cell transfer (ACT) therapy refers to an immunotherapy approach for the treatment of cancer that involves the infusion of the tumor-bearing host of cells with antitumor activity that can recognize cancer antigens and result in the destruction of cancer cells. Although it is still experimental, ACT has emerged among the most effective treatments for patients with metastatic melanoma; 50% to 70% of patients with metastatic melanoma experience objective cancer regressions by RECIST when treated with ACT.^{268,269}

ACT has a variety of advantages compared with other forms of cancer immunotherapy.^{270,271} T-lymphocytes, once identified as cancer reactive, can be expanded to large numbers in vitro using cytokine growth factors. Thus, patients can be administered very large numbers of cells, often much larger than can be naturally generated in vivo. These antitumor lymphocytes can be activated in vitro to express appropriate effector functions such as the ability to lyse tumor cells and secrete cytokines. Secreted cytokines can have a variety of secondary antitumor effects at the cancer site such as the destruction of surrounding blood vessels, the direct lysis of

tumor cells, and providing chemokine signals to attract additional effector cell types, such as activated macrophages, to the tumor site. Perhaps most important, when using ACT, it is possible to modify the host to enhance the ability of the infused cells to establish, grow, and function in vivo. The ability to immunosuppress the host prior to cell infusion is unique to ACT. Immunosuppression can counteract the impact of T-regulatory cells that can suppress cellular immune reactions as well as remove other endogenous lymphocytes that compete with the infused cells for homeostatic cytokines such as IL-7 and IL-15, which are necessary for antitumor T-cell expansion in vivo.²⁷⁰

A critical step in the development of effective ACT for human cancer was the demonstration in 1987 that lymphocytes infiltrating into deposits of human metastatic melanoma could be grown in IL-2. Tumor-infiltrating lymphocytes (TIL) with antitumor activity could be generated from approximately 70% of patients with metastatic melanoma. Using these human TILs, over 50 different antigenic epitopes have been identified in patients with melanoma, including antigens such as MART1 and gp100 that are widely shared among melanomas from different individuals.

The first report of ACT in humans in 1988²⁷¹ and extended in 1994²⁷² used the transfer of autologous TIL followed by the administration of high-dose IL-2. A major improvement in human ACT occurred when immunosuppressive regimens were administered prior to cell infusions, and this change led to a new generation of ACT clinical protocols.^{269,273} A schematic of ACT treatment in humans with metastatic melanoma developed in the Surgery Branch of the National Cancer Institute is shown in Figure 94.16,

Figure 94.16 A schematic representation of the adoptive transfer of tumor-infiltrating lymphocytes into patients following a lymphodepleting preparative regimen.

Figure 94.17 The preparative regimen administered prior to the administration of T-cell transfer with typical recovery of neutrophils (ANC), lymphocytes (ALC), and white blood cells (WBC).

and the preparative regimen prior to cell transfer is shown in Figure 94.17. In this treatment, metastatic melanoma deposits are resected and used to generate cultures of TILs with antitumor activity. When cultures reach from 5 to 10×10^{10} cells, they are infused into patients following an immunosuppressive preparative regimen. The first trial of this approach used a nonmyeloablative preparative regimen consisting of 60 mg/kg of cyclophosphamide for 2 days followed by 5 days of fludarabine at 25 mg/m². On the day following the last dose of fludarabine, the TILs were administered intravenously and IL-2 was then administered for 2 to 3 days at 720,000 IU/kg intravenously every 8 hours. An objective response rate by standard RECIST criteria was seen in 21 of 43 patients (49%)²⁶⁸ (Fig. 94.18).

Because animal models demonstrated that more profound lymphodepletion was associated with higher antitumor effects, two additional clinical trials were performed in 25 patients each who received this cyclophosphamide–fludarabine chemotherapy plus 2 Gy or 12 Gy of whole-body irradiation. Objective tumor regressions were seen in 13 of 25 (52%) and in 18 of 25 (72%) patients, respectively, including 10 complete regressions (40%) in the latter trial.²⁶⁸ In these trials, only 1 of 20 complete responders

has recurred, with the others ongoing at 63 to 108 months²⁶⁹ (Fig. 94.19). These results, although still experimental and available in only a few centers, represent the most effective treatments for patients with metastatic melanoma.^{268,269} Factors associated with clinical response included higher telomere lengths, increased numbers of CD27+CD28+ T cells, and increased in vivo persistence at 1 month of the transferred TILs. Among a small subset of 11 patients who had previously been treated with anti-CTLA4, survival and response rate appeared to be higher.

Recent studies using the adoptive transfer of autologous peripheral lymphocytes transduced with genes encoding antitumor T-cell receptors directed against the melanoma/melanocyte antigens MART-1 and gp100 have also shown objective responses in patients with metastatic melanoma,^{274,275} though toxicities directed against melanocyte in the eyes and ears limits the application of this gene therapy approach. Analysis of the antigens recognized by TILs associated with complete cancer regression indicate that these transferred cells recognize unique mutations present in each patient's melanoma.²⁷⁶

Recently, adoptive transfer of autologous lymphocytes transduced with genes encoding T-cell receptors against the NY-ESO-1 cancer-testis antigen have also mediated regressions in patients with metastatic melanoma.²⁷⁷

RADIATION THERAPY FOR METASTATIC MELANOMA (STAGE IV)

The Role of Radiation Therapy in the Management of Distant Metastatic Disease

In general, patients with one to two sites of metastatic melanoma, good performance status, and long interval from diagnosis of the primary lesion should be considered for surgical resection. Patients with widespread metastatic disease may be managed with systemic immunotherapy, targeted therapy, or chemotherapy, with palliative radiation to symptomatic areas of progressive disease. From a radiotherapy perspective, patients with distant metastasis of melanoma are generally managed similar to patients with distant metastases of other solid tumors, with the only main area of controversy being the role of whole-brain radiation therapy (WBRT) for patients with melanoma brain metastases. Patients with widespread systemic disease and short life expectancies should be treated with short courses of high dose per fraction radiation.

Cell Transfer Therapy

Treatment	Total	PR	CR	OR (%)
Number of patients (duration in months)				
No TBI	43	16 (37%) (84, 36, 29, 28, 14, 12, 11, 7, 7, 7, 7, 4, 4, 2, 2, 2)	5 (12%) (114+, 112+, 111+, 97+, 86+)	21 (49%)
200 TBI	25	8 (32%) (14, 9, 6, 6, 5, 4, 3, 3)	5 (20%) (101+, 98+, 93+, 90+, 70+)	13 (52%)
1200 TBI	25	8 (32%) (21, 13, 7, 6, 6, 5, 3, 2)	10 (40%) (81+, 78+, 77+, 72+, 72+, 71+, 71+, 70+, 70+, 19)	18 (72%)

(20 complete responses: 19 ongoing at 70 to 114 months)

Figure 94.18 The objective response by RECIST criteria of patients receiving cell transfer therapy using either the nonmyeloablative preparative regimen (No TBI) or with addition of 200 or 1,200 cGy total whole body irradiation (TBI). TBI, total body irradiation.

Figure 94.19 Survival curves of the 93 patients receiving autologous tumor-infiltrating lymphocytes and interleukin-2 following lymphodepleting preparative regimens. Twenty of the ninety-three patients achieved a complete response, and only one has recurred with the remaining complete responders continually disease free beyond 60 months.

Radiation Therapy for Brain Metastases

Carella et al.²⁷⁸ retrospectively analyzed 60 patients from two RTOG studies performed in the 1970s with cerebral metastases from malignant melanoma to determine the response to whole-brain irradiation and reported that the palliative and survival benefit of WBRT for melanoma patients was comparable to those found for all other primary tumors. However, the median survival times for the two studies were short, only 10 and 14 weeks, and response was measured as symptomatic improvement, which may have been at least partially due to corticosteroids given to reduce cerebral edema. In a retrospective study from the MD Anderson Cancer Center reporting on 87 patients treated for metastatic melanoma to the brain with WBRT with total doses of at least 30 Gy, it was concluded that the frequent use of corticosteroids made it difficult to assess palliative benefit from the radiation, although some patients may have derived benefit as approximately 50% of patients were able to discontinue corticosteroids on the completion of radiation treatments. However, despite this potential benefit, the median survival was only 19 weeks.²⁷⁹

Several prospective clinical trials with objective imaging criteria have been conducted to assess tumor response to WBRT alone or with concurrent chemotherapy (temozolomide, fotemustine) in patients with melanoma brain metastases.^{254,258,280} These studies suggest that WBRT has limited activity in the treatment of malignant melanoma metastatic to the brain and should be reserved for patients with widespread systemic metastases or diffuse brain metastases that are not amenable to surgical resection or stereotactic radiosurgery.

Stereotactic radiosurgery delivers high doses of radiation in a single fraction to cerebral lesions that are generally <3 cm in diameter and do not involve the brainstem. Yu et al.²⁸¹ reported one of the largest retrospective studies to date from the University of California, Los Angeles, consisting of 122 consecutive patients with 332 intracranial melanoma metastases who underwent gamma knife radiosurgery with a median prescribed dose of 20 Gy (range, 14 to 24 Gy). One-third of the patients also received WBRT. The overall median survival was 7 months from radiosurgery and 9.1 months from the onset of brain metastasis. In multivariate analysis, WBRT did not improve survival, and freedom from subsequent brain metastasis depended on intracranial tumor volume.

The RTOG trial 9508 was a phase 3 randomized trial that enrolled 333 patients with one to three brain metastases with

multiple histologies (4% of patients had melanoma) to receive WBRT to a total dose of 37.5 Gy in 15 fractions over 3 weeks with and without a radiosurgery boost, with the dose depending on the tumor volume (tumors ≤ 2 cm received 24 Gy, tumors > 2 cm and ≤ 3 cm received 18 Gy, and tumors > 3 cm and ≤ 4 cm received 15 Gy).²⁸² Patients with a single brain metastasis had statistically improved survival with a radiosurgical boost compared with those without a boost (6.5 versus 4.9 months, respectively), and the authors concluded that WBRT and stereotactic radiosurgical boost should be the treatment of choice for patients with solitary unresectable brain metastasis. Given the historic data suggesting limited benefit from WBRT for patients with melanoma brain metastasis, the ECOG initiated study E6397, which was a phase 2 trial of radiosurgery for one to three newly diagnosed brain metastases for renal cell carcinoma, melanoma, and sarcoma without WBRT.²⁸³ The dose prescription was based on tumor size and was similar to the RTOG 9508 trial. Thirty-one eligible patients were accrued to this study. The median survival was 8.3 months. The intracranial failure rate in and outside the radiosurgically treated volume at 3 months was 19% and 16%, and at 6 months it was 32% and 32%, respectively. The authors concluded that delaying WBRT may be appropriate for some subgroups of patients with radioresistant tumors, but routine avoidance of WBRT should be approached judiciously given the high intracranial failure rates.

In summary, current data would support the following treatment recommendations for patients with brain metastases from melanoma. All patients with symptomatic cerebral edema should be administered corticosteroids initially. Patients with good performance status and no or minimal systemic disease and a solitary resectable brain lesion should undergo resection. Similar patients with an unresectable brain lesion or up to five small metastatic lesions should be treated with stereotactic radiosurgery, and both groups should be considered for WBRT or close observation with serial imaging. Patients with poor performance status, diffuse systemic disease, and more than five brain lesions have a poor overall prognosis and should be considered for palliative WBRT.

Radiation Therapy for Vertebral Metastases

Patients with vertebral metastases causing spinal cord compression with a reasonable life expectancy of >1 to 2 months should be treated with corticosteroids and surgical decompression if they are operative candidates, with subsequent postoperative radiotherapy as opposed to palliative radiation alone, as this has been shown to result in superior preservation of neurologic function.²⁸⁴ Patients who are not operative candidates should be considered for radiation therapy. Recent advancements in radiation therapy planning and delivery have led to the development of stereotactic body radiation therapy (SBRT) for lesions in multiple organ sites (lung, liver, and spine). With SBRT, patients are treated with one to five fractions of high-dose and highly conformal radiation isodose distributions.²⁸⁵ Patients who have limited systemic disease burden who are not considered surgical candidates, or patients with spinal cord compression from disease progression following palliative conventional radiation therapy, should be considered for SBRT.

Current Radiation Research for Melanoma: Interactions with Immune Therapy

Radiation has been reported to have immunomodulatory effects in melanoma animal models thought to be secondary to cell death and inflammation leading to enhanced antigen presentation and antigen-specific cellular immunity, which has been termed the abscopal effect.²⁸⁶ The two main strategies of integration of radia-

tion into immune-based treatment strategies include local tumor irradiation resulting in enhanced tumor-antigen presentation and antigen-specific cellular immunity,^{286,287} and total body irradiation-induced host lymphodepletion resulting in enhanced efficacy of adoptive T-cell transfer-based immunotherapy.²⁸⁸ Recent

case reports have documented systemic responses triggered after localized radiation therapy in patients receiving the anti-CTLA4 antibody ipilimumab.^{289,290} These cases have triggered a renewed interest in the prospective testing of radiation therapy combined with immunotherapy in prospective clinical trials.

95 Genetic Testing in Skin Cancer

Michele Gabree and Meredith L. Seidel

INTRODUCTION

Many hereditary cancer predisposition syndromes are associated with cutaneous findings. Identification of unique dermatologic features provides an opportunity to distinguish hereditary cancer syndromes with similar associated internal malignancies. Although skin findings are an important diagnostic tool for a number of cancer syndromes, including Cowden syndrome, Birt-Hogg-Dubé, hereditary leiomyomatosis renal cell carcinoma, and others (Table 95.1),¹⁻¹⁸ this section will focus on skin cancer as well as tumor syndromes with cutaneous findings that are not included elsewhere in this book, including hereditary melanoma, basal cell nevus syndrome (BCNS), and neurofibromatosis type 1 (NF1), and neurofibromatosis type 2 (NF2).

The identification of dermatologic abnormalities and their association with internal malignancies often require thorough observation from clinicians. A consultation with a dermatologist may be helpful to identify specific dermatologic abnormalities. In some cases, biopsy and pathology may be necessary for a diagnosis.

GENETIC COUNSELING

Genetic counseling for hereditary skin diseases is similar to the process for other cancer predisposition syndromes. The genetic counseling process generally includes a detailed family and medical history, risk assessment, discussion of benefits, and limitations of available genetic testing, including possible test results, discussion of medical management, and implications for family members.¹⁹ Dermatologic evaluation and review of pathology records pertaining to the cutaneous findings may provide clarification on specific dermatologic observations. Consultation with a dermatologist and/or other specialist who is knowledgeable about hereditary syndromes is often essential to a clinical evaluation. When possible, reviewing the medical records of family members is also helpful to confirm dermatologic diagnoses, as reports of some skin findings in family members may contain some inaccuracies.²⁰

HEREDITARY SKIN CANCER AND THE NEUROFIBROMATOSES

In addition to a few known single-gene disorders associated with skin cancers, confounding environmental factors, including solar ultraviolet radiation, as well as other genetic factors also are known to be associated with a varying degree of skin cancer risk. Separately, other hereditary tumor and cancer predisposition syndromes, such as NF1 and NF2, contain benign cutaneous features as common and sometimes predominant findings. General characteristics of a hereditary cancer predisposition syndrome include multiple tumors or cutaneous features in one individual, multiple affected family members, and individuals or families with related tumors, cancers, or unique physical characteristics. In some cases, young age at onset may also suggest a higher likelihood of a hereditary syndrome.

Hereditary Melanoma

Approximately 10% of melanoma cases are attributed to hereditary predisposition. Hereditary melanoma has been associated with mutations in two genes, cyclin-dependent kinase inhibitor 2A (*CDKN2A*) and cyclin-dependent kinase 4 (*CDK4*). Mutations in *CDK4* are rare and have been identified in only a few hereditary melanoma families.²¹ Of families with hereditary melanoma, defined as three or more diagnoses of melanoma in one family, approximately 20% to 40% will have a detectable mutation in *CDKN2A*.²²

CDKN2A and *CDK4* both function as tumor suppressors. *CDKN2A* encodes two transcripts: p16 and p14ARF through alternate reading frames. The majority of *CDKN2A* mutation-carrying families have been found to have mutations that affect the p16 protein. Mutations affecting the function of p14ARF are reportedly rare in cutaneous melanoma families.²³

Phenotype

Hereditary melanoma has also been referred to as familial atypical mole melanoma syndrome.²⁴ Although the presence of atypical moles has been associated with an increased risk for melanoma, it has not been identified as a strong predictor of *CDKN2A* mutation status.^{25,26}

The penetrance of *CDKN2A* mutations has been observed to be dependent on geography. This is likely due to varying environmental and other genetic factors across geographic regions. A study of *CDKN2A* carriers selected based on positive personal and family history of melanoma observed the melanoma risk for *CDKN2A* mutation carriers to be 58% in Europe, 76% in the United States, and 91% in Australia.²⁷ In a population-based study of patients with melanoma, the penetrance of *CDKN2A* mutations was observed to be lower (28% risk for melanoma by the age of 80 years).²⁸ Variants in the melanocortin 1 receptor (*MC1R*) gene have been associated with increased *CDKN2A* penetrance.²⁹ The prevalence of *MC1R* has been observed to differ with ethnic background and is one example of a genetic factor influencing melanoma risk that varies by geographical region.³⁰

In addition to melanoma, other cancers have also been observed in increased frequency in *CDKN2A* mutation carriers. Most notably, an increased risk for pancreatic cancer has been reported in some *CDKN2A* mutation-carrying families.³¹ Less commonly, an increased risk for other cancers, including neural system tumors, nonmelanoma skin cancers, uveal melanoma, and head and neck cancers, has also been reported in individuals with *CDKN2A* mutations.^{31,32}

In the United States, which is an area of moderate to high melanoma incidence, genetic counseling for hereditary melanoma has been generally recommended in families in which (1) three or more relatives are affected with melanoma, (2) one individual has three or more primary melanomas, or (3) both pancreatic cancer and melanoma are present in one family (Table 95.2).¹⁵ Early age at onset in the absence of a family history of melanoma is not highly suggestive of a *CDKN2A* mutation.^{33,34}

TABLE 95.1

Summary of Hereditary Cancer Syndromes with Cutaneous Features

	Cutaneous Features	Internal Tumor Site
Benign cutaneous features prominent		
Cowden syndrome ^{1,2}	Trichilemmoma, palmoplantar keratoses, oral mucosal papillomas, cutaneous facial papules, lipomas, macular pigmentation of the glans penis	Breast, thyroid, uterus
Birt-Hogg-Dubé ³	Fibrofolliculomas, trichodiscomas, angiofibromas, perifollicular fibromas, acrochordons	Kidney
Childhood cancer syndrome (homozygous Lynch syndrome) ⁴	Neurofibromas, CALMs	Hematologic, neural system, colon, small intestine, urinary tract
Hereditary leiomyomatosis renal cell carcinoma ⁵	Cutaneous leiomyomas	Kidney, uterus
Multiple endocrine neoplasia type 2B ⁶	Mucosal neuromas of the lips/tongue	Thyroid, adrenal gland, gastrointestinal tract
NF1 ^{7,8}	Neurofibromas (cutaneous and subcutaneous), CALMs, freckling (inguinal, axillary), hypopigmented macules, cutaneous angiomas xanthogranulomas, glomus tumors, hyperpigmentation	Brain, spine, peripheral nervous system, optic pathway, small intestine, neuroendocrine, breast
NF2 ⁹	CALMs (usually one to three), plaque lesions, intradermal schwannomas, subcutaneous schwannomas, cutaneous neurofibromas (uncommon)	Brain, spine, peripheral nervous system, optic pathway
Peutz-Jeghers syndrome ¹⁰	Mucocutaneous pigmentation	Breast, stomach, small intestine, colon, pancreas, ovary, testicle
Tuberous sclerosis complex ¹¹	Hypomelanotic macules, facial angiofibromas, shagreen patches, fibrous facial plaques, unguis fibromas	Brain, kidney, heart, neuroendocrine
Benign cutaneous features sometimes present		
Multiple endocrine neoplasia type 1 ¹²	Facial angiofibromas, collagenomas, lipomas	Pituitary, pancreas, parathyroid, gastroenteropancreatic tract
Familial adenomatous polyposis ¹³	Lipomas, fibromas, and epidermal cysts	Colon, thyroid, small intestine, liver, brain, pancreas, ampulla of Vater
Skin cancer prominent		
BCNS ¹⁴	Basal cell carcinoma	Brain, ovary, heart
Hereditary melanoma ¹⁵	Melanoma, dysplastic nevi	Pancreas
Xeroderma pigmentosum ¹⁶	Melanoma, basal cell and squamous cell carcinoma, severe sunburn, lentigos, xerosis, erythema, actinic keratoses, poikiloderma	Oral cavity
Skin cancer sometimes present		
Hereditary breast and ovarian cancer syndrome ¹⁷	Melanoma	Breast, ovary, prostate, pancreas
Lynch syndrome ¹⁸	Sebaceous neoplasms, keratoacanthomas	Colon, uterus, stomach, ovary, hepatobiliary tract, urinary tract, small intestine, brain

CALM, café-au-lait macule; NF1, neurofibromatosis type 1; NF2, neurofibromatosis type 2; BCNS, basal cell nevus syndrome.

TABLE 95.2

Referral Criteria for Hereditary Melanoma Genetic Counseling

Three or more relatives on the same side of the family with melanoma
Three or more primary melanomas in one individual
Pancreatic cancer and melanoma on the same side of the family

From Leachman SA, Carucci J, Kohlmann W, et al. Selection criteria for genetic assessment of patients with familial melanoma. *J Am Acad Dermatol* 2009;61:677e1-677e14.

Genetic Testing

Clinical testing for *CDKN2A* and *CDK4* is available in the United States at several commercial laboratories. However, some of the laboratories offering hereditary melanoma testing perform analysis of only *CDKN2A*, given the relatively low-frequency *CDK4* mutations reported.

The utility of genetic testing for *CDKN2A* mutations remains a source of debate. This is partly due to the relatively low frequency of *CDKN2A* mutations in families with melanoma. In addition, many individuals with a personal and/or family history of melanoma are under close surveillance and aware of risk-reduction recommendations; therefore, genetic test results would not alter

TABLE 95.3

CDKN2A Genetic Testing Results and Medical Management Recommendations

Test Result	Medical Management
CDKN2A mutation positive	<p>Melanoma surveillance:</p> <ul style="list-style-type: none"> ■ Clinical skin examination with dermatologist every 4–6 mo ■ Biopsy should be performed on suspected lesions ■ Avoid prolonged direct sunlight and use sun-protective clothing and sunscreen ■ Monthly self-skin examinations ■ Inform at-risk relatives <p>Pancreatic cancer surveillance^a:</p> <ul style="list-style-type: none"> ■ Recommended for individuals with a family history of pancreatic cancer and may be considered in other cases ■ Refer to gastroenterologist for discussion of pancreatic screening options ■ Inform at-risk relatives
CDKN2A variation of unknown significance	<p>Etiology of the melanoma remains unknown:</p> <ul style="list-style-type: none"> ■ Consider if genetic testing is indicated for other affected relatives ■ Proband and family remain at increased risk for melanoma ■ Screening recommendations should be based on personal and family history
CDKN2A mutation negative	<p>No mutation previously identified in family:</p> <ul style="list-style-type: none"> ■ Etiology of the melanoma remains unknown ■ Consider if genetic testing is indicated for other affected relatives ■ Proband and family remain at increased risk for melanoma ■ Screening recommendations should be based on personal and family history <p>Mutation previously identified in family:</p> <ul style="list-style-type: none"> ■ Proband and family remain at increased risk for melanoma, although the risk is lower than for relatives who carry a CDKN2A mutation ■ Screening recommendations should be based on personal and family history

^aTo date, pancreatic cancer surveillance has not been proven to be effective at improving pancreatic cancer outcome.

clinical management.²⁵ Also, the role of pancreatic cancer surveillance in CDKN2A carriers remains under investigation. Some studies have suggested that knowledge of CDKN2A mutation status improves short-term compliance to risk-reducing behaviors.^{35,36} However, information regarding the long-term impact of CDKN2A testing is limited at this time. The possible genetic test results for an individual undergoing CDKN2A genetic testing are shown in Table 95.3.

Individuals with a CDKN2A mutation have a 50% chance of passing the mutation on to their children.

Medical Management

CDKN2A mutation carriers, or individuals at 50% risk to be a carrier, should be monitored carefully for melanoma through clinical and self-examinations (see Table 95.3). In addition, CDKN2A carriers are recommended to avoid prolonged direct sunlight and utilize sun-protective clothing and sunscreen.^{25,37}

Individuals who test negative for a familial CDKN2A mutation may also have an increased risk for melanoma. However, this risk has been observed to be lower than the melanoma risk for CDKN2A mutation carriers.²⁸

As noted in Table 95.3, CDKN2A mutation carriers, especially those with a family history of pancreatic cancer, are candidates for pancreatic cancer surveillance and should discuss the risks, benefits, and limitations of screening with a gastroenterology specialist.³⁸ However, to date, the effectiveness of pancreatic surveillance remains under investigation.³⁹

Basal Cell Nevus Syndrome

BCNS, also known as Gorlin syndrome or nevoid basal cell carcinoma syndrome, is an autosomal dominant syndrome associated with cutaneous findings, including basal cell carcinoma,

as well as skeletal system, nervous system, and ocular abnormalities.⁴⁰ Although BCNS has complete penetrance, the expression is variable.⁴¹

BCNS is thought to be relatively uncommon, and the incidence of BCNS has been estimated to be 1:30,827 to 1:57,000.⁴² The variable expression may cause difficulty in diagnosing BCNS.

BCNS has been associated with mutations in the *patched gene 1 (PTCH1)* gene. *PTCH1* functions as a tumor suppressor in the sonic hedgehog (Shh) pathway, which is also involved in embryonic development.⁴³ Chromosomal abnormalities of 9q22.3 region, which includes *PTCH1*, have been reported in a few individuals with features of BCNS as well as other features, including short stature, developmental delay, and seizures.⁴⁴ Rarely, mutations in other genes, including *SUFU* and *PTCH2*, have also been reported in individuals with features of BCNS.^{45,46}

Phenotype

The phenotype of BCNS is variable, and some characteristics are present at different life stages. Therefore, it is important to obtain a complete medical history, including physical examination and dermatologic, cardiac, and gynecologic examinations as well as radiologic studies to confirm a diagnosis of BCNS.

The clinical manifestations of BCNS include the following.

Skin

Basal Cell Carcinoma. Approximately 50% to 75% of individuals with BCNS will develop basal cell carcinomas.⁴⁷ Typically, basal cell carcinomas develop in the late teens through the 30s, but some published reports have indicated the detection of basal cell carcinomas in early childhood in individuals with BCNS. The presence of basal cell carcinomas is also dependent on other factors, including skin type and radiation exposure, including sun exposure.^{40,41}

Noncancerous Cutaneous Features. The majority of individuals with BCNS will have multiple nevi present by adulthood.⁴⁰ In addition, BCNS is associated with an increased prevalence of facial milia, dermoid cysts, and skin tags. Palmar and plantar pits are also a common feature of BCNS and usually are evident by early adulthood.⁴⁰

Skeletal

Skeletal abnormalities, including rib and spinal abnormalities, are reported with increased frequency in BCNS. The majority of individuals with BCNS are reported to have macrocephaly.⁴⁸

Central Nervous System

Ectopic Calcification. Ectopic calcification, particularly of the falx cerebri, has been reported as a common finding in individuals with BCNS.⁴⁸

Brain Tumor. Although other types of brain tumors have been reported in individuals with BCNS, medulloblastoma, typically desmoplastic type, is the most common.⁴⁹ Approximately 5% of individuals with BCNS are diagnosed with medulloblastoma, usually around 2 years of age.

Other Features

Jaw Keratocysts. Approximately 75% of affected individuals with BCNS develop multiple jaw keratocysts.⁵⁰

Characteristic Facial Features. Facial features characteristic of BCNS, including macrocephaly, bossing of the forehead, coarse facial features, and facial milia, have been observed in approximately 60% of BCNS cases.¹⁴

In addition to these features, congenital malformations such as cleft lip/palate, polydactyly, and eye anomalies have also been reported as features of BCNS.⁴⁰

Additional associated tumors including cardiac and ovarian fibromas have also been reported to occur with increased frequency in BCNS.^{51,52}

Diagnosis and Genetic Testing

A diagnosis of BCNS was initially based on clinical criteria; however, the availability of molecular testing has identified mutations in individuals with a more variable phenotype. The First International Colloquium on BCNS concluded that the clinical criteria should be used to consider a suspected diagnosis of BCNS rather than as diagnostic criteria.⁵³ The colloquium recommends that a suspected diagnosis of BCNS be considered in individuals with an identified *PTCH1* mutation and one major clinical criterion, individuals who express two major criteria, and individuals with one major and two minor criteria (Table 95.4).

Genetic testing for the *PTCH1* gene is clinically available. Approximately 50% to 85% of individuals with clinical features of BCNS will have a detectable mutation in the *PTCH1* gene through gene sequencing analysis. Deletions and duplications of the *PTCH1* gene have also been reported.⁵⁴

Approximately 20% to 30% of individuals with BCNS are de novo, meaning that neither parent carries the associated gene mutation.¹⁴ Individuals affected with BCNS have a 50% chance of having an affected child. In cases where a mutation has been identified, testing is an option for at-risk family members. In addition, both preconception genetic diagnosis and prenatal testing are available for known *PTCH1* mutations.

Medical Management

Because of the many variable symptoms of BCNS, individuals with BCNS should be referred to an appropriate specialist depending on the symptoms.

TABLE 95.4

Clinical Criteria for Suspected Diagnosis of Basal Cell Nevus Syndrome

Major criteria

- Early-onset/multiple basal cell carcinoma
- Odontogenic keratocyst of the jaw (<20 y of age)
- Palmar/plantar pitting
- Calcification of the falx cerebri
- Medulloblastoma (usually desmoplastic)
- First-degree relative with BCNS

Minor criteria

- Rib anomalies
- Skeletal malformations and radiologic changes
- Macrocephaly
- Cleft lip/palate
- Ovarian/cardiac fibroma
- Lymphoenteric cysts
- Ocular abnormalities

BCNS, basal cell nevus syndrome.

From Bree AF, Shah MR. Consensus statement from the first international colloquium on basal cell nevus syndrome (BCNS). *Am J Med Genet A* 2011; 155A:2091–2097.

Basal Cell Carcinoma. Early diagnosis is important for management and to limit cosmetic damage. Surgery, oral retinoids, topical therapies, and photodynamic therapy have all been utilized with varying degrees of success for individuals with BCNS.⁴⁷

Medulloblastoma. Consideration of developmental assessment and physical examination every 6 months is an option for children during infancy and early childhood. Imaging for medulloblastoma surveillance is not currently recommended.¹⁴

Jaw Keratocysts. Clinical examinations and imaging are recommended for individuals with BCNS, starting during childhood. These tumors may sometimes be detected during routine dental examinations.⁵⁵

Ovarian and Cardiac Fibromas. Affected individuals with cardiac fibromas should be referred to a cardiologist. Ovarian fibromas also warrant a specialty referral and may require surgery, ideally with the aim of preserving fertility.⁵⁶

Radiation Exposure. Given the known increased risk for basal cell carcinoma, it is recommended that individuals with BCNS avoid sun exposure. In addition, it is recommended that other radiation exposure also be avoided if possible, including radiation as treatment for medulloblastoma.⁴⁹

Neurofibromatosis Type 1

NF1 is one of the most common genetic disorders, affecting an estimated 1:2,500 to 1:3,000 individuals at birth.⁷ Formerly known as von Recklinghausen disease or peripheral neurofibromatosis, manifestations of the disease affect multiple areas of the body, including, but not limited to, the central and peripheral nervous systems, skin, eyes, skeleton, gastrointestinal system, and the cardiovascular system. Historically, observations of patients with NF1 date back to the 13th century, but the disorder was first formally described in 1882 by Friedrich von Recklinghausen.^{7,57,58}

NF1 is a completely penetrant autosomal dominant condition with widely variable expression, both within and between families.⁵⁹ No ethnic, racial, or sex predilection has been observed.⁵⁷ NF1 is caused by mutations in the NF1 gene on 17q11.2. The

protein product of NF1 is neurofibromin, a GTPase-activating protein that is expressed across many tissue types and in particularly high levels within neurocutaneous tissue. It acts as a negative regulator of intracellular Ras signaling pathways involved in cell growth and proliferation.^{7,60,61} More recently, NF1 has also been linked to the development of skeletal muscle.⁶²

Phenotype

In 1987, the National Institutes of Health developed clinical diagnostic criteria for NF1 (Table 95.5) on which diagnosis of the disease is most often based.⁵⁹ The disease usually presents in childhood, beginning with skin findings, which are often present by 1 year of age. In general, the clinical manifestations of NF1 are age dependent: By the age of 6 years, approximately 90% of individuals with NF1 meet diagnostic criteria; by 8 years of age, 97% meet criteria, and virtually all meet the criteria by the time they are 20 years old.⁵⁹

Skin

Among the numerous and variable clinical manifestations of NF1, cutaneous findings feature prominently and can even be the sole basis for a diagnosis of NF1. The following skin findings are hallmark features of NF1, and each is a component of the diagnostic criteria (see Table 95.5).

Café-Au-Lait Macules. Café-au-lait macules (CALM) are the most common and often the earliest presenting feature of NF1. CALMs may be congenital and are observed in almost all patients with NF1 within the first year of life. They often become larger and more numerous through adolescence and may fade as an adult.⁵⁷

Intertriginous Freckling. Skinfold freckling, or Crowe sign, is a cardinal feature of NF1.⁵⁹ Freckling occurs most often in the axillary and inguinal regions of the body and is exhibited by up to 90% of patients, usually beginning in childhood. Freckling may also be found in other areas of the body including beneath the breasts in females, on the neck, above the eyelids, around the mouth, and on the trunk in adults.⁵⁸

Neurofibromas. The hallmark feature of NF1, neurofibromas can develop in almost any part of the body, including on or just below the surface of the skin. Cutaneous neurofibromas vary in size (<1 mm to large/disfiguring) and number; they are soft and fleshy, and may be raised or flat, ranging in color from blue/purple to brown to flesh colored. Subcutaneous neurofibromas are firm,

tender nodules that are often visible beneath the skin. Cutaneous and/or subcutaneous neurofibromas usually manifest later than CALMs and freckling, either later in childhood or in early adolescence.^{58,59}

Less common, nondiagnostic cutaneous features of NF1 include hyperpigmentation, which may be generalized or appearing in conjunction with affected body areas in segmental NF1, glomus tumors, hypopigmented macules (usually on the trunk), xantho-granulomas, cutaneous angiomas, and pruritus.^{7,57,60}

Neurologic

Tumors of the central and peripheral nervous systems are prevalent among individuals with NF1. These include spinal neurofibromas, peripheral nerve sheath tumors, plexiform neurofibromas, and astrocytomas. In addition, optic pathway gliomas (OPG) are slow-growing tumors occurring among 15% to 20% of patients, usually by the age of 6 years. OPGs are symptomatic in only 5% of individuals, in which case they are most often diagnosed by the age of 3 years.^{7,57,60}

A variety of nontumor neurologic manifestations are reported among individuals with NF1. These include learning disabilities, which occur in 60% or more of children with NF1, decreased IQ (occasionally <70), attention-deficit/hyperactivity disorder, and other behavior difficulties. Unidentified bright objects (UBO) are a characteristic magnetic resonance imaging (MRI) finding in NF1. The clinical significance of UBOS is not known, but some evidence correlates UBO prevalence with severity of cognitive and behavioral difficulties.^{58,59} Seizure disorders and multiple sclerosis also occur at a higher frequency in NF1, and Chiari type I malformation, aqueductal stenosis, and macrocephaly have all been reported.^{7,59}

Eye

Lisch nodules, or melanocytic iris hamartomas, are asymptomatic eye findings present in most individuals with NF1, usually by the age of 5 to 10 years. Lisch nodules are pathognomonic for NF1 and are most reliably detected by an experienced ophthalmologist by slit-lamp examination.^{7,8,60} Glaucoma, choroidal abnormalities, and ptosis are less common but have all been reported in patients with NF1.⁷

Skeletal

Bony growths and other abnormalities of the bone are key features of NF1. Diagnostic bone findings include thinning of the long-bone cortex (with or without pseudoarthrosis) and sphenoid wing dysplasia. In addition, there is an increased frequency of short stature, scoliosis, and, more recently noted, osteopenia and osteoporosis among individuals with NF1.^{7,57,60}

Cardiovascular

Cardiovascular complications occur at a higher frequency among patients with NF1 and include congenital heart disease (pulmonary stenosis, coarctation of the aorta), hypertension, cerebrovascular disease, and renal artery stenosis.^{7,63} Pulmonary stenosis is more prevalent among patients with classic NF1 but may also be found as part of a variant phenotype that combines features of NF1 and Noonan syndrome.⁵⁹

Other Features

Respiratory Complications. Respiratory complications include restrictive lung disease caused by compression from neurofibroma and metastases from malignant peripheral nerve sheath tumors.⁷

Neurofibromatosis Type 1–Associated Malignancies. The overall increased risk of cancer in NF1 patients is 2.7-fold, and the cumulative risk for patients older than 50 years is 20%.⁶¹ Malignant peripheral nerve sheath tumors are the most common cancerous tumors in NF1. Other malignancies include chronic myelogenous

TABLE 95.5

National Institutes of Health Diagnostic Criteria: Neurofibromatosis Type 1

Clinical diagnosis of NF1 can be made for an individual exhibiting any two (or more) of the following:

Six or more café-au-lait macules:

- ≥5 mm prepubertal
- ≥15 mm postpubertal

Two or more neurofibromas of any type, or one or more plexiform neurofibromas

Freckling in the axillary or inguinal region

Optic glioma

Two or more Lisch nodules (iris hamartomas)

A distinctive osseous lesion such as sphenoid dysplasia or tibial pseudoarthrosis

A first-degree relative with NF1 as defined by the above criteria

NF1, neurofibromatosis type 1.

From Evans DG, Raymond FL, Barwell JG, et al. Genetic testing and screening of individuals at risk of NF2. *Clin Genet* 2012;82:416–424.

leukemia, astrocytoma, rhabdomyosarcoma, gastrointestinal stromal tumors, carcinoid tumors (small intestine), pheochromocytomas (although usually not malignant), and breast carcinoma.⁶¹ There are also a few reports of higher rates of melanoma seen in NF1; however, this association remains controversial.⁵⁷

Diagnosis and Genetic Testing

Up to 50% of individuals with NF1 have no family history and represent de novo mutations. The *NF1* gene has one of the highest spontaneous mutations rates, about 1:10,000, and more than 500 pathogenic mutations have been identified.⁶¹ The reason for the high mutation rate is not fully understood, but may be due in part to the large size of the gene.⁵⁹

Although diagnosis of NF1 is almost always made on a clinical basis using the established criteria, genetic testing is available and can be useful, particularly in certain situations. Mutations are identifiable in 95% of individuals who meet the NF1 clinical diagnostic criteria.⁶⁴ In young children with no family history who do not yet meet the diagnostic criteria, genetic testing may aid in differentiating NF1 from other disorders with phenotypic overlap such as Legius syndrome, familial café-au-lait spots, and NF2. Genetic testing may also help identify rare variant forms of the disease that do not satisfy the National Institutes of Health criteria. In families with a previously identified mutation, prenatal diagnosis and prenatal testing are available. A common challenge in prenatal counseling and testing for NF1 arises from the variability and unpredictability of the disease presentation.^{7,65}

Given the wide variability in expression of the disease even among members of the same family, it stands to reason that very few genotype–phenotype correlations have been described. It has been noted that individuals carrying a deletion of an entire NF1 allele (approximately 4% to 5% of cases) are likely to exhibit a more severe phenotype, including a greater number of cutaneous neurofibromas, often occurring at younger ages. Cognitive abnormalities are also more frequent and severe, and somatic overgrowth, large hands and feet, and dysmorphic facial features have been reported.⁶⁵ In addition, individuals with a three-base-pair in-frame deletion of exon 17 of NF1 may exhibit the common nontumor cutaneous features of NF1, without cutaneous or surface plexiform neurofibromas.⁶³

In addition to the high rate of spontaneous mutations, another challenge associated with genetic counseling for NF1 is the high rate of mosaicism. Approximately 40% to 50% of cases are segmental, or mosaic, representing postzygotic NF1 mutations. In these cases, recurrence risks can be difficult to predict; however, they are usually estimated to be <1% unless the germline is affected. Indeed, there are cases of individuals with segmental NF1 bearing children with constitutional disease.⁶³

Medical Management

Management of NF1 requires multidisciplinary input and, ideally, should be overseen by practitioners experienced in caring for patients with neurofibromatosis.^{58,60}

Recommended surveillance for children with NF1 may vary somewhat by center, but typically includes annual physical and ophthalmologic examination until the age of 8 years. Between the ages of 8 and 18 years, examinations every other year may be sufficient.^{58,60,64} Blood pressure monitoring should take place at least annually because of the risk of pheochromocytoma and renal artery stenosis.^{58,64} In addition, annual neurologic examinations are advisable, with consideration of neuroimaging in the presence of any abnormal findings.⁵⁸ In addition, ongoing developmental and neuropsychological evaluation is recommended to assess cognitive function and to identify learning disabilities.^{8,57}

Screening by way of MRI, electroencephalogram, and/or X-ray may be dictated by symptoms, clinical findings, and/or personal and family history. For certain findings, more frequent monitoring may be indicated and, in some cases, treatment may be available.

Plexiform Neurofibroma. Perform MRI every 6 to 12 months to monitor growing lesions. Depending on the location of the lesion, surgical debulking may be possible but is often incomplete, resulting in regrowth.^{8,60,64}

Optic Pathway Gliomas. Once identified, MRI is used to monitor OPGs. Quarterly ophthalmologic evaluation is suggested for the first year, followed by annual examination of patients for at least 3 years or until the age of 8 years. Evaluation by endocrinology may be recommended. For symptomatic OPGs, chemotherapy treatment is available, but radiotherapy is not recommended.^{8,57}

Malignant Peripheral Nerve Sheath Tumor. Monitor individuals with plexiform neurofibroma for increased size and pain, as well as changes in tumor texture; monitor unexplained neurologic changes. If possible, complete surgical resection is desired, but should be followed by radiation therapy if it is not complete.^{8,64}

Cutaneous Neurofibromas. Surgical removal of neurofibromas may be possible when necessary for cosmetic or pain-related reasons.^{8,57}

As necessary, referrals should be made to a variety of specialties, including cardiology, nephrology, plastic surgery, otolaryngology, and gastroenterology.

Neurofibromatosis Type 2

NF2 was first described by J. H. Wishart in 1822, at least 50 years prior to von Recklinghausen's description of NF1. Although there is relatively little overlap in the clinical phenotype of the two conditions, NF2 is much less common and was, until relatively recently, often mistaken as a variant form of NF1. It was not until 1987 when linkage studies attributed the conditions to two different genes on different chromosomes that the diseases were formally recognized as separate. Although more common than it was once thought to be, the estimated incidence of NF2 is approximately 1/10 of that of NF1, or 1:30,000 to 1:40,000.⁶⁶

NF2 is inherited in an autosomal dominant manner and is virtually 100% penetrant by the age of 60 years.⁹ It is caused by mutations in the NF2 gene on chromosome 22q12. The product of the NF2 gene is the protein known as merlin (moesin–ezrin–radixin-like protein) or schwannomin, and it is thought to function in cell membrane protein organization, cellular adhesion, and negative regulation of cellular growth, proliferation, and motility.^{60,64} The specific mechanism of the tumor suppressor function of merlin has not yet been fully elucidated and is an area of active investigation.⁶⁰

A key difference between NF1 and NF2 relates to cutaneous findings, which, in NF2, may aid in diagnosis but are not diagnostic in and of themselves. The cardinal feature of NF2 is vestibular schwannoma, which arise bilaterally on the eighth cranial nerve in almost all cases of the disease.⁷

Phenotype

Contrary to the name of the disorder, schwannomas and meningiomas, not neurofibromas, are the most prominent tumor types found in NF2.^{9,67} Individuals with NF2 most often present between 20 and 30 years of age with hearing loss (frequently unilateral) related to the presence of a vestibular schwannoma. Tinnitus, dizziness, and imbalance are also common adult symptoms at presentation.⁹ Although children may also develop similar symptoms, they are more likely to present with less common features of NF2, making examination of other systems the key to accurate diagnosis. In these cases, neurologic examination, eye examination, and careful examination of the skin become crucial.⁶⁴ Several sets of NF2 diagnostic criteria exist, and the criteria may still be evolving⁶⁸; however, currently, the most widely used criteria set is the Manchester Diagnostic Criteria, shown in Table 95.6.⁶⁰

TABLE 95.6

Diagnostic Criteria for Neurofibromatosis Type 2

Manchester Diagnostic Criteria for NF2

- Bilateral vestibular schwannoma
or
- First-degree family member with NF2 and unilateral vestibular schwannoma, or any two of meningioma, glioma, neurofibroma, schwannoma, posterior subcapsular lenticular opacities
or
- Unilateral vestibular schwannoma and any two of meningioma, glioma, neurofibroma, schwannoma, posterior subcapsular lenticular opacities
or
- Multiple meningiomas (≥ 2) and unilateral vestibular schwannoma or any two of glioma, neurofibroma, schwannoma, cataract

NF2, neurofibromatosis type 2.

Skin

Although not hallmarks of the disease, the cutaneous manifestations of NF2 are prevalent and can be detected in up to 70% of cases.⁷ As with NF1, skin findings include CALMs; however, when CALMs are present in NF2, it is generally fewer, about one to three per person. Individuals with NF2 may also exhibit plaque lesions on the surface of the skin, intradermal schwannomas, subcutaneous schwannomas, and, very rarely,^{7,57,60} cutaneous neurofibromas.^{7,9}

Neurologic

Tumors. Bilateral vestibular schwannomas occur in 90% to 95% of patients with NF2.⁷ Although malignancy is rare, the location of growth is a common cause of increased morbidity, often causing progressive hearing loss and balance issues.⁵⁸ Schwannomas of other cranial nerves are not uncommon among patients with NF2⁹; in addition, spinal and peripheral nerve schwannomas often develop.⁶⁴ Meningiomas are the second most common tumor type, found in 58% to 75% of patients with NF2. Both cranial and spinal meningiomas can be found in NF2.⁶⁴ More rare, but also observed, are spinal and brainstem ependymomas, as well as spinal and cranial astrocytoma.⁷

Peripheral Neuropathy. The majority of patients with NF2 will develop peripheral neuropathy within their lifetime, often in childhood presenting as a hand or foot drop, or a palsy. Neuropathy is sometimes but not always related to tumor compression.⁹

Eye

Subcapsular lenticular opacities are a key diagnostic feature of NF2. They are found in 60% to 81% of patients and may develop into cataracts.^{9,58} Additional ocular findings include epiretinal membranes, or thin translucent or semitranslucent sheets of fibrous tissue, which usually do not decrease visual acuity.⁹ In

addition, retinal hamartomas appear in 6% to 22% of patients with NF2 and can cause a loss of visual acuity.⁹

Diagnosis and Genetic Testing

In patients with suspected NF2 and a positive family history (two or more family members affected), genetic testing reveals mutations in $\geq 90\%$. However, approximately 50% of individuals with NF2 represent de novo mutations in the *NF2* gene. In isolated cases of classic NF2 with no known family history, mutations are identified in approximately 60% to 72%. In families with an identified mutation, presymptomatic genetic testing of at-risk family members is important for management of the disease. Prenatal genetic testing and preimplantation genetic diagnosis are also available.⁶⁹

Somatic mosaicism is observed in roughly 33% of individuals with de novo cases of NF2, and identification of these individuals often relies on confirming the presence of the same mutation in tissue from two distinct NF2-related lesions.⁶⁷ Finally, for some mutations, genotype–phenotype correlation data are available.⁹

Medical Management

In general, as with NF1, it is best if patients with NF2 are able to be followed by experienced practitioners in a comprehensive clinic setting. Screening recommendations may include initiation of MRI screening for vestibular schwannomas at the age of 10 years, as symptoms of the tumors are rare in younger patients. When present, growth of vestibular schwannomas is best measured by tumor volume using MRI.⁶⁰ Head and spinal MRI is the primary screening tool and should be performed every 2 years for at-risk children younger than 20 years with no symptoms or tumors. After the age of 20 years, the tumors grow slower and screening can be decreased to every 3 to 5 years.⁶⁹ Annual ophthalmologic examination is recommended from infancy in at-risk or affected individuals. In addition, the following annual examinations, initiated in infancy, may be recommended: Neurologic examination and audiology with auditory brainstem evoked potentials.⁹

When it is possible, surgery is the primary mode of treatment for NF2 tumors, with the intent of improving quality of life and maintenance of function. Surgery is not always possible and, in some cases, radiation therapy may be used as an alternative. Overall, patients with NF2 have a shorter life expectancy.⁶⁰

CONCLUSION

Dermatologic examinations, when combined with a thorough personal and family medical history, play an important role in the diagnosis of many cancer predisposition syndromes. Although some cutaneous features are strongly indicative of a specific diagnosis, others may be less common or less strongly associated with a particular syndrome; therefore, it remains important to consider these findings in the context of a patient's complete medical and family history. The current availability of molecular testing for many hereditary syndromes has significantly advanced the ability to distinguish and confirm a suspected clinical diagnosis. In addition to the syndromes listed in this chapter, it is important to note that other cancer predisposition syndromes may also have cutaneous components, and with the advancement of molecular testing, additional syndromes are likely to be identified in the future.

96 Molecular Biology of Central Nervous System Tumors

Victoria Clark, Jennifer Moliterno Günel, and Murat Günel

GLIOMAS

Gliomas account for 26.4% of all primary brain tumors, with malignant gliomas (grade III or IV) accounting for 19.9% of all primary brain tumors.¹ The World Health Organization (WHO) classifies gliomas by the cells they morphologically resemble (astrocytes, oligodendrocytes, or a mixture) and groups the tumors into four grades based on histology and aggressiveness.² High-grade gliomas (WHO grades III and IV) have a dismal prognosis, with the median survival for grade IV astrocytomas (glioblastoma multiforme [GBM]) less than 15 to 20 months.³ Low-grade gliomas (WHO grades I and II) are heterogeneous in terms of their prognosis and likelihood to progress to high-grade gliomas.

Adult Low-Grade Gliomas

What drives some adult low-grade gliomas to progression whereas others remain indolent is an area of active investigation. Grade I gliomas, the majority of which are pilocytic astrocytomas, are histologically benign tumors with low potential for malignant progression that primarily occur in the pediatric population and are discussed in detail in the pediatric low-grade glioma section, which follows. Histologically, WHO grade II gliomas can be divided into tumors that arise from astrocytes (diffuse astrocytomas), oligodendrocytes (oligodendrogliomas), or tumors with elements of both cellular populations (oligoastrocytomas).² All three histologic subtypes have frequent neomorphic driver mutations affecting the R132 residue of isocitrate dehydrogenase 1 (IDH1),⁴ a mutation that generates the oncometabolite 2-hydroxyglutarate (2HG).⁵ Ultimately, the IDH1 R132 mutation drives gliomagenesis through epigenetic dysregulation, including DNA CpG hypermethylation (G-CIMP phenotype)⁶ and alterations in histone methylation.⁷⁻⁹ Despite sharing the IDH1 R132 driver mutation, grade II oligodendrogliomas have improved median overall survival (11.6 years for grade II oligodendrogliomas versus 5.6 years for grade II astrocytoma),¹⁰ and a much lower rate of progression to a high-grade glioma (45% for oligodendroglioma versus 74% for astrocytoma).¹ The survival and progression benefit seen in IDH1 mutant grade II gliomas is likely modified by comutations. Oligodendrogliomas commonly have a loss of heterozygosity (LOH) on chromosomes 1p and 19q,¹¹⁻¹³ which is usually the result of a single pericentromeric translocation event.¹⁴ The 1p/19q loss in oligodendrogliomas frequently co-occurs with somatic mutations in capicua transcriptional repressor (CIC, located on chr1) or far upstream element (FUSE) binding protein 1 (FUBP1, located on chr19),¹⁵ and IDH1-CIC/FUBP1-1p/19q loss gliomas have a median survival of 8 years.¹⁶ In contrast, grade II astrocytomas commonly have somatic mutations in the chromatin modifier alpha thalassemia/mental retardation syndrome X-linked (ATRX),¹⁶ mutations in tumor protein p53 (TP53),⁴ and LOH at chr17 (where

TP53 is found), and IDH1-ATRX-TP53 gliomas have a median survival of 5 years.¹⁶ This latter group is likely to progress to form secondary GBMs, a process mediated by epigenomic dysregulation and deletion of retinoblastoma 1 (RBI), cyclin-dependent kinase inhibitor 2A (CDKN2A), and phosphatase and tensin homolog (PTEN).^{17,18} Oligoastrocytomas have a combination of mutations and chromosomal LOH found in astrocytomas and oligoastrocytomas and a median survival of 6.6 years.¹⁰

Adult High-Grade Gliomas

Glioblastoma multiforme (WHO grade IV) is the most common malignant brain tumor, accounting for 15.6% of all primary brain tumors and 60% of all gliomas.¹ There are two major routes to GBM formation: *de novo* formation (primary GBM, 95% of cases), or progression from low-grade glioma (secondary GBM, 5% of cases) (Fig. 96.1).¹⁷ Secondary GBMs occur in younger patients, result in improved survival, and bear IDH1 mutations with common co-mutations in ATRX and TP53 and deletion of RBI, CDKN2A, and PTEN.¹⁶⁻²¹ In contrast, primary GBMs occur in older patients, have poor survival, and have dysregulation of three core pathways: p53, retinoblastoma (Rb), and receptor tyrosine kinase/Ras/phosphoinositide 3-kinase (PI3K) signaling (RTK/Ras/PI3K signaling).^{17,20,22-24} A recent large-scale GBM next-generation sequencing study by The Cancer Genome Atlas (TCGA) found that the p53 pathway is somatically disrupted in 85.3% of GBMs, through p53 loss (27.9%), homozygous deletion of CDKN2A (57.8%), and amplification of MDM1/2/4 (15.1%).²⁴ The Rb pathway is also impacted by frequent CDKN2A deletion, and other hits to Rb signaling have been seen via RBI loss (7.6%) or amplification of cyclin-dependent kinase 4 or 6 (CDK4/6) (15.5%), for a total of 78.9% alteration of Rb signaling.²⁴ Somatic alterations in receptor tyrosine kinases were observed in 67.3% of GBMs, most prominently in epidermal growth factor receptor (EGFR) (57.4%) and platelet-derived growth factor receptor alpha (PDGFRA) (13.1%).²⁴ Of GBMs showed either PTEN loss or PI3K mutation, and neurofibromin 1 (NF1) loss was seen in 10% of tumors.²⁴ In combination, the RTK/Ras/PI3K signaling was hit once in 89.6% of tumors and hit multiple times in 39% of tumors.²⁴ Additionally, 83.3% of GBMs were reported to have recurrent telomerase reverse transcriptase (TERT) promoter mutations (C228T or C250T), and these mutations are mutually exclusive with ATRX mutations.²⁵

Based on gene expression profiling, GBMs cluster into four groups: classical (chromosome 7 amplification with chromosome 10 loss, deletion of CDKN2A), mesenchymal (NF1 focal deletions or mutations), proneural (IDH1 mutant or PDGFRA amplification), and neural (EGFR amplification with a neural expression signature).²³ These classifications have a utility for predicting response to therapy; for example, the classical subtype

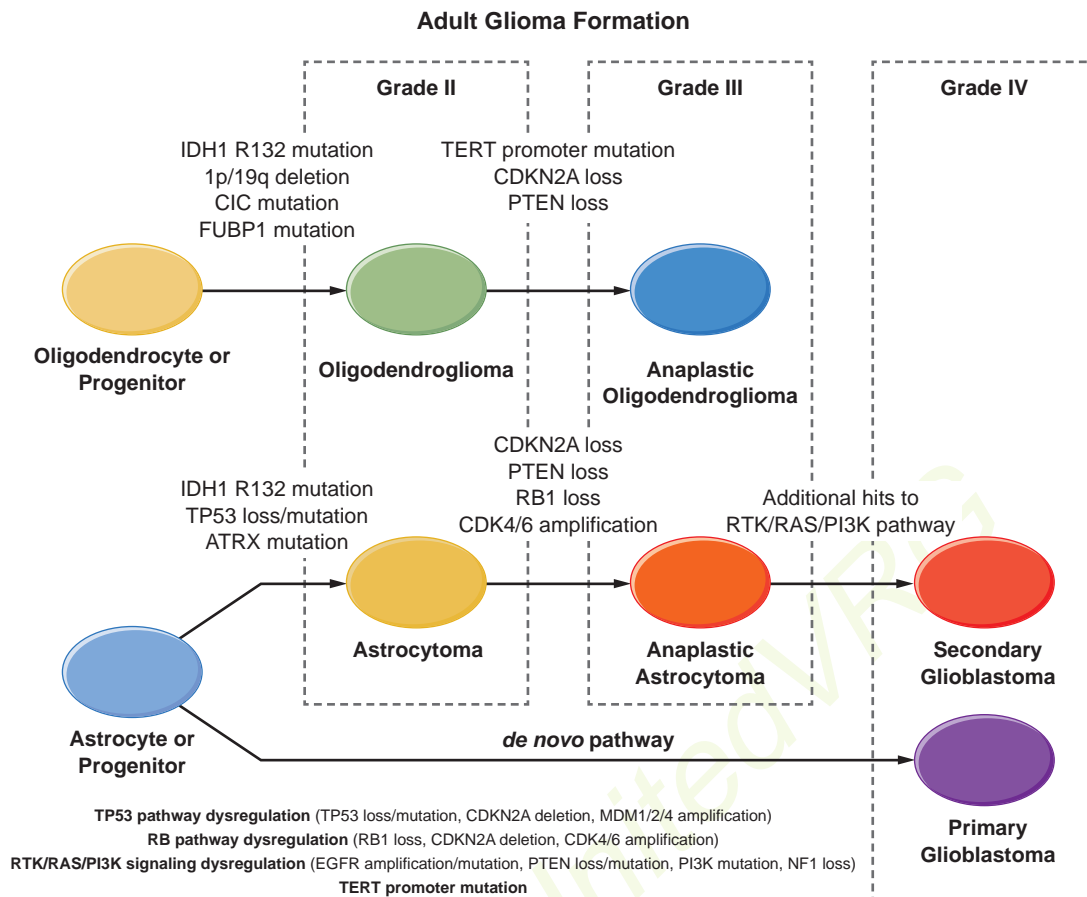

Figure 96.1 Driver events in adult gliomagenesis. Glioblastoma multiforme can either arise from progression of lower grade gliomas (secondary GBM) or *de novo* (primary GBM). IDH1, isocitrate dehydrogenase 1; CIC, capicua transcriptional repressor; FUBP1, far upstream element (FUSE) binding protein 1; TERT, telomerase reverse transcriptase; CDKN2A, cyclin-dependent kinase inhibitor 2A; PTEN, phosphatase and tensin homolog; TP53, tumor protein p53; ATRX, alpha thalassemia/mental retardation syndrome X-linked; RB1, retinoblastoma 1; CDK4/6, cyclin-dependent kinase 4/6; RTK, receptor tyrosine kinase; PI3K, phosphoinositide 3-kinase; EGFR, epidermal growth factor receptor; NF1, neurofibromin 1.

responds to more intensive therapy whereas the proneural subtype shows no benefit to this regimen.²³ Another prognostic indicator is the CpG island methylator phenotype (G-CIMP) demonstrated in IDH1 mutant proneural tumors, which had a significantly better survival (median of 150 weeks) compared to proneural G-CIMP-negative patients (median survival of 42 weeks) or other GBM subtypes (median survival 54 weeks).⁶ Also clinically useful to predict response to therapy is O-6-methylguanine-DNA methyltransferase (MGMT) promoter methylation status,^{19,26} because tumors with silenced MGMT are unable to remove the alkyl groups deposited on the O6 position of guanine by alkylating agents such as temozolomide.²⁷

Anaplastic (grade III) gliomas, including anaplastic astrocytomas, anaplastic oligoastrocytomas, and anaplastic oligodendrogliomas, are not as well characterized genomically as GBMs. Clinically, they can arise without a prior history of low-grade glioma (presumed *de novo*) or through progression from low-grade gliomas (secondary anaplastic glioma). Grade III gliomas have a high risk of progression to GBM, although the rate of progression and prognosis varies by histology, with anaplastic astrocytomas having a 5-year overall survival of 26.5% and anaplastic oligodendrogloma having a 5-year overall survival of 50.7%.¹ IDH1 mutations have been observed in 75% to 90% of grade III gliomas.^{4,16,28} Anaplastic astrocytomas, accounting for 1.7% of primary brain tumors,¹ commonly have mutations in ATRX, IDH1, and loss of p53 as well as alterations to the Rb pathway (including RB1 loss, CDKN2A deletion, and CDK4/6 amplification).^{16,18,28} It is believed that

additional hits in the RTK/Ras/PI3K pathway, including LOH at chr10q, lead to progression to frank glioblastoma.^{17,18,21} Anaplastic oligodendrogliomas are rare (0.5% of primary brain tumors),¹ and the progression from grade II oligodendrogliomas (characterized by chr1p/19q loss and IDH1-CIC/FUBP1 mutations) is likely mediated by additional deletion of CDKN2A and PTEN.¹³ Like GBMs, recurrent TERT promoter mutations (C288T or C250T) have been identified in anaplastic gliomas, reported in 14.8% of anaplastic astrocytomas, 26.7% of anaplastic oligoastrocytomas, and 88.4% of anaplastic oligodendrogliomas.²⁵ The differences in TERT promoter mutations between the subtypes is probably due to the higher frequency of ATRX mutations in anaplastic astrocytomas, because TERT promoter mutations are mutually exclusive with ATRX mutations in GBMs and other tumors.²⁵

Pediatric Low-Grade Gliomas

Pediatric low-grade gliomas (WHO grade I and II) are the most common brain tumors in children¹ and can be broadly divided into nondiffuse (e.g., pilocytic astrocytomas) and diffuse gliomas. Pilocytic astrocytomas (WHO grade I) are histologically benign tumors with a low probability of malignant progression that are usually pediatric, are primarily found in the cerebellar hemisphere (67%)¹⁰, and are cystic.² The mitogen-activated protein kinase/extracellular signal-regulated kinase (MAPK/ERK) pathway was originally implicated in driving the formation of pilocytic

astrocytomas through studies of the hereditary tumor syndrome neurofibromatosis type 1, in which ~15% of patients with germline loss-of-function mutations in *NF1*, a negative regulator of Ras signaling, develop pilocytic astrocytomas in addition to café-au-lait spots and cutaneous neurofibromas.²⁹ Further investigation has revealed that MAPK/ERK pathway activation is crucial to sporadic pilocytic astrocytoma formation, with 90% of cerebellar pilocytic astrocytomas demonstrating a *KIAA1549-BRAF* (B-Raf proto-oncogene, serine/threonine kinase) fusion gene that results in constitutively active BRAF signaling via a truncation of the BRAF autoinhibitory domain.^{30–33} Pilocytic astrocytomas can also have constitutive activation of MAPK/ERK through somatic *BRAF V600E* mutations, Kirsten rat sarcoma viral oncogene homolog (*KRAS*) mutations, Raf-1 proto-oncogene, serine/threonine kinase (*RAF1*) fusions, and *NF1* loss-of-function mutations.^{32,33} Approximately 20% of noncerebellar pilocytic astrocytomas lack the *KIAA1549-BRAF* fusion, and these fusion-negative tumors have recently been discovered to activate MAPK signaling through additional methods, including fibroblast growth factor receptor 1 (*FGFR1*) alterations (mutations, tyrosine kinase domain [TK] duplications, and gene fusions with transforming, acidic coiled-coil containing protein 1 [*TACC1*]),^{32,33} neurotrophic tyrosine kinase, receptor, type 2 (*NTRK2*) fusions resulting in TK truncations that are predicted to induce constitutive dimerization,³³ and protein tyrosine phosphatase, non-receptor type 11 (*PTPN11*) hotspot mutations in tumors co-mutated for *FGFR1*.³³

Pediatric diffuse gliomas, including diffuse astrocytomas, gangliogliomas, angiocentric gliomas, pleomorphic xanthoastrocytomas, oligodendrogliomas, and oligoastrocytomas,^{32,34} differ from pilocytic astrocytomas in their diffuse growth pattern, anatomic location (generally supratentorial), and their propensity for malignant transformation.² In a recent study by Zhang et al.,³² 52% (12 out of 23) of diffuse astrocytomas (WHO grade II) demonstrated ERK/MAPK signaling activation via *FGFR1/3* alterations (fusions or *FGFR1* TK duplication), *BRAF* alterations (*V600E* mutations or fusions), or *KRAS* activating mutation (*Q61H*). This same series identified common, recurrent *FGFR1* alterations in oligodendrogliomas (3 out of 5: *FGFR1* TK duplications) and oligoastrocytomas (6 out of 8, 4 *FGFR1* TK duplications; 1 fusion; 1 mutation).³² A subset of ERK/MAPK activated diffuse astrocytomas (2 out of 12; 16.67%) had the recurrent H3 histone, family 3A (*H3F3A*) *K27M* mutation, an alteration that has been frequently described in pediatric glioblastomas.³²

The majority of other diffuse low-grade gliomas also demonstrate MAPK/ERK activation. Pleomorphic xanthoastrocytomas (WHO grade II) are rare, supratentorial astrocytomas that are found in the pediatric population two-thirds of the time.³⁵ The 5-year overall survival is 81%, and malignant progression can occur but is generally rare.³⁶ A recent study showed that 7 out of 10 pleomorphic xanthoastrocytomas had *BRAF V600E* mutations.³² Similarly, this study found 55.6% (5 out of 9) of gangliogliomas showed ERK/MAPK activation by *BRAF* alterations (*V600E* = 3; *BRAF* fusion production = 2).³²

In contrast to pilocytic astrocytomas, about one-quarter of pediatric diffuse astrocytomas (6 out of 23; 26%) demonstrated alterations in v-myb avian myeloblastosis viral oncogene homolog (*MYB*), including gene fusion with protocadherin gamma subfamily A, 1 (*PCDHGA1*) or episome formation, and one case of v-myb avian myeloblastosis viral oncogene homolog-like 1 (*MYBL1*) rearrangement.³² In an independent, copy number alteration study, Ramkissoon et al.³⁴ identified focal amplification resulting in tandem duplication/truncation of *MYBL1* in 28% (5 out of 18) of pediatric diffuse astrocytomas. These *MYB/MYBL1* alterations were not observed in pilocytic astrocytomas, although two out of two angiocentric gliomas from Zhang et al.³² and an additional two angiocentric gliomas from Ramkissoon et al.³⁴ bore *MYB* or *MYBL1* fusions, providing further implication of this pathway as specific to a subset of diffuse pediatric gliomas.

Pediatric High-Grade Gliomas

Although histologically similar to adult glioblastomas, a subset of pediatric glioblastomas have distinct genomic hits driving tumor formation that implicate epigenetic dysregulation in the formation of these tumors. In a study by Schwartzentruber et al.,³⁷ recurrent mutations in histone variant H3.3 (*H3F3A K27M*; *G34R/V*), commonly co-occurring with damaging mutations in the chromatin remodelers *ATRX* or death-domain associated protein (*DAXX*) and *TP53*, drove pediatric glioblastoma formation in 31% of pediatric GBMs. This percentage may be higher in diffuse intrinsic pontine gliomas (DIPG), where an independent study found that 78% of DIPG contained somatic *K27M* mutations in *H3F3A* or histone cluster 1, H3b (*HIST1H3B*), whereas *H3F3A G34R* was restricted to non-brain stem pediatric glioblastomas.³⁸ Recently, *H3K27 K27M* was characterized to be a dominant-negative mutation that results in a genome-wide reduction of *H3K27me3* repressive marks due to altered binding with the polycomb repressive complex 2 (*PRC2*) and also causes global DNA hypomethylation.³⁹ In pediatric glioblastomas, these H3.3 mutations were mutually exclusive with the neomorphic *IDH1 R132H*,^{8,37} which was rarely seen in pediatric GBM but has been shown to cause epigenomic dysregulation and DNA hypermethylation (G-CIMP) phenotype.⁹ Similar to pediatric low-grade gliomas, the *BRAF V600E* mutation has been reported in ~10% of pediatric high-grade gliomas⁴⁰; however, unlike the pediatric low-grade gliomas, this mutation commonly co-occurs with homozygous *CDKN2A/B* deletion.⁴¹

In terms of structural variation, pediatric glioblastomas differ from the classic, primary adult GBM findings of chr7 amplification (74% in adult versus 13% in pediatric) and chr10 loss (80% adult versus 35% pediatric).⁴² However, pediatric glioblastomas have more frequent 1q gain (30% in pediatric versus 9% in adult), frequent focal amplification of *PDGFRA* in 12% of tumors, and frequent focal, homozygous deletion of *CDKN2A/B* in 19% of tumors.⁴² The driver events for adult and pediatric gliomas are summarized in Table 96.1.

MENINGIOMAS

Meningiomas are the most common primary intracranial tumor, accounting for one-third of all primary brain tumors.¹ Thought to arise from the arachnoid layer of the meninges, meningiomas can be found throughout the neuraxis, and are notable for a wide variety of histologic subtypes (15 according to the 2007 WHO classifications).⁴³ Although 70% to 80% of meningiomas are benign (WHO grade I), the remaining subset can exhibit more aggressive behavior (WHO grade II and grade III).⁴³ Recent genomic studies have revealed that 80% of meningiomas can be neatly categorized into three clinically relevant, mutually exclusive genetic groups with differences in histology, anatomic location, and likelihood for malignant progression (Fig. 96.2).^{44–46}

The first and largest group, *NF2/chr22 loss* tumors, is characterized by biallelic loss of the tumor suppressor neurofibromin 2 (merlin, *NF2*). One of the hallmarks of the inherited tumor syndrome neurofibromatosis type II is multiple meningiomas due to germline mutations in the tumor suppressor *NF2*,⁴⁷ and biallelic loss of *NF2* drives ~50% of sporadic meningioma formation⁴⁸ and is a risk factor for malignant transformation. At least 75% of WHO grade II tumors have *NF2/chr22 loss*.^{43,44} *NF2/chr22 loss* tumors are more likely to form in the meninges flanking the cerebral convexities, but when they grow in the skull base, the growth is restricted to the posterior and lateral portions of the skull.⁴⁴ *NF2/chr22 loss* is also commonly found in spinal meningiomas. Rarely, *NF2/chr22 loss* tumors also have a biallelic loss of the chromatin remodeling gene *SWI/SNF* related, matrix associated, actin dependent regulator of chromatin, subfamily b, member 1 (*SMARCB1*).⁴⁹ Loss of the tumor suppressor *SMARCB1*, which is also found on chromosome 22, has been reported in various malignant rhabdoid

TABLE 96.1

Summary of Driver Events in Pediatric and Adult Gliomas

WHO Grade	Population	Diagnosis	Pathways Affected	Hallmark Mutations or Structural Abnormalities	Notes
I	Pediatric	Pilocytic astrocytoma	MAPK/ERK pathway	KIAA1549-BRAF fusion (90% of cerebellar)	Single hit to MAPK/ERK signaling
				BRAF V600E	
				KRAS	
				RAF1 fusions	
				NF1 loss of function	
FGFR1 alterations (mutations, fusion with TACC1), co-mutations in PTPN11 hotspots					
II	Pediatric	Diffuse astrocytoma	MAPK/ERK pathway	FGFR1/3 alterations (fusions or FGFR1 TK duplication)	
				BRAF alterations (V600E mutations or fusions)	
			MYB	MYB, including fusion with PCDHGA1 or episome formation, and 1 case of MYBL1 rearrangement	
II	Adult	Diffuse astrocytoma	Epigenetic dysregulation	IDH1 R132H/C/S	More likely to progress to high grade glioma
			Chromatin remodeling	ATRX	
			TP53 pathway	Mutations in TP53, LOH at chr17	
		Oligodendroglioma	Epigenetic dysregulation	IDH1 R132H/C/S	
			Unknown	1p/19q loss	
				CIC FUBP1	
Oligoastrocytoma	Epigenetic dysregulation	IDH1 R132H/C/S	Combination of genetic events seen in astrocytes and oligodendrocytes		
III	Adult	Anaplastic astrocytoma	Epigenetic dysregulation	IDH1 R132H/C/S	Additional hits in RTK/RAS/P13K pathway drive progression to frank glioblastoma
			Telomere maintenance	TERT promoter mutations	
			Chromatin remodeling	ATRX mutations	
			p53 pathway	TP53 mutations and LOH at chr17 CDKN2A loss	
			Rb pathway	RB1 loss CDKN2A loss CDK4/6 amplification	
IV	Pediatric	GBM	Chromatin remodeling	H3F3A K27M; G34R/V	
				ATRX mutations	
				DAXX mutations	
			p53 pathway	TP53

	PI3K		PTEN loss			
			PI3K mutation			
RAS	NF1 loss					
Telomere maintenance	TERT					

BRAF, B-Raf proto-oncogene, serine/threonine kinase; KRAS, Kirsten rat sarcoma viral oncogene homolog; RAF1, v-raf-1 murine leukemia viral oncogene homolog 1; TACC1, transforming, acidic coiled-coil containing protein 1; PTPN11, protein tyrosine phosphatase, non-receptor type 11; FGFR1/3, fibroblast growth factor receptor 1/3; TK, tyrosine kinase domain; MYB, v-myb avian myeloblastosis viral oncogene homolog; PCDHGA1, protocadherin gamma subfamily a, 1; MYBL1, v-myb avian myeloblastosis viral oncogene homolog-like 1; IDH1, isocitrate dehydrogenase 1; ATRX, alpha thalassemia/mental retardation syndrome X-linked; TP53, tumor protein p53; CIC, capicua transcriptional repressor; FUBP1, far upstream element (FUSE) binding protein 1; TERT, telomerase reverse transcriptase; CDKN2A, cyclin-dependent kinase inhibitor 2A; RB1, retinoblastoma 1; CDK4/6, cyclin-dependent kinase 4/6; H3F3A, H3 histone, family 3A; DAXX, death-domain associated protein; PTEN, phosphatase and tensin homolog; EGFR, epidermal growth factor receptor; PDGFRA, platelet-derived growth factor receptor alpha; PI3K, phosphoinositide 3-kinase; NF1, neurofibromin 1.

tumors^{50,51} as well as in families with multiple meningiomas with schwannomatosis.⁵²

The second group of meningiomas, *TRAF7* mutant tumors, have a lower risk of malignant transformation.⁴⁴ Somatic mutations in tumor necrosis factor (TNF) receptor-associated factor 7 (*TRAF7*), a proapoptotic N-terminal RING and zinc finger domain protein with E3 ubiquitin ligase activity, have been reported in ~25% of meningiomas (including 27% of grade I tumors). *TRAF7* mutant tumors are commonly mutated for AKT/PI3K/mammalian target of rapamycin (mTOR) pathway members, most notably the recurrent v-akt murine thymoma viral oncogene homolog 1 (*AKT1*) E17K mutation, which activates PI3K signaling and is reported in 14% of grade I meningiomas.^{44,45} A second *TRAF7* subgroup is defined by mutations in the transcription factor Kruppel-like factor 4 (*KLF4*),^{44,46} an important regulator of development and one of four Yamanaka factors capable of reprogramming differentiated cells into an induced pluripotent stem cell state.⁵³ The recurrent *KLF4* K409Q mutation, seen in 12% of WHO grade I meningiomas, is in the DNA-binding domain, suggesting that the mutation may alter binding to the consensus sequence.^{44,46} Noted for their increased risk of postoperative peritumoral edema⁵⁴, 100% of secretory meningiomas are mutated for *KLF4* K409Q and *TRAF7*^{44,46}. *TRAF7* mutant tumors are typically found in the midline of the skull base, especially the anterior skull base, although they can grow in the meninges flanking the frontal lobe.⁴⁴

The third major group of meningiomas is the sonic Hedgehog (SHH) group. Approximately 3% of benign meningiomas have mutations in smoothened, frizzled class (SMO) that activate SHH signaling.^{44,45} Interestingly, tumors with *SMO* L412F (n = 5) all localized to the medial anterior fossa.⁴⁴ Germline loss-of-function mutations in suppressor of fused homolog (*Drosophila*) (*SUFU*), which is downstream of SMO and inhibits SHH signaling, have been reported in a family with multiple meningiomas.⁵⁵

MEDULLOBLASTOMAS

Arising in the cerebellum, medulloblastomas (WHO grade IV) are the most common malignant brain tumors in children. These invasive embryonal tumors commonly metastasize to the leptomeninges via the cerebrospinal fluid system, gaining access by extending through the fourth ventricle.² The past decade of research has revealed that medulloblastoma is not a homogeneous disease; rather, these tumors can be divided into four subgroups with marked differences in transcriptional profiles, somatic copy number alterations, underlying driver mutations, cell of origin, anatomic location, prognosis, tendency to metastasize, and response to targeted therapies (Fig. 96.3).

The first hints of the existence of different molecular subgroups came from studies of hereditary tumor syndromes. The SHH pathway was implicated in driving medulloblastoma and nevoid basal

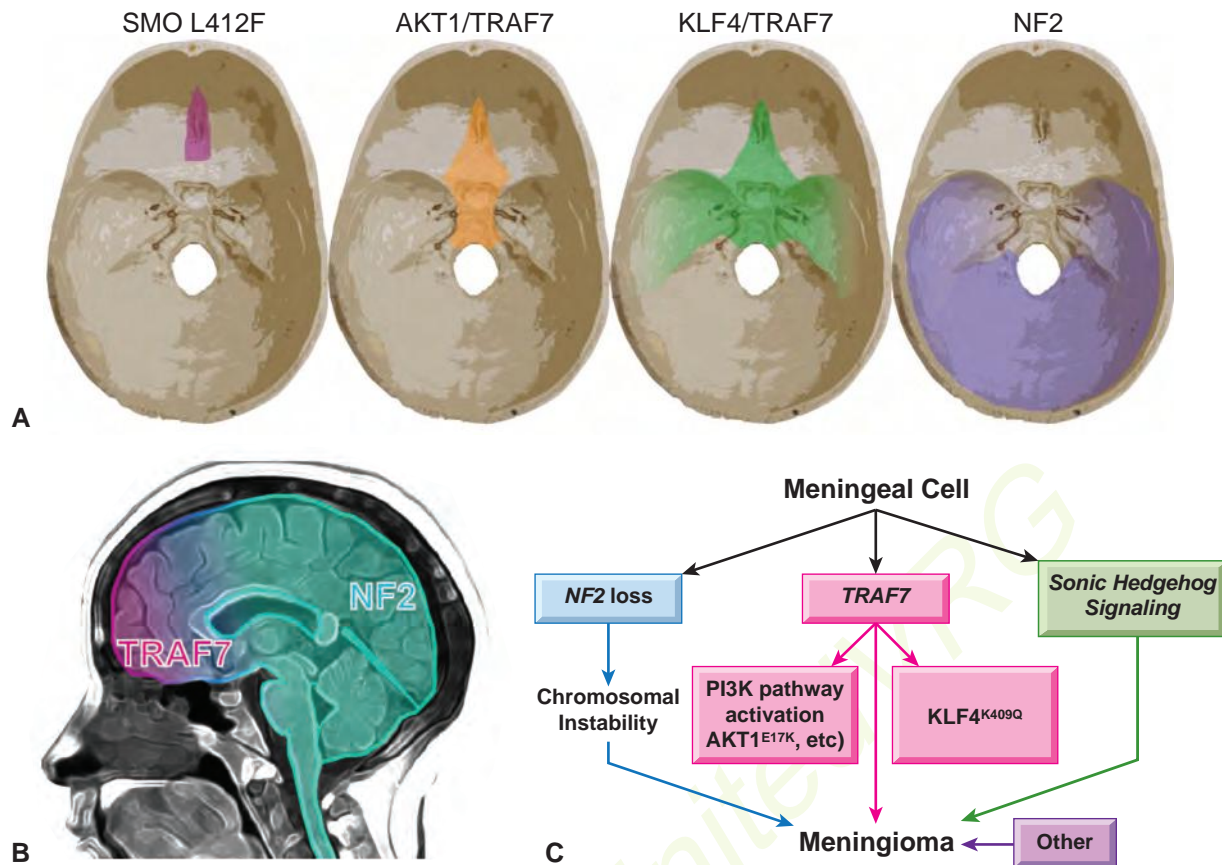

Figure 96.2 Driver events in meningioma formation. **(A)** For grade 1 meningiomas, growth of *NF2/chr22* loss meningiomas is restricted to the posterior and lateral skull base, whereas non-*NF2* mutant tumors grow in the midline of the skull base. **(B)** For meningiomas flanking the convexities, *TRAF7* mutant tumors are found anteriorly. **(C)** Summary of meningioma driver events and known pathway activations. *NF2*, neurofibromin 2; *TRAF7*, TNF receptor-associated factor 7; *AKT1*, v-akt murine thymoma viral oncogene 1; *KLF4*, Kruppel-like factor 4 (gut); *SMO*, smoothened, frizzled class receptor.

cell carcinoma formation in patients with Gorlin syndrome, who have activated SHH signaling due to a germline loss of patched 1 (*PTCH1*).^{56,57} The WNT pathway was implicated in driving medulloblastoma formation in patients with Turcot syndrome (now called familial adenomatous polyposis), a subset of whom

had medulloblastomas in addition to inherited colonic polyposis as a result of germline loss-of-function adenomatous polyposis coli (*APC*) mutations.⁵⁸

Candidate gene studies identified somatic mutations in SHH or WNT pathway genes were found in sporadic medulloblastomas,^{59,60}

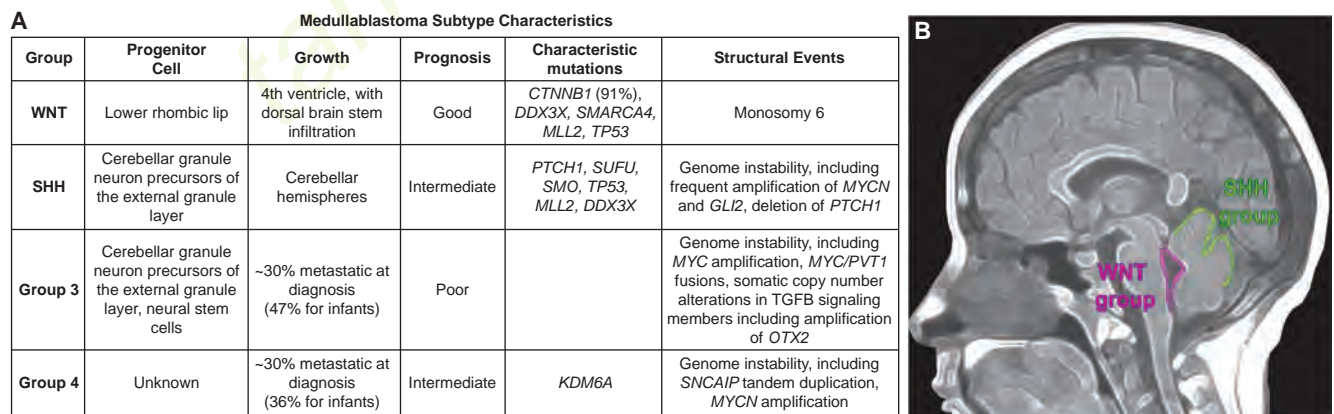

Figure 96.3 Medulloblastoma subtype characteristics. **(A)** Table summarizing the genomic underpinnings, anatomic location, and presumed progenitor cell for the four medulloblastoma subtypes. **(B)** WNT group medulloblastomas arise in the fourth ventricle, whereas SHH group medulloblastomas arise in the cerebellar hemispheres. *CTNNB1*, catenin (cadherin-associated protein), beta 1, 88kDa; *DDX3X*, DEAD (Asp-Glu-Ala-Asp) box helicase 3, X-linked; *SMARCA4*, SWI/SNF related, matrix associated, actin dependent regulator of chromatin, subfamily a, member 4; *MLL2*, lysine (K)-specific methyltransferase 2D; *TP53*, tumor protein p53; *PTCH1*, patched 1; *SUFU*, suppressor of fused homolog (*Drosophila*); *SMO*, smoothened, frizzled class receptor; *KDM6A*, Lysine (K)-Specific Demethylase 6A; *MYCN*, v-myc avian myelocytomatosis viral oncogene neuroblastoma derived homolog; *GLI2*, GLI family zinc finger 2; *MYC*, v-myc avian myelocytomatosis viral oncogene homolog; *OTX2*, orthodenticle homeobox 2; *SNCAIP*, synuclein, alpha interacting protein.

but the development of microarray-based transcriptional profiling and next-generation sequencing have clarified four medulloblastoma subgroups with differential pathway activations and underlying genomic changes. The WNT group (~10% of medulloblastomas), initially identified by unsupervised hierarchical clustering of gene expression profiles,⁶¹ is characterized by somatic activating mutations in beta-catenin (*CTNNB1*) in 91% of cases.^{62–65} *CTNNB1* is commonly comutated with DEAD (Asp-Glu-Ala-Asp) box helicase 3, X-linked (*DDX3X*) in 50% of cases, and this group is also defined by frequent mutations in the chromatin modifier SWI/SNF related, matrix associated, actin dependent regulator of chromatin, subfamily a, member 4 (*SMARCA4*, 26.3%), lysine (K)-specific methyltransferase 2D (*KMT2D* or *MLL2*, 12.5%), and *TP53* (12.5%).^{62–65} In terms of structural variation, this group has monosomy chromosome 6 but an otherwise stable genome.⁶⁶ Elegant mouse modeling experiments have provided compelling evidence that WNT medulloblastomas originate from lower rhombic lip progenitor cells, and WNT subtype medulloblastomas grow within the fourth ventricle and infiltrate the dorsal brain stem.⁶⁷ The WNT group has the best prognosis, with a 95% overall 5-year survival.⁶⁸ These tumors rarely recur.⁶⁹

The SHH group (~30% of medulloblastomas) shows increased expression of SHH signaling,⁷⁰ and commonly bears somatic mutations (*PTCH1*, *SUFU*, *SMO*),^{61–64} or somatic copy number alterations (amplification of v-myc avian myelocytomatosis viral oncogene neuroblastoma derived homolog (*MYCN*) and *GLI* Family Zinc Finger 2 (*GLI2*); deletion of *PTCH1*)⁶⁶ impacting SHH pathway members. In addition to Gorlin syndrome, patients with germline *TP53* mutations (Li-Fraumeni syndrome) can develop SHH medulloblastomas by chromothripsis-mediated amplification of SHH oncogenes,⁷¹ and *TP53* mutations or deletions are seen in 13.6% of SHH tumors.^{62,64–66} The subset of SHH medulloblastomas that bear *TP53* mutations or deletions, have a particularly a poor prognosis, with a 5-year overall survival of 41% in *TP53* mutant SHH cases versus 81% for *TP53* wild-type SHH cases.⁷² Like the WNT group, the SHH tumors also bear mutations in *MLL2* (12.9%) and *DDX3X* (11.7%).^{62–65} However, SHH tumors are more genomically unstable in terms of their structural variation and have frequent focal copy number changes in SHH signaling (18%), p53 signaling (9.4%), and/or RTK/PI3K signaling (10%).⁶⁶ In contrast to WNT medulloblastomas, mouse SHH medulloblastomas arise from external granule layer progenitor cells, and in humans are found in the cerebellar hemispheres.⁶⁷ SHH tumors have a worse prognosis

than WNT tumors, with a 5-year survival of ~75%.^{65,70} They are also more likely to recur than WNT tumors, and the recurrence is generally local (versus metastatic).⁷³ Clinical use of SHH inhibitors (e.g., SMO inhibitors) has shown initial but transient response.^{74,75}

The remaining two groups of medulloblastomas, group 3 and group 4, currently bear generic names while the underlying biology is clarified. Both groups demonstrate genomic instability and tend to present with metastases at diagnosis in ~30% of cases.⁷⁰ Group 3 tumors (~25% of medulloblastomas) have high *MYC* amplification and express a gene signature consistent with photoreceptors/GABAergic (gamma-aminobutyric acid) neurons.^{76,77} A recent somatic copy number alterations (SCNA) analysis of >1,000 medulloblastomas revealed that SCNAs found in group 3 are enriched for transforming growth factor beta (TGFB) signaling, including frequent amplification of orthodenticle homeobox 2 (*OTX2*), which is a TGFB target during neurodevelopment.⁶⁶ Mutually exclusive with *OTX2* amplification are group 3 tumors with *MYC* amplification, a large subset of which harbor recurrent *MYC/PVT1* gene fusions as a result of chromothripsis on chromosome 8.⁶⁶ The 5-year overall survival for group 4 tumors is ~50%.^{65,70} Group 4 tumors (~35%) express a neuronal gene signature. Compared to group 3 tumors, group 4 tumors do not have *MYC* amplification, but have *MYCN* amplification in 6.3% of tumors (which is also seen in ~8.2% of SHH tumors).^{65,66} Damaging mutations in *KDM6A*, a histone H3K27 demethylase, were restricted to group 4 tumors, but only explain the formation of 12% of tumors.^{62–66} Of group 4 tumors, 10.4% had a recurrent synuclein, alpha interacting protein (*SNCAIP*) tandem duplication, which plays a role in Lewy body formation in Parkinson disease.⁶⁶ The 5-year overall survival for group 4 tumors is 75%.^{65,70}

EPENDYMAL TUMORS

Ependymomas are glial tumors that arise from cells lining the ventricular system. Interestingly, the anatomic location of ependymoma growth predicts prognosis, with infratentorial ependymomas in children bearing the worst prognosis. Emerging evidence subcategorizing ependymomas by anatomic location has identified differences in age of onset, prognosis, driver mutations, structural variants, and transcriptional profiles (Fig. 96.4). The candidate cancer stem cell of ependymomas is the radial glial cell,⁷⁸ which has region-specific patterns of gene expression that

A

Ependymoma Subtype Characteristics

Anatomical Location	Population	Genomic characteristic
Supratentorial	Adult	<i>CDKN2A</i> deletion, amplification of <i>EPHB2</i>
Infratentorial, medial	Pediatric	chr1q gain
Infratentorial, lateral	Young adult	<i>NF2</i> /chr22 loss
Spinal	Adult	<i>NF2</i> /chr22 loss

B

Figure 96.4 Anatomic location correlates with mutation and susceptible population for ependymomas. **(A)** Table summarizing the genomic driver events anatomic location and affected population for ependymomas. **(B)** Spinal ependymomas and lateral infratentorial ependymomas are characterized by *NF2*/chr22 loss, medial infratentorial ependymomas have chr1q gain, and supratentorial ependymomas have *CDKN2A* deletion and *EPHB2* amplification. *NF2*, neurofibromin 2; *CDKN2A*, cyclin-dependent kinase inhibitor 2A; *EPHB2*, EPH receptor b2.

match the expression profiles of CD133+ ependymal cells harvested from the correlating anatomic compartment (spinal cord versus intratentorial versus supratentorial).⁷⁹ For example, patients with the inherited tumor syndrome neurofibromatosis type II frequently have intramedullary spinal ependymomas but not cortical ependymomas, and up to 95% of adult sporadic spinal cord ependymomas have monosomy chr22.⁸⁰ In contrast, >90% of supratentorial ependymomas have deletion of *CDKN2A*, frequently with co-occurring focal amplification of *EPH Receptor B2 (Ephb2)*. Posterior fossa ependymomas appear to be split into two groups by anatomic location.⁸¹ Lateral posterior fossa tumors are more chromosomally stable, occur in younger patients, have 1q gain, are more likely to recur with metastasis, and have a poor prognosis.⁸¹ In contrast, midline posterior fossa ependymomas have more widespread chromosomal instability, are older, and have chr22 loss.⁸¹

SUMMARY

In just a few short years, the use of next-generation sequencing technologies has ushered about a golden age of discovery for the molecular pathways driving the formation of central nervous system tumors. Tumors classifications, once based primarily on observable histopathologic findings, are increasingly refined to distinct, clinically relevant entities based on differences in gene mutations, genomic stability, epigenetic changes, differences in gene expression profiles, differences in the anatomic location of growth, differences in response to therapy, and differences in overall survival. The challenge of translating the emerging molecular classifications of brain tumors to successful individualized cancer therapy is daunting, but the major advances brought about by genomic characterization serve as an ideal starting point for hypothesis-driven clinical research.

EPIDEMIOLOGY OF BRAIN TUMORS

Incidence and Prevalence

The incidence and prevalence of brain and central nervous system (CNS) tumors is imprecisely documented because benign tumors were not required to be reported prior to 2003, and metastatic disease to the brain remains unreported. The major data sources for the United States include the Surveillance, Epidemiology, and End Results (SEER) program and the Central Brain Tumor Registry of the United States (CBTRUS).¹⁻² The CBTRUS database from 2006 to 2010 reported 326,711 incident tumors (112,458 malignant and 214,253 nonmalignant), with an overall average annual age-adjusted incidence of 21.03 per 100,000. The overall incidence rate was 5.26 per 100,000 for children 0 to 19 years of age (5.14 per 100,000 for children less than 15 years), and 27.38 per 100,000 for adults (20+ years).² The median age at diagnosis is 59 years with approximately 7% of the cases in individuals less than 20 years of age. The distribution patterns of histologies within age groups differ substantially. The most frequently reported histology was nonmalignant meningioma, accounting for about one-third of all tumors. Of all brain and CNS tumors, 42% occurred in males. For the malignant histologies, 55% occurred in males, and in the nonmalignant histologies, 36% occurred in males. The aggregate average annual age-adjusted mortality is 4.25 deaths per 100,000 with considerable variation noted by state. Males were found to have a statistically higher mortality rate for brain and CNS than females in the United States population (5.19 versus 3.46 per 100,000). The estimated total number of new cases is 66,240 (22,810 malignant and 43,430 nonmalignant) for 2014.

In 1993, the World Health Organization (WHO) ratified a new classification, assuming that each tumor results from a specific cell type. Most registries do not contain detailed information regarding the distribution of various CNS tumors, as specified in the WHO classification.³⁻⁴ Many of these tumors are radiographically and clinically diagnosed; examples include infiltrating pontine gliomas, vestibular schwannomas, skull-base meningiomas, and brain metastases. Specific CNS tumor types also differ in incidence based on anatomic location. Figure 97.1 presents a simplified distribution by subtype.

The increased utilization of cranial imaging for headaches, seizures, and trauma has led to an increase in the diagnosis of benign tumors. SEER suggests that between 1975 and 1987, there was a significant increase in the incidence of CNS tumors, which leveled off between 1991 and 2006. Because many patients with CNS tumors survive for several years, the prevalence exceeds the incidence. Overall prevalence rate of individuals with a brain tumor was estimated to be 209 per 100,000 in 2004 and 221.8 per 100,000 in 2010. The female prevalence rate (264.8 per 100,000) was higher than that in males (158.7 per 100,000). The averaged prevalence rate for malignant tumors (42.5 per 100,000) was lower than the prevalence for nonmalignant tumors (166.5 per 100,000). Estimates of the expected number of individuals living with

primary brain tumor diagnoses in the United States was 612,770 in 2004 and 688,096 in 2010.⁵

Etiologic Factors

No agent has been definitively implicated in the causation of CNS tumors, and risk factors can be identified only in a minority. Commonly implicated associations described with other malignancies, such as diet, exercise, alcohol, tobacco, and viruses, are generally not considered to be significant for CNS tumors.⁶

Environmental Factors

Farmers and petrochemical workers have been shown to have a higher incidence of primary brain tumors. A variety of chemical exposures have been linked.⁷ Ionizing and nonionizing radiation has been implicated, with the clearest association coming from the occurrence of superficial meningiomas in individuals receiving cranial or scalp irradiation, with the association being stronger for young children receiving low doses of irradiation for benign conditions.⁸ Exposure to ionizing radiation is a known risk factor for a small percentage of astrocytomas, sarcomas, and other tumors.⁹ There is a 2.3% incidence of primary brain tumors in long-term survivors among children given prophylactic cranial irradiation for acute leukemia, a fourfold increase over the expected rate.¹⁰

In addition, a retrospective study suggests an increased risk for developing gliomas in children undergoing computed tomography (CT) scans.¹¹ Exposure to dental x-rays performed at a time when radiation exposure was greater than currently used appears to be associated with an increased risk of intracranial meningioma.¹²

There are conflicting reports regarding nonionizing radiation emitted by cellular telephones.¹³⁻¹⁹ Several investigators have reported meta-analyses of case control studies evaluating cell phone use and the development of a brain tumor. Kan et al.¹⁶ reviewed nine studies (5,259 cases and 12,074 controls) and showed an overall odds ratio (OR) of 0.90 for cellular phone use and brain tumor development; the OR was 1.25 for long-term users. An OR of 0.98 for developing malignant and benign tumors of the brain as well as the head and neck was reported by Myung et al.¹⁷ when collating 23 case control studies (12,544 cases and 25,572 controls). The International Commission for Non-Ionizing Radiation Protection Standing Committee on Epidemiology reviewed the epidemiologic evidence, and they concluded that there was not a causal association between mobile phone use and malignant gliomas, but for slow-growing tumors, the observation period was too short for conclusive statements.¹⁸ A recent report of the INTERPHONE study, an international, population-based case control study, also did not find an increased risk of gliomas or meningiomas.¹⁹ Glioma incidence has not followed the increase in cell phone use, but because of the potential for a lag in trends, continued surveillance on children who are exposed from an early age is warranted.¹⁵

Figure 97.1 Proportionate distribution of the incidence of central nervous system neoplasms by histopathologic type, based on the Central Brain Tumor Registry of the United States database.

Viral Associations

Although certain canine and feline CNS tumors may have a viral association, the human evidence remains weak. Specifically, no increase in the risk of developing a brain tumor has been associated with previous polio vaccination, which discredits claims that simian virus 40, which contaminated older polio vaccine preparations, caused brain tumors.²⁰ The exception to this is primary CNS lymphoma, which has been shown to be associated with Epstein-Barr virus.²¹ An increase in incidence of primary CNS lymphoma is most likely due to the increasing numbers of immunosuppressed patients in the setting of HIV and posttransplant use of immunosuppressants.^{21–22}

The association between human cytomegalovirus (HCMV) infection and glioblastoma was first described by Cobbs et al.²³ in 2002. The presence of HCMV was also demonstrated in glioblastoma and in other gliomas.^{24–25} HCMV may have tropism for microglia and CD133-positive glioma cancer stem cells and further work is needed to evaluate the role of this virus.²⁶

Hereditary Syndromes

Neurofibromatosis type 1 (NF1) is an autosomal-dominant disorder associated with intra- and extracranial Schwann cell tumors. Optic gliomas, astrocytomas, and meningiomas also occur at higher frequency in NF1. NF2 is characterized by bilateral vestibular schwannomas and meningiomas. Systemic schwannomas also occur in NF2. Subependymal giant cell astrocytoma commonly occur in children with tuberous sclerosis, an autosomal-dominant disorder caused by mutation in the *TSC1* and *TSC2* genes. Other hereditary tumor syndromes affecting the CNS include Li-Fraumeni syndrome (germline mutation in one p53 allele; malignant gliomas); von Hippel-Lindau syndrome (germline mutation of the *VHL* gene; hemangioblastomas), and Turcot syndrome (germline mutations of the adenomatous polyposis gene; medulloblastoma).^{27,28} The nevoid basal cell carcinoma syndrome (Gorlin syndrome) is associated with medulloblastomas (and possibly meningiomas) and represents mutations in the *PTCH* suppressor gene or other members of the Sonic hedgehog pathway.^{29,30}

Meningiomas and schwannomas are more common in females; gliomas, medulloblastomas, and most other CNS tumors

are more common in males. Meningiomas are more common in African Americans and gliomas and medulloblastomas are more common in Caucasians. It has been suggested that there is a lower incidence of meningiomas and a higher incidence of gliomas and vestibular schwannomas in higher socioeconomic groups.^{31–34}

CLASSIFICATION

Primary CNS tumors are of ecto- and mesodermal origin and arise from the brain, cranial nerves, meninges, pituitary, pineal, and vascular elements. The WHO classification lists approximately 100 subtypes of CNS malignancies in seven broad categories (Table 97.1).^{3,4,35} In spite of the low proliferation rate within the meninges, meningiomas are among the most common CNS tumors. Astrocytes are among the most mitogenically competent cells, and astrocytomas, also referred to interchangeably as *gliomas*, are among the more common primary CNS tumors. The precise cell of origin of gliomas, however, remains unclear.

The WHO classification can be reduced to a simpler working formulation, categorizing the neoplasms into tumors presumably derived from glia, neurons, or from cells that surround the CNS or form specialized anatomic structures. Glial cells are believed to give rise to astrocytomas, oligodendrogliomas, and ependymomas. Neuronal cells are involved in the development of medulloblastoma and primitive neuroectodermal tumors (PNET). In PNETs, anatomic location is pivotal; the transformation of cortical neuroblasts leads to cortical PNETs, retinal neuroblasts form retinoblastoma, and pineal neuroblasts form pineoblastomas. Specialized anatomic structures within the CNS give rise to pituitary adenomas, pineocytomas, chordomas, hemangioblastomas, germ cell tumors, and choroid plexus papillomas and carcinomas.

This working formulation is speculative, based on scant phenotypic and immunohistochemical evidence. For example, oligodendrogliomas are diagnosed based on cellular morphology, including prominent nuclei surrounded by a cytoplasmic halo with a characteristic “fried egg” appearance, and many have deletions of 1p and 19q. However, no definitive markers for oligodendrogliomas currently exist; these tumors can stain both for glial fibrillary acidic protein, an astrocytic marker, and for synaptophysin, a presumptive neuronal marker.³⁶ A third of all gliomas have

morphologic characteristics of both astrocytoma and oligodendroglioma, leading some to separate gliomas based on their molecular and genetic characteristics.³⁷ Evidence that suggests that some oligodendrocytes derive from a neuronal lineage, whereas some neuron-derived tumors (embryonal tumors) can show significant areas of glial differentiation, highlights the uncertainty.^{38,39} An alternative hypothesis is that all neuroepithelial cells are derived from a common precursor cell (i.e., a multipotent neural stem cell), and hence all neuroepithelial tumors are derived from neural stem cells or their committed progeny.⁴⁰ The recent discovery, isolation, and characterization of cancer stem cells from human brain tumors provides supportive evidence.⁴¹ However, more recently it was shown in an animal experiment that gliomas can originate from differentiated cells in the CNS, including cortical neurons.⁴²

Approximately 15% of all primary CNS tumors arise in the spinal cord, where the distribution of tumor types is significantly different from that in the brain. Tumors of the lining of the spinal cord and nerve roots predominate (50% to 80% of all spinal tumors); schwannomas and meningiomas are most common, followed by ependymomas. Primary gliomas of the spinal cord are uncommon.⁴³ In children, three-quarters of tumors are comprised of ependymomas, pilocytic astrocytomas, and other neuroepithelial neoplasms.²

ANATOMIC LOCATION AND CLINICAL CONSIDERATIONS

Intracranial Tumors

Intracranial tumors produce five categories of symptoms: those arising from increased intracranial pressure (ICP), seizures, physiologic deficits specific to location, higher order neurocognitive deficits, and endocrinologic dysfunction. A headache arises from irritation of the dura or intracranial vessels or due to elevated ICP from tumor bulk, edema, or obstruction of a cerebrospinal fluid (CSF) pathway. Slow-growing tumors may grow to a remarkably large size without producing headaches, whereas rapidly growing tumors can cause headaches early in their course. Small tumors can cause headaches by growing in an enclosed space that is richly innervated with pain fibers, such as the cavernous sinus, or by causing obstructive hydrocephalus. Nausea and vomiting, gait and balance alterations, personality changes, and slowing of psychomotor function or even somnolence may be present with increased ICP. Because ICP increases with recumbency and hypoventilation during sleep, early-morning headaches that awaken the patient are typical. Sometimes the only presenting symptoms are changes in personality, mood, or mental capacity or slowing of psychomotor activity. Such changes may be confused with depression, especially in older patients. Although fewer than 6% of first seizures result from brain tumors, almost one-half of patients with supratentorial brain tumors present with seizures. An adult with a first seizure that occurs without an obvious precipitating event should undergo magnetic resonance imaging (MRI).

Tumors are sometimes associated with location-specific symptoms. Frontal tumors cause changes in personality, loss of initiative, and abulia (loss of ability to make independent decisions). Posterior frontal tumors can produce contralateral weakness by affecting the motor cortex and expressive aphasia if they involve the dominant (usually the left) frontal lobe. Bifrontal disease, seen with “butterfly” gliomas and lymphomas, may cause memory impairment, labile mood, gait imbalance, and urinary incontinence. These symptoms may be related to alteration of normal cortex and white matter by the tumor itself, or by surrounding tumor-related edema. Improvement of symptoms after a short course of high-dose glucocorticoids is often an indicator of whether the findings are related to tumor-associated edema. In the case of CNS lymphoma, corticosteroids can have a cytotoxic effect also with a reduction in the tumor mass.

Temporal tumors might cause symptoms detectable only on careful testing of perception and spatial judgment, but can also impair memory. Homonymous superior quadrantanopsia, auditory hallucinations, and abnormal behavior can occur with tumors in either temporal lobe. Nondominant temporal tumors can cause minor perceptual problems and spatial disorientation. Dominant temporal lobe tumors can present with dysnomia, impaired perception of verbal commands, and ultimately fluent (Wernicke-like) aphasia. Seizures are more common from tumors in this location.

Parietal tumors affect sensory and perceptual functions. Sensory disorders range from mild sensory extinction or stereognosis, which are observable only by testing, to a more severe sensory loss such as hemianesthesia. Poor proprioception in the affected limb is common and is sometimes associated with gait instability. Homonymous inferior quadrantanopsia, incongruent hemianopsia, or visual inattention may occur. Nondominant parietal tumors may cause contralateral neglect and, in severe cases, anosognosia and apraxia. Dominant parietal tumors lead to alexia, dysgraphia, and certain types of apraxia. Occipital tumors can produce contralateral homonymous hemianopsia or complex visual aberrations, affecting perception of color, size, or location. Bilateral occipital tumors can produce cortical blindness.

Classic corpus callosum disconnection syndromes are rare in brain tumor patients, even though infiltrative gliomas often cross the corpus callosum in the region of the genu or the splenium. Interruption of the anterior corpus callosum can cause a failure of the left hand to carry out spoken commands. Lesions in the posterior corpus callosum interrupt visual fibers that connect the right occipital lobe to the left angular gyrus, causing an inability to read or name colors.

Thalamic tumors can cause local effects and also obstructive hydrocephalus. Either sensory or motor syndromes or, on the dominant side, aphasia is possible. *Thalamic* pain disorders or motor syndromes from basal ganglia involvement may also occur. The most common brainstem tumor is the pontine glioma, which presents most frequently with cranial nerve VI and VII palsies. Long tract signs usually follow, with hemiplegia, unilateral limb ataxia, gait ataxia, paraplegia, hemisensory syndromes, gaze disorders, and occasionally, hiccups. Tectal involvement causes Parinaud syndrome, peduncular lesions cause contralateral motor impairment, and obstruction of the aqueduct causes hydrocephalus.

Tumors in the medulla can have a fulminant course, including dysphagia, dysarthria, and deficits in cranial nerves IX, X, and XII. Involvement of the medullary cardiac and respiratory centers can result in a rapidly fatal course. Fourth ventricular tumors, because of their location, cause symptomatic obstructive hydrocephalus at a relatively small size, with associated disturbances of gait and balance. In addition, nausea and vomiting can be a symptom of a fourth ventricular mass. Rapidly enlarging lesions may end in cerebellar herniation.

Cerebellar tumors have variable localizing presentations. Midline lesions in and around the vermis cause truncal and gait ataxia, whereas more lateral hemispheric lesions lead to unilateral appendicular ataxia, usually worst in the arm. Abnormal head position, with the head tilting back and away from the side of the tumor, is seen often in children but rarely in adults. Mass lesions within or abutting the brain or spinal cord can cause displacement of vital neurologic structures. This can lead, in the brain, to herniation syndromes with respiratory arrest and death and, in the spine, to paraplegia or quadriplegia. A hemorrhage into a tumor can also cause acute neurologic deterioration. This is often associated with iatrogenic coagulopathies such as thrombocytopenia due to chemotherapy or anticoagulation therapy for deep venous thrombosis. Primary tumors that most often bleed de novo are glioblastoma and oligodendrogliomas; of the metastatic tumors, lung cancer, melanoma, renal cell cancer, thyroid cancer, and choriocarcinoma most often show hemorrhage.

Lumbar puncture should not be performed in any of the acute herniation syndromes or when herniation is imminent. In fact, a lumbar puncture should be avoided in the setting of significantly elevated ICP that is directly related to a tumor's mass effect or to obstructive hydrocephalus.

Spinal Axis Tumors

For the clinical presentation of tumors of the spinal axis to be understood, the local anatomy must be appreciated. A spinal tumor can produce local (focal) and distal (remote) symptoms, or both. Local effects indicate the tumor's location along the spinal axis, and distal effects reflect involvement of motor and sensory long tracts within the cord.

Distal symptoms and signs are confined to structures innervated below the level of the tumor. Neurologic manifestations often begin unilaterally, with weakness and spasticity, if the tumor lies above the conus medullaris, or weakness and flaccidity if the tumor is at or below the conus. Impairment of sphincter and sexual function occurs later unless the tumor is in the conus. The upper level of impaired long-tract function usually is several segments below the tumor's actual site. Local manifestations may reflect involvement of bone (with axial pain) or spinal roots, with radicular pain and loss of motor and sensory functions of the root or roots.

NEURODIAGNOSTIC TESTS

Magnetic Resonance Imaging

The imaging modality of choice for most CNS tumors is MRI, which can demonstrate anatomy and pathologic processes in detail.⁴⁴ CT is generally reserved for those unable (e.g., because of an implanted pacemaker, metal fragment, or paramagnetic surgical clips) or unwilling (e.g., because of claustrophobia) to undergo MRI. Because of the link of nephrogenic systemic fibrosis to the infusion of gadolinium-based contrast agents, there are new preventative guidelines regarding the administration of gadolinium in patients who may be at high risk.⁴⁵

The most useful imaging studies are T1-weighted sagittal images, gadolinium (Gd)-enhanced and unenhanced T1 axial images, and T2-weighted axial images (Fig. 97.2). Contrast-enhanced MRI provides an improved ability to discern tumors from other pathologic entities, one tumor type from another, and putatively higher from lower grade malignancies. There are, however, limitations in anatomic MRI to definitively diagnose a mass lesion as a tumor.⁴⁶ Other confounding diagnoses

include bacterial abscesses, inflammatory disease such as sarcoidosis, tumefactive demyelination, and acute ischemic disease. It is conventionally believed that most low-grade gliomas (except pilocytic astrocytomas and pleomorphic xanthoastrocytoma) do not enhance, but in reviewing imaging studies of patients enrolled in several clinical trials, it is apparent that this may not be so categorical, in that even low-grade gliomas may frequently contain areas of enhancement, raising the concern that these areas might represent high-grade or malignant transformation (Fig. 97.3).⁴⁷ In addition, some high-grade lesions may not have contrast enhancement on MRI. Imaging is also unable to discern different histologic subtypes; however, the presence of calcifications is typical of oligodendroglioma.

Neuraxis or Spinal Imaging

In the evaluation of spinal cord tumors, MRI is also the preferred modality, providing superb visualization of the spinal cord contour and (with gadolinium contrast) of most intrinsic tumors (such as ependymomas, astrocytomas, meningiomas, and schwannomas), as well as facilitating the diagnosis of leptomeningeal dissemination. Tumor cysts are readily identified on MRI, and spinal cord tumors can often be distinguished from syringomyelia. Ideally, neuraxis imaging should be performed before surgery. In the immediate postoperative period, spinal MRI scans may be difficult to interpret because arachnoiditis and blood products can mimic leptomeningeal metastasis. Delayed spinal MRI (more than 3 weeks after surgery) combined with an increased dose of gadolinium is a sensitive imaging study for leptomeningeal disease.

Newer Imaging Modalities

Newer MRI techniques include magnetic resonance spectroscopy, dynamic contrast-enhanced MRI, diffusion-perfusion MRI, and functional MRI.⁴⁸ In addition, metabolic imaging using positron-emission tomography using various tracers is being explored.⁴⁹ These newer techniques remain to be validated as biomarkers of biological behavior or clinical outcome. Posttreatment metabolic scans may help distinguish recurrence from treatment-related

Figure 97.2 Magnetic resonance imaging of a patient with a malignant glioma demonstrates a large mass with heterogenous enhancement (**A**) and significant edema (**B**) on the T2-weighted sequences.

Figure 97.3 **A:** Low-grade astrocytomas often do not enhance and contrast-enhanced T1-weighted magnetic resonance sequences considerably underestimate the true infiltrative extent of these neoplasms. **B:** The fluid-attenuated inversion recovery (FLAIR) sequence is considerably more useful in appreciating the true extent of such neoplasms.

changes, although most modalities have a relatively high false negative rate. A modification of the standard MRI is quick brain MRI, which uses single-shot, fast-spin echo imaging to allow for adequate demonstration of ventricular anatomy and appropriate evaluation of shunt function.⁵⁰

Pseudoresponse and Pseudoprogression

In malignant gliomas treated with combined modality therapy, it is speculated that 25% to 40% or even more may experience imaging changes relatively early in the course of therapy, usually within a few months, which appears consistent with radiographic progression. However, with time and without any therapy, many of these changes actually improve or even resolve (pseudoprogression), and in patients operated on with a presumptive diagnosis of tumor, the histopathology often reveals large areas of tumor necrosis.^{51,52} With the advent of antiangiogenic therapies for malignant gliomas, rapid resolution of tumor enhancement is visualized on MRI, sometimes within days. This is consistent with the traditional definition of response, but in several instances, especially with time, even in the absence of contrast enhancement, tumor progression and clinical deterioration occurs, which is sometimes appreciated as T2 or fluid-attenuated inversion recovery (FLAIR) changes; this phenomenon is labeled as *pseudoresponse*.⁵³

Cerebrospinal Fluid Examination

Typically, medulloblastoma, ependymoma, choroid plexus carcinoma, lymphoma, and some embryonal pineal and suprasellar region tumors have a high enough likelihood of spreading to justify CSF examinations to evaluate for malignant cells (cytology) and specific markers, such as human chorionic gonadotropin- β and α -fetoprotein.

CSF spread of a tumor may be associated with several possible findings, including CSF pressure above 150 mm H₂O at the lumbar level in a laterally positioned patient; elevated protein, typically greater than 40 mg/dL; reduced glucose (below 50 mg/mL); and tumor cells by cytologic examination. A high protein concentration with normal glucose levels and normal cytology is also

seen with base of skull tumors, such as vestibular schwannoma, and with spinal cord tumors that obstruct the subarachnoid space and produce stasis of the CSF in the caudal lumbar sac. Sampling of the CSF in the immediate postoperative period may lead to false-positive results, however, and is best done before surgery or more than 3 weeks after surgery, as long as there is no uncontrolled raised intracranial pressure.

SURGERY

Preoperative Considerations

The major objectives of surgery are to maximally remove bulk tumor, reduce tumor-associated mass effect and elevated ICP, and provide tissue for pathologic analysis in a manner that minimizes risk to neurologic functioning. For some tumors, a complete resection can be curative. However, most brain tumors are diffusely infiltrative; for these, surgical cure is rarely possible. Nonetheless, surgery can rapidly reduce tumor bulk with potential benefits in terms of mass effect, edema, and hydrocephalus. Furthermore, there is mostly retrospective evidence for both high-grade and low-grade infiltrative gliomas for which maximizing the extent of bulk tumor removal is associated with a better outcome, albeit so long as new, permanent neurologic deficits are avoided.⁵⁴⁻⁵⁷ The requirement for histopathologic confirmation of diagnosis is not necessary in certain well-defined situations, but a tissue diagnosis is still required to determine the appropriate treatment course in most circumstances. As molecularly targeted therapies become useful, tissue removal for molecular analysis will become more necessary to guide therapy. Pseudoprogression may make tissue-based confirmation necessary before changes in therapy are instituted.⁵³ Technologic advances in surgical approaches, techniques, and instrumentation have rendered most tumors amenable to resection; however, for some tumor types or locations, the risk of open operation supports the choice of biopsy for obtaining diagnostic tissue. Biopsy techniques include stereotactic biopsy (with or without a stereotactic frame) using CT, MRI, or both, to choose the target. Metabolic or spectroscopic imaging can be coregistered with anatomic images to choose targets that may be of higher biologic

aggressiveness within a tumor that appears homogeneous on standard imaging. In certain settings, an approach using simple ultrasonic guidance can also be considered for obtaining diagnostic tissue.

Unless a lymphoma is being considered, patients are given corticosteroids, usually dexamethasone, immediately preoperatively and often for several days before surgery to reduce cerebral edema and thus minimize secondary brain injury from cerebral retraction. Steroid administration is then continued in the immediate postoperative period and tapered off as quickly as possible. Antibiotics are given just before making the incision to decrease the risk of wound infection.

Anesthesia and Positioning

The routine use of prophylactic anticonvulsants in the perioperative period is a common practice despite recommendations that would seem to discourage that practice.^{58,59} Patients with a history of seizures need to have their anticonvulsants maintained at therapeutic dose levels. Under certain circumstances, such as for awake craniotomies with electrocorticography, the use of anticonvulsants for a short time might be warranted.

General Surgical Principles

In the past, localization of the surgical incision and craniotomy were most often performed by a neurosurgeon's understanding of cranial anatomy and an interpretation of preoperative imaging. More recently, image-guided navigation systems have been employed to more effectively localize tumor margins as they project to the cranial surface and thus allow for smaller, precisely positioned craniotomies.^{59,60} For tumors not resectable because of their location or diffuseness, a biopsy can be performed stereotactically using frameless or frame-based techniques. Tumors that are limited to the cortical surface may be best sampled with an open biopsy, under direct vision, due to the risk of inadvertent injury to a cortical vessel with a more limited, needle-based approach.

Specialized technology can be used to help define the completeness of a resection. Often, preoperative mapping of functional areas and their connections with MRI-based techniques are used to delineate both cortical areas and important subcortical white matter tracts that subservise speech and motor function.⁶¹ Image-guided navigation systems are almost always employed, but the guidance may lose accuracy over the course of an operation due to brain shift or cyst decompression. Intraoperative imaging with ultrasound, CT, or MRI may be used to determine the extent of residual tumor and to further localize areas where additional tumor may be removed safely.⁶² There has been growing use of 5-aminolevulinic acid (5-ALA), a prodrug, which is converted by glioma cells into fluorescent porphyrins that can be visualized with an operating microscope equipped with a fluorescent imaging system. The impact of the use of 5-ALA to guide resection of glioblastoma (GBM) on completeness of surgical resection and progression-free survival (PFS) has been demonstrated in a phase III trial.⁶³ Its use is limited to tumors that enhance with contrast on MRI (or CT), because the conversion of prodrug in low-grade tumors does not produce a sufficient amount of fluorescent porphyrin to be visualized intraoperatively. However, this conversion can be detected with the use of specialized optical instrumentation.⁵⁷ Use of 5-ALA in this manner is approved by regulatory authorities in Europe; its use in the United States remains investigational at this time.

Intraoperative cortical-stimulation mapping facilitates the resection of tumors in or adjacent to functionally critical areas. Motor functions can be mapped even under general anesthesia; however, anesthetic agents may increase the threshold to response and hence decrease the sensitivity of mapping. Sensory and speech-associated cortex are typically mapped during an awake craniotomy. Patients are monitored in the specialized care unit

overnight after surgery, and an MRI is done within 24 to 48 hours to evaluate the extent of any remaining tumor. It is important that this MRI is done before 72 hours to minimize the appearance of nonspecific contrast enhancement that is related to surgery and might be mistaken for residual tumor.^{64,65}

Re-resection of recurrent cerebral astrocytomas can be modestly efficacious.⁶⁶ When the initial tumor was low grade, histologic resampling may be necessary to guide further treatment at recurrence. Reoperation offers a chance to implant polymer wafers containing carmustine (bis-chloroethylnitrosourea [BCNU]) or to administer experimental agents, such as gene therapy agents or immunotoxins. A smaller volume of disease at initiation of chemotherapy predicts longer survival; thus, reoperation may improve the efficacy of adjuvant treatment as well as relieve mass effect in some patients.⁶⁷ An increasingly important aspect of resection is the need for tumor sampling to allow for a molecular marker analysis, which might provide and aid in assessing the prognosis as well as the probability of benefit from both chemotherapeutic and targeted therapies.

RADIATION THERAPY

General Concepts

Radiation therapy plays an integral role in the treatment of most malignant and many benign primary CNS tumors. It is often employed postoperatively as adjuvant treatment to decrease local failure, to delay recurrence, and to prolong survival in gliomas; as definitive treatment in more radiosensitive diseases such as PNET and germ cell tumors; or as therapy to halt further tumor growth in schwannomas, meningiomas, pituitary tumors, and craniopharyngiomas, and as ablative therapy to abrogate hormonal overproduction in secretory pituitary adenomas. Radiation therapy is also the primary modality in palliating brain metastases, and symptomatic spinal and osseous, as well as soft-tissue skull lesions.

Radiobiologic and Toxicity Considerations

Most neoplasms can potentially be cured if the correct radiation dose can be delivered to the entire tumor and its microscopic extensions. This is not always feasible because the maximum radiation dose deliverable is limited by the tolerance of the surrounding normal tissues, and the identification of regions of microscopic extension remains vague. Radiation tolerance of the CNS depends on several factors, including total dose, fraction size, volume irradiated, underlying comorbidities (particularly hypertension and diabetes), and innate sensitivity. Adverse reactions to cranial irradiation differ in pathogenesis and temporal presentation and are not discussed in detail here.

A major radiobiologic consideration revolves around the selection of total dose and the fractionation schedule. Late or long-term toxicities are generally a function of fraction size (i.e., dose per daily fraction of treatment), and therefore, as the fraction size is increased, such as with radiosurgery, higher late toxicity rates must be anticipated, assuming that normal tissue is encompassed within the high dose field. These late toxicities from larger fraction sizes can be minimized by minimizing the volume irradiated, as is done with radiosurgery, thereby drastically reducing the volume of normal tissues exposed to high doses. Proton and charged particle therapy, such as carbon, etc., are characterized by minimal to no exit dose beyond the target (where the so-called Bragg peak [i.e., the peak region of dose deposition] is placed), thereby sharply targeting the dose, and advantageously sparing tissue distal to the target. For radiosurgery, doses in the order of 12 to 21 Gy in single fractions are often utilized. In conventional radiotherapy, fraction sizes of 2 Gy are routinely utilized and may be lowered to 1.8 Gy per fraction in proximity to the visual apparatus or may be increased

to 3 Gy or more per fraction in patients in whom shorter palliative schedules, with lesser concern regarding long-term morbidities, exist. In general, the entire target is treated with a relatively uniform dose, but with the advent of newer delivery methods, it is possible to create dose gradients or dose inhomogeneities within the tumor to match differential radiosensitivity. However, this concept of dose painting remains investigational.

Treatment Planning and Delivery Methods

High-resolution MR fusion with CT planning images has allowed for more precise delineation of targets, although a significant margin, particularly with gliomas, is still necessary to cover microscopic extension.⁶⁸ Patient immobilization devices limit intrafraction motion and provide precision in positioning, decreasing the margin required for setup variability. Image-guided radiotherapy (IGRT), using biplanar orthogonal x-ray imaging systems, cone beam CT, megavoltage CT, surface tracking, fiducial monitoring, etc., further improves setup reproducibility and allows for decreased margins. Newer systems in development incorporate on-board MRI, but remain investigational.

IGRT can be incorporated with any radiotherapy method, such as fractionated external-beam radiotherapy and stereotactic

radiosurgery (SRS), and is practically mandatory for charged-particle therapy, frameless radiosurgery, fractionated stereotactic radiotherapy (FSRT), and intensity-modulated radiotherapy (IMRT). CT-based three-dimensional conformal radiation (3D-CRT) in which noncoplanar fields with unique entrance and exit pathways can be mapped on the target has improved normal tissue sparing. This allows for avoidance of critical structures, such as the brainstem, optic apparatus, and spinal cord. In IMRT, the photon flux of a beam is modulated in multiple directions during treatment, aimed at mimicking the shape of the target from various viewpoints, thereby producing improved conformality and non-uniform dose distribution. IMRT is increasingly being utilized for CNS tumors, based primarily on dosimetric studies, which suggest superior tumor coverage and reduction in the dose to critical structures (Fig. 97.4).⁶⁹ This can be beneficial in specific instances, such as to preserve cochlear function, vision, or pituitary activity.⁷⁰

In FSRT, the concepts of 3D-CRT or IMRT are merged with the accuracy and precision in delivery that characterizes SRS, and, typically, the radiation fraction size is considerably increased, so that the total course of therapy is reduced from the typical 20 to 30 or more fractions to 5 or fewer fractions. Various FSRT systems have been developed, with reported precision between 1 to 3 mm.^{71,72} FSRT is often used for larger lesions (e.g., 4 cm or more) and for lesions located in critical regions where single-fraction

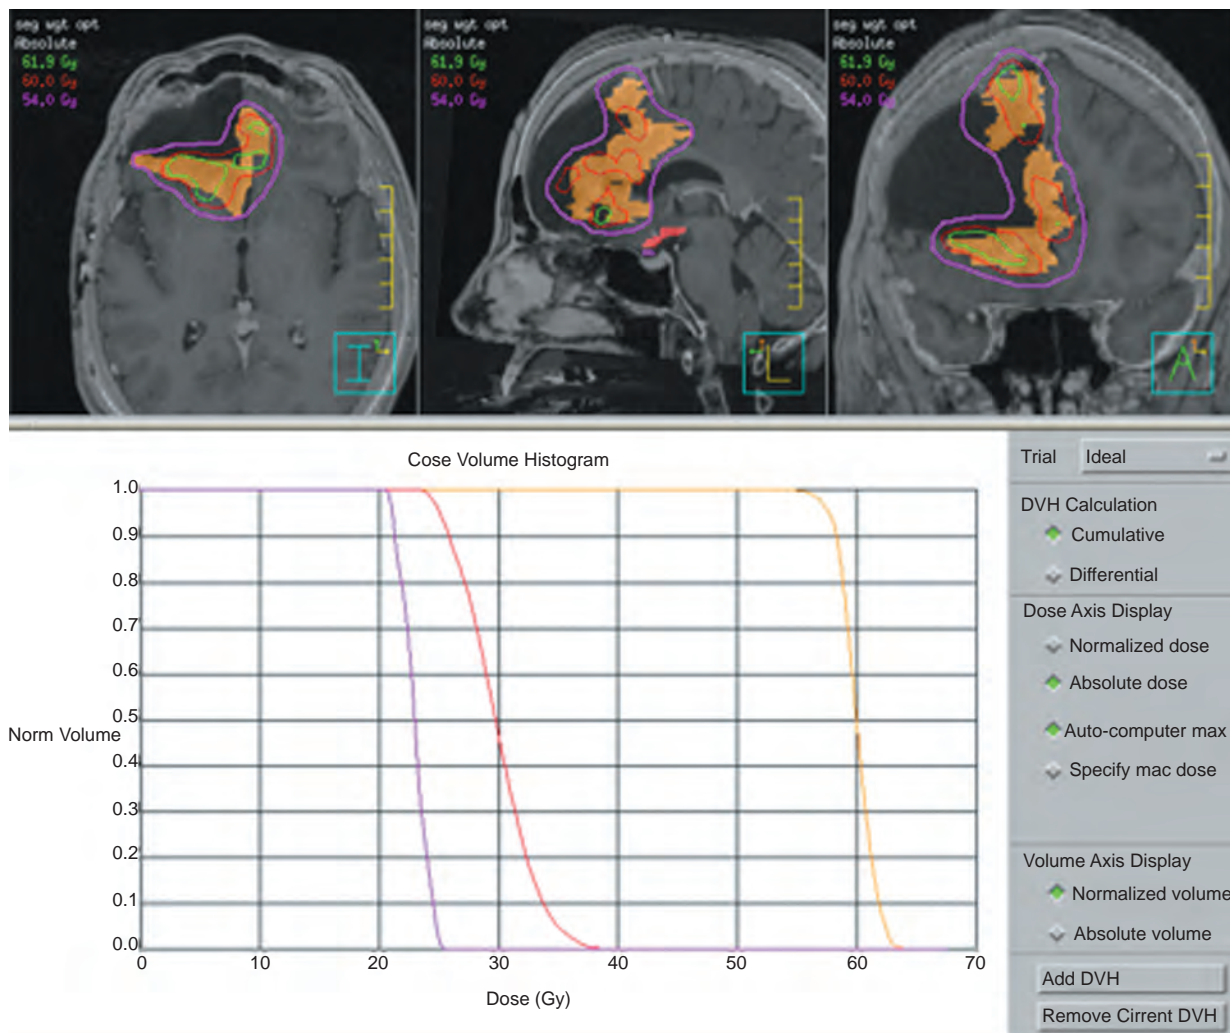

Figure 97.4 Intensity-modulated radiotherapy allows dose shaping to avoid critical structures. In this treatment plan of a right frontal oligodendroglioma (orange), tight target coverage and excellent conformal avoidance of the optic chiasm (red) and pituitary (purple) are achieved, as evidenced by the dose-volume histogram (DVH).

Figure 97.5 Example of radiosurgery dose distribution. This schwannoma is being treated with radiosurgery; the 12.5-Gy prescription isodose line conforms to the lesion.

SRS is disadvantageous because of a higher risk of toxicity, such as larger vestibular schwannomas or meningiomas.

SRS is used to treat a diverse group of lesions. Treatment can be carried out using either a modified or dedicated linear accelerator, cobalt-60 units, or charged particle devices. Several commercial devices have now been developed, each with slightly unique features, including robots that position the linear accelerator at various angles, collimation systems that provide prefixed circular collimators of various sizes or shaped collimated beams, and even intensity-modulated delivery from one or multiple directions, delivered serially, helically, or volumetrically.⁷³ Radiosurgery plays a dominant role in the treatment of oligometastases to the brain, arteriovenous malformations, schwannomas, and meningiomas and is occasionally used to treat malignant recurrences (Fig. 97.5).

Charged-particle beams, including protons (but not electrons), deposit the majority of their dose at a depth dependent on the initial energy, avoiding the exit dose of photon therapy. This localized dose is known as the *Bragg peak*. Historically, in order to cover larger volumes, proton beams have been modified by passive range modulators that disperse the Bragg peak and broaden the dose deposition, resulting in decreased proximal sparing, while still maintaining distal sparing. Charged-particle radiotherapy has been particularly utilized to treat tumors of the skull base to doses higher than can be achieved conventionally, and in reirradiation settings where conventional techniques are too unsafe. In particular, chordomas and chondrosarcomas require high radiation doses for local control. Proton beams have also been advocated for childhood tumors and tumors in young adults, because they decrease integral radiation dose, thereby decreasing the risk of second malignancies, although concern about incidental neutron production exists.^{74,75} The neutron contamination issue is almost nonexistent with approaches similar to the photon technique of intensity modulation, often also referred to as intensity modulated proton therapy (IMPT) and allows for significantly superior *dose sculpting*. Increasingly, this approach is being utilized in patients with lower grade neoplasms of the CNS, where survival is anticipated to be in years, and where reduction in the volume of normal brain irradiated is likely to produce benefits in cognitive, functional, and endocrine domains.

Brachytherapy has historically been widely used, but currently has a limited role in the CNS, although it has enjoyed some resurgence and is occasionally used for recurrent gliomas. A liquid colloid of organically bound iodine-125 (¹²⁵I) in a spherical balloon continues to be used to treat both recurrent and newly diagnosed malignant gliomas and brain metastases in the postoperative context.⁷⁶ At least two randomized trials using seed implants have failed to demonstrate a survival advantage in malignant gliomas. The injection of radioisotopes within the cystic portion of

craniopharyngiomas allows ablation of the secretory lining. A select group of patients with cystic tumors may benefit from the direct instillation of colloidal phosphorus-32 (³²P), yttrium-90 (⁹⁰Y), or gold-198 (¹⁹⁸Au).^{77,78} This technique will deliver between 200 to 400 Gy to the cyst wall.

Radiolabeled therapy is in the developmental phase. The most commonly used antigenic targets for CNS malignancies are the epidermal growth factor receptor (EGFR), neural cell adhesion molecule (NCAM), tenascin, placental alkaline phosphatase (PLAP), and phosphatidylinositol. Institutions using this technique have utilized murine, chimeric, or humanized monoclonal antibodies attached to ¹³¹I, ⁹⁰Y, rhenium-188 (¹⁸⁸Re), and astatine-211 (²¹¹At). The evolution of these trials has seen the delivery route move from systemic (intra-arterial or intravenous) to local instillation of the agent into a surgically created resection cavity. Even though the blood-brain barrier is often disrupted by a rapidly growing CNS malignancy, 150 kDa antibodies would still not likely cross to a significant degree.⁷⁹ Most of the trials to date are of *dose searching pilot* or phase I design. Using ¹³¹I-81C6 (antitenascin monoclonal antibody), a trend toward significant improvement in median survival was shown for patients receiving 40 to 48 Gy versus less than 40 Gy.⁸⁰ Unlike seed brachytherapy, there appears to be a very low rate of CNS toxicity with targeted isotope therapy, and a minimal need for surgical intervention for the removal of necrotic regions.

CHEMOTHERAPY AND TARGETED AGENTS

Drug therapies alone are effective for only a few types of CNS tumors (e.g., primary CNS lymphoma) but are useful as adjunctive therapy for many CNS tumors. Among the reasons for the poor efficacy of chemotherapeutic and targeted agents is the low concentration of drug penetration to the tumor because of the difficulty of agents to cross the blood-brain barrier, active transport mechanisms of drug efflux, and high plasma protein binding of agents, thereby lowering the volume of distribution of agents in the brain parenchyma.⁸¹ Intrinsic and acquired resistance remains an important reason for the lowered efficacy of chemotherapy. Although targeted agents are in early testing, multiplicity and alternate signaling pathways limit their efficacy.

The Blood-Brain Barrier

Central to treating CNS tumors is the issue of drug delivery, due to the blood-brain barrier (BBB), a physiologic and functional barrier. The CNS microvasculature has several unique features, including the lack of fenestrations between adjacent endothelial cells and relatively fewer pinocytotic and endocytotic endothelial

vesicles. Additionally, adjacent BBB endothelial cells are connected by a continuous extension of tight junctions, which limit passive diffusion between endothelial cells and through capillary structures. Tight junctions within the BBB are also enveloped by astrocytic foot processes, which increase the barrier to passive diffusion across the BBB.

Brain microvasculature selectively transports nutrients through 20 or more active or facilitated carrier transport systems expressed on the endothelial surface.⁸² The endothelium is rich with efflux pumps, including the multidrug resistance (MDR) gene–encoded P-glycoprotein that actively removes substrate molecules that may have passed the BBB.⁸³ There are several methods to disrupt or circumvent the BBB, including the intra-arterial administration of mannitol,⁸⁴ which has resulted in significant toxicities and thus have limited its universal use.⁸⁵ Noninvasive delivery systems using specialized carriers such as nanosystems (colloidal carriers) with favorable pharmacokinetic and pharmacodynamic properties are being explored.^{86,87} Other methods include local administration (Gliadel wafer)⁸⁸ or local drug delivery such as convection-enhanced delivery (CED). CED requires the implantation of catheters directly into the brain, followed by continuous infusion of the drug under a constant pressure gradient. Proof of principle for CED has been demonstrated in several studies, but unfortunately, phase III results have been disappointing.^{89,90} Another approach is the direct administration of the agent into the CSF. With a few exceptions (e.g., methotrexate, cytarabine, thioTEPA), most compounds cause unacceptable neurologic toxicity, including death, when given into the CSF. Because of this, intrathecal chemotherapy is principally used to treat leptomeningeal metastases and for CNS prophylaxis for high-risk leukemia.

Challenges Specific for Targeted Agents

Despite the availability of targeted agents specific to aberrant signaling pathways in high-grade gliomas, the results of phase II studies of many agents have been disappointing. In addition to the difficulty of delivery of agents across the BBB, there are other challenges that limit the efficacy of these agents. These include accounting for the heterogeneity of tumors, redundancy of pathway interactions, a lack of accurate and reproducible biomarkers to select patients for specific therapies, and difficulty in assessing target modulation.^{91–93} Bayesian adaptive randomized designs in clinical trials may allow for more efficient trials compared to those with balanced randomization.⁹⁴

Other Systemic Therapy Considerations

Many antiepileptic agents, including phenytoin, carbamazepine, and phenobarbital, induce the hepatic cytochrome P-450 isoenzyme and glucuronidation drug-elimination systems. The specific isoenzymes induced by these drugs are often capable of metabolizing many agents. For example, standard paclitaxel doses commonly result in subtherapeutic serum levels in patients also using phenytoin.⁹⁵ In fact, the maximally tolerated paclitaxel dose in patients using enzyme-inducing P-450 antiepileptics is nearly threefold higher than in patients not using such agents. Similar observations have been made with regard to 9-aminocapthecin, vincristine, teniposide, irinotecan, and targeted agents.^{96–99} In addition to different maximal tolerated dose (MTDs) being established depending on the use of enzyme-inducing antiepileptics, the side effect profile and dose-limiting toxicities can also differ.^{99,100} Most phase I clinical trials in brain tumor patients now use separate arms for patients who are or are not taking enzyme-inducing antiepileptic drugs or limit enrollment to patients not taking enzyme-inducing antiepileptic drugs. It may be preferable to change to a non-enzyme-inducing antiepileptic agent (e.g., levetiracetam [Keppra]), although it may take days to make the switch and some time for the P-450 enzyme induction to resolve.

SPECIFIC CENTRAL NERVOUS SYSTEM NEOPLASMS

Cerebral Glioma

Pathologic Classification

The histologic subtypes of gliomas include tumors of astrocytic, oligodendroglial, ependymal, and neuroepithelial origin (Table 97.2). Based on the WHO classification,⁵ noninfiltrative gliomas are classified as grade I, and infiltrating gliomas are subsequently categorized from grades II to IV. Infiltrative astrocytic tumors are divided into three categories: astrocytoma (including grade II fibrillary, gemistocytic, and protoplasmic), anaplastic astrocytoma (grade III), and glioblastoma (including grade IV giant cell glioblastoma and gliosarcoma). Oligodendrogliomas and ependymomas are either grade II or anaplastic (grade III).

WHO Grade I: Astrocytoma

Low-grade astrocytomas (WHO grade I) such as pilocytic astrocytoma, pleomorphic xanthoastrocytoma, and subependymal giant cell astrocytoma are typically circumscribed and indolent tumors. Missense mutations of the V600E type in the v-RAF murine sarcoma viral oncogene homolog B1 (BRAF) gene were identified

TABLE 97.2

The Variety of Central Nervous System Glial Tumors (Based on 2007 World Health Organization Classification)

- **Astrocytic tumors**

 - Anaplastic astroblastoma
 - Chordoid glioma of the third ventricle

in these noninfiltrative neoplasms.¹⁰¹ The highest frequencies were found in pleomorphic xanthoastrocytomas (66%; 65% in its anaplastic variant), gangliogliomas (18%), and pilocytic astrocytomas (9%, especially in tumors with extracerebellar location).¹⁰¹

Complete surgical resection, whenever feasible, is the curative mainstay therapy for such tumors. Despite aggressive near total resection, delayed recurrence and eventual malignant transformation are, unfortunately, common. The resection of a low-grade glioma can be difficult in locations such as the optic pathway, hypothalamus, and in those involving deep midline structures. In these instances, asymptomatic patients can be observed carefully for a prolonged period of time and undergo a maximally safe resection only at the time of progression.

In patients who have a recurrent tumor that are not amenable to further resection or who have a residual tumor causing significant morbidity, adjuvant chemotherapy or radiotherapy can improve recurrence-free survival, although the role of chemotherapy in adults remains controversial. Immediate postoperative adjuvant therapies may be appropriate in some cases depending on the location of the tumor, the extent of residual disease, the impracticability of repeated surgical excision, and the availability for follow-up. Generally, radiotherapy is the primary adjuvant treatment used in older children and adults with low-grade gliomas. In young children with unresectable, progressive low-grade gliomas, there is a desire to avoid or delay radiotherapy owing to the long-term radiation-related sequelae; chemotherapy is often utilized here as the initial therapeutic option.¹⁰²⁻¹⁰⁵ Some responses from chemotherapy can last for years, and nearly half of all children treated with chemotherapy ultimately require radiotherapy for tumor progression.

In terms of radiotherapy used with a curative intent, in children, the most common situation is with cerebellar and optic-pathway pilocytic astrocytoma, typically after progression on chemotherapy, whereas in adults, this tends to occur most commonly with hypothalamic pilocytic astrocytoma. The typical radiation dose used in this setting is 50.4 to 54.0 Gy, in 1.8 Gy fractions. There is evidence of improved PFS in this situation.¹⁰⁶ Given the young age and long expected survival of these patients, proton beam therapy is often considered for these patients, with the desire to decrease the risk of a second neoplasm, and to treat less normal brain tissue with radiation.¹⁰⁶

Subependymal giant cell astrocytomas can be effectively treated with everolimus. In a prospective randomized study, 35% of patients in the everolimus group had at least a 50% reduction in the volume of their tumor versus none in the placebo group, although complete responses still remain uncommon, even with this therapy.¹⁰⁷

WHO Grade II: Low-Grade Glioma

Nonpilocytic or diffusely infiltrating low-grade gliomas are classified as WHO grade II tumors. They may arise from astrocytic, oligodendrocytic, or mixed lineage. Like astrocytomas, oligodendrogliomas display various degrees of clinical aggressiveness. Three common genetic alterations, inactivation of the TP53 tumor suppressor gene, heterozygous point mutations of the isocitrate dehydrogenase-1 (IDH1), and loss of chromosome 22q are involved in the formation of WHO grade II astrocytoma. TP53, located on chromosome 17p, encodes the p53 protein that has an important role in a number of cellular processes, including cell cycle arrest, apoptosis, and response to DNA damage.¹⁰⁸

Somatic mutations at codon 132 in IDH1 are present in 50% to 80% of WHO grade II and III astrocytic tumors and oligodendroglial tumors, as well as in secondary grade IV glioblastomas.^{109,110} These IDH mutations promote the conversion of α -ketoglutarate into D-2-hydroxyglutarate, an oncometabolite that mediates the oncogenic activity of IDH mutations and can be measured by magnetic spectroscopy.¹¹¹ Tumors that have IDH mutations carry a better prognosis than do IDH wild-type gliomas of the same histologic grade.^{112,113}

An unbalanced t(1;19)(q10;p10) translocation results in a combined loss of chromosomal arms 1p and 19q, which leads to the loss of one hybrid chromosome, and thus, a loss of heterozygosity.¹¹⁴ This cytogenetic alteration is usually associated with oligodendroglial histology and is rarely found in other tumors. Patients with 1p- and 19q-codeleted tumors have a better prognosis than do histologically similar tumors of the same grade that do not harbor this codeletion.¹¹⁵

In addition to histology and molecular characteristics, several variables have been found to be of prognostic importance in low-grade gliomas. Pignatti et al.¹¹⁶ performed the most comprehensive of these analyses and developed a scoring system to identify patients at varying level of risk for mortality. A multivariate analysis showed that age 40 years or older, astrocytoma histology, maximum diameter 6 cm or greater, tumor crossing the midline, and presence of neurologic deficits negatively impacted survival. Patients with up to two factors were considered low risk (median survival, 7.7 years) and patients with three or more were considered high risk (median survival, 3.2 years). Recently, 339 European Organisation for Research and Treatment of Cancer (EORTC) patients with central-pathology confirmed LGGs were used to develop a new prognostic model for PFS and overall survival (OS).¹¹⁷ Data from 450 patients with centrally diagnosed LGGs recruited into two large studies conducted by North American cooperative groups were used to validate the models. Both PFS and OS were negatively influenced by the presence of baseline neurologic deficits, a shorter time since first symptoms, an astrocytic tumor type, and tumors larger than 5 cm in diameter.¹¹⁷

Surgery for Low-Grade Glioma

Retrospective analyses have suggested that the extent of resection is a significant prognostic variable. The Radiation Therapy Oncology Group (RTOG) performed a prospective evaluation of the natural history of completely resected low-grade gliomas (RTOG-9802), evaluating the recurrence risk in 111 patients with surgeon-defined gross total resections (GTR) and found that the extent of postoperative residual disease was an important variable for time to first relapse.¹¹⁸ Five-year recurrence rates were 26% versus 68% for patients with less than 1-cm residual tumors versus 1- to 2-cm residual tumors.

Radiation Therapy

The role of radiotherapy—particularly the timing—remains somewhat controversial. Early intervention is indicated for patients with increasing symptoms and radiographic progression. In younger patients (less than 40 years) who have undergone complete resection, observation with imaging is an option. In RTOG-9802, median time to progression in 111 good-risk patients defined as younger than 40 years and with a gross total tumor resection was 5 years.¹¹⁸ In those who have undergone a subtotal resection or those with high-risk features, postoperative radiotherapy may be recommended, typically 50.4 Gy in 1.8 Gy fractions.

Three phase III trials provide the best evidence with respect to the indications for radiotherapy as well as the dose. In a study by the EORTC (EORTC-22845), 314 patients were randomized to postoperative radiotherapy to 54 Gy (n = 157) or radiotherapy at progression (n = 157).¹¹⁹ A statistically significant improvement in PFS was associated with early radiotherapy, 5.3 versus 3.4 years ($p < 0.0001$), without a difference in median survival, 7.4 versus 7.2 years.

Two other trials investigated the dose question. In EORTC-22844, 379 patients were randomized to 45 Gy versus 59.4 Gy.¹²⁰ With a median follow-up of 74 months, OS (58% versus 59%) and PFS (47% versus 50%) were similar. In an Intergroup study, 203 patients were randomized to 50.4 Gy (n = 101) or 64.8 Gy.¹²¹ There was no significant difference in PFS or OS.

To assess the OS and cause-specific survival (CSS) impact of early adjuvant radiotherapy (EART) following the resection of supratentorial LGG in adults (16 to 65 years), 2,021 patients in

the SEER database from 1988 to 2007 were evaluated.¹²² Of the 2,021 patients, 871 (43%) received EART, and 1,150 (57%) did not. In the multivariate Cox proportional hazards model, EART was associated with worse OS and CSS. Using a propensity score and instrumental variable analyses to account for known and unknown prognostic factors demonstrated unmeasured confounding variables that may affect this finding.

Consequently, low-dose radiotherapy, 50.4 to 54.0 Gy in 1.8 Gy fractions, has become an accepted practice for selected patients with low-grade gliomas. The target volume is local, with a margin of 2 cm beyond changes demonstrated on traditional MRI sequences. FLAIR images usually show considerable abnormality beyond any enhancing or nonenhancing tumor and whether a smaller margin may be used for planning if FLAIR sequences are utilized is unknown.

Posttreatment cognition remains an important consideration. Brown et al.¹²³ reviewed the results of the Mini-Mental Status Examination for 203 adults irradiated for low-grade gliomas. Most patients maintained stable neurocognitive status after radiotherapy, and patients with abnormal baseline results were more likely to have improvement in cognitive abilities than to deteriorate after therapy; few patients showed cognitive decline. A more in-depth analysis of formal neurocognitive testing suggest that the tumor itself may have the most deleterious effect on cognitive function.¹²⁴ Recognition has been gaining that long-term neurocognitive functional (NCF) impairment following radiotherapy for benign or low-grade adult brain tumors could be associated with hippocampal dose. A dose to 40% of the bilateral hippocampi greater than 7.3 Gy was recently shown to be associated with long-term impairment in list-learning delayed recall.¹²⁵ Based on such data, the role of proton therapy as a potential approach to reduce cognitive deficits and other side effects is being explored.

Chemotherapy

Low-grade gliomas have historically been considered chemotherapy resistant. With the recent demonstration of the chemotherapy responsiveness of some low-grade astrocytomas and oligodendrogliomas has renewed interest in investigating chemotherapy for low-grade gliomas.^{126,127} It has been demonstrated that some low-grade gliomas, especially optic pathway and hypothalamic tumors, can be responsive to chemotherapy.^{31,128} In children, various single and multichemotherapeutic and biological agents are effective at controlling the growth of a low-grade glioma in a setting of a newly progressive lesion, multiply recurrent, or unresectable residual tumors.^{102-105,129,130} Platinum-containing regimens result in radiographic response rates greater than 60%.¹²⁹ Vinblastine has also demonstrated substantial activity in recurrent low-grade gliomas and is a commonly used second-line agent after treatment failure with vincristine and carboplatin.^{131,132} Other second- and third-line therapies for multiply recurrent tumors include thioguanine, procarbazine, lomustine, and vincristine (TPCV) and temozolomide. Irinotecan and bevacizumab are currently being investigated in a multi-institutional phase II trial

for the treatment of progressive low-grade gliomas. Rapamycin, an oral immunosuppressive agent, has been effective at reducing the growth of astrocytomas associated with tuberous sclerosis.¹³³ Most of the chemotherapy responses seen in children with low-grade gliomas are for contrast-enhancing masses that probably represent pilocytic astrocytomas. Some of these responses can last for years, although nearly half of all children treated with chemotherapy ultimately require radiotherapy. Nonenhancing, diffusely infiltrating astrocytomas in children appear to be much less responsive to chemotherapy. Data on the use of chemotherapy for low-grade glioma in adults are sparse. In a small Southwest Oncology Group trial, adults with incompletely excised low-grade gliomas were randomly assigned to radiation therapy (RT) alone or RT and lomustine ([2-chloroethyl]-3-cyclohexyl]-1-nitrosourea [CCNU]). There was no difference in survival between the two arms.¹³⁴ The role of adjuvant procarbazine, CCNU, and vincristine (PCV) for high-risk patients (e.g., less than total resection, age older than 40 years) with low-grade gliomas was evaluated in RTOG-9802. From 1998 to 2002, 251 patients were randomly assigned to RT alone or RT followed by six cycles of PCV. An initial report of this study showed that the 5-year OS rates for RT versus RT/PCV were 7.5 years versus not reached respectively (hazard ratio [HR] = 0.72, 95% confidence interval [CI], 0.47 to 1.10; $p = 0.33$).¹³⁵ At the time of that report, however, 65% of the patients were still alive. A recent National Institute of Health press release on more mature results of this study reported significant improvement in OS in the PCV chemotherapy plus RT group (13.3 years) compared to those assigned to RT alone (7.8 years) at a median follow-up of 12 years.¹³⁶ Molecular and cytogenetic analyses (isocitrate dehydrogenase mutations and loss of heterozygosity of 1p and 19q, as well as methylation of methylguanine methyltransferase status) and clinical outcome are pending to identify predictive factors for patients with LGG.

Several studies have evaluated PCV in the recurrent setting, and, more recently, temozolomide has also been evaluated (Tables 97.3 and 97.4).^{126,127,137-146} In general, approximately half of the patients treated with either temozolomide or PCV experienced imaging stability or improvement of neurologic symptoms. Although results are encouraging, the number of patients treated in these studies was small, and there are questions regarding the criteria used for radiographic response. In the first report of RTOG 0424, the primary endpoint was to compare the 3-year OS of a regimen of concurrent and adjuvant temozolomide and RT in a high-risk low-grade glioma population to the 3-year OS rate of the high-risk EORTC LGG patients reported by Pignatti et al.¹¹⁶ With a median follow-up time of 4.1 years and a minimum follow-up of 3 years, MST has not yet been reached. The 3-year OS rate was 73.1% (95% CI, 65.3 to 80.8%), significantly improved in comparison to the prespecified historical control with a p value < 0.0001 .¹⁴⁷ An ongoing intergroup phase III trial is attempting to answer this issue more definitively.

Patients with low-grade oligodendroglial tumors with 1p/19q deletion or t(1p;19q) have longer PFS and OS than those without.¹¹⁴ Consequently, 1p/19q determination is important in

patient counseling and in assessing the results of outcomes in future clinical trials. A randomized phase III EORTC trial stratified patients with low-grade glioma by 1p status prior to randomization to RT versus temozolomide.¹⁴⁸ In the initial results of the trial presented, PFS was not significantly different, and median OS was not reached. 1p deletion was a positive prognostic factor irrespective of treatment (PFS: 0.0003; HR = 0.59; 95% CI, 0.45 to 0.78); OS: 0.002; HR = 0.49; 95% CI, 0.32 to 0.77). First-line treatment with temozolomide compared to radiotherapy did not improve PFS in high-risk LGG patients. A molecular and genetic analysis of LGG has revealed aberrant signaling in the phosphatidylinositol-3-kinase (PI3K)/AKT/mammalian target of rapamycin (mTOR) network; however, a defined role for the inhibition of this pathway in the treatment of LGG remains to be established.^{149,150} Targeting this pathway is a therapeutic approach that is being investigated in clinical trials in recurrent LGG patients.

WHO Grade III: Anaplastic Astrocytoma

Prospective and/or randomized evidence indicating that a complete resection of enhancing or an MRI-visible tumor improves survival is lacking, but retrospective analyses reaffirm that this relationship is likely to be present. Nonetheless, almost all of these tumors are characterized by postoperative residual microscopic disease, and radiotherapy is used adjunctively, resulting in a 3-year survival of approximately 55%.¹⁵¹

Radiation Therapy

Partial brain fields are used for the treatment of anaplastic astrocytoma; the initial gross tumor volume (GTV) is defined as the T2 or FLAIR abnormality; the boost GTV is defined as the contrast-enhancing volume or the surgical bed; for smaller, nonenhancing tumors, the initial and the boost GTV are often equivalent.¹⁵² The clinical tumor volume (CTV) is defined as an approximately 2-cm margin surrounding the GTV, but not expanding across natural barriers. The initial volume is typically treated to 46 Gy, with the boost volume to 60 Gy. No survival advantage for the use of bromodeoxyuridine as a radiosensitizer was demonstrated.¹⁵³ Early versus delayed radiotherapy, utilizing chemotherapy as part of the regimen, was evaluated in a German phase III trial (NOA-04), which is described in the section that follows.

Chemotherapy

The role of chemotherapy remains controversial. Most phase III trials have demonstrated no benefit compared with radiation

alone. Both single-agent carmustine and PCV are associated with minimal improvement in survival. Although, for a period of time, PCV was considered the “superior” regimen, database analyses have belied this claim.¹⁵¹ A meta-analysis by the Glioma Meta-Analysis Trialists’ group demonstrated an approximate 6% absolute increase in 1- and 2-year survival for patients who received chemotherapy (2-year survival of 37% versus 31%).¹⁵⁴ A large randomized trial by the Medical Research Council found no benefit of adjuvant PCV compared with RT alone.¹⁵⁵ Although temozolomide is effective for the treatment of recurrent anaplastic astrocytoma, its role as an adjuvant to RT has not been rigorously assessed. Based on these results in recurrent anaplastic astrocytoma, the RTOG initiated a phase III trial (RTOG 9813) to compare radiation with BCNU or CCNU to radiation with temozolomide, and the results are pending.

A comparison of the efficacy and safety of radiotherapy versus chemotherapy with either PCV or temozolomide as initial therapy on patients with newly diagnosed anaplastic glioma showed comparable results in terms of time to treatment failure.¹⁵⁶ Because of the potential prognostic and predictive value of hypermethylation of the O6-methylguanine DNA-methyltransferase (MGMT) promoter and mutations of the *IDH1* gene in malignant gliomas, analyses of these was a correlative part of the study.^{110,157,158} Hypermethylation of MGMT promoter and mutations of the *IDH1* gene as well as oligodendroglioma histology reduced the risk of progression. Hypermethylation of MGMT promoter was associated with prolonged PFS in the chemotherapy and RT arms.

Difluoromethylornithine (DFMO), an inhibitor of ornithine decarboxylase, was evaluated in a phase III trial.¹⁵⁹ Of 228 patients, the majority had anaplastic astrocytoma. Following RT, patients were randomized to PCV or PCV plus DFMO. There was a difference in survival during the first 2 years, but this did not continue after 2 years.

Chemotherapy for Recurrent Anaplastic Astrocytomas

Chemotherapy for anaplastic astrocytomas that recur following radiation is of benefit, and both nitrosourea-based regimens and temozolomide have efficacy. The U.S. Food and Drug Administration (FDA) granted accelerated approval for temozolomide on the basis of its activity in recurrent anaplastic astrocytoma; the response rate was 35% for patients who had not received chemotherapy and 20% for patients who had received nitrosourea-based therapy.¹⁶⁰ Many patients are being treated with temozolomide early in the course of their illnesses; therefore, for recurrent anaplastic astrocytoma, nontemozolomide regimens used in glioblastoma are often

considered.¹⁶¹ Several clinical trials to evaluate targeted agents in recurrent malignant glioma often include recurrent grade III histology. Based on documented activity of the antivascular endothelial growth factor antibody in recurrent glioblastoma, this agent has also been used in patients with recurrent anaplastic astrocytoma.¹⁶² A retrospective study reported a 64% radiographic response and a 6-month PFS rate of 60% in 25 patients.¹⁶³ Prospective studies are pending.

The NOA-04 phase III trial compared efficacy and safety of RT followed by chemotherapy at progression with the reverse sequence in patients with newly diagnosed anaplastic gliomas.¹⁵⁶ Patients received conventional RT: procarbazine, lomustine (CCNU), and vincristine, or temozolomide at diagnosis. At occurrence of unacceptable toxicity or disease progression, patients in the RT arm were treated with PCV or temozolomide, whereas patients in chemotherapy arms received RT. Median time to failure, PFS, and OS were similar for all arms. Hypermethylation of the MGMT promoter was associated with prolonged PFS in the chemotherapy and RT arm. This study showed that IDH1 mutations are a positive prognostic factor in anaplastic gliomas, with a favorable impact stronger than that of 1p/19q codeletion or MGMT promoter methylation.¹⁵⁶

WHO Grade III: Anaplastic Oligodendroglioma

Surgery

Surgery retains its role as the principal modality of treatment, as with other glial neoplasms, and the maximum safe resection is considered the standard of care. However, the consideration of risks versus benefits of an aggressive surgical resection should take into account the 1p/19q deletion status of the tumor and the potential for a more favorable natural history and response to medical therapy.

Radiation Therapy

No randomized trials that focus only on these tumors comparing radiation versus no RT have been completed. In general, patients with pure and mixed anaplastic oligodendrogliomas receive post-operative irradiation to 60 Gy in conventional daily fractions of 1.8 to 2.0 Gy using an approach similar to that used for other malignant gliomas. Recent data show a categorical and very large survival benefit for both the 1p19q codeleted and the IDH-mutated anaplastic oligodendrogliomas treated with combination chemoradiotherapy, in comparison to RT alone. Therefore, up-front RT alone should not be the preferred treatment for these good prognosis patients. Conversely, no level I data exist to support treating these patients with up-front chemotherapy alone, either, and although this practice is sometimes adopted in practice, it should be subjected to rigorous clinical evaluation, because of the potential for the loss of long-term survivorship in these favorable patients, if either therapy is compromised. These results are described in greater detail in the section that follows.

Chemotherapy

Retrospective series and phase II trials first suggested that oligodendrogliomas are chemosensitive.^{157,164,165} In two phase III trials, RT alone was compared with RT plus PCV. In the North American trial (RTOG 9402) patients received PCV for four cycles prior to radiation or no up-front PCV. Survival in the two groups was the same. Patients with 1p and 19q deletions had significantly better outcomes, regardless of treatment.¹⁶⁶ An unpre-specified analysis of PFS demonstrated that the benefit from PCV was most notable in patients with 1p and 19q deletions. Long-term results of this study demonstrated that patients with codeleted tumors lived longer than those with non-codeleted tumors irrespective of therapy, and the median survival of those with codeleted tumors treated

with PCV plus RT was twice that of patients receiving RT (14.7 versus 7.3 years).¹⁶⁷ There was no difference in median survival for patients with tumors lacking 1p and 19q deletion.

In the European trial, patients received PCV or no immediate chemotherapy after radiation.¹⁶⁸ PFS was better in the PCV group, but OS was not different. Patients with 1p and 19q deletion had superior survival, regardless of treatment. A further molecular analysis of this cohort demonstrated that MGMT promoter methylation was of prognostic value.^{169,170} Long-term follow-up showed that PFS and OS were better in the PCV group, but OS was not different between the two groups (OS in the RT/PCV arm, 42.3 months; in the RT arm, 30.6 months). In patients with a 1p/19q codeletion, there was a trend to more benefit from adjuvant PCV (OS not reached in the RT/PCV group versus 112 months in the RT group).¹⁷¹ Both trials confirmed the prognostic value of 1p and 19q.

Temozolomide has produced high response rates in patients with anaplastic oligodendroglioma. In 27 newly diagnosed patients treated with temozolomide prior to radiotherapy, the objective response rate was 33% and the 6-month progression rate was 10%.¹⁷²

Chemotherapy for Recurrent Anaplastic Oligodendroglioma

Prospective trials have demonstrated that approximately 50% to 70% of patients with anaplastic oligodendrogliomas that recur after RT respond to chemotherapy.¹⁴³ In a study of 48 patients with anaplastic oligodendroglioma/oligoastrocytoma who progressed on PCV, the objective response rate to temozolomide was 44%.¹⁷³ Although there is no evidence that the sequence of temozolomide and PCV is superior in terms of efficacy, the absence of cumulative myelosuppression with temozolomide argues for its use initially in the setting of recurrent disease.

Ongoing Clinical Trials for Newly Diagnosed Grade 3 Glioma

Two international trials are being conducted in patients with newly diagnosed grade 3 glioma stratified by 1p 19q status rather than histology. Nondeleted patients are randomized to radiation with or without temozolomide; following RT, there is a second randomization to adjuvant temozolomide or not. Codeleted patients are randomized to three arms, temozolomide alone (phase II group), RT with concomitant and adjuvant temozolomide, or RT with adjuvant PCV (phase III).

WHO Grade IV: Glioblastoma

Surgery

Gliomas are heterogeneous, and therapy is guided by the most aggressive grade in the specimen. Resection provides the best opportunity to obtain an accurate diagnosis. Studies have shown that more complete resections are more likely to provide a high-grade diagnosis and to detect an oligodendroglial component.¹⁷⁴ Two randomized trials of resection of malignant gliomas have been published. In a study by Vuorinen et al.,¹⁷⁵ survival was twice as long with resection compared to biopsy alone. Stummer et al.⁶³ reported that patients without residual contrast-enhancing tumor had a higher overall median survival time than did those with residual enhancing tumor (17.9 months versus 12.9 months, respectively; $p < 0.001$). Complete resection of an enhancing tumor enhances certain approved or investigational adjuvant therapies (e.g., carmustine wafers, immunotherapy). Resection also is superior to stereotactic biopsy alone for the provision of adequate tissue for the evaluation of molecular and cytogenetic classifications and certain prognostic markers (e.g., MGMT), which may be a requirement for entry into some clinical trials.

There has been extensive work in molecular subtypes of GBM in recent years that include a report of the Cancer Genome Atlas

Research Network¹⁷⁶ and follow-up transcriptome work of glioblastoma provided insights into the major structural and expression alterations that may drive disease pathogenesis and biology in glioblastoma.^{177,178} Verhaak et al.¹⁷⁸ proposed a gene expression-based molecular classification of GBM into proneural, neural, classical, and mesenchymal subtypes. Aberrations and gene expression of EGFR, NF1, and platelet-derived growth factor receptor α (PDGFR- α)/IDH1 were utilized to define the classical, mesenchymal, and proneural subtypes, respectively. These investigations into the genome and transcriptome reveal GBM as a heterogeneous collection of distinct diseases with multiple dependencies both within and across each particular subtype.¹⁷⁹

Radiotherapy

Randomized trials have demonstrated a survival benefit with RT.¹⁸⁰ Localized radiation volumes are recommended based on evidence from several sources that GBMs typically recur locally, and the bulk of the infiltrative disease is within a few centimeters of the enhancing rim. However, the wide and somewhat unpredictable degree and direction of dissemination, which is not visualized well with any imaging technique, renders an RT field definition difficult. Outside of clinical trials, consensus regarding the exact field design remains difficult to obtain. In the large randomized trial RTOG 0525 for newly diagnosed GBM, which allowed both a single field treatment or a separate boost field to be utilized, no survival differences were identified, although the number of patients treated with the single field was rather small, in comparison (>80% versus <20%).¹⁸¹

Standard therapy uses a total dose of 60 Gy in 30 to 33 fractions based on dose response studies showing a survival improvement for 60 Gy compared to lower doses and without a benefit for higher doses.¹⁸²⁻²¹⁵ For patients with poor prognostic factors and for those who are not able to tolerate conventional treatment, a shorter course may provide palliation. Older patients (older than 65 years), especially those with poor performance status, have been shown to have limited posttreatment improvement following conventional RT,¹⁸³ and several studies have not shown a significant survival difference using shorter courses.¹⁸⁴⁻²¹⁸ A number of trials have evaluated the role of temozolomide versus RT in elderly patients with glioblastoma. The German phase III trial (NOA-08) randomized patients 65 years or older with anaplastic astrocytoma or glioblastoma with a minimum Karnofsky performance status (KPS) of 60 to either temozolomide or radiotherapy. Of 412 patients who were randomized, 373 received at least one dose of treatment and were included in efficacy analyses. Median survival was 8.6 months in the temozolomide arm compared to 9.6 months with RT. These results met the criteria of "noninferiority" of temozolomide.¹⁸⁵ In an unplanned post hoc analysis, MGMT promoter methylation status was evaluated in 209 patients; promoter methylation was associated with longer OS (11.9 versus 8.2 months). Event-free survival was longer in patients with MGMT methylation who received temozolomide alone versus RT, whereas the opposite was true for patients without MGMT promoter methylation. Therefore, MGMT methylation seems to be a useful predictive biomarker and could aid decision making in elderly patients not fit to receive concurrent chemoradiation.

The Nordic three-arm phase III trial randomized elderly (>60 years) patients with glioblastoma to two different radiotherapy schedules of 60 Gy in 2 Gy per fraction (fxs) over 6 weeks or a hypofractionated schedule of 34 Gy in 3.4 Gy fxs over 2 weeks, versus temozolomide alone.¹⁸⁶ Median survival was significantly longer with temozolomide versus conventional RT (8.3 versus 6.0 months; HR, 0.70; $p = 0.01$), but not hypofractionated radiotherapy (7.5 months; HR, 0.85; $p = 0.24$). This trial suggests that both temozolomide alone and hypofractionated RT alone produce equivalent survival in elderly patients with glioblastoma, and both are superior to standard RT.

These trials did not address the issue of concomitant chemoradiotherapy for the elderly. An ongoing, phase III trial (EORTC

26062-22061 NCIC CTG CE6) compares the OS rates between short-course RT alone and short-course RT given together with temozolomide in newly diagnosed patients with glioblastoma who are older than 65 years of age and who are not fit for standard treatment. This study has completed accrual and results are pending.

Dose Escalation

In the pretemozolomide era, studies evaluating radiosurgery or brachytherapy boosts to conventional RT have not demonstrated a survival advantage.²²²⁻²²⁵

The feasibility and toxicity of dose-escalated photon radiotherapy concurrent with BCNU chemotherapy in patients with supratentorial GBM¹⁸⁷ was the goal of RTOG 9803. There were 209 patients who were enrolled and stratified into two groups based on the size of planned target volume (<75 mL versus ≥ 75 mL). Within each stratum, four RT dose levels were evaluated: 64, 72, 78, and 84 Gy; all treatments were delivered with a fraction size of 2 Gy. Acute and late grade ≥ 3 radiotherapy-related toxicities were no more frequent at higher RT doses or with larger tumors. No dose-limiting toxicities were observed at any dose level in either stratum, and as a result, the dose was escalated to 84 Gy in both strata. Median time to RT-related necrosis was 8.8 months (range, 5.1 to 12.5 months). This study demonstrated the feasibility and tolerability of photon dose escalation with an acceptable risk of late CNS toxicity with doses as high as 84 Gy. However, this study was conducted with concurrent BCNU chemotherapy, not the current standard approach of concurrent and adjuvant temozolomide. This chemoradiotherapy regimen has become the backbone of standard postoperative treatment for patients with GBM but has never adequately been tested in a RT dose-escalation or -intensification context. With this standard postoperative chemoradiotherapy regimen, the predominant pattern of failure remains local, highlighting the importance of investigating more intensive local therapies.

Recently, the University of Michigan published results of a clinical trial that escalated dose and dose-per-fraction from 66 Gy to 81 Gy in 30 fractions during chemoradiotherapy with temozolomide for patients with GBM.¹⁸⁸ The maximum tolerated dose with concurrent temozolomide was 75 Gy in 30 fractions (2.5 Gy per fraction). Median survival was 20.1 months, suggesting improved efficacy comparable to other contemporary studies. Interestingly, the probability of in-field failure decreased with increasing dose escalation, setting the stage for more definitive investigations of this approach. Small phase II studies of dose escalation using mixed photon/proton irradiation demonstrated median survival times of 20 to 22 months, and more formal comparative studies need to be performed.^{244,245} Alternate particle radiation modalities used in the treatment of gliomas include neutrons, helium ions, other heavy nuclei such as carbon, negative pi-mesons, and thermal neutrons in conjunction with boronated compounds (boron neutron capture therapy). To date, most studies have been designed to determine optimal dose scheduling, efficacy, and safety.

Radiosensitizers and Radioimmunotherapy

Studies using various radiation modifiers such as hyperbaric oxygen, nitroimidazoles and tirapazamine, RSR-13, or carbogen and nicotinamide to overcome the hypoxia present in malignant gliomas have generally yielded disappointing results with no survival advantage.^{228,232} Halogenated pyrimidines are incorporated into the DNA of dividing cells due to their biochemical similarity to thymidine. After being incorporated, cells are much more susceptible to single-strand breaks from radiation-induced free radicals and have impaired ability to repair DNA. Prospective clinical studies, however, have not demonstrated a survival advantage.¹⁶⁹ Motexafin gadolinium (MGd) is a redox-active drug that

Number at risk							
Unmethylated, radiotherapy	54	47	25	5	0	0	0
Unmethylated, radiotherapy plus temozolomide	60	53	34	11	7	4	1
Methylated, radiotherapy	46	42	30	18	8	0	0
Methylated, radiotherapy plus temozolomide	46	42	34	28	16	7	1

Figure 97.6 Kaplan-Meier survival curves for the two arms of the international glioblastoma trial, demonstrating a significant survival benefit from chemoradiotherapy, compared with radiotherapy. The patients are evaluated by methylguanine DNA-methyltransferase (MGMT) gene promoter methylation status, and the maximum survival benefit is seen in the combination arm when the gene promoter is silenced. (Redrawn from Hegi ME, Diserens AC, Gorlia T, et al. MGMT gene silencing and benefit from temozolomide in glioblastoma. *N Engl J Med* 2005;352:997)

selectively accumulates in tumor cells. It is thought to sensitize tumors through the production of reactive oxygen species that destabilize cellular metabolism. A phase II RTOG trial did not demonstrate superiority in survival.¹⁸⁹ Studies of radiation synergistic cytotoxics such as the camptothecins or platinum agents also did not demonstrate a survival benefit.²³⁵ Radioimmunotherapy, using various monoclonal antibodies against EGFR or tenascin tagged with ¹²⁵I have been evaluated.^{237,238} These were small studies and demonstrated feasibility; however, randomized controlled studies have not been performed.

Chemotherapy

In a landmark international trial, patients were randomized to RT with or without concurrent and adjuvant temozolomide. Median and 2-year survival were increased by 2.5 months and 16.1%, respectively, in patients receiving temozolomide, and long-term follow-up showed a persistent survival benefit.¹⁹⁰ A companion correlative study demonstrated that methylation of the promoter region of the *MGMT* gene in the tumor was associated with superior survival, regardless of treatment received, but the benefit was maximal for methylated patients.¹⁵⁷ *MGMT* removes the methyl group from the O6 position of guanine, reversing the cytotoxic effects of methylating agents (such as temozolomide), making the tumor resistant to treatment, while methylation of the promoter region of *MGMT* results in inactivation of *MGMT*. *MGMT* status was strongly associated with survival (Fig. 97.6). Recognizing that a different schedule of temozolomide may overcome chemotherapy resistance, there have been several studies of alternative dosing of temozolomide both at the time of recurrence and in the newly diagnosed setting.^{191,192} A large phase III randomized international study led by the RTOG compared the standard treatment versus a 21- or 28-day adjuvant temozolomide schedule.¹⁸¹

Dose-dense temozolomide failed to result in improved efficacy regardless of tumor methylation status but was associated with more profound lymphopenia and fatigue. Strategies to increase the therapeutic ratio of existing chemotherapies, such as the

inhibition of DNA repair enzymes (i.e., poly[ADP-ribose] polymerase [PARP]) are being evaluated. These agents are being combined with radiation and chemotherapy to increase the cytotoxicity of the combination approach.¹⁹³⁻¹⁹⁵

Although nitrosourea-based chemotherapy is modestly effective for patients with GBM, its use has been supplanted by temozolomide. There is evidence that carmustine-impregnated wafers implanted into the brain at the time of resection provide modest improvement in outcomes in selected patients compared with patients who received placebo wafers.¹⁹⁶

Chemotherapy for Recurrent Glioblastoma

Treatment options for recurrent GBM must be tailored to the individual. Few agents have proven activity. A randomized phase II trial of temozolomide versus procarbazine in 225 patients with GBM at first relapse demonstrated that treatment with temozolomide improved median PFS (12.4 weeks versus 8.3 weeks; $p < 0.006$). Radiographic responses were disappointing (5.4% versus 5.3%). Several agents such as the platinoids, taxanes, 5-fluorouracil (5-FU), and irinotecan have been tested, most demonstrating very little activity. In a review of eight clinical trials with 225 recurrent malignant gliomas, the 6-month survival was 15% versus 31% for GBM versus anaplastic astrocytoma.¹⁹⁷

Targeted Therapies

As the genetic and molecular pathogenesis of gliomas is better understood, new targets are being identified and inhibitors of associated signaling pathways are being developed. One example is EGFR as a frequently deregulated signaling molecule in GBM, prompting phase I and II trials of erlotinib and gefitinib for recurrent high-grade gliomas. Both have shown limited activity.^{97,198-200} Patients whose tumors demonstrate the variant 3 mutant (EGFRvIII), with resulting constitutive activation of EGFR tyrosine kinase activity, along with intact phosphatase and tensin analog (PTEN),

appear to be more responsive to EGFR inhibitors.²⁰¹ There are two reports of the combination of erlotinib with radiation and chemotherapy for newly diagnosed glioblastoma showing modest additional benefit to standard radiochemotherapy, none of which show convincing survival improvement.^{202,203} Similarly, RTOG 0211, which evaluated the benefit of RT with concurrent gefitinib, showed median survival similar to that in a historical control cohort treated with radiation alone.²⁰⁴ Irreversible EGFR inhibitors such as afatinib did not show efficacy when used alone or in combination with temozolomide in recurrent GBM.²⁰⁵ There is an ongoing phase II study with the second-generation EGFR inhibitor, dacomitinib.

Preliminary reports using other targeted agents, including the mTOR inhibitor, temsirolimus, and the farnesyl transferase inhibitor, tipifarnib, have shown objective responses in a few high-grade gliomas.²⁰⁶⁻²¹⁰

The most promising results have been seen for angiogenic inhibitors. The most important mediator of angiogenesis in GBM is vascular endothelial growth factor (VEGF). Antiangiogenic therapies such as the anti-VEGF monoclonal antibody bevacizumab have produced dramatic radiologic responses and prolonged PFS relative to historical controls.^{211,212} Based on the results of a randomized phase II study of 167 patients who received bevacizumab with or without irinotecan, the FDA granted accelerated approval to bevacizumab for recurrent glioblastoma in 2009.¹⁶² The PFS at 6 months was 43% for single-agent bevacizumab and 50% for the combination arm. The objective response rates were 28% and 38% for the two arms, and median survival times were 9.2 months and 8.7 months, respectively. The most common side effects associated with bevacizumab include fatigue, headache, and hypertension; proteinuria and poor wound healing are also seen. The addition of chemotherapy or targeted therapy to bevacizumab has failed to show any added benefit in recurrent GBM trials, with the exception of the BELOB study, a three-arm multicenter randomized phase II study, in which 148 patients with recurrent glioblastoma were treated with bevacizumab alone, lomustine alone, or the combination of the two. Survival at 9 months was 38%, 43%, and 59%, respectively, and the PFS at 6 months was 16%, 13%, and 41%, respectively, in the three arms.²¹³ The value of the combination of bevacizumab and lomustine in recurrent GBM is currently being evaluated in EORTC 26101, which was initially a randomized phase II study modified into a two-arm phase III trial to address this question.

There are several reports of small single-arm phase II studies of the combination of bevacizumab with radiation and temozolomide in the newly diagnosed setting.²¹⁴ Two large randomized trials evaluated the addition of bevacizumab to the initial combined modality therapy of RT and temozolomide. In RTOG 0825, a randomized, double-blinded, placebo-controlled trial, the addition of bevacizumab to temozolomide and radiation resulted in a longer PFS that did not reach the preset level of significance (10.7 months versus 7.3 months; HR, 0.79). There was no difference in OS between two arms (16.1 versus 15.7 months; HR, 1.13).²¹⁵ Another phase III, placebo-controlled randomized trial (AVAglio study) in newly diagnosed glioblastoma showed that the addition of bevacizumab to radiation and temozolomide (experimental arm) significantly prolonged PFS (HR, 0.64; $p < 0.0001$; median, 10.6 versus 6.2 months) as compared to radiation and temozolomide (control arm).²¹⁶ However, the median OS was not significantly different in both arms. One-year OS was 72% and 66%, respectively ($p = 0.049$); 2-year OS was 34% and 30%, respectively ($p = 0.24$) in the experimental and control arm. Safety was consistent with known bevacizumab side effects, serious adverse events (AEs) (grade ≥ 3) were 28.7% versus 15.2% grade in the two arms.

As previously discussed, patients with MGMT-nonmethylated GBM have inferior outcomes as compared to those with MGMT-methylated GBM, and temozolomide is less effective in these patients. The open-label GLARIUS trial was a randomized, multicenter study of 170 patients in which MGMT-nonmethylated

GBM patients were randomized (2:1) to radiation with bevacizumab during RT followed by maintenance bevacizumab and irinotecan (experimental arm) compared to standard therapy with daily temozolomide during radiation followed by 6 cycles of temozolomide (control arm).²¹⁷ The PFS at 6 months rate of 71.1% was significantly higher in the experimental arm compared to 26.2% in the control arm ($p < 0.0001$ log-rank test).

Recognizing that tumors ultimately evade the effect of antiangiogenic agents through various mechanisms, other strategies include the evaluation of the combination of bevacizumab with chemotherapeutic and targeted agents, and the investigation of other VEGF-targeted agents. Batchelor et al.²¹⁸ reported a reduction in contrast enhancement and edema in 12 of 16 GBM patients who received cediranib (AZD2171), an orally administered pan-VEGF receptor inhibitor, with a median PFS of 3.7 months. However, a phase III randomized trial comparing the efficacy of cediranib failed to show any improvement in PFS with cediranib either as monotherapy or in combination with lomustine compared to lomustine alone in recurrent GBM.²¹⁹

VEGF Trap (afibercept), a recombinantly produced fusion protein that captures circulating VEGF and CT-322 (Angiocept, Adnexus Therapeutics, Waltham, MA), a pegylated recombinant peptide with a high affinity for VEGF was tested in the recurrent and in the newly diagnosed setting. The phase II study showed afibercept had minimal evidence of single-agent activity in unselected patients with recurrent malignant glioma.²²⁰

Cilengitide (EMD121974), an integrin inhibitor that showed promise in the recurrent GBM,^{221,222} was evaluated in two large, newly diagnosed studies. The first study, CENTRIC, a phase III trial investigated the role of cilengitide combined with the standard treatment for patients with newly diagnosed glioblastoma with MGMT promoter methylation.²²³ The study failed to show any additional benefit with cilengitide in this patient population.²²³ The other study, CORE, investigated the benefit of cilengitide in the unmethylated MGMT gene promoter in a multicenter, open-randomized phase II trial. There was suggestion of benefit of cilengitide with a median OS of 16.3 months in one of the cilengitide arms compared to the median OS of 13.4 months in the control group (HR: 0.69; $p = 0.033$). However, this drug is not being further developed.

The other antiangiogenic agents that have undergone investigation in recurrent glioblastoma include XL184, a multitargeted tyrosine kinase inhibitor that acts on the VEGFR, hepatocyte growth factor receptor (MET), and c-KIT; and enzastaurin, an inhibitor of protein kinase C-beta that targets VEGF as well as the mTOR pathway.²²⁴ The initial results of these studies have shown similar or inferior outcomes to those reported with other agents.²²⁴⁻²²⁶

Other mechanisms of cell growth that are being targeted include epigenetic modulation through histone deacetylase inhibitors, the proteasome inhibitor bortezomib, and the glutamate receptor inhibitor talampanel.²²⁷⁻²²⁹

Gene Therapy Strategies

The efficacy and safety of a locally applied adenovirus-mediated gene therapy with a prodrug-converting enzyme (herpes simplex virus thymidine kinase; sitimagene ceradenovec) followed by intravenous ganciclovir was evaluated in 250 patients with newly diagnosed resectable glioblastoma. Temozolomide was not given in all patients. There was no evidence of a survival advantage to this approach.²³⁰ Previous strategies have similarly been negative, and the challenges of adequate delivery of the virus and gene transduction into the tumor remain paramount.

Immunotherapies

Immunotherapeutic strategies targeting glioblastomas include recombinant immunotoxins, restoration of local and systemic immunosuppression, *one-size-fits-all*, and individualized autologous dendritic cell vaccines.^{89,231-233}

Issues in Study Designs for Novel Agents

Several key issues confront the incorporation of new agents in the up-front management of malignant gliomas. First, there is the issue of defining the appropriate end point. In recurrent malignant gliomas, PFS is frequently employed, but because of insufficient evidence linking this to survival in newly diagnosed malignant gliomas, survival remains the gold standard. However, there is considerable heterogeneity in survival outcomes based on clinical and possibly molecular prognostic variables. An adequate staging system has never been developed. The RTOG has analyzed an extensive database of prospectively treated patients (primarily with surgery, radiotherapy, and alkylating chemotherapy), and using a statistical method known as recursive partitioning analysis, has developed six prognostic groups, referred to as RTOG recursive partitioning analysis classes I to VI. Patients can be segmented into classes using eight variables: age, histology, Karnofsky performance score, mental status, neurologic function, symptom duration, extent of resection, and radiotherapy dose. GBM patients fall in classes III through VI, and their median survival ranges from 4.6 months to 17.9 months (Table 97.5).²³⁴

GLIOMATOSIS CEREBRI

Gliomatosis cerebri is a rare condition with diffuse involvement of multiple parts of the brain (greater than two lobes). On MRI, there is typically diffuse increased signal on T2-weighted and FLAIR images and a low or absent signal in the affected areas on T1-weighted images (Fig. 97.7). Prognostic factors include age and histology as well as Karnofsky performance score. Treatment remains undefined and includes radiation and chemotherapy.²⁹¹⁻²⁹³

OPTIC, CHIASMAL, AND HYPOTHALAMIC GLIOMAS

Clinical Considerations

Nearly all gliomas of the optic nerve and chiasm are discovered in patients younger than 20 and most occur in those under 10 years of age. Of patients with optic pathway glioma (OPG), 20% to 50% are affected by NF1.²³⁵ Patients with NF1 are more likely to have

TABLE 97.5

Radiation Therapy Oncology Group Recursive Partitioning Analysis (RPA) Classification: Survival by Class

RPA Class	Number of Patients	Median Survival (mos)	2-Year Survival (%)
I	139	58.6	76
II	34	37.4	68
III	175	17.9	35
IV	457	11.1	15
V	395	8.9	6
VI	263	4.6	4

lesions involving one or both optic nerves (anterior), whereas chiasmatic or hypothalamic (posterior) involvement is commonly seen among non-NF1 patients (sporadic). Lewis et al.²³⁵ found that gliomas along the anterior visual pathway occurred in 15% of NF1 patients and were occasionally bilateral; 67% of these were neither suspected clinically nor obvious on ophthalmologic examination. In one series, 25% involved the chiasm alone, 33% the chiasm and hypothalamus, and 42% the chiasm and optic nerves or tracts.²³⁶ Clinically, they cause loss of visual acuity (70%), strabismus and nystagmus (33%), visual field impairment (bitemporal hemianopsia, 8%), developmental delay, macrocephaly, ataxia, hemiparesis, proptosis, and precocious puberty. Funduscopy evaluation demonstrates a range of findings from normal optic discs, to venous engorgement, to disc pallor because of atrophy. Chiasmatic tumors often grow to involve the hypothalamus, causing a diencephalic syndrome characterized by emaciation (especially in children between 3 months and 2 years of age), motor overactivity, and euphoria. In general, optic nerve gliomas have a better prognosis than those involving the chiasm, and tumors confined to the anterior chiasm have a better outcome than posterior chiasmatic tumors.

The natural history of these tumors ranges from indolent growth or spontaneous regression (with NF1) to rapid progression or dissemination (with hypothalamic lesions).²³⁷⁻²³⁹ Generally, the

Figure 97.7 Two case examples of gliomatosis cerebri. Note the extensive changes visualized on fluid-attenuated inversion recovery (FLAIR) imaging, involving multiple lobes of the brain, and even an entire hemisphere.

prognosis of OPG is good with overall 5-year survival rates ranging between 70% and 90%; however, the long-term morbidity is high.²³⁹⁻²⁴² NF1 and age less than 5 years at diagnosis have better PFS.^{239,243}

Pathologic Considerations

Histopathologically, a majority of these tumors are low-grade gliomas, typically pilocytic or fibrillary astrocytomas. They range from primarily piloid and stellate astrocytes (most common), with or without oligodendroglia, through the gamut of malignant astrocytomas to GBM (rarely). Typically, optic gliomas appear as fusiform expansions of any part of the nerve. They may bridge through the optic foramen and expand as dumbbell tumors. The nerve can be infiltrated by tumor originating in the chiasm, the walls of the third ventricle, or the hypothalamus. A subset of optic pathway tumors can show the more aggressive pathologic variant of *pilocyoid astrocytoma* as compared to the better known pilocytic astrocytoma.²⁴⁴

Imaging Findings

Diagnosis is best made by MRI, which demonstrates enlargement of the affected optic pathway, often with enhancement. The T2 signal may extend posteriorly along the optic tracts as far as the visual cortex, which may represent tumor infiltration or edema. Cysts and calcification are uncommon, but the hypothalamic component can be cystic.

Treatment Decision Making

In general, children with asymptomatic lesions of the optic pathways found by MRI are not treated unless clinical or radiographic progression is documented. Tumors in children with NF1 tend to be more indolent than sporadic tumors. Only one-third to one-half of children with NF1 with asymptomatic optic pathway tumors found on screening MRIs require treatment for increasing visual symptoms.²⁴⁵ Most children with sporadic tumors undergo imaging because of symptoms and should be treated. Sporadic tumors often present with advanced findings such as hydrocephalus, decreased visual acuity, and endocrinopathies.²⁴⁶ Rarely, both sporadic and NF-associated optic pathway gliomas can regress spontaneously.²³⁸

Surgery

Surgery is only rarely indicated for optic pathway gliomas. In appropriate patients, surgery may decrease the recurrence rate and increase the time to recurrence. Patients treated with surgery, followed by radiation and chemotherapy, appear to have the highest long-term control.²⁴⁷ In patients with progressive symptoms (e.g., severe visual loss and proptosis), unilateral anterior tumors that do not involve the optic chiasm may be resected. Biopsy or subtotal resection can be performed for posterior optic pathway gliomas that involve the hypothalamus and optic tract, particularly if they are symptomatic because of local compression and mass effect. Resection of the chiasm is not indicated due to resultant bilateral blindness.

If the tumor involves the chiasm and the MRI raises suspicion of another tumor type, such as an optic nerve sheath meningioma or another parasellar mass, a confirmatory biopsy can be performed. This is rarely needed in patients with NF1, in whom there is a high index of suspicion for an optic nerve glioma. A subtotal resection is indicated if mass effect produces dysfunction of adjacent structures such as the hypothalamus or the nerve itself. Hydrocephalus can be produced by more posteriorly situated tumors and may be alleviated by debulking. If hydrocephalus persists after debulking, CSF shunting (which may need to be biventricular or

require fenestration of the septum) becomes necessary. For unknown reasons, hydrocephalus is often persistent after the CSF pathways have been cleared, requiring the insertion of a CSF diversion device even after tumor removal.

Radiation Therapy

Untreated optic gliomas, especially those involving the chiasm or extending into the hypothalamus or optic tracts, progress locally or are fatal in 75% of patients. Tenny et al.²⁴⁸ found that only 21% of patients who were followed after biopsy or exploration survived compared with 64% of those who received RT.

Routine postoperative irradiation is not indicated for gliomas confined to the optic nerve, which can be completely resected.²⁴⁹ RT can prevent tumor progression, improve disease-free survival, and stabilize or improve vision in patients with chiasmal lesions, for whom postoperative residual is the rule. Wong et al.²⁵⁰ reported that 86% of chiasmal gliomas not treated with RT progressed locally, whereas treatment failure occurred in 45% that underwent RT. Furthermore, control was achieved in 87% of the irradiated patients who received a dose of 50 to 55 Gy compared to 55% of those who received 46 Gy or less.

The prognosis for patients with optic nerve tumors may be better than for those with chiasmal-hypothalamic lesions. In a literature review, local control was found to be achieved for 154 of 189 irradiated anterior chiasmal tumors (81%), whereas 92 of 142 posterior tumors (65%) were controlled. Vision improved in 61 of 210 evaluable patients (29%) and remained stable in 118 of 210 patients (56%).²⁵¹ For chiasmal-hypothalamic tumors, RT produced radiographic shrinkage in 11 of 24 (46%) with a median PFS of 70 months compared with 30 months for patients who did not receive RT.²⁵² Age and tumor location were important prognostic factors, with younger children (less than 3 years), and children with lesions posterior to the chiasm faring less well after radiotherapy.

Three-dimensional conformal radiotherapy, IMRT, and stereotactic techniques are used to minimize the dose to adjacent structures. A report by Debus et al.²⁵³ summarized results in patients treated with fractionated stereotactic radiation therapy (FSRT) (52.2 Gy median dose at 1.8 Gy per day).²⁵³ All patients remained disease free, and no significant complications or marginal failures were seen despite highly conformal radiation fields. Because these tumors are often focal, techniques like FSRT can offer both excellent local control and decreased late effects.

Chemotherapy

In recent years, chemotherapy has played a pivotal role in the management of OPG in young children in order to spare the developing brain from the adverse effects of irradiation.^{241,254-257} This is especially important in patients with NF1 who are at significant risk of developing vasculopathy such as moyamoya syndrome and secondary malignancy after receiving radiotherapy.^{256,258} Retrospective series suggest that cognitive function is preserved better in children who receive initial chemotherapy compared with RT.^{241,259} Although the appropriate agents are still evolving, vincristine plus carboplatin remains the most common first-line regimen.¹²⁸ Gnekow et al.²⁶⁰ reported a 5-year PFS of 73% in 55 patients who were treated with this regimen. The randomized Children's Oncology Group A9952 study showed a 5-year PFS of 35% using carboplatin with vincristine and 48% using thioguanine, procarbazine, lomustine, and vincristine regimen in children with newly diagnosed progressive low-grade glioma.²⁶¹ Cisplatin-based regimens have shown responses between 50% and 60% and 5-year PFS of 50%.²⁶²⁻²⁶⁴ Other studies have shown temozolomide to be effective.²⁶⁵⁻²⁶⁷ Vinblastine has also been active in these tumors and is generally a second-line agent.^{131,132} Collectively, these data suggest that chemotherapy is helpful in delaying tumor progression in a significant portion of children.

Whether chemotherapy alone can improve vision is controversial. Most studies in the literature lack objective data on visual outcome prior to and after chemotherapy. Moreno et al.²⁶⁸ conducted a systematic review of eight reports and found only 14.4% of the children treated with chemotherapy had improvement in their vision. Due to the risk of second malignancy, alkylator-based chemotherapies are generally avoided in patients with NF1.

BRAINSTEM GLIOMAS

Clinical and Pathologic Considerations

Brainstem gliomas account for 15% of all pediatric brain tumors but are rare in adults. They can be divided into several distinct types. The diffuse intrinsic pontine gliomas (DIPG) tumors are generally high-grade astrocytomas, either anaplastic astrocytomas or GBM. Completely separate, and clinically distinct are the focal, dorsally exophytic or cervicomedullary lesions that are usually low grade with a better prognosis. Although rare, ependymomas, PNETs, and atypical teratoid-rhabdoid tumors also occur in the brainstem. Nonneoplastic processes that may be confused with a brainstem tumor include neurofibromatosis, demyelinating diseases, arteriovenous malformations, abscess, and encephalitis.

The diagnosis of a DIPG is usually based on a short history of rapidly developing neurologic findings of multiple cranial nerve palsies (most commonly VI and VII), hemiparesis, and ataxia. The initial manifestations of a brainstem glioma are unilateral palsies of cranial nerves VI and VII in approximately 90% of patients. The classic MRI finding is diffuse enlargement of the pons with poorly marginated T2 signal involving 50% or greater of the pons (Fig. 97.8).²⁶⁹ Most are nonenhancing; in children, enhancing lesions could have either a pilocytic or malignant component; in adults, enhancement is worrisome for a malignant glioma.²⁷⁰ Cervicomedullary tumors are nonenhancing, well-circumscribed lesions with an exophytic component. Tectal gliomas are

nonenhancing and enlarge the tectal plate, often expanding it into the supracerebellar cistern with associated hydrocephalus. Overall, the prognosis is poor for patients with DIPG, with few patients surviving longer than 1 year.²⁷¹

Surgery

Complete resection is almost never possible for the majority of brainstem tumors, and even a biopsy is restricted because of substantial morbidity and mortality.^{272,273} In most centers, biopsy of DIPG is not undertaken for very typical cases. Stereotactic needle biopsy can be performed if atypical imaging findings or clinical characteristics suggest another diffuse brainstem disorder. Resection has no place in the treatment of diffuse pontine gliomas in children or adults. For the rare focal astrocytic lesions of the adult or pediatric brainstem, surgery may play a larger role. Tectal gliomas have a typical imaging appearance, and biopsy is neither necessary nor safe. However, the accompanying noncommunicating hydrocephalus (from compression of the aqueduct of Sylvius) can be treated with CSF diversion, either by third ventriculocisternostomy or by ventriculoperitoneal shunting.²⁷⁴ Dorsally exophytic astrocytomas within the fourth ventricle or at the cervicomedullary junction are often partially resectable with low morbidity and excellent long-term results.²⁷⁵ These dorsally exophytic brainstem tumors arise from the substance of the pons and are very dangerous to resect in totality. Because many of them will remain indolent after partial resection, complete removal at the first surgery is likely not warranted and associated with severe neurologic deficits. Intrinsic astrocytomas or ependymomas at the cervicomedullary junction can often be completely removed through a posterior midline approach.²⁷⁶ In a retrospective review of 28 patients with juvenile pilocytic astrocytoma of the brainstem treated with resection in 25 cases and biopsy in 3,²⁷⁷ the 5- and 10-year PFS rates were 74% and 62%, respectively, after gross total resection or resection with linear enhancement and 19% and 19%, respectively, when solid residual tumor was present, suggesting that long-term survival after resection of these tumors may relate to the extent of initial excision.

Figure 97.8 Typical magnetic resonance appearance of a diffuse pontine glioma. Diffuse enlargement of the pons is visualized on the T2-weighted image (A); a small amount of hemorrhage is visualized on the noncontrast T1-weighted image (B).

Radiation Therapy

RT, the primary treatment for brainstem tumors, improves survival and can stabilize or reverse neurologic dysfunction in 75% to 90% of patients. The GTV is usually best defined using T2-weighted or FLAIR MRI. A margin of 1.0 to 1.5 cm is added to create a CTV. These lesions should be treated to 54 to 60 Gy using daily fractions of 1.8 to 2.0 Gy. In a multi-institutional survey by Freeman and Suissa,²⁷⁸ the 1-, 2-, and 5-year survival rates of children treated with conventional RT techniques were 50%, 29%, and 23%, respectively. Hyperfractionation, designed to deliver higher tumor doses, has been evaluated, without a significant survival advantage (median survival, 8.5 months versus 8.0 months for conventional versus hyperfractionated regimens).²⁷⁹ Several drugs, such as topotecan, and motexafin-gadolinium have been investigated as radiosensitizers, without clear evidence of benefit, and therefore, the role of sensitizers remains investigational.

Fewer data exist with respect to brainstem glioma in adults, but there is some evidence that these tumors may be less aggressive in adults, with OS that ranges from 45% to 66% at 2 to 5 years, perhaps because of a greater frequency of more favorable tumor types.²⁸⁰ In the series from ANOCEF, 48 adult patients with brainstem gliomas were grouped on the basis of their clinical, radiologic, and histologic features.^{270,281} Nearly half had nonenhancing, diffusely infiltrative tumors and had symptoms that were present for longer than 3 months. Eleven of these 22 patients underwent biopsy, and 9 had low-grade histology. Nearly all underwent radiotherapy and had a median survival of 7.3 years. A second group of 15 patients who had presented with rapid progression of symptoms and had contrast enhancement on MRI were described. Fourteen of these patients underwent biopsy, and anaplasia was identified in all 14 specimens. Despite radiotherapy, the median survival in this group was 11.2 months, which approximates the survival in pediatric series.

Chemotherapy

Despite numerous clinical trials, there is no clear evidence to show increased survival for patients with DIPG who receive radiation and chemotherapy as compared to radiation alone. The recent discovery that the majority of DIPGs harbor mutations of lysine 27 (K27) in the histone 3.3 gene (so called K27M mutations) may allow for the development of targeted therapies.^{282,283} Similarly, a subset of DIPGs have amplifications of receptor tyrosine kinase family members (i.e., PDGFR- α) suggesting other avenues to targeted therapy.²⁸⁴ Clinical trials using temozolomide during and after RT have not shown improvement in the outcome.²⁸⁵⁻²⁸⁷ Thus, no agent used either during or after radiation treatment has been shown to have benefit over radiation alone.

CEREBELLAR ASTROCYTOMAS

Clinical and Pathologic Considerations

Cerebellar astrocytomas, which occur most often during the first 2 decades of life, arise in the vermis or more laterally in a cerebellar hemisphere. They are usually well circumscribed and can be cystic, solid, or some combination of both. It is not uncommon to have a small tumor (mural nodule) associated with a large cystic cavity.

Histologically, most are low-grade pilocytic astrocytomas that lack anaplastic features. In a series of 451 children, cerebellar astrocytomas accounted for 25% of all posterior fossa tumors, and 89% of the 111 cerebellar astrocytomas were low grade.²⁸⁸ Approximately 75% of these tumors are located only in the cerebellum, with the remainder involving the brainstem as well. Because these tumors usually arise in the vermis or median cerebellar hemisphere, the clinical presentation is similar to that of medulloblastoma, with

truncal ataxia, headache, nausea, and vomiting. In infants, head enlargement from hydrocephalus is seen. The majority of cerebellar pilocytic astrocytomas have an oncogenic fusion gene (KIAA1549-BRAF) that results in the activation of the BRAF oncogene, and which might be a rational target for future therapy.^{289,290}

Surgery

Gross total resection is tantamount to a cure for these lesions.^{291,292} In most cases, incomplete removal should be managed by conservative monitoring because the majority of remnants will not grow, will remain low grade, and are easy to remove if they progress in the future.

Radiation Therapy

Nearly all completely resected cerebellar astrocytomas do not require RT. Even when they progress, repeat resection is reasonable if a majority of the tumor can be removed. Only in the most exceptional circumstances would RT be necessary for the treatment of child with a true cerebellar pilocytic astrocytoma.

Chemotherapy

In general, chemotherapy is not indicated. Based on the experience with optic pathway gliomas, several of which have pilocytic features, carboplatin has been used for recurrent tumors.^{293,294} There is limited experience with the use of temozolomide in this setting. High-grade gliomas that arise in the cerebellum are treated with regimens identical to their supratentorial counterparts.

GANGLIOGLIOMAS

Clinical and Pathologic Considerations

Gangliogliomas, along with pilocytic astrocytomas, pleomorphic xanthoastrocytomas, and subependymal giant cell astrocytomas, are considered *astroglial variant* forms of low-grade gliomas.²⁹⁵ They are more circumscribed than diffuse low-grade gliomas, are classified as grade 1 or 2, and do not typically invade the normal brain. Because they less frequently progress to higher grade lesions, surgery alone is often curative. Gangliogliomas are more common in children than adults. They are the most common neoplasms to cause chronic focal epileptic disorders, and they typically arise in the temporal lobe but may also occur in the brainstem, spinal cord, and diencephalon.²⁹⁶ They may include a cystic component, and the solid portion is free of normal brain parenchyma. Unlike diffuse low-grade gliomas, gangliogliomas enhance on MRI scans. They contain both glial and neuronal elements. The glial elements, which stain for glial fibrillary acidic protein, are almost always astrocytic and often pilocytic, but fibrillary astrocytes are also common. The glial elements dictate whether the lesion is grade 1 or 2. The neurons in the tumor are neoplastic and are characteristically large and relatively mature (i.e., they contain ganglion cells). The presence of neoplastic neurons may be confirmed by immunostaining for neuron-specific enolase and synaptophysin. Grade 2 lesions have rarely been observed to progress to a higher grade.^{297,298}

Surgery

Surgical resection is directed at removal of the contrast-enhancing portion of the tumor. Nevertheless, although lesions located within eloquent brain regions are resectable, they may present significant surgical challenges because the boundary between tumor and functional brain may be difficult to define, even with the aid of

modern surgical adjuncts (e.g., operating microscope, computer-assisted navigation, functional brain mapping). Although no phase 3 prospective studies have documented the superiority of surgery over other approaches (e.g., radiotherapy), retrospective studies have indicated that complete resection is associated with a very favorable long-term survival.^{297–299} Resection of gangliogliomas also can result in seizure control.³⁰⁰ Grade 2 gangliogliomas may recur, and some patients do poorly. The degree of anaplasia determines the prognosis.

Radiation Therapy

Because resection has the potential to cure most of these lesions, radiotherapy is generally reserved for subtotally resected cases or for recurrences.³⁰¹ It is also used for lesions in complex locations where further resection may result in significant morbidity. To determine the optimal strategy for gangliogliomas, Rades et al.³⁰² conducted a literature-based retrospective study of more than 400 patients treated for ganglioglioma. They examined four different treatment strategies (GTR or subtotal resection [STR] with or without radiotherapy) in 402 patients identified from reports published between 1978 and 2007. Surgery was found to be the mainstay of therapy, with 209 patients undergoing GTR and 193 undergoing STR. Adjuvant radiotherapy was used in 101 patients (20 following GTR and 81 following STR). Patients who underwent GTR had higher rates of OS and PFS than individuals who underwent STR. For patients undergoing GTR, the 10-year rates of local control and OS were 89% and 95%, respectively, better than the 52% and 62% observed for patients undergoing STR. This indirectly indicates that GTR is the most effective treatment strategy for gangliogliomas. For patients undergoing STR followed by postoperative radiotherapy, the 10-year rate of local control was 62%, better than the 52% for patients undergoing STR without postoperative radiotherapy; although the 10-year survival also improved from 65% to 74% with the use of postoperative radiotherapy in patients with subtotally resected tumors, this did not reach statistical significance. For the 40 patients undergoing STR for whom radiotherapy details were known, local recurrence was observed in 6 of 22 (27%) receiving 54 Gy, compared to 7 of 18 (39%) receiving greater than 54 Gy, implying no specific dose–response relationship.

Chemotherapy

Chemotherapy for gangliogliomas is generally reserved for young children who have undergone subtotal resection and who demonstrate disease progression. In older patients, it is typically used as salvage therapy to treat recurrent tumors after the failure of surgery and RT. In general, for astroglial variants such as gangliogliomas, no optimal chemotherapeutic regimens have been defined, and most researchers consider disease stabilization (rather than a complete tumor response) to be a successful outcome.

EPENDYMOMA

Clinical and Pathologic Features

Ependymomas were originally thought to arise from the ependymal cells lining the cerebral ventricles and the vestigial central canal of the spinal cord as they resemble this tissue under the microscope, although more recently it has been accepted that they arise from radial glial cells, a type of CNS stem cell.^{303,304} Ependymomas can arise throughout the nervous system, and are usually divided into those from the supratentorial, infratentorial (posterior fossa), and spinal regions. Those in the spinal region are broken down into the intramedullary lesions and the myxopapillary ep-

endymomas of the conus medullaris and cauda equine. Although these tumors look very similar under the microscope (histology), they are demographically, clinically, transcriptionally, and genetically distinct and should not be regarded as the same entity.^{304,305} More recently, it has been shown that there are two clear groups of posterior fossa ependymoma, the posterior fossa type A (PFA) tumors and the posterior fossa type B (PFB) tumors.^{306,307} PFA tumors occur in young children (infants), are more likely to be lateral (CP angle), and have a terrible prognosis. PFB tumors are diagnosed in older children, found in the midline, and have a much better prognosis than PFA tumors. Figure 97.9 shows the typical magnetic resonance appearance of a midline, the posterior fossa ependymoma. In the past, much was made of the pattern of anaplasia in ependymoma histology, with the diagnosis of anaplasia taking an ependymoma from WHO grade II to WHO grade III. More recently, a number of luminaries in the field of neuro-oncology have shown that the intra- and interobserver reliability in the diagnosis of anaplasia in ependymoma is very high and its clinical utility is, therefore, very limited.³⁰⁸

Clinical presentation depends on location. Tumors with ventricular involvement often cause increased ICP and hydrocephalus by obstruction of CSF pathways. Headaches, nausea and vomiting, papilledema, ataxia, and vertigo are frequent. Focal neurologic signs and symptoms are seen with supratentorial ependymomas that involve the parenchyma. The presence of calcification in a fourth ventricular tumor on CT is very suggestive of an ependymoma. Supratentorial parenchymal tumors cannot be readily distinguished from other gliomas by imaging. Posterior fossa tumors in infants that protrude below the foramen magnum are more likely to be ependymomas, as are posterior fossa tumors that cause a head tilt (due to compression of the XIth cranial nerve as it crosses the foramen magnum).

Metastatic dissemination of ependymomas occurs in the leptomeningeal space in a similar pattern to that seen in medulloblastomas, albeit at a much lower rate (<5% of patients at presentation).

Figure 97.9 Typical magnetic resonance appearance of a posterior fossa ependymoma. The tumor arises from the floor of the fourth ventricle and rapidly expands to occupy it, and compresses the pons/medulla ventrally and the vermis of the cerebellum dorsally. The enhancement is typically heterogeneous.

This low rate of observable dissemination at diagnosis has led to the almost universal use of local, rather than craniospinal radiotherapy at diagnosis for patients with ependymoma.

Subependymomas are benign tumors with an admixture of fibrillary subependymal astrocytes. They are distinct from subependymal giant cell astrocytomas, which occur in the lateral ventricles in tuberous sclerosis. Subependymomas occur most often in the floor or walls of the fourth ventricle in older men. Most are asymptomatic and slow growing, and treatment is rarely needed except for hydrocephalus or demonstrated growth. They are often incidentally found at autopsy.

Surgery

Several retrospective studies support the relationship between post-surgical residual ependymoma and a poorer outcome, and therefore, maximal safe resection is the goal.³⁰⁹⁻³¹¹ These tumors may also extend through the foramen of Luschka, entangling the cranial nerves in the basal cisterns, which also precludes a complete resection. The less common supratentorial tumors are removed as with any glioma. Avoidance of bleeding into the ventricular system is important to prevent postoperative hydrocephalus.

Radiation Therapy

Postoperative irradiation improves the recurrence-free survival of patients with intracranial ependymomas, and 5-year survival rates with doses of 45 Gy or more range from 40% to 87%.¹⁵² Therapeutic utility of local radiation is established for ependymoma patients, even in infants.³¹² Because local failure usually dominates the recurrence patterns, low-grade supratentorial ependymomas are typically treated using partial brain fields with a dose of approximately 54 Gy. Low-grade infratentorial ependymomas are also treated using limited fields. The best survival results in retrospective series have been shown for patients who undergo gross total resection followed by radiotherapy.^{374,375} For most patients, a more usual volume consists of the tumor bed and any residual disease plus an anatomically defined margin of 1 to 1.5 cm to create a CTV. Larger margins may be required in areas of infiltration, and special attention must be paid to areas of spread along the cervical spine because 10% to 30% of fourth ventricular tumors extend down through the foramen magnum to the upper cervical spine.^{313,314} Patients with neuraxis spread (positive MRI or positive CSF cytology) should receive craniospinal irradiation (40 to 45 Gy) with boosts to the areas of gross disease and to the primary tumor to total doses of 50 to 54 Gy.

Chemotherapy

There is no evidence that any type of chemotherapy improves survival in children with ependymomas.³¹⁵ Single-agent carboplatin, cisplatin, and etoposide, as well as multiagent chemotherapy, have been evaluated in small series and, to date, few if any drugs have shown even modest consistent activity in ependymomas.³⁷⁷⁻³⁸⁰

Although a complete removal of the ependymoma has a positive impact on the outcome, a complete resection is achieved in only 40% to 60% of cases.^{316,317} Therefore, responsiveness to preirradiation chemotherapy was investigated in a Children's Oncology Group (COG) study where an objective response rate of 58% to preirradiation chemotherapy, consisting of cisplatin, etoposide, cyclophosphamide, and vincristine, in children with incompletely resected ependymoma was seen.³⁸³ The 3-year event-free survival in patients assigned to preirradiation chemotherapy because of incomplete resection was 58% and was comparable to those who had a complete resection and were assigned to irradiation alone. However, 15% of the children who received preirradiation

chemotherapy experienced progression prior to RT. Therefore, a subsequent COG study was carried out that aimed to decrease the progression rate prior to radiotherapy by employing a strategy of *second-look* surgery following the preirradiation chemotherapy in children with residual disease. In this study, patients who had a complete resection of a differentiated supratentorial ependymoma were observed without any further therapy. The results of this study are pending. The recently opened randomized COG study is exploring whether maintenance chemotherapy following radiation will improve event-free survival and OS.

The primary application of chemotherapy, therefore, is investigational, and it is within the realm of neoadjuvant therapy to improve resectability, as primary adjuvant therapy in young children to delay radiotherapy and as possible salvage. In the Baby Pediatric Oncology Group study, a 48% response rate was reported to two cycles of vincristine and cyclophosphamide in 25 children younger than 3 years of age with ependymoma, allowing a delay in radiotherapy by 1 year without impacting the outcome.³¹⁸ However, the use of chemotherapy to delay radiotherapy has to be approached cautiously. In a trial of 34 patients with anaplastic ependymoma, 25 patients relapsed relatively rapidly and only 3 patients who did not receive radiotherapy survived.³¹⁹

Despite multimodal therapy, 50% of the patients with ependymoma will experience a relapse. The majority of the recurrences are local, and prognosis is poor after relapse.³²⁰ Resection, reirradiation, and chemotherapy are the common treatment modalities for relapsed ependymoma. Various antineoplastic agents such as etoposide, cyclophosphamide, temozolomide, cisplatin, and irinotecan have failed to improve survival in these patients.^{287,321,322} Novel therapies to target molecular pathways are currently under investigation.

MENINGIOMAS

Clinical and Pathologic Considerations

Meningiomas are believed to arise from epithelioid cells on the outer surface of arachnoid villi in the meninges, also known as *arachnoidal cap cells*. The most frequent locations are along the sagittal sinus and over the cerebral convexity (Fig. 97.10). Meningiomas are extra-axial, intracranial, and sometimes intradural—extramedullary spinal tumors that produce symptoms and signs through the compression of adjacent brain tissue and cranial nerves. They often also produce hyperostosis; bony invasion does not indicate malignancy. They rarely metastasize except after multiple resections when they may spread to the lung, where growth is typically slow.

The WHO categorizes this tumor into three grades.⁴ Benign (WHO grade I) meningiomas comprise about 70% to 85% of intracranial primaries. With appropriate treatment, approximately 80% of WHO grade I meningiomas remain progression free at 10 or more years.³²³ Atypical (WHO grade II) meningiomas account for 15% to 25% of patients. These have greater proliferative capacity, and a seven- to eightfold increased recurrence risk within 5 years.³²⁴ Only about 35% of patients with WHO grade II meningiomas remain disease free at 10 years. About 1% to 3% of intracranial meningiomas are anaplastic (WHO grade III). These aggressive malignant tumors have a median OS of less than 2 years.³²⁵

Surgery

The goal is total resection, including a dural margin, because this is often curative for WHO grade I tumors. The risks of resection must be balanced against the advantages of less-aggressive removal because these tumors are typically slow growing, and the patients are sometimes elderly. Observation is appropriate for some, especially small tumors that are incidentally discovered. In a series of 603 patients who had asymptomatic meningiomas that were

Figure 97.10 These five images show various appearances of meningioma. The most common location is parasagittal (**A**). Some meningiomas remain small (**B**), whereas others achieve a massive size with midline shift (**C**). An optic nerve meningioma (*arrow*) is illustrated in (**D**), whereas spinal locations are also possible (**E**).

treated conservatively, Yano and Kuratsu³²⁵ found that approximately 63% exhibited no growth, and only 6% ultimately experienced symptoms. However, a subsequent study of 244 patients with 273 meningiomas indicated that T2 hyperintensity, lack of calcification, size greater than 25 mm, and edema are associated with a shorter time to progression, and those tumors should be followed more closely.³²⁶

Preoperative Planning

Meningioma surgery requires a detailed knowledge of surgical anatomy. A preoperative angiogram to assess vascularity and to identify or embolize surgically inaccessible feeding arteries is sometimes indicated. Typically, embolization is done within 24 to 96 hours of surgery so that collateral vascular supply to the tumor does not develop. Normally, only the vascular supply from the external carotid artery can be embolized safely. In meningiomas that receive more than 50% of their blood supply from this artery, Kai et al.³²⁷ found the optimum interval between embolization and surgery to be 7 to 9 days, which allowed the greatest degree of tumor softening. For convexity and parafalcine tumors, preoperative imaging may be performed to allow for the use of a neuronavigation system to aid in planning the scalp incision and bony opening.

Simpson Grades of Resection

The completeness of surgical removal is a crucial prognostic factor, and historically, the definitions provided by Donald Simpson have served as a useful guideline.³²⁸ By following 470 patients during a 26-year span, he described five *grades of resection* based on recurrence. A grade 5 resection refers to a biopsy only and is

associated with near-universal progression. A partial tumor resection is labeled Simpson grade 4 and is associated with a recurrence rate of 44%. A Simpson grade 3 resection refers to gross total resection of the tumor, without addressing hyperostotic bone or dural attachments, and is associated with a 29% rate of relapse. A Simpson grade 2 resection includes gross tumor removal, and the dural attachments are either removed or coagulated and the relapse rate drops to 19%; and finally, when hyperostotic bone is also removed for a Simpson grade 1 resection, the relapse rate is 9%.

This definition has subsequently been expanded to include a category referred to as grade 0 resection. Kinjo et al.³²⁹ reported on 37 convexity meningioma patients who underwent gross total resection of the tumor, any hyperostotic bone, and all involved dura with a 2-cm dural margin, and observed no local recurrences, with over half of the patients followed beyond 5 years; this is now widely termed the grade 0 resection. However, apart from convexity primaries, resection to this extent is usually not feasible in other locations.

The likelihood of gross total resection varies considerably among primary sites, with convexity lesions most amenable to complete resection and skull-base lesions least likely to be completely resected. In most surgical series, at least a third of meningiomas reported are not fully resectable.³³⁰

Recurrence Following Resection

Gross total resection for benign meningiomas remains the preferred treatment and is generally considered definitive. Three large series with extended follow-up are available (Table 97.6). These have remarkably similar rates of local recurrence after gross-total

TABLE 97.6

Recurrence After Gross Total Resection Alone of Meningioma

Study (Ref.)	Number of Patients	Local Recurrence Rate (%)		
		5-Y	10-Y	15-Y
Mirimanoff et al. ³³⁰	145	7	20	32
Stafford et al. ³³³	465	12	25	—
Condra et al. ³³¹	175	7	20	24
Total	785	7–12	20–25	24–32

resection: 7% to 12% at 5 years, 20% to 25% at 10 years, and 24% to 32% at 15 years.^{330–333}

As expected, recurrence following subtotal resection is more frequent. Outcomes following subtotal resection alone, from four single institutions with up to 20 years of follow-up, are available. Collectively, the rates of progression following subtotal resection at 5, 10, and 15 years are 37% to 47%, 55% to 63%, and 74%, respectively.^{330–333}

Radiation Therapy

Given the long natural history of meningiomas and the relatively late recurrences, radiotherapy has not been routinely adopted in the adjuvant context. Further, there is a paucity of clinical trials on which to base recommendations. However, in almost every retrospective series, cohort comparisons suggest that radiotherapy leads to a decrease in recurrence, and some suggest possible survival improvement.

The need for adjunctive RT is determined by the extent of resection, tumor grade, patient age, and performance status. The risk of recurrence following resection has been outlined previously. In general, it is common practice to not use adjunctive radiotherapy after Simpson grade 0, 1, 2, and sometimes 3 resection for grade 1 meningioma.

The risk of relapse after subtotal resection is high.^{330–333} Several reports, now numbering over 60, suggest that postoperative irradiation prolongs the time to recurrence. As an illustrative series, Goldsmith et al.³³⁴ reported the results for 140 patients (117 with benign and 23 with malignant tumors) treated with subtotal resection and postoperative irradiation. For patients with benign meningiomas, the 5- and 10-year PFS rates were 89% and 77%, respectively. Patients who received at least 52 Gy had a 20-year PFS rate of greater than 90%. The 5-year PFS of patients treated after 1980 was 98%, compared to 77% for those treated prior to 1980. This improvement was attributed to the availability of cross-sectional imaging for tumor localization and 3-D treatment planning. The size of the residual tumor as well as grade can affect the outcome after radiotherapy. Connell et al.³³⁵ showed that for tumors 5 cm or larger, the 5-year PFS rate was 40%, significantly lower than the 93% observed for smaller tumors. Among patients irradiated for unresectable tumors and in those with residual disease, the volume of visible tumor on imaging studies rarely decreases by more than 15% and often only after many years.

Radiation Therapy for Anaplastic and Malignant Meningioma

Atypical and malignant meningiomas behave more aggressively. Goldsmith et al.³³⁴ reported a 5-year PFS of 48% for 23 patients treated by subtotal resection and irradiation. The recurrence rate

among 53 patients with malignant meningiomas collected from six series in the literature was 49%. The recurrence rates were 33% for patients treated with complete resection alone, 12% for those undergoing complete resection and RT, 55% for patients treated by subtotal resection and irradiation, and 100% for those treated by subtotal resection alone.³³⁶ However, other studies in the literature do not categorically support a reduction in local failure with the use of adjuvant radiotherapy for gross totally resected G2 meningioma, and given that the patients referred for this therapy are often selected because of a variety of one or more negative prognostic factors, compared to the cohort of patients that is observed, conclusions regarding the precise value of postoperative radiotherapy for G2 totally resected meningioma remain nonunifrom. However, most data suggest that all patients with malignant G3 meningiomas, regardless of the extent of resection, and those with subtotally resected G2 meningioma should be offered postoperative irradiation.^{337,338}

Primary Radiotherapy

RT has been used as primary treatment following biopsy or on the basis of imaging findings alone in several small series. An early report from the Royal Marsden Hospital found 47% disease-free survivorship at 15 years in 32 patients.³³⁹ In a recent series, Debus et al.³⁴⁰ noted no recurrences in patients treated by radiotherapy alone (n = 59).

Optic nerve sheath meningiomas are rare tumors, generally not resected, but treated with radiotherapy as primary management. Narayan et al.³⁴¹ found no radiographic progression in any of 14 optic nerve sheath meningioma patients treated with conformal radiotherapy, with more than 5 years of median follow-up. In a study by Turbin et al.,³⁴² RT alone provided more favorable outcome than observation or surgery alone.

Radiation Dose and Volume Considerations

For benign meningiomas, the planning target volume consists of the residual tumor with a modest margin of normal tissue, defined by MRI and modified by the neurosurgeon's description of the site of residual disease. Extensive tumors of the base of the skull and malignant meningiomas require more generous margins, with special attention to dural extensions toward and through the skull foramina. The preoperative tumor volume is used for planning for completely resected malignant lesions. A dose of 54 Gy in daily fractions of 1.8 Gy is recommended for benign meningiomas, and 60 Gy or higher for atypical and malignant tumors. Complex 3D-CRT treatment planning and delivery techniques and IMRT are used to restrict the dose to normal tissues.

Radiosurgery

Numerous retrospective reports describe the use of radiosurgery for small meningiomas, either residual or progressive after resection, or untreated, skull-base lesions. Local control rates range from 75% to 100% at 5 to 10 years. Complications such as cranial neuropathies, transient neurologic deficits, radiation necrosis, and significant edema have been reported in 6% to 42% of patients treated with radiosurgery.^{343,344} Complications are more frequent in patients with large or deep-seated tumors and in those treated with high single doses.^{345,346} Fractionated radiotherapy may be preferable for larger tumors.

Chemotherapy

There is currently no defined role for chemotherapy for newly diagnosed or nonirradiated meningiomas. Chemotherapy is generally reserved for recurrent meningioma not amenable to further surgery or radiotherapy. Responses are anecdotal, with no drug or a combination yielding consistent responses. Because many

meningiomas express estrogen and progesterone receptors, there have been unsuccessful attempts to use agents such as tamoxifen or antiprogesterones.^{347,348} Preliminary data suggest that hydroxyurea^{349,350} or interferon-alpha-2B (IFN α -2B)³⁵¹ may have activity; however, assessment of efficacy is limited by small numbers of patients treated. Targeted agents such as STI-571 (imatinib), angiogenesis inhibitors such as sunitinib, vatalanib, and EGFR inhibitors have been evaluated, without clear efficacy.^{352–355}

PRIMITIVE NEUROECTODERMAL OR EMBRYONAL CENTRAL NERVOUS SYSTEM NEOPLASMS

These tumors of putative embryonal origin predominantly arise in children and include supratentorial PNETs, pineoblastomas, medulloblastomas, ependymoblastomas, and atypical teratoid or rhabdoid tumors. They are characterized by sheets of small, round, blue cells with scant cytoplasm. Historically, small round cell tumors arising in the posterior fossa were called *medulloblastomas*. Given the cytologic similarity between all these tumors regardless of location, it was suggested in the 1980s that they all be designated as PNETs. Although still controversial, the current WHO classification retains medulloblastoma as a distinct type of PNET within the larger group of *embryonal* tumors that includes medulloepitheliomas, neuroblastomas, and ependymoblastomas. Pineoblastomas also retain a separate position within the category of pineal parenchymal tumors. Regardless of formal classification, these tumors are viewed as developmentally aberrant early neural (glial or neuronal or both) progenitor or stem cell neoplasms.

Embryonal tumors with abundant neuropil and true rosettes (ETANTR) are a recently identified variant of PNET and, histologically, have features of ependymoblastomas and neuroblastomas, demonstrating areas of fine fibrillary neuropils intermingled with ependymoblastic rosettes and zones of undifferentiated neuroepithelial cells. ETANTRs are distinguished pathologically from other embryonal tumors by the striking abundance of neuropils.³⁵⁶

Recent data have shown quite clearly that medulloblastomas, supratentorial PNETs, atypical teratoid rhabdoid tumor (ATRTs), ETANTRs, and pineoblastomas probably all represent very distinct entities, each with their own biologies and indeed, in many cases, their own biologically important subgroups.^{357–363}

Medulloblastoma

Epidemiology

Medulloblastomas comprise 15% to 30% of CNS tumors in children and an estimated 350 to 400 cases are diagnosed in the United States annually.⁴ There is a 1.5:1 male-to-female predominance, and 70% are diagnosed by age 20 years. Medulloblastomas become progressively more rare with increasing age, with few cases found in those older than 50 years.^{364,365} Gorlin and Turcot syndromes have increased rates of medulloblastoma, but account for only 1% to 2% of medulloblastomas.^{29,366}

Pathology

Classically, medulloblastomas have Homer-Wright (neuroblastic) rosettes, although these are found in less than 40% of the cases.³⁶⁷ Mitoses are frequent, representing a high proliferative index. Immunohistochemical analyses are positive for synaptophysin, which is most prominent in nodules and within the centers of the Homer-Wright rosettes, correlating with a presumed neuronal progenitor origin.³⁶⁸ According to the last round of WHO classification, medulloblastomas are histologically grade IV and classified into five variants: classical, desmoplastic/nodular, medulloblastoma with extensive nodularity, anaplastic, and large cell.⁴ The desmoplastic subtype has collagen bundles interspersed with the densely packed

undifferentiated cells of the classic subtype as well as nodular, reticulin-free “pale islands,” or follicles.³⁶⁹ Medulloblastomas with extensive nodularity are similar to the desmoplastic variant except that the reticulin-free zones are large and rich in neuropil-like tissue. Anaplastic medulloblastomas are relatively rare, accounting for approximately 4% of cases, and have marked nuclear pleomorphism, nuclear moulding, cell-cell wrapping, and high mitotic activity, with a high degree of atypia.

More recently, it has become agreed upon and apparent that, in fact, medulloblastomas are comprised of at least four different molecular subgroups (Wnt, Shh, Group 3, and Group 4), each with their own demographic, clinical, epidemiologic, transcriptional, genetic, and epigenetic features.^{359–361,363,370} Because targeted therapies are likely to only be effective within a single subgroup, the next group of clinical trials will likely be subgroup specific.

Radiographic and Clinical Features

Childhood medulloblastomas typically arise within the vermis, expanding into the fourth ventricle. In older patients, tumors in the lateral cerebellar hemispheres are more common (greater than 50% in adults compared with 10% in children).³⁶⁴

Clinical signs and symptoms depend on both age, with infants having less specific symptoms, and the anatomic location within posterior fossa. Midline tumors usually present with symptoms of increased intracranial pressure, including nocturnal or morning headaches, nausea and vomiting, irritability, and lethargy—manifestations of progressive hydrocephalus from fourth ventricle compression. Truncal ataxia may be present because of involvement of the vermis, and sixth nerve palsies are the most common nerve deficit. In younger children, a bulging of open fontanelles may occur. Tumors of a lateral origin more frequently have ataxia and unilateral dysmetria. On CT, medulloblastomas are classically discrete vermian masses that are hyperattenuated compared with the adjacent brain and enhance avidly. Imaging variance is common, with frequent cyst formation and calcification (59% and 22% of cases, respectively).³⁷¹ MRI is the gold standard. Medulloblastomas are typically iso- to hypointense on T1-weighted images, of variable signal intensity on T2-weighted images, and enhance heterogeneously.³⁷² MRI provides improved evaluation of foraminal extent beyond the fourth ventricle, invasion of the brainstem, and subarachnoid metastases. Diffusion-weighted images exhibit restriction, allowing PNETs to be distinguished from ependymomas.^{373,374}

Staging and Risk Groups

A modified version of the Chang staging system is currently used.³⁷⁵ T stage has been made less relevant than the extent of residual disease due to advances in neurosurgical techniques. M stage remains crucial. M0 represents no tumor dissemination, whereas M1 represents tumor cells in the CSF. M2 represents presence of gross tumor nodules in the intracranial, subarachnoid, or ventricular space, and M3 represents gross tumor nodules in the spinal subarachnoid space. M4 represents systemic metastasis.

Clinical staging requires the assessment of tumor dissemination and includes CSF cytologic examination. This is frequently not performed prior to surgery because of concern for cerebellar herniation from increased pressure within the posterior fossa. Ventricular fluid is not as sensitive as lumbar fluid in detecting dissemination within the neuraxis.³⁷⁶ Negative CSF cytology does not preclude more advanced leptomeningeal disease.³⁷⁷ An MRI examination of the spine has supplanted conventional myelography. CSF dissemination is identified on MRI scans as diffuse enhancement of the thecal sac, nodular enhancement of the spinal cord or nerve roots, or nerve root clumping, predominantly seen along the posterior aspect of the spinal cord based on CSF circulatory patterns.³⁷² Spine MRI is ideally performed prior to surgery if a medulloblastoma is suspected and the patient is stable; otherwise, 10 to 14 days should elapse after surgery to avoid a potential false

positive interpretation from surgical cellular debris and blood products.³⁷⁸ Metastases outside the CNS are less common and occur in less than 5% of patients and correlate with advanced disease within the neuraxis. Eighty percent of systemic metastases are osseous. A bone scan, chest x-ray, and bilateral marrow biopsies should be routinely performed for M2 and M3 stages.

Patients with medulloblastomas are currently classified as *average* or *high risk* based on age, M stage, extent of residual disease, and pathology. Average-risk patients have M0 stage arising within the posterior fossa, are more than 3 years old, and have less than 1.5-cm tumor residual. Due to the poor prognosis, all patients with anaplastic medulloblastoma are classified as high risk.^{379,380} Patients less than 3 years old have particularly poor prognoses. This may represent the presence of more primitive, aggressive tumors, but could also be due to the higher likelihood metastatic disease, subtotal resection, and reduced dose or withholding of radiotherapy. Between 20% and 30% of patients present with neuraxial dissemination, most commonly along the spinal cord. The presence of metastatic disease is prognostically significant, with 5-year PFS rates of 70% for M0 disease, to 57% for M1, and to 40% for M2 or higher in CCG-921.³⁸¹ The disease-free survival of high-risk patients treated with craniospinal irradiation (CSI) with or without chemotherapy is 25% to 30%.⁴⁰¹ Historically, average-risk patients have had a 5-year disease-free survival of 66% to 70%, which has increased to 70% to 80% in recent reports.^{381,382}

Surgery

In one study, 3-year survival was reduced by 60% in patients who had an incomplete resection of their primary tumor.³⁸³ Although hydrocephalus associated with medulloblastoma obstructing the fourth ventricle can be relieved with a ventriculostomy, ICP may be controlled with corticosteroids, and in most patients, aggressive tumor resection is sufficient to relieve hydrocephalus. Following surgery, gradual weaning of the ventriculostomy is attempted, with internalization 7 or more days after surgery if clamping is untenable. Postoperative shunting for hydrocephalus is necessary in approximately 35% to 40% of patients because of scarring and decreased capacity to resorb CSF.³⁸⁴ Patients who require long-term shunting are younger and have larger ventricles and a more extensive tumor at presentation.³⁸⁵ Concern has existed that a ventriculoperitoneal shunting (VP) shunt may cause peritoneal seeding, but this has not been upheld.³⁸⁶

With advances in neurosurgical technique, the number of patients not undergoing a gross total or near-total resection is dwindling. MRI should be performed to evaluate the extent of residual disease within 48 to 72 hours following surgery to prevent postsurgical changes from influencing interpretation. Patients with either gross total resection or subtotal resection have better 5-year OS and posterior fossa local control rates than patients who undergo biopsy alone. Although retrospective data infer that a total resection is prognostically favorable, the majority of trials have found that patients who undergo substantial subtotal resection with minimal residual disease treated with both chemotherapy and radiation do just as well as those who undergo total resection.³⁸⁷ This justifies opting for a near-total resection, particularly when there is invasion of the floor of the fourth ventricle or envelopment of cranial nerves or the posterior inferior cerebellar artery. It is clear, however, that the extent of resection does not impact survival in patients with disseminated disease.³⁸⁷

The value of an aggressive resection must be balanced against surgical complications, interchangeably referred to as *posterior fossa syndrome* or *cerebellar mutism syndrome*. These conditions consist of diminished speech and can include emotional lability, hypotonia, long-tract signs, bulbar dysfunction, decreased respiratory drive, urinary retention, and ataxia. These changes can be seen in up to 25% of patients who have undergone a resection of a midline posterior fossa tumor.³⁸⁸ Although thought to be a temporary, a significant number have persistent deficits.

Radiation Therapy

The aims of radiotherapy are to treat residual posterior fossa disease (or gross deposits of disease anywhere in the craniospinal axis) and also to treat microscopic disease in the craniospinal axis. Historically, CSI has been delivered to 36 Gy with a posterior fossa boost of 54 Gy using conventional fractionation of 1.8 Gy per day.³⁸⁹ Radiation is typically initially withheld in patients younger than 3 years of age because of the higher risk of neurocognitive damage. Supratentorial PNETs and other embryonal tumors have been treated with the same CSI regimen, with a boost to the tumor bed and residual disease. Supratentorial PNETs treated with an appropriate dose and volume of radiotherapy were found to have a 49% PFS at 3 years compared with 7% with major violations of radiotherapy.³⁹⁰

Various alterations to the radiotherapy regimen have been made endeavoring to limit late toxicities. Hyperfractionation has been examined, with one study showing no improvement in survival and an excess of failures outside the primary site, although this was likely attributable to a reduced craniospinal dose of 30 Gy.³⁹¹ A recent trial showed that with a reduction in craniospinal dose, adequate disease-free survival with possible preservation of intellectual function is possible.³⁹² IMRT has been used to provide radiation to the posterior fossa, with a 32% reduction in craniospinal dose, adequate disease-free survival with possible preservation of intellectual function is possible. Reduction in dose to the cochlear apparatus, reducing the risk of grade 3 or 4 hearing loss from 64% to 13%.⁷⁰ Improved imaging methods have allowed for more precise delineation of the tumor within the posterior fossa, providing the possibility of avoiding treatment to the entire posterior fossa with the boost dose. Although standard practice has been to boost the entire posterior fossa, retrospective data have shown isolated recurrences outside the tumor bed to be rare.^{393,394} Encompassing the tumor bed and a 2-cm margin only for the boost led to less than 5% isolated posterior fossa recurrences.³⁹⁵

A combined CCG/Pediatric Oncology Group trial compared standard and reduced dose CSI (36 versus 23.4 Gy) with a posterior fossa boost to 54 Gy in average-risk patients. All patients received concurrent vincristine during radiation with no adjuvant chemotherapy. Patients who received the lower dose had a higher rate of early relapse, lower 5-year event-free survival (67% versus 52%), and lower OS.³⁹⁶ A comparison of CSI doses of 35 versus 25 Gy in the International Society of Paediatric Oncology (SIOP) II yielded similar results.³⁹⁷ Further dose reduction is being evaluated in ongoing prospective trials.

Strong advocates for proton therapy have emerged as a result of the sharply diminished exit dose from spinal irradiation and the more conformal treatment of the posterior fossa. A dosimetric analysis that compared photons to protons has demonstrated a decrease in the dose to 50% of the heart volume from 72.2% to 0.5%, and the dose to the cochlea was reduced from 101.2% of the prescribed posterior fossa boost dose to 2.4%.³⁹⁸ Proton-based radiotherapy also demonstrated a decreased radiation dose to normal tissues compared with IMRT. Overall, a reduction in second malignancies is also anticipated and modeled based on available data, although one controversial report contends that the older generation of proton-beam machines might pose a greater risk of second malignancies because of a higher rate of neutron production and contamination, which is more carcinogenic.⁷⁴

Chemotherapy

Chemotherapy has been used in medulloblastomas with the dual goals of reducing the radiation dose while maintaining optimal disease-free survival rates in average-risk patients and improving disease-free survival in high-risk patients. Tait et al.³⁹⁹ in SIOP I compared radiotherapy alone versus radiotherapy with concurrent vincristine followed by maintenance vincristine and CCNU. Overall, there was no survival benefit from chemotherapy, but an

unprespecified post hoc subgroup analysis identified subgroups that appeared to benefit from chemotherapy, including T3 or T4 disease, and subtotal resection. Similar results were seen in a CCG study.³⁸² The 5-year disease-free survival rates in the CCG and SIOP studies were 59% and 55%, respectively, for RT plus chemotherapy, and 50% and 43% for RT alone. Based on these results, the routine use of chemotherapy for “high”-risk medulloblastomas has become standard.

For “standard”-risk patients, chemotherapy has been postulated to lead to a reduction in the CSI dose necessary to control microscopic disease. A phase II trial of CCNU, vincristine, and cisplatin for eight cycles following the reduced CSI prescription of 23.4 Gy had a PFS rate of 86% and 79% at 3 and 5 years, respectively.³⁹⁶ This was superior to historical controls, and CSI to 23.4 Gy with chemotherapy was adopted as the standard of care and reference dose for further trials.

The most recent COG trial for average-risk patients compared cisplatin and vincristine with either CCNU or cyclophosphamide and 23.4 Gy CSI. No differences in outcome were noted, with a 5-year event-free survival and OS rates of 81% and 86%, respectively. The overall outcomes indirectly validated the use of reduced-dose CSI in conjunction with chemotherapy. The ongoing COG trial for average-risk patients is investigating a CSI dose of 18 Gy in patients between 3 to 7 years of age. The 2 × 2 randomization also compares boosting the entire posterior fossa versus a local boost.

Current approaches for high-risk medulloblastomas focus on chemotherapy dose intensification. Vincristine, CCNU, and prednisone had a 63% 5-year PFS rate, better than an 8-in-1 chemotherapy regimen. High-dose cyclophosphamide with autologous stem cell rescue is feasible and provided a 5-year event-free survival of 70% in patients with high-risk disease.⁴⁰⁰ In a pilot study involving 57 children, the COG incorporated carboplatin as a radiosensitizer with CSI to 36 Gy and a posterior fossa boost followed by six cycles of maintenance cyclophosphamide, vincristine, and cisplatin. Four-year OS and PFS rates were 81% and 66%, respectively, with an inferior outcome in patients with anaplastic medulloblastoma.

Because the risk of cognitive deficits increases with decreasing patient age, extensive effort has been made to develop regimens that can delay or potentially eliminate the need for radiation in patients younger than 3 years of age. The avoidance of radiation has proved to be more feasible for patients with M0 disease.⁴⁰¹ The addition of intraventricular methotrexate following surgery in a five-drug chemotherapy regimen provided 5-year PFS and OS rates of 58% and 66%, respectively.³⁸³ Although asymptomatic leukoencephalopathy was detected by MRI and mean intelligence quotient (IQ) scores were lower than healthy controls, the mean IQ scores were significantly higher than previous cohorts who had received radiation. A prospective randomized trial of supratentorial PNETs in children younger than 3 years old treated with chemotherapy and omitted or delayed radiation yielded less promising results, with a PFS and OS rates at 3 years of 15% and 17%, respectively. The administration of radiation was the only positive prognostic variable for PFS and OS.⁴⁰² The Head Start I trial for young children with localized medulloblastoma consisted of five cycles of cisplatin, vincristine, etoposide, and cyclophosphamide followed by a single high-dose myeloablative chemotherapy regimen of thioTEPA, carboplatin, and etoposide.⁴⁰³ The 5-year survival was 79%. With the addition of methotrexate, children with disseminated disease had a 5-year PFS of 45% and an OS of 54%.⁴⁰⁴

The addition of conformal RT limited to the posterior fossa and primary site to chemotherapy (cyclophosphamide, vincristine, cisplatin, etoposide) in children between 8 months and 3 years of age with nonmetastatic medulloblastoma increased event-free survival compared with the use of postoperative chemotherapy alone (Children's Oncology Group trial P9934). Neurodevelopmental assessments did not show a decline in cognitive or motor function.⁴⁰⁵

Recurrent medulloblastomas are essentially an incurable and lethal disease. Although it is responsive to a variety of neoplastic

agents, including vincristine, nitrosoureas, procarbazine, cyclophosphamide, etoposide, and cisplatin, with several regimens yielding relatively high response rates, durability is limited. A CCG trial to evaluate carboplatin, thioTEPA, and etoposide with peripheral stem cell rescue showed a 3-year event-free survival and OS of 34% and 46%, respectively.

Long-term effects from treatment can be categorized as neurocognitive, neuropsychiatric, neuroendocrine, and growth retardation. Hypothalamic and pituitary endocrinopathies such as delayed hypothyroidism and decreased growth hormone secretion may occur. Growth retardation can also be secondary to delayed or reduced bone growth, leading to a reduction in sitting height. Neurocognitive deficits have long been recognized secondary to surgery, radiotherapy, and chemotherapy. In one study, 58% of children showed an IQ above 80 at 5 years after treatment, but by 10 years after treatment, only 15% of the patients had an IQ that remained above 80.⁴⁰⁶ A prospective study of cognitive function showed an average decline of 14 points in mean IQ, with an average decline of 25 points in patients younger than 7 years of age.⁴⁰⁷ Even with risk-adapted RT, patients had a significant yearly decrease in mean IQ, reading, spelling, and math.⁴⁰⁸ Psychologic secondary effects are partially attributable to the diminished cognitive function as well as the social challenges caused by the physical manifestations of CSI (e.g., hearing loss, decreased truncal stature, and thin hair) and potential ataxia and abnormal speech patterns. The risk for secondary malignancies also exists. A population-based study tabulated a 5.4-fold increased rate of malignancy when compared with the general population, although this only affected 20 of 1,262 patients at risk.⁴⁰⁹

PINEAL REGION TUMORS AND GERM CELL TUMORS

Clinical and Pathologic Considerations

Pineal and germ cell tumors account for less than 1% of intracranial tumors in adults and 3% to 8% of brain tumors in children.⁴¹⁰ Germinomas are the most common type, accounting for 33% to 50% of pineal tumors. The peak incidence of germ cell tumors is in the 2nd decade, and few present after the 3rd decade. Gliomas are the next most common pineal region tumor (approximately 25%). Pineal parenchymal tumors are nearly as common as glial tumors and are called *pineocytomas* if benign and *pineoblastomas* (a variant of PNET) if malignant; a rare intermediate form also exists.

Germ cell tumors commonly involve the two midline sites, suprasellar and pineal regions, and occasionally are found in other areas such as the basal ganglia, ventricles, cerebral hemispheres, and the spinal cord. Germinomas can occur bifocally or, rarely, even multifocally; the most common bifocal presentation is synchronous involvement of the suprasellar region and the pineal gland.⁴¹¹ Based on histology and the presence of tumor markers in the serum or CSF, the WHO classification system divides intracranial germ cell tumors into germinomas and nongerminomatous germ cell tumors.⁴ Nongerminomatous germ cell tumors are further divided into embryonal carcinomas, yolk sac tumors, choriocarcinomas, and teratomas (mature, immature, or teratoma with malignant transformation). A quarter of the intracranial germ cell tumors have more than one histologic component and are known as mixed germ cell tumors. Alpha-fetoprotein (elevated in yolk sac tumors) and β -human chorionic gonadotropin (elevated in choriocarcinoma, and to a moderate extent in germinoma) are generally secreted by these tumors. Mature teratomas do not have elevated tumor markers.

Neurologic signs and symptoms are caused by obstructive hydrocephalus and involvement of ocular pathways. Major symptoms are headache, nausea and vomiting, lethargy, and diplopia. Signs are primarily ocular, but can include ataxia and hemiparesis. The major ocular manifestation is paralysis of conjugate upward

gaze (Parinaud syndrome), but pupillary and convergence abnormalities are seen, as are skew deviation and papilledema. Some patients with a pineal germ cell tumor can present with symptoms of diabetes insipidus (DI) without any radiologic evidence of overt suprasellar disease.^{412,413}

On CT, these lesions are hyperdense. On MRI, the mass is hypointense on T2-weighted sequences (due to the high cellularity of the mass) and shows enhancement with gadolinium. Calcification and fat may be seen in teratomas or mixed malignant germ cell tumors. Germinomas tend to surround a calcified pineal gland, whereas pineal parenchymal tumors tend to disperse the calcification into multiple small foci. The potential for leptomeningeal dissemination requires imaging of the neuraxis before surgery. Determination of histology, tumor markers, and extent of disease is critical for the optimal management of pineal region tumors. The prognosis varies depending on the histologic type, the size of the tumor, and the extent of disease at presentation.

Surgery

Because pineal tumors are often near the center of the brain, they are among the most difficult brain tumors to remove. Having said that, there is no role for cytoreductive surgery in the treatment of germinoma, which requires only a biopsy from the neurosurgeon followed by radiation, chemotherapy, or both. The application of modern surgical technology with superb illumination, magnification, surgical guidance, and neuroanesthesia has made this region much more accessible. Surgeons can choose from several approaches depending on preference and the tumor's position and extent.⁴¹⁴ The current recommendation is to obtain tissue when a diagnosis cannot be made from serum tumor markers, CSF tumor markers or cytologic examination. Whenever possible, the tumor is completely excised, except when a germinoma is found at open surgery; a biopsy suffices in this situation because germinomas respond well to radiation.⁴¹⁵ Resection is important when tumors are radioresistant or when an excision may be curative (e.g., as in teratomas, arachnoid cysts, and pineal parenchymal tumors).

The place of stereotactic biopsy in the diagnosis of pineal region tumors is unclear. Although biopsies have been described as safe, particularly for large tumors, some avoid it because of the risk of damaging large veins that flank the pineal gland.⁴¹⁶ In addition, there is a risk that tissue sampling of these heterogeneous tumors may not depict the correct histologic nature of all parts of the tumor. Without an accurate diagnosis, treatment planning may be erroneous or inadequate. In favor of biopsy are the advantages of a rapid tissue diagnosis and shortened hospital stay. A transventricular endoscopic biopsy is a much more common clinical scenario currently because it can be performed under direct vision with little risk of damaging deep venous structures. The downside of an endoscopic biopsy is the small size of the biopsy, which can be problematic in the face of a polyphenotypic germ cell tumor.

In patients with a pineal mass and obstructive hydrocephalus from blockage of the aqueduct of Sylvius, endoscopic surgery can play a special role. An endoscopic third ventriculostomy is performed by making a fenestration in the floor of the third ventricle, which relieves hydrocephalus, and the mass in the posterior third ventricle can be viewed and biopsied through a flexible endoscope. A rigid endoscope can also be safely used by placing a second burr hole for the biopsy. CSF for cytology and marker studies can also be obtained, and the walls of the third ventricle inspected for tumor studding. There is a small risk of intraventricular hemorrhage.⁴¹⁷

Radiation Therapy

With certain exceptions, such as benign teratomas, RT has an established role in the curative treatment of pineal germ cell and parenchymal tumors. The location and infiltrative nature of these

lesions often does not allow for a complete resection. In the past, the risk of biopsy or attempted resection often led to the use of RT without histologic confirmation. In such instances, response to low-dose RT, the measurement of α -fetoprotein and human chorionic gonadotropin- β , and CSF cytology were used to provide diagnostic information. There is a tendency to increase the use of biopsy and resection, and treatment without histology is less common.

Five-year survival rates with RT range from 44% to 78% and vary with histology, extent of disease, age, radiation volume, and dose to the primary tumor.¹⁵² In a multi-institutional survey by Wara and Evans,⁴¹⁸ the survival of patients with pineal parenchymal cell tumors or malignant teratomas was 21% (3 of 14) compared with 72% (26 of 36) for those with germinomas. Wolden et al.⁴¹⁹ reported 5-year disease-free survival rates of 91% for germinomas, 63% for unbiopsied tumors, and 60% for nongerminomatous germ cell tumors irradiated to 50 to 54 Gy to the local site with or without treatment to the whole brain or ventricular system. Patients younger than 25 to 30 years old have survival rates of 65% to 80% compared with 35% to 40% for older patients. This may reflect the increased incidence of germinomas in younger patients.

Germinomas are infiltrative tumors that tend to spread along the ventricular walls or throughout the leptomeninges. The incidence of CSF seeding ranges from 7% to 12%. For this reason, fields encompassing the entire ventricular system, the whole brain, and even the entire craniospinal axis have been recommended. The appropriate treatment volume for pineal germinomas was evaluated by Haas-Kogan et al.⁴²⁰ in 93 patients treated at the University of California–San Francisco (UCSF) or at Stanford. The UCSF group favored whole ventricular irradiation; the Stanford group included CSI. Five-year survival for the combined cohort was 93%, with no difference in survival or distant failure regardless of whether CSI or whole ventricular radiation was given. In some institutions, 25.5 Gy (1.5 Gy per day) whole-brain or whole-ventricular radiation is followed by a boost to the primary site to 45 to 50 Gy. CSI is reserved for patients with disseminated disease at presentation.

Neoadjuvant chemotherapy and low-dose (30 to 40 Gy) focal irradiation is employed by some.^{421,422} Chemotherapy might be useful in the young child to defer irradiation. For disseminated or multiple midline germinomas, systemic chemotherapy or CSI is given. CSI doses of 20 to 35 Gy have been used when CSF cytology results are positive. When response to primary chemotherapy is incomplete or the tumor recurs, salvage radiotherapy yields good results.⁴²³

Nongerminomatous malignant germ cell tumors, whether localized or disseminated, are treated with chemotherapy followed by restaging. After restaging, localized tumors receive focal RT to 54 to 60 Gy, and disseminated tumors receive CSI (54 to 60 Gy to the primary, 45 Gy to the ventricular system [controversial], 35 Gy to the spinal cord, and 45 Gy to localized cord lesions).⁴¹⁹ In a German study, 63 supratentorial PNETs were treated with chemotherapy before or after radiation (35 Gy CSI with a boost to the primary of 54 Gy).³⁹⁰ The 3-year survival was 49.3% in those for whom treatment was delivered as prescribed, but only 6.7% in those with major protocol violations. This indicates the importance of CSI in pineoblastoma, analogous to the situation with medulloblastoma.

Tumors that tend not to metastasize to the cord, such as teratomas, pineocytomas, and low-grade gliomas, are treated by resection, with localized radiotherapy reserved for patients with residual disease.⁴²⁴ For selected patients with small residual disease, radiotherapy has been shown to be effective in terms of local control.

Chemotherapy

Chemotherapy for pineal glial neoplasms is similar to that for gliomas elsewhere. Germinomas are chemosensitive and responsive to cisplatin, carboplatin, ifosfamide, cyclophosphamide, bleomycin,

and etoposide. Adjuvant multidrug therapy with radiotherapy has produced encouraging disease-free survival and OS. Newly diagnosed germinomas treated with two courses of high-dose cyclophosphamide showed a complete response rate of 91%.⁴²⁵ Building on this, several studies have reported excellent outcomes with reduced dose radiation combined with chemotherapy.^{298,495,499-502}

Given the poor outcome of CNS nongerminomatous germ cell tumors after radiotherapy alone, there is significant interest in the use of chemotherapy. Balmaceda et al.⁴²⁶ reported the results from using four cycles of carboplatin, etoposide, and bleomycin without radiation. Of 71 patients (45 germinoma and 26 nongerminomatous), 68 were assessable for response; after four cycles, the complete response rate was 57%. The 29 patients with less than a complete response received dose-intensified chemotherapy or surgery, and a further 16 achieved a complete response, for an overall complete response rate of 78%. Despite these high response rates, only 28 of 71 (39%) patients were alive and progression free within 31 months. Subsequently, they treated 20 patients with two cycles of cisplatin, etoposide, cyclophosphamide, and bleomycin, and the 16 patients achieving a complete response received two additional cycles of carboplatin, etoposide, and bleomycin.⁴²⁷ Nine of the 14 survivors received RT. The chemotherapy response rate was 94%, 5-year OS was 75%, and 36% of patients were event free. Although the complete response rate was high, approximately half the patients developed recurrent disease, suggesting that a multimodal therapeutic approach of surgery, chemotherapy, and radiotherapy is necessary to improve the overall outcome of these tumors. Matsutani et al.⁴²⁸ analyzed 153 germ cell tumors treated with surgery and RT with or without chemotherapy. The 10-year survival rates for mature and malignant teratomas were 92.9% and 70.7%, respectively. Patients with pure malignant germ cell tumors (embryonal carcinoma, yolk sac tumor, or choriocarcinoma) had a 3-year survival rate of 27.3%. The mixed tumors were divided into three subgroups: (1) mixed germinoma and teratoma; (2) mixed tumors whose predominant characteristics were germinoma or teratoma combined with some elements of pure malignant tumors; and (3) mixed tumors with predominantly pure malignant elements. The 3-year survival rates were 94.1%, 70.0%, and 9.3%, respectively, for the three groups.

High-dose chemotherapy with autologous stem cell rescue has been used for pineoblastoma.⁴²⁹ Twelve patients were treated with induction chemotherapy followed by CSI with a pineal boost (36 Gy CSI, 59.4 Gy to primary), then with high-dose chemotherapy with stem cell support. Nine of the 12 patients remained disease free, including two infants who never received radiation. The actuarial 4-year PFS and OS were 69% and 71%, respectively. Although still considered investigational, the survival results are impressive. The use of high-dose chemotherapy and autologous bone marrow support has not been as promising for patients with recurrent tumors, although reported data are few.⁴²⁹

PITUITARY ADENOMAS

Clinical and Pathologic Considerations

Pituitary tumors are identified incidentally or present through symptoms of local mass effect or as a result of endocrine effects. Pituitary adenomas almost always arise from the anterior pituitary, the adenohypophysis. The tumor initially compresses the gland and, subsequently, the optic chiasm and nerves. Tumors less than 10 mm—microadenomas—rarely compress the optic apparatus. Larger macroadenomas can involve the cavernous sinus bilaterally, the third ventricle (sometimes producing hydrocephalus), and, less commonly, the middle, anterior, or even the posterior fossae. The classic ophthalmologic finding is visual loss, typically starting with bitemporal hemianopsia and loss of color discrimination. Automated visual field testing is more sensitive than simple

confrontation. Occasionally, extraocular palsies can result from the compression or invasion of the nerves in the cavernous sinus. Tumors that present with mass effect are often nonsecreting, but prolactin, growth hormone, thyrotropin, and gonadotropin-producing tumors may also present in this way.

Neuroendocrine abnormalities are usually from tumors that oversecrete hormones but can also result from compression of the pituitary gland and the stalk. The most commonly secreted hormones are prolactin, adrenocorticotropic hormone, or growth hormone. The incidence of the various types of adenoma is variable. In 800 patients operated on at UCSF between 1970 and 1981, 79% were endocrinologically active. Of these, 52% were prolactin secreting, 27% were growth hormone secreting, 20% were corticotropin secreting, and only 0.3% were thyroid-stimulating hormone secreting.⁴³⁰ Sexual impotence in men and amenorrhea and galactorrhea in women are hallmarks of a prolactin-secreting tumor. Hypogonadism, infertility, and osteopenia are also common.⁴³¹ Growth hormone hypersecretion causes acromegaly or, in the rare patient with a tumor occurring before epiphyseal closure, gigantism. The secondary production of insulin-like growth factor-1 (IGF-1; primarily from the liver) or somatomedin C produces skeletal overgrowth changes (e.g., increased hand and foot size, macroglossia, frontal bossing). Soft tissue swelling, peripheral nerve entrapment syndromes, and arthropathies may occur. Hypertension, cardiomyopathy, diabetes, and an increased risk of colon cancer are prevalent with acromegaly. Adrenocorticotropic hormone hypersecretion by a pituitary tumor results in Cushing disease, with weight gain, hypertension, striae, hyperglycemia, infertility, osteoporosis, increased skin pigmentation, and psychiatric symptoms. Rarely, pituitary adenomas can present acutely with headaches, visual loss, and confusion, which can progress to obtundation. This potentially life-threatening condition is termed *pituitary apoplexy*. The etiology of apoplexy is thought to involve tumor infarction due to interruption of its blood supply, but the exact mechanism is not known. Symptomatic pituitary apoplexy is a surgical emergency, and patients need to be carefully medically managed with judicious fluid and salt replacement and administration of high-dose corticosteroids. A need for prolonged hormone replacement therapy is often a consequence of apoplexy.

On MRI, pituitary microadenomas are generally seen within the gland according to the distribution of normal cells. For example, prolactinomas tend to be located laterally within the sella. Microadenomas show subtle hypointensity to the normal gland on T1-weighted sequences and are often more difficult to detect on T2 sequences.⁴³² Immediately after the administration of contrast, adenomas show less enhancement than adjacent normal glands (Fig. 97.11). On delayed views, the tumor enhances more than the normal gland. Indentation of the sellar floor, stalk deviation, and mass effect on adjacent structures also provide evidence of the presence of tumor.

Surgery

There are two primary goals of surgery for macroadenomas: to decompress the visual pathways by reducing tumor bulk and, for secreting tumors, to normalize hypersecretion, with the preservation of remaining normal pituitary function.

The standard surgical approach for the majority of pituitary tumors is transsphenoidal, which is safer and better tolerated than the transcranial (frontotemporal craniotomy) approach.⁴³³⁻⁴³⁵ The transsphenoidal approach is used for microadenomas that occupy the sella turcica and for many macroadenomas. Image-guided neuronavigation and intraoperative fluoroscopy are essential to reduce the risk of injury to the carotid arteries. Even when the majority of tumor is actually suprasellar, a transsphenoidal resection can be safely accomplished if the tumor consistency is soft (and tumor aspiration and curettage can thus easily be performed) and if the tumor is situated so that it can drop into the sella with progressive

Figure 97.11 Pituitary adenomas are usually isointense to the gland on noncontrast T1-weighted magnetic resonance images; on contrast administration, the normal gland enhances early, as visualized on this sagittal image, whereas the adenoma (arrow) continues to remain unenhanced. With late imaging, the adenoma enhances.

resection. Tough, fibrous suprasellar tumors and those that extend laterally into the middle fossa, anteriorly beneath the frontal lobes, or into the posterior fossa may require a craniotomy for resection.⁴³⁶ A tumor that invades the cavernous sinus is generally not removed. The role of endoscopic transsphenoidal surgery for pituitary adenomas is currently being expanded. Potential advantages include a less invasive surgical approach with a wider field of view and quicker postoperative recovery. Moreover, Cappabianca et al.⁴³⁶ observed a decreased incidence of complications in a series of 146 consecutively treated patients who underwent an endoscopic endonasal transsphenoidal approach to the sellar region for resection of these tumors, compared with large historical series that employed the traditional microsurgical transsphenoidal approach.

Current surgical cure rates for hormonally active adenomas are 80% to 90% if there is no involvement of the cavernous sinus, suprasellar region, or clivus.⁴³⁷ Patients with microadenomas have a higher surgical cure rate than patients with macroadenomas.⁴³⁸ Patients cured of their endocrine disease can expect to have a normal lifespan; however, those with persistent endocrinopathies, and particularly those with acromegaly, may not enjoy a normal lifespan due to the impact of the high hormone levels on multiple organ systems.⁴³⁷ In patients not biochemically cured with initial surgery, the tumor is often found at the time of second surgery just next to the original site. Patients with persistent acromegaly, however, may not be amenable to biochemical cure with a second surgery because the residual growth hormone secreting cells can be difficult to visualize. Growth through the dura into the adjacent cavernous sinus is often found at repeat surgery even when no tumor is seen preoperatively on MRI.⁴³⁹ Benveniste et al.⁴⁴⁰ found that, although repeated transsphenoidal surgery to treat a recurrent or residual tumor mass was associated with a 93% rate of clinical remission, its use to treat recurrent or persistent hormone hypersecretion produced only a 57% rate of initial endocrinologic remission, with a 37% likelihood of sustaining such remission at a mean of 31 months. Thus, they suggested that for the treatment of residual or recurrent adenomas that cause persistent or recurrent hormone hypersecretion, radiosurgery may be a better option.

Radiation Therapy

RT may be indicated for hormone-secreting adenomas that are not surgically cured and are refractory to pharmacologic management. After subtotal resection of a macroadenoma, more than 50% of patients demonstrate radiographic evidence of progression within 5 years.⁴⁴¹ Younger patients (less than 50 years old) with residual disease have faster tumor regrowth. Ki-67 antigen labeling of more than 1.5% predicts more rapid growth.⁴⁴² For these patients, earlier postoperative radiotherapy should be considered.

RT decreases serum growth hormone concentrations to “normal” levels in 80% to 85% of acromegalic patients, but the definition of normalization has varied over time.⁴⁴³ Growth hormone levels decrease at a rate of 10% to 30% per year, so several years may be required for the levels to normalize.⁴⁴³ The probability of endocrine cure is highest for tumors with relatively low pre-RT growth hormone elevations (30 to 50 ng/mL); response is less reliable for tumors that produce higher growth hormone levels. In contrast, serum IGF-1 levels remain elevated after radiotherapy, and long-term treatment with somatostatin or its analogs may be required.^{444,445} RT controls hypercortisolism in 50% to 75% of adults and 80% of children with Cushing disease. Response occurs within 6 to 9 months of treatment.⁴⁴⁶

Pituitary adenomas may be treated using several different techniques. The most commonly used techniques include 3D-CRT, IMRT, and stereotactic radiotherapy or radiosurgery. Treatment with charged-particle beams has been used at select centers.^{447,448} The total dose used for nonfunctioning lesions is 45 to 50 Gy in 25 to 28 fractions of 1.8 Gy. Slightly higher total doses are recommended for secretory lesions. This controls tumor growth in 90% of cases at 10 years.^{449–451} Radiation-induced injury to the optic apparatus or adjacent brain with this dose-fractionation scheme is rare, whereas larger fractions or greater total doses lead to a higher incidence of injury. Hypopituitarism may develop, often years after radiation treatment.⁴⁵¹ It is more common in patients who have had both surgery and RT than in those treated with either modality alone. Hypopituitarism is largely correctable by hormone-replacement therapy. One publication suggests that patients treated with surgery and radiation have an elevated risk for late cerebrovascular mortality.⁴⁵² Possible contributing factors include hypopituitarism, radiotherapy, and extent of initial surgery. The risk of developing a radiation-induced brain tumor after treatment is 1.3% to 2.7% at 10 years and beyond.^{452–454}

Radiosurgery is increasingly being used for treating small residual adenomas.^{448,455} In general, patients are eligible for radiosurgery only if the superior extent of the lesions is more than 3 to 5 mm from the optic chiasm. Doses of more than 10 Gy in a single fraction to the optic pathways can cause visual loss.⁴⁵⁶ Radiosurgery results in excellent tumor control and appears to cause more rapid biochemical normalization than is seen with conventional RT, with the caveat that it is used primarily for smaller tumors.^{457–459} Side effects such as hypopituitarism and cranial nerve injury is also lower with radiosurgery.^{460,461}

Reirradiation can be considered for patients with recurrent pituitary adenomas when there has been a long interval after the first course of radiotherapy and other therapeutic methods have been unsuccessful.⁴⁶²

Medical Therapy

Medical therapy is very important and effective for patients with secreting pituitary tumors.⁴⁶³ Dopamine agonists (e.g., bromocriptine or cabergoline) are the most effective therapy for prolactinomas and are often used as primary treatment, with definitive treatment reserved for patients who either cannot tolerate or do not respond to a dopamine agonist. Somatostatin analogs (e.g., octreotide and lanreotide) are effective for patients with acromegaly and are usually reserved when there is persistent growth hormone

hypersecretion after resection. Control rates with octreotide are approximately 50%; dopamine agonists can control growth hormone production in 10% to 34%.⁴⁶⁴ A recently approved growth hormone receptor antagonist (pegvisomant) can be used for patients for whom somatostatin analogs fail. Rates of IGF-1 level normalization as high as 97% have been reported with this agent, but concerns persist that because it acts at the end-organ receptor level, tumor growth may continue in some patients, and the lifetime cost of the agent is prohibitive.⁴⁶⁵ Medical therapy for patients with Cushing disease is directed at the adrenal glands to reduce cortisol hypersecretion (ketoconazole). Unfortunately, no known drug effectively reduces pituitary corticotropin production.

CRANIOPHARYNGIOMAS

Clinical and Pathologic Considerations

Craniopharyngiomas are the most common benign nonglial brain tumors in children, occurring primarily in the late 1st and 2nd decades, although they can present at any age.^{2,466} Craniopharyngiomas are thought to arise from epithelial cell rests that are remnants of the Rathke pouch at the juncture of the infundibular stalk and the pituitary gland. Most have a significant associated cystic component with only 10% being purely solid. Most craniopharyngiomas become symptomatic because of effects of the combined tumor and cyst on the optic apparatus or hypothalamus or both. They may also compress the pituitary gland or extend superiorly into the third ventricle. Cyst fluid is proteinaceous, and this can be seen on MRI. A CT shows calcification in 30% to 50% of cases.

Common presenting symptoms include headache, visual complaints, nausea, vomiting, and intellectual dysfunction (especially memory loss). Specific visual signs include optic atrophy, papilledema, hemianopsia, unilateral or total blindness, and diplopia with associated cranial nerve palsies. Endocrine abnormalities at presentation can include growth retardation, menstrual abnormalities, and disorders of sexual development or regression of secondary sexual characteristics (or both). DI is uncommon at presentation.⁴⁶⁷

The optimal treatment of any specific patient with a craniopharyngioma is complicated, and open to debate. Variables such as patient age, endocrine status, visual status, aeration of the sinuses, extent of solid disease, extent of cystic disease, and involvement of the hypothalamus either unilaterally or bilaterally can all contribute to the decision of optimal therapy. In general, the number of options for therapy for a given patient will vary directly with the number of opinions sought because there are many different approaches and schools of thought as to how best treat this highly variable disease.

Surgery

Craniopharyngiomas are generally resected using a microsurgical subfrontal or pterional approach. More recently, some surgeons have been approaching some lesions using an endoscopic skull base approach from the sphenoid sinus. Larger tumors may require bifrontal or skull-base approaches, including a supraorbital craniotomy. Endoscopically assisted surgery is sometimes used, although outcome advantages have not yet been clearly shown. Although complete resection remains the optimal surgical goal, the risk of devastating long-term effects on hypothalamic function and quality of life cannot be ignored. In some cases, there is no clearly defined plane between tumor and surrounding hypothalamus, which makes aggressive resection dangerous. Aggressive removal is frequently associated with some injury to the pituitary stalk, with subsequent temporary or permanent DI and elements of hypopituitarism.⁴⁶⁸⁻⁴⁷⁰ These patients require lifelong replacement hormones and inhaled desmopressin acetate spray for the control of

DI. Most patients with preoperative visual loss can expect at least some improvement after surgery. The reported mortality rates for craniopharyngioma resection range from 2% to 43%, with severe morbidity in 12% to 61%.⁴⁷¹ Complications are less likely with experienced surgeons. Alternative approaches include placement of an Ommaya reservoir for largely cystic tumors through which one can instill sclerosing agents (e.g., bleomycin, interferons, or radioisotopes.)

Radiation Therapy

Radioisotope Therapy

Predominantly cystic craniopharyngiomas can be treated with stereotactic or endoscopic instillation of colloidal therapeutic radioisotopes, particularly ⁹⁰Y or ³²P.^{469,472} The short penetration of the beta-particles emitted by these isotopes allows the epithelial cells lining the cyst to be treated without significant dose to neighboring structures. Intracystic therapy may have a role in treating cysts that recur after conventional external-beam irradiation, or even as a primary cyst treatment. Although most cysts shrink with intracystic therapy, one-third of patients require further surgery later.

External-Beam Radiation Therapy

Numerous reports demonstrate that subtotal removal and irradiation produce local tumor control and survival rates comparable to those after radical excision.⁴⁷³⁻⁴⁷⁵ The local control rates after complete resection, subtotal resection alone, and subtotal resection with postoperative irradiation are 70%, 26%, and 75%, respectively. A study from Children's Memorial Hospital in Chicago found a 32% rate of recurrence after complete resection and 0% after subtotal resection and adjuvant radiotherapy.⁴⁷⁶ Ten-year survival rates range from 24% to 100% for complete resection, 31% to 52% for subtotal resection, 62% to 86% for incomplete resection and irradiation, and 100% after radiotherapy alone.^{471,473,474,476,477} Patients who undergo conservative treatment, including biopsy and cyst drainage and irradiation, appear to enjoy a better quality of life and demonstrate less psychosocial impairment than those initially treated with more extensive resections.⁴⁷³ Furthermore, conservative therapy is associated with less hypothalamic and pituitary dysfunction and a lower incidence of persistent DI than when a total or near-total excision is attempted. More extensive resections, using a subfrontal approach, may be associated with frontal lobe and visual perceptual dysfunction. The negative impact on IQ is greater in patients treated with aggressive resection than in those treated with conservative surgery and postoperative irradiation.⁴⁷⁸

The radiation treatment volume is based on CT and MRI scans, with relatively small margins. Generally, more sophisticated 3D-CRT and IMRT approaches and stereotactic radiotherapy techniques are increasingly being used to spare surrounding normal tissues.⁴⁷⁷ One report showed excellent tumor control (100%) with minimal late toxicity when FSRT (mean dose, 52.2 Gy in 29 fractions) was used.⁴⁷⁹ No significant effect on cognition or visual injury was reported. The total dose is 50 to 55 Gy, given in daily 1.8-Gy increments. One review suggested better local control when doses of 55 Gy or more are delivered.⁴⁸⁰

Radiosurgery

The use of radiosurgery is limited by the proximity of most lesions to the optic chiasm and brainstem,⁴⁸¹ and should be reserved for those uncommon tumors confined to the pituitary fossa and away from the chiasm and hypothalamus.⁴⁸² Kobayashi et al.⁴⁸³ reviewed long-term results (follow-up of 65.5 months) of radiosurgical treatment for residual or recurrent craniopharyngiomas after microsurgery in 98 consecutive patients and found only a 20.4% tumor progression rate. They used a tumor margin dose of 11.5 Gy at the

retrochiasm and ventral stalk area, which decreased the rate of visual and pituitary function loss so that deterioration both in vision and endocrinologic functions occurred in only six patients (6.1%). Similarly, Albright et al.⁴⁶⁹ used radiosurgery as the initial treatment for the solid component of craniopharyngiomas in five children, limiting radiation to the optic chiasm to 8 Gy, and reported no operative morbidity or mortality, whereas 5 of 27 children who underwent microsurgical tumor resection suffered worsened vision postoperatively.

VESTIBULAR SCHWANNOMAS

Clinical and Pathologic Considerations

Schwannomas, also known as *neurilemmomas* or *neurinomas*, are benign neoplasms derived from Schwann cells that show a predilection for sensory nerves. Most intracranial schwannomas arise from the vestibulocochlear nerve, with trigeminal nerves being a distant second in frequency. Previously called *acoustic neuromas*, these neoplasms are more correctly termed *vestibular schwannomas* because they arise from both the superior and inferior portions of the vestibular nerve rather than the cochlear nerve. Vestibular schwannomas are equally common between genders and median age at diagnosis is approximately 50 years, with an overall increased incidence between 45 and 64 years of age. Vestibular schwannomas account for approximately 6% to 8% of intracranial neoplasms. The incidence of vestibular schwannomas is between 0.8 and 1.7 per 100,000, with an increasing incidence since the early 1980s.^{484,485} This increased incidence may represent the discovery of asymptomatic lesions by a rising number of cranial imaging studies, predominantly MRI. The rate of incidental vestibular schwannomas detected on MRI ranges from 0.02 to 0.07%.^{486,487} More than 90% of vestibular schwannomas are sporadic and unilateral. Bilateral vestibular schwannoma is virtually pathognomonic for NF2 and is one of the key components of the Manchester criteria for the diagnosis of NF2.⁴⁸⁸ When associated with NF2, vestibular schwannomas have a significantly earlier disease manifestation and tend to occur in the 2nd or 3rd decade of life.

Vestibular schwannomas arise along the zone of transition between the central and peripheral myelin located near the medial aperture of the internal auditory canal (IAC). Macroscopically, they are typically lobulated, with the eighth cranial nerve located eccentrically along the surface because these tumors grow in an expansile fashion, displacing rather than invading nerves. Vestibular schwannomas in NF2 tend to embed within the seventh and eighth cranial nerve bundles more frequently.⁴⁸⁹ As with peripheral schwannomas, a microscopic examination yields Antoni A and B tissue patterns. Vestibular schwannomas are benign, with few case reports of malignant dedifferentiation.

Although vestibular schwannomas arise from the vestibular portion of cranial nerve VIII, cochlear symptoms predominate, with the two most common being hearing loss and tinnitus.⁴⁹⁰ Progressive unilateral sensorineural hearing loss is characteristic. An evaluation is typically delayed, with the duration of hypacusis averaging 3.7 years prior to diagnosis. Vertigo and unsteadiness are the most common vestibular symptoms. Facial nerve paresis or spasm may be seen. Large tumors can compress the trigeminal nerve, with paresthesias or neuralgia. Impingement of the brainstem or cerebellum may lead to ataxia and long-tract signs as well as involvement of the lower cranial nerves. Most ominous is the rare patient with nausea and vomiting from fourth ventricular compression and obstructive hydrocephalus.

MRI with thin-section, high-resolution, gadolinium-enhanced T1- and T2-weighted images of the cerebellopontine angle is the study of choice. Vestibular schwannomas typically enhance along the course of the eighth cranial nerve with variable intra- and extracanalicular components. Cystic changes are frequently identified

in larger lesions. An MRI allows for the identification of the lesion and potential differentiation from other masses of the cerebellopontine angle such as meningiomas, epidermoid cysts, arachnoid cysts, and, rarely, lipomas. Auditory brainstem response audiometry is less sensitive than MRI.⁴⁹¹ Pure tone and speech audiometry continue to be performed to document hearing loss. Hearing loss is more pronounced at higher frequencies, and the degree of speech discrimination loss is disproportionately worse than the pure tone hearing loss.

Treatment

Treatment revolves around the dual goals of local control and cranial nerve function preservation. Factors that influence treatment choice include tumor size, location, patient age, the presence and degree of symptoms such as tinnitus and vertigo, whether a patient has NF2, the status of contralateral hearing, and patient preference. Consultation with a multidisciplinary team is essential.

Observation

Vestibular schwannomas are typically slow growing, and various studies have shown an increase in size ranging from 0.35 to 2.2 mm per year (mean, 1.42 mm per year).⁴⁹² Chalabi et al.⁴⁹³ reported that with mean follow-up of 4.2 years, 85% of observed vestibular schwannoma were noted to have exhibited measurable growth. Given the slow growth pattern and the recognition that neither surgery nor RT restore hearing lost to a vestibular schwannoma and both pose risks to cranial nerve function, observation is a reasonable choice for some patients. Such an approach requires that the patient be willing to undergo regular annual or semiannual clinical and imaging follow-ups. This course may be selected by many patients with small acoustic neuromas, particularly older patients and patients with multiple medical comorbidities. Patients with functional hearing must understand that further hearing loss, including sudden hearing loss, can occur while under observation.

Surgery

Surgery has the unique advantage of removal of the schwannoma, with a low risk of recurrence following complete resection. Microsurgical resection has been the mainstay of treatment for many years and was previously recommended as the standard of care in a 1991 consensus statement.⁴⁹⁴ However, stereotactic radiosurgery has also become accepted as a standard treatment for these tumors.⁴⁹⁵ Surgical risks include the inherent risk of general anesthesia, CSF leak, meningitis, headache, hearing loss, and facial nerve paralysis. Hearing preservation is influenced by preoperative hearing acuity, location of the tumor, and size. Loss of facial nerve function is the most significant surgical concern, as well as morbidity. Again, tumor size is a factor, as is the relationship between the facial nerve and tumor. Surgery is made particularly challenging by the increased adherence and infiltration in NF2.⁴⁹⁶ The risk of facial nerve injury has decreased since the advent of facial nerve electromyography for intraoperative monitoring. The auditory brainstem response may also be used to evaluate the integrity of the cochlear portion of the eighth cranial nerve intraoperatively, improving the odds of potential avoidance and preservation.

Most modern surgical series achieve complete resection in more than 90% of patients, with some reporting significantly higher rates.^{490,497} Subtotal resections are frequently deliberate to preserve hearing or provide emergent, life-saving decompression of the brainstem and fourth ventricle. Results appear to be both surgeon and volume dependent, leading to questions of the widespread applicability of results obtained by subspecialty surgeons in academic institutions.⁴⁹⁸ There also appears to be a significant learning curve of 20 to 60 patients with new surgical teams.^{499,500} An extensive surgical series of 962 patients undergoing 1,000 vestibular schwannoma operations has been compiled

by Samii and Matthies,⁴⁹⁰ who reported a 98% complete resection rate with fewer than 1% of non-NF2 patients having a recurrence. The facial and cochlear nerves were preserved in 93% and 68% of patients, respectively, and functional preservation was 39% for patients with intact hearing preoperatively. Mortality was 1.1%, although this included several individuals who were disabled with advanced disease prior to surgery. If hearing is to be preserved, the auditory nerve is also identified and preserved; preservation of hearing is more likely in patients lacking severe adhesion in the interface between the cochlear nerve and the tumor.⁵⁰¹ Life-threatening complications of acoustic neuroma resections are rare except in patients with extremely large tumors.⁵⁰² The tendency of postoperative CSF leaks to develop in patients (10% to 13%) is independent of the surgical approach employed and tumor size and may stem from factors such as transient postoperative increases in CSF pressure.²⁴⁹ Postoperative headaches were a significant morbidity in a cohort of 1,657 patients who underwent surgery for acoustic neuroma.⁵⁰³ Patients who underwent tumor resection by the retrosigmoid approach (82.3%) were significantly more likely to report their worst postoperative headache as “severe” than those resected using the translabyrinthine (75.2%) or middle fossa approaches (63.3%). In another quality-of-life study, hearing loss was perceived as the most disabling symptom among 386 patients who underwent acoustic neuroma surgery.⁵⁰⁴

Radiosurgery

The most substantial experience in radiation-based treatment is with SRS. Both Gamma Knife units and SRS-compatible linear accelerators may be used to perform SRS. The University of Pittsburgh published a review of 162 consecutive patients treated with SRS to a mean dose of 16 Gy with a tumor control rate of 98%.⁵⁰⁵ Subsequent surgical resection was required in four patients. Normal facial function was preserved in 79% and normal trigeminal function was preserved in 73% of patients. Because of the unacceptable cranial nerve morbidity in this and other series, the prescription dose for radiosurgery was lowered to 12 to 13 Gy. Results from the decreased prescription dose have a similarly low rate of recurrence, with 97% tumor control at a mean dose of 13 Gy.⁵⁰⁶ The risk of facial nerve weakness dropped to 1%, and hearing preservation improved to 71%. These results were confirmed with longer follow-up.⁵⁰⁷ Recently, a prospective cohort study of 82 patients with unilateral vestibular schwannomas smaller than 3 cm compared surgery and SRS and provided level 2 evidence favoring SRS over microscopic surgical resection. Tumor control was not statistically different (100% for surgery versus 96% for SRS). Normal facial movement and preservation of serviceable hearing was more frequent in the SRS group at all time points, and no quality-of-life decline was seen in the SRS group.⁵⁰⁸ New incomplete trigeminal and facial cranial neuropathies typically develop at approximately 6 or more months after radiosurgery. These tend to be mild and usually improve within a year after onset. Approximately half of patients with useful hearing before radiosurgery maintain their pretreatment hearing level, and hearing lost before treatment is not regained. The risk of treatment-induced cranial neuropathy is directly related to the volume of the lesion, the dose given, and the length of nerve irradiated.

Fractionated Radiation Therapy

Different fractionation regimens have been tried to capitalize on theoretical radiobiologic differences between the neoplastic vestibular schwannoma and the surrounding normal tissue. Multiple fractions also allow for the treatment of lesions that would otherwise not be amenable to treatment with SRS based on size (more than 3 cm) or location (direct compression of the brainstem). Hypofractionation was examined in a series that compared 25 Gy in five fractions and 30 Gy in 10 fractions. Actuarial hearing preservation rate was 90% at 2 years, and no recurrence or facial nerve weakness occurred.⁵⁰⁹ A nonrandomized prospective trial from the Netherlands, however, had a nonstatistically inferior outcome in

hearing preservation when comparing hypofractionation to SRS at 10 to 12 Gy.⁵¹⁰ A comparison of FSRT (50 Gy in 25 fractions) to SRS in a prospective trial showed comparable high control rates and minimal cranial nerve injury, with the exception of retention of useful hearing, which was 81% versus 33% at 1 year (in favor of FSRT) when followed by serial audiometry.⁵¹¹ Similar rates of tumor control and hearing preservation have been reported by single-institution experiences elsewhere.⁵¹²⁻⁵¹⁴

Several issues confound radiation outcomes assessments for vestibular schwannomas. First, documentation of recurrences can be confounded by inherently slow growth rates and transient post-procedure lesion enlargement.^{515,516} Second, ionizing radiation does carry a small inherent risk of inducing secondary neoplasms or malignant transformation of the vestibular schwannoma.^{517,518} The risk of a secondary neoplasm can be particularly concerning in tumor-prone genetic conditions such as NF2. However, given the immense number of individuals who have undergone SRS worldwide, the number of presumed radiation-induced malignancies is only a handful and represents, at most, 1 per 1,000 patients. This is substantially lower than the rate of surgery-related mortality. Malignant transformations can also be seen in resected vestibular schwannoma patients who did not receive radiation.⁵¹⁹ Finally, because of increased adherence of the facial nerve to the tumor, eighth nerve preservation rates are lower when the excision is performed for regrowth after radiation when compared to a non-irradiated control group.⁵²⁰

Targeted Therapy for Vestibular Schwannoma

There is significant interest in the development of medical therapy for patients with refractory vestibular schwannoma. Aberrant signaling pathways are known to be present, and there are now reports of the use of targeted agents in this disease. In a single patient case report, the EGFR inhibitor erlotinib was associated with radiographic response of the tumor and improved audiologic function.⁵²¹ There are also two reports of the use of bevacizumab in the treatment of vestibular schwannoma in the setting of NF1 in patients with a single hearing ear.^{522,523} These studies consisted of a small number of patients, but the demonstration of objective regression of tumors and improvement in hearing was impressive, highlighting the need for larger prospective trials of antiangiogenic agents for this disease. There is also a report of using bevacizumab in treating vestibular schwannoma in the patients who have NF2.⁵²²

GLOMUS JUGULARE TUMORS

Clinical and Pathologic Considerations

Glomus jugulare tumors (paragangliomas) arise from glomus tissue in the adventitia of the jugular bulb (glomus jugulare) or along the Jacobson nerve in the temporal bone, sometimes multifocally. The tumor invades the temporal bone diffusely, but growth is characteristically slow. Sometimes these tumors are endocrine active, with a carcinoid- or pheochromocytoma-like syndrome.⁵²⁴ Because glomus jugulare tumors occur in the jugular foramen, they commonly cause lower cranial nerve palsies and early symptoms of hoarseness and difficulty swallowing. Facial weakness, hearing loss, and atrophy of the tongue from hypoglossal palsy can follow. Pulsating tinnitus also may be a presenting symptom, and a red pulsating mass is often visible behind the eardrum. A presumptive diagnosis of glomus tumor can be made by CT or MRI scanning, with jugular schwannoma and meningioma being the main differential diagnoses. On CT scans, glomus tumors show a characteristic salt-and-pepper appearance in involved bone; MRI often discloses large blood vessels within the mass. Glomus tumors give positive results on octreotide scintigraphy. These tumors incite a tremendous blood supply, particularly by way of the ascending pharyngeal

artery. An angiography provides the definitive diagnosis. Because preoperative tumor embolization is essential to the surgical removal of glomus tumors, the diagnostic angiogram should be taken before surgery. Histopathologically, numerous vascular channels are distinctive. The background is composed of clear cells clumped in a fibrous matrix. A small percentage of glomus tumors are malignant. There is a familial form in which the tumors are multiple.

Surgery

The treatment of glomus jugulare tumors is controversial, with advocates for surgery, RT, radiosurgery, and combined approaches. Although surgery can often provide a cure for these benign tumors, especially for small lesions, RT and radiosurgery avoid the morbidities that may follow surgical removal (e.g., lower cranial nerve and facial palsies). Surgery for glomus tumors is most often jointly performed by a neurosurgeon and an otorhinolaryngologist after preoperative embolization, which may decrease intraoperative blood loss during the resection of these extremely vascular tumors. Complications of this procedure can include swallowing and aspiration problems, CSF leak, and facial palsy.

Radiation Therapy

Even though glomus tumors are histologically benign, RT is effective and has been recommended for symptomatic lesions that cannot be totally resected, even as primary treatment.⁵²⁵ These tumors regress slowly after irradiation, and the success of RT is measured by the amelioration of symptoms and the absence of disease progression. A review of the literature demonstrated local control rates with radiation in excess of 90% with or without surgery.⁵²⁶ A dose of 45 to 50 Gy over the course of 5 weeks is recommended.

Radiosurgery

A literature review by Gottfried et al.⁵²⁷ showed that the use of SRS to treat glomus jugulare tumors has increased. Compared with conventional radiotherapy, radiosurgery involves a shorter treatment time, precise stereotactic localization, and irradiation of a small volume of normal tissue, which results in a reduced incidence of complications. Among 142 patients treated radiosurgically in eight series reviewed by Gottfried et al., tumors diminished in 36.5%, tumor size was unchanged in 61.3%, and subjective or objective improvements occurred in 39%. Although a residual tumor was present in all of these patients, only 2.1% experienced progression, the morbidity rate was 8.5%, and no deaths occurred; however, the incidence of late recurrence is unknown. In another study of eight patients who underwent radiosurgery (median dose of 15 Gy to the tumor margin) for recurrent, residual, or unresectable glomus jugulare tumors, all remained stable without cranial nerve palsies at a median follow-up of 28 months.⁵²⁸ The authors suggested treatment of small glomus tumors (3 cm or less in average dimension) with radiosurgery and treatment of young patients with large tumors (3 cm or more in average dimension) and patients with symptomatic tumors with surgical resection.

A recent meta-analysis based on data from 19 studies revealed radiosurgical tumor control in 97% of patients. In eight studies with a median follow-up time exceeding 36 months, 96% of patients achieved tumor control.⁵²⁹

HEMANGIOBLASTOMAS

Clinical and Pathologic Considerations

Hemangioblastomas account for 1% to 2% of intracranial tumors, arising most often in the cerebellar hemispheres and vermis.

Although usually solitary, these tumors can be multiple and may also occur in the brainstem, spinal cord, and less often, the cerebrum. Cerebellar hemangioblastomas can be sporadic or occur as part of the autosomal-dominant von Hippel-Lindau complex, which is transmitted with more than 90% penetrance.⁵³⁰ Other entities associated with von Hippel-Lindau disease are retinal angiomas, polycystic kidneys, pancreatic cysts, pheochromocytoma, and renal cell carcinoma. Identification of the *VHL* gene on chromosome band 3p25–26 allows individuals who are at risk for the syndrome, or who have some of its components as an apparent sporadic case, to undergo genetic testing with a high degree of accuracy.⁵³¹

Cerebellar hemangioblastomas usually are recognized in the 3rd decade in patients with von Hippel-Lindau disease and in the 4th decade or later in patients with sporadic tumors. These tumors can cause symptoms and signs of cerebellar dysfunction, especially gait disturbance and ataxia, and hydrocephalus from obstruction of CSF pathways. These tumors tend to enlarge slowly, but patients may become symptomatic from tumor cysts, which can grow quickly.⁵³²

Hemangioblastomas are composed of capillary and sinusoidal channels lined with endothelial cells. Interspersed are groups of polygonal stromal cells with lipid-laden cytoplasm and hyperchromatic nuclei. An immunohistochemical study of these cells shows expression of neuron-specific enolase, vimentin, and S100 protein, but not epithelial membrane antigen or glial fibrillary acidic protein.⁵³³ Grossly, the tumor is often cystic, containing proteinaceous, xanthochromic fluid and with an orange-red, vascular, and firm mural nodule. The cyst wall is a glial nonneoplastic reaction to fluid secreted by the nodule. Some hemangioblastomas lack cysts, especially in the brainstem and spinal cord, but cystic lesions are more often symptomatic, at least in patients with von Hippel-Lindau disease.⁵³²

The natural history of spinal hemangioblastomas has been described.⁵³² The authors reviewed the clinical records and MRIs of 160 consecutively treated patients with 331 spinal hemangioblastomas. Most lesions were located in the posterior cord. Cysts were commonly associated with the lesions, often showing faster growth than the solid portion of the tumor. When symptoms appeared, the mass effect derived more from the cyst than from the tumor. These tumors often have alternating periods of tumor growth and stability, and some remain stable in size for many years. These factors have to be considered in the timing and choice of treatment.

Surgery

A complete resection of a hemangioblastoma is often curative. Patients with preoperative hypertension should be evaluated for the presence of a pheochromocytoma, which can be associated with von Hippel-Lindau disease. Hemangioblastomas are very vascular lesions, and a biopsy of a suspected hemangioblastoma, either through an open approach or stereotactically, is usually ill advised because of the high risk of hemorrhage. Surgical resection should be carried out en bloc with avoidance of entry into the lesion, which can result in fierce bleeding reminiscent of an arteriovenous malformation. Preoperative, transarterial embolization is rarely safe because these tumors often receive supply from distal segments of the intra-axial circulation. Fortunately, these hemangioblastomas can be resected with minimal bleeding if resection is carried out entirely in the gliotic plane that surrounds the mass. This is straightforward in most cerebellar tumors, for which a margin of gliotic tissue can be resected with the lesion with little neurologic risk. In contrast, brainstem hemangioblastomas are immediately adjacent to critical structures.^{534,535} Sometimes, dissection immediately adjacent to the tumor can cause significant bleeding, with a high risk of inducing neurologic deficits.

These tumors are often associated with significant cysts. Surgery is the optimal treatment for the rapid relief of mass effect.

The cyst wall is not lined with tumor cells, and drainage, rather than excision, of the cyst lining is required. The mural tumor nodule must be entirely resected to avoid cyst recurrence. Cysts can be drained before opening the dura completely to provide brain relaxation, but great care must be taken not to disturb the tumor nodule during this maneuver to avoid inducing significant bleeding. The risk of hemorrhage during the resection is minimized by coagulating and dividing arterial feeders, if they can be visualized, before tumor removal. Finally, hemangioblastomas that occur in patients known to have von Hippel-Lindau disease may not need to be resected or otherwise treated unless they have demonstrated active growth or are symptomatic from mass effect or hydrocephalus. Because many of these patients harbor multiple tumors, other approaches, including radiosurgery, should also be considered, although surgery remains the only option that has a proven benefit.

Radiation Therapy

RT is recommended for patients with unresectable, incompletely excised, and recurrent hemangioblastomas and for those who are medically inoperable. Doses of at least 50 to 55 Gy over the course of 5.5 to 6 weeks appear to be warranted.⁵³⁶ Because of the noninvasive nature of these lesions, conformal radiotherapy or radiosurgery is indicated.

Radiosurgery should be considered for surgically unresectable hemangioblastomas, as adjuvant treatment for incompletely excised tumors, as definitive treatment for multifocal disease, and as salvage therapy for discrete recurrences after surgery.^{100,537} Although SRS treatment of hemangioblastomas in von Hippel-Lindau disease has a low risk for adverse radiation effects, it is associated with diminishing control over a long-term follow-up,⁵³⁸ and SRS should not be used to prophylactically treat asymptomatic tumors and should be reserved for the treatment of tumors that are not surgically resectable.

Chemotherapy

Because stromal cells in hemangioblastomas secrete VEGF, there is much interest in evaluating small-molecule inhibitors of the vascular endothelial growth factor -2 (VEGF-2) (KDR, FLK-1) receptor as medical management for these tumors, especially for patients with von Hippel-Lindau disease, who routinely harbor multiple hemangioblastomas. Unfortunately, the extreme heterogeneity of tumor growth, with periods of spontaneous stability and a slow overall growth rate, makes it extremely difficult to design trials to rigorously test the efficacy of any systemic therapy. In a small study of sunitinib therapy in 15 patients with von Hippel-Lindau disease-associated tumors, one-third of individuals with renal cell carcinoma achieved a partial response but none with hemangioblastomas.⁵³⁹

CHORDOMAS AND CHONDROSARCOMAS

Chordomas and chondrosarcomas are rare, locally destructive, slow-growing, malignant bone tumors. Although skull-base chordomas and chondrosarcomas are sometimes pooled together, recent studies have shown important differences between these entities.

Clinical and Pathologic Considerations

Chordomas arise within aberrant chordal vestiges along the pathway of the primitive notochord that extends from the tip of the dorsum sellae to the coccyx.⁵⁴⁰ One-third of chordomas arise cranially, with this location more common in women and younger individuals.⁵⁴¹ Chordomas are extradural, pseudoencapsulated, multilobulated tumors, with a gelatinous consistency centered in

the bone, classically with soft tissue extension. Microscopically, the typical chordoma is characterized by cordlike rows of *physaliferous* cells with multiple round, clear cytoplasmic vacuoles that impart a bubbly appearance to the cytoplasm. Two pathologic variants have been described. The *chondroid chordoma* has areas with cartilaginous features but a genetic profile distinct from chondrosarcomas.⁵⁴² The *dedifferentiated chordoma* contains areas of typical chordoma admixed with components that resemble high-grade or poorly differentiated spindle cell sarcoma. In typical chordomas, mitotic figures and atypia are rare; a higher mitotic rate and Ki-67 more than 6% are associated with a shorter doubling time.⁵⁴³

Chondrosarcomas are cartilage-producing neoplasm that arise within any of the complex synchondroses in the skull base, with the most common sites of origin being the temporo-occipital synchondrosis (66%), the sphenoid-occiput synchondrosis (28%), and the sphenoid complex (6%).⁵⁴⁴ Thus, chondrosarcomas predominantly originate in more lateral skull-base structures, unlike most chordomas, which originate in the midline. Chondrosarcomas can be difficult to differentiate from chordomas on a pathologic examination. Immunohistochemical advances have improved differentiation between chordomas and chondrosarcomas. In one series of 200 chondrosarcomas, 99% stained positive for S100, 0% for keratin, and epithelial membrane antigen was expressed in 8%.⁵⁴⁴ These immunohistochemical studies allow a chondrosarcoma to be differentiated from a chordoma, which is reactive for keratin and epithelial membrane antigen. The same series confirmed the low-grade nature of base of skull chondrosarcomas because a majority were grade 1, with no grade 3 tumors identified. Mesenchymal chondrosarcomas may have a separate, more aggressive natural history.⁵⁴⁵

Symptoms that prompt evaluation are typically cranial nerve deficits with the precise deficit dependent on the location and extent of the tumor. In one series, the most common presentation was headaches with intermittent abducens nerve palsy.⁵⁴⁶ Additional symptoms can be caused by intracranial extension with compression of the brainstem, pituitary gland, or optic apparatus. Neck pain may develop in lower clival tumors, possibly the result of pathologic fracture or periosteal expansion.

The differential diagnosis of cranial chordoma and chondrosarcoma includes basal meningioma, schwannoma (neurilemoma), nasopharyngeal carcinoma, pituitary adenoma, and craniopharyngioma. Chondrosarcomas and chordomas cannot be reliably distinguished from each other based on imaging features or location alone.⁵⁴⁷ High-resolution CT images with bone and soft tissue algorithms show a discrete, expansile soft tissue mass with extensive bony destruction.⁵⁴⁸ On MRI scanning, both chordomas and chondrosarcomas are hyperintense on T2-weighted sequences, with variegated enhancement. The location may be useful in distinguishing chordomas (midline clivus) from chondrosarcomas (petrous apex), although there is considerable overlap. Given the low risk of nodal or hematogenous dissemination, imaging beyond the primary site other than a chest x-ray is typically not indicated unless metastatic disease is suspected clinically.⁵⁴⁹ A baseline endocrine evaluation and neuro-ophthalmologic examination are both recommended if diagnostic imaging or symptoms suggest involvement.

Surgery

Surgery for cranial chordomas and chondrosarcomas provides the backbone of treatment and is obligatory to obtain diagnostic tissue, to enhance the effectiveness of subsequent RT, and to improve the patient's clinical condition. An aggressive initial approach may improve overall outcome.¹²⁶ Intracranial chordomas occur at the base of the skull, a region relatively remote from surgical access. Approaches to skull-base chordomas and chondrosarcomas often involve teams that include both neurosurgeons and otolaryngologists. There is developing interest in the use of endoscopy for the primary removal of chordomas or to assist in the removal of these

tumors via traditional open approaches. Although most series remain small, excellent results have been reported in appropriately selected patients not having extension lateral to the carotid arteries.^{550,551} A combination of exposures and procedures can be used for extremely large tumors. One goal of surgery is to remove as much tumor from the optic system and brainstem as possible so that very high doses of radiation can be delivered safely. Optimal treatment of these lesions is complete resection, if possible.

A potentially serious complication of the transsphenoidal, transsphenothmoid, and transoral approaches is CSF leakage into the nose or oropharynx and consequent meningitis. Therefore, every attempt is made to keep the dura intact during these procedures. Because dural invasion by cranial chordomas may occur 50% of the time, dural entry during tumor resection is sometimes unavoidable. Careful intraoperative patching of the leak with fat and muscle grafts followed by postoperative spinal CSF drainage should be undertaken to decrease the risk of infection in these cases. This may be more challenging in the setting of a total endoscopic tumor removal, although some techniques appear to be associated with reasonably low rates of CSF leak. Surgical series have reported gross total resection rates of 43% to 72%, with the most recent series using modern imaging and microsurgical techniques reporting the highest gross total resection rate. In this series, there was a 31% recurrence-free survival at 10 years, which was improved for those without previous intervention, and a 35% recurrence after gross total resection.^{552,553} The extent of resection correlated with both recurrence rates and survival. Surgical morbidity can be significant, with Gay et al.⁵⁵⁴ reporting a significant transient (53%) and permanent (43%) worsening of the Karnofsky performance score following surgery.

Approaches for chondrosarcomas are different because of the paramedian location of the tumors. Like chordomas, chondrosarcomas begin as extradural tumors, and maintaining the intact dural barrier is paramount. A complete tumor excision, which is paramount in chordoma surgery, is less critical for chondrosarcomas because tumor control rates with adjuvant high-dose radiation are high. Surgery is often tailored to emphasize the removal of tumor portions abutting critical structures such as the chiasm or brainstem to allow adequate radiation treatment. Cranial chordomas often recur after surgery and RT. In this situation, reoperation directed toward symptomatic improvement is the only treatment option. Reoperations are complicated by surgical scarring and tissue compromise from irradiation, and CSF leaks and other complications are more frequent.

Radiation Therapy

A radical excision with negative margins is often not feasible, and even gross excision is often obtained piecemeal with the risk of persistent microscopic disease. Because relentless extension is typical of chordomas and chondrosarcomas and recurrence is a strong predictor of OS, adequate local control is paramount in determining outcome. Radiotherapy is a mainstay of treatment in preventing recurrence or progression of tumor.

Local control of chordomas appears to be dose dependent. Conventional radiation at doses of 50 to 55 Gy does not offer satisfactory local control. A median dose of 50 Gy to chordomas of the skull, sacrum, and mobile spine provided only a 27% local control rate with a median time to progression of 35 months.⁵⁴⁹ Durable control was worse in base of skull disease, with only 1 out of 13 clival chordomas remaining disease free. FSRT to 37 sphenoccipital chordomas to a mean dose of 66.6 Gy provided local control rates of 82% at 2 years and 50% at 5 years. Despite a median tumor volume of 55.6 mL, complications were limited with one patient developing a pontine infarct 25 months posttreatment. No instances of optic neuropathy were identified. Chondrosarcomas treated with the same fractionation scheme had 100% 5-year local control.⁵⁵⁵

Radiosurgery

SRS has been used to treat chordomas and chondrosarcomas of the skull base, although its application is limited because of size constraints and proximity to critical structures. In one series, candidates were limited to less than 3 cm in greatest diameter and 5 mm from the optic chiasm, with a mean treatment volume of 4.6 mL and a maximum volume of 10.3 mL.⁵⁵⁶ With a mean margin dose of 18 Gy, more than 50% of patients in this mixed series of chondrosarcomas and chordomas had symptomatic improvement and, at a mean follow-up of 40 months, 20% had recurred locally outside of the treatment field. Krishnan et al.⁵⁵⁷ reported a similar local control rate (24%) with both in-field and out-of-field recurrences, although no recurrences occurred in patients with chondroid chordomas or chondrosarcomas. The risk of significant radiation-related complications was high at 34%, although complications were seen only in patients who had received prior fractionated radiotherapy.

Particle-Beam Therapy

Charged-particle therapy, because of its innate dose-distribution advantages, has been used for many years to escalate dose to chordomas and chondrosarcomas while minimizing radiation-related side effects. The most extensive experience in treating base of skull chordomas and chondrosarcomas with proton therapy arises from the experience at the Harvard Cyclotron Laboratory. Chordoma relapse-free survival was 59% at 4 years and 44% at 10 years, with similar rates seen in other series.⁵⁵⁸⁻⁵⁶¹ Mean dose ranged from 67 to 70.7 cobalt gray equivalent (CGE). Female gender, dose heterogeneity, large tumor size (more than 25 to 75 mL), brainstem invasion, and dose constrained by proximity to critical structures were all associated with higher rates of recurrence.⁵⁶² In a study of skull-base chordomas in 73 children and adolescents (mean age, 9.7 years), patients were treated with partial or gross surgical excision and postoperative proton beam irradiation.⁵⁵⁹ The mean follow-up period was 7.25 years, and the overall patient survival rate was 81% among 42 patients with conventional chordomas, 17 with chondroid chordomas, and 14 with cellular chordomas, 6 of which were poorly differentiated and highly aggressive. The most recent relatively large proton experience for managing skull-based chordomas comes from the Paul Scherrer Institute (PSI) in Switzerland. They have reported an 81% 5-year local control with surgery plus scanning proton beam therapy in 42 patients, possibly the best data reported in this disease to date. Median total dose for chordomas was 73.5 Gy at 1.8 to 2.0 Gy per fraction. Actuarial 5-year freedom from high-grade toxicity was 94%.⁵⁶³

Chondrosarcomas of the skull base had remarkably high local control rates of 99% and 98% at 5 and 10 years, respectively. Pituitary dysfunction and hearing loss were the most common side effects, with depression, memory loss, temporal necrosis, hearing loss, and blindness being less common. Given the relative lack of morbidity and the suboptimal local control for chordomas, dose escalation has been proposed. Recent radiotherapeutic advances include spot-scanning proton radiation.⁵⁶⁴ Carbon ion radiotherapy—charged-particle therapy using a heavier ion—has also been used with good local control with a short follow-up and better than expected radiographic responses.⁵⁶⁵ Amichetti et al.⁵⁶⁶ recently conducted a systematic review of the scientific literature published between 1980 and 2008 on data regarding irradiation of chondrosarcoma of the skull base with proton therapy. From 49 reports retrieved, there were no prospective trials and 9 uncontrolled single-arm studies mainly related to advanced and frequently incompletely resected tumors. According to the inclusion criteria, only four articles, reporting the most recent updated results of the publishing institution, were included in the analysis, providing clinical outcomes for 254 patients. The major findings corroborated the high control rates with low morbidity described previously.

Chemotherapy

In a prospective, phase II clinical study trial, 56 patients with advanced disease were treated with imatinib.⁵⁶⁷ In 50 evaluable patients, one partial response (PR) and 35 stable disease (SD, 70%) and a 64% clinical benefit rate (i.e., Response Evaluation Criteria in Solid Tumors [RECIST] complete response + PR + SD ≥ 6 months) was noted.⁵⁶⁷ Patients who have progressed after an initial response to imatinib can respond to combinations of imatinib and sirolimus.⁵⁶⁸

CHOROID PLEXUS TUMORS

Clinical and Pathologic Considerations

Primary tumors of the choroid plexus (CP) are classified according to the WHO as choroid plexus papilloma (CPP, WHO grade I), atypical CPP (grade II), and choroid plexus carcinoma (CPC, grade III).⁴ These are rare tumors that occur most often in children younger than 12 years of age. Although the grade might imply a clinical progression, typical CPP are a distinct entity, and almost never progress to CPC. Choroid plexus tumors appear irregular and lobulated, often very red because of underlying vasculature. Histopathologic examinations of papillomas often show an apparently normal choroid plexus, with increased cellular crowding and elongation. CPC show malignant features such as increased cellularity, high mitotic activity, loss of typical cellular architecture, and invasion of the brain parenchyma. Bridging the CPP and CPC is the entity called atypical CPP. Histologically, atypical CPP retains the architecture of the CPP but has high mitotic activity and an increase probability for recurrence after surgical resection. CPCs are commonly seen in families who carry a germline mutation in either the *TP53* gene (Li-Fraumeni syndrome).⁵⁶⁹ However, most patients with CPP and sporadic CPC do not harbor a germline *TP53* mutation.

In children, CPCs most often occur in the lateral ventricles. In adults, the fourth ventricular papilloma is most common. Third ventricle tumors are exceedingly rare. Because papillomas tend to grow slowly within ventricles, they expand to fill the ventricle and block CSF flow. In addition, papillomas can secrete CSF. CPPs and CPCs can produce hydrocephalus secondary to obstruction of the CSF, CSF overproduction by the tumor, or damage to the CSF resorptive bed from recurrent hemorrhages. As a result, increased ICP without focal findings is the most common presentation. Fourth ventricular tumors can also be associated with focal findings of ataxia and nystagmus. Although CPPs rarely seed throughout the CSF spaces, seeding from carcinomas is frequent and often symptomatic. CPCs will show invasion of the surrounding brain with resultant increased signal on T2-weighted MRI, and signs of rich vascularity (flow voids), often arising medially from the choroidal vessels.

Choroid plexus tumors are seen easily by MRI. Imaging demonstrates a lobulated, well-circumscribed, enhancing, intraventricular lesion, often with associated hydrocephalus. Calcification is not common. Choroid carcinomas may show areas consistent with necrosis and brain invasion.⁵⁷⁰

Surgery

The complete treatment of CPPs is total excision. Hydrocephalus is the rule and simplifies the exposure once the ventricle is opened. Tumor-associated branches of the choroidal vessels are coagulated and divided as early as is feasible in the procedure because this greatly reduces hemorrhaging. Smaller tumors are removed intact and larger tumors are removed piecemeal. Perioperative CSF drainage is used to prevent subdural hygromas. In half of patients, hydrocephalus is relieved by tumor resection, but persistent hydrocephalus requires shunting. The ability to perform a complete resection depends on histologic type, with nearly a 100%

complete resection rate for papillomas versus as low as a 33% complete resection rate for CPCs.⁵⁷¹ A meta-analysis of all individual cases of CPC reported as of 2004 (347 patients) showed that in the subgroup of incompletely resected carcinomas, 22.6% of patients required a second surgery.⁵⁷² The prognosis for these patients appeared better than for those with incomplete resections who did not undergo a second surgery (2-year OS times were 69% and 30%, respectively).

In the pediatric age group, when the diagnosis of CPC is suspected, the primary tumor resection should not be attempted because these tumors are extremely vascular, leading to the loss of multiple blood volumes and not infrequent intra-operative deaths. Cases of suspected CPC should be treated with an open biopsy, followed by ICE chemotherapy to devascularize the tumor. Subsequent postchemotherapy surgery is much safer and results in a greatly reduced blood loss.

Radiation Therapy

Because CPPs are often cured by a complete resection, radiotherapy is infrequently employed. Further, in a study of 41 patients, Krishnan et al.⁵⁷³ noted that reoperation for recurrence was required only half the time after the initial subtotal resection, suggesting that adjuvant radiotherapy may not be necessary after the initial subtotal resection in all patients. Because local control outcome at first relapse was poor after the subtotal resection, they concluded that the most reasonable role for RT is after a subtotal resection of a recurrence.

Chemotherapy

Chemotherapy is not used for CPPs, although it has been attempted for CPCs. As with many of the less common CNS tumors, there are no firm guidelines. Anecdotal reports have cited moderate responses to the platinum compounds, as well as to alkylating agents, etoposide, methotrexate, and possibly anthracyclines. A Pediatric Oncology Group study of eight infants with CPC suggests that radiation can be forestalled by using chemotherapy in some infants with these tumors.⁵⁷⁴ In a meta-analysis conducted by Wrede et al.,⁵⁷⁵ CPCs were analyzed; 104 cases with CPC received chemotherapy and had a statistically better survival than those without chemotherapy.

SPINAL AXIS TUMORS

Clinical and Pathologic Considerations

Most primary spinal axis tumors produce symptoms and signs as a result of cord and nerve root compression rather than parenchymal invasion. The frequency of primary spinal cord tumors is between 10% and 19% of all primary CNS tumors. Parenthetically, the majority of neoplasms that affect the spine are extradural metastases, whereas most primary tumors are intradural. Of the intradural neoplasms, extramedullary schwannomas and meningiomas are the most common. Schwannomas and meningiomas are normally intradural, but occasionally, may present as extradural tumors. Other intradural, extramedullary neoplasms include vascular tumors, chordomas, and epidermoids. Intramedullary tumors include ependymomas, comprising approximately 40% of intramedullary tumors; the remainder are astrocytomas, oligodendrogliomas, gangliogliomas, medulloblastomas, and heman-gioblastomas. Approximately half of spinal tumors involve the thoracic spinal canal (the longest spinal segment), 30% involve the lumbosacral spine, and the remainder involve the cervical spine, including the foramen magnum. Schwannomas occur with greatest frequency in the thoracic spine, although they can be found at

other levels. They often extend through an intervertebral foramen in a dumbbell configuration. Meningiomas are dural based and arise preferentially at the foramen magnum and in the thoracic spine. Most patients are women. Astrocytomas are distributed throughout the spinal cord, and most ependymomas involve the conus medullaris and the cauda equina. Spinal chordomas are characteristically sacral and only rarely affect the cervical region or the rest of the mobile spine.

Patients may present with a sensorimotor spinal tract syndrome, a painful radicular spinal cord syndrome, or a central syringomyelic syndrome. In the sensorimotor presentation, symptoms and signs reflect compression of the cord. The onset is gradual during weeks to months, initial presentation is asymmetric, and motor weakness predominates. The level of impairment determines the muscle groups involved. Because of external compression, dorsal column involvement results in paresthesia and abnormalities of pain and temperature on the side contralateral to the motor weakness.

Radicular spinal cord syndromes occur because of external compression and infiltration of spinal roots. The main symptom is sharp, radicular pain in the distribution of a sensory nerve root. The intense pain is often of short duration, with pain that is more aching in nature persisting for longer periods. Pain may be exacerbated by coughing and sneezing or other maneuvers that increase ICP. Local paresthesia and numbness are common, as are weakness and muscle wasting. These findings often precede cord compression by months. Often, the pain is difficult for the clinician to differentiate from ordinary musculoskeletal symptoms, which causes diagnostic delay.

Intramedullary tumors, in particular, can give rise to syringomyelic dysfunction by destruction and cavitation within the central gray matter of the cord. This produces lower motor neuron destruction with associated segmental muscle weakness, atrophy, and hyporeflexia. There is also a dissociated sensory loss of pain and temperature sensation with the preservation of touch. As the syrinx increases in size, all sensory modalities are affected.

Surgery

The operating microscope is essential for spinal cord tumor surgery. Ultrasonography can be used to examine the spinal cord through either intact or open dura to find the level of maximum tumor involvement or to differentiate tumor cysts from solid tumors. Intraoperative monitoring of somatosensory-evoked potentials is commonly used, although some surgeons think that changes in somatosensory-evoked potentials may occur only after irretrievable damage has occurred, and this remains a topic of controversy. Motor-evoked potentials are used in some centers to guide resection and have retrospectively been shown by some to decrease long-term motor deficits.

MRI is invaluable for the diagnosis, localization, and characterization of spinal tumors. For extremely vascular tumors—notably, hemangioblastoma—angiography may provide important preoperative delineation of the tumor blood supply. CT scanning is useful for tumors of the bony axis. Determination of the spinal level of the tumor and its exact relation to the cord is important. Corticosteroids are given before, during, and after spinal cord tumor surgery to help control spinal cord edema.

Meningiomas and schwannomas occur in the intradural, extramedullary spinal compartment. Most of these tumors can be completely resected through a laminectomy. They can be easily separated away from the cord, which is displaced but not invaded by tumor. Schwannomas arise most often in the dorsal spinal rootlets, and their removal includes the rootlets involved. They can grow along the nerve root in a dumbbell fashion through a neural foramen. Some of these can be removed by extending the initial laminectomy exposure laterally, whereas others require a separate operation (e.g., a thoracotomy, costotransversectomy, or a retroperitoneal approach). Strictly anteriorly situated cervical tumors can

successfully be removed via an anterior approach using a corpectomy of the appropriate vertebral levels, followed by strut grafting after the tumor resection.

The most common intramedullary tumors are ependymomas and astrocytomas. Except for malignant astrocytomas, resection is the principal treatment for these tumors. Intramedullary tumors are approached through a laminectomy. After dural opening, a longitudinal myelotomy is made, usually in the midline or dorsal root entry zone. The incision is deepened several millimeters to the tumor surface. Dissection planes around the tumor are sought microscopically and, in the case of ependymomas, usually found and extended gradually around the tumor's surface, whereas removal of the central tumor bulk (by carbon dioxide laser or ultrasonic aspirator) causes the tumor to collapse. Such tumors are usually completely removed, with good long-term outcomes.⁵⁷⁶ Some patients later develop a spinal deformity, requiring stabilization procedures.⁵⁷⁷ Tumors without clear dissection planes (usually astrocytomas) cannot be removed completely, but bulk reduction can cause long-term palliation. If a frozen-section analysis shows a tumor to be a malignant glioma, a less aggressive surgery is typically performed due to the increased risk of morbidity with little benefit achieved from an extensive debulking procedure.

Radiation Therapy

RT is recommended for unresectable and incompletely resected neoplasms of the spinal axis. In general, doses of 50 to 54 Gy (1.8 Gy per day) are used so that the risk of injury to the cord from radiation is minimized. When lesions involve only the cauda equina or when complete, irreversible myelopathy already has occurred, higher doses are used.

Ependymomas have a longer natural history than astrocytomas. Recurrence of ependymomas may be delayed for as long as 12 years.^{578,579} RT is not necessary when ependymomas are removed completely in an en bloc fashion.⁵⁷⁶ All nonirradiated patients with incompletely excised lesions reported by Barone and Elvidge⁵⁸⁰ and by Shuman et al.⁵⁸¹ experienced recurrence. Postoperative irradiation appears to improve tumor control for incompletely resected ependymomas. Five- and 10-year survival rates in irradiated patients with localized ependymomas range from 60% to 100% and 68% to 95%, respectively, whereas 10-year relapse-free survival rates vary from 43% to 61%.⁵⁸² The tumor grade has a significant effect on outcome. Waldron et al.⁵⁷⁹ found that for patients with well-differentiated tumors, the 5-year cause-specific survival was 97% compared with 71% for patients with intermediate or poorly differentiated tumors ($p = 0.005$). Myxopapillary ependymomas that arise in the conus medullaris and filum terminale have a better prognosis than the cellular ependymomas that arise in the cord.⁵⁸³ Local recurrence is the predominant pattern of treatment failure, occurring in 25% of irradiated patients.⁵⁷⁹

The 5- and 10-year survival rates for irradiated patients with low-grade astrocytomas of the spinal cord vary from 60% to 90% and 40% to 90%, respectively; 5- and 10-year relapse-free survival rates range from 66% to 83% and 53% to 83%, respectively.^{577,579} Fifty percent to 65% of astrocytomas are controlled locally. Good neurologic condition at the time of irradiation, lower histologic grade, and younger age are favorable factors.⁵⁸⁴ Patterns of recurrence for malignant astrocytomas of the spine have been analyzed by MRI.⁵⁸⁵ Despite surgery and full-dose radiation, spinal or brain dissemination is the predominant mode of failure.

Chemotherapy

There are no significant controlled clinical trials of chemotherapy for primary spinal axis tumors. Drugs active against intracranial tumors logically may be assumed to be equally efficacious against histologically identical tumors in the spinal cord. Temozolomide is being increasingly used in this setting.

98 Molecular Biology of Childhood Cancers

Lee J. Helman and David Malkin

INTRODUCTION

Tumors of childhood are clinically, histopathologically, and biologically distinct from that of adult-onset malignancies. Childhood cancers tend to have short latency periods, are often rapidly growing and aggressively invasive, are rarely associated with exposure to carcinogens, and are generally more responsive to standard modalities of treatment, in particular chemotherapy. Most childhood tumors occur sporadically in families with, at most, a weak history of cancer. In at least 10% to 15% of cases, however, a strong familial association is recognized or the child has a congenital or genetic disorder that imparts a higher likelihood of specific cancer types.¹ Examples of genetic disorders that render a child at increased risk of tumor development include xeroderma pigmentosa, Bloom syndrome, or ataxia telangiectasia, which predispose to skin cancers, leukemias, or lymphoid malignancies, respectively. In all three cases, constitutional gene alterations that disrupt normal mechanisms of genomic DNA repair are blamed for the propensity to cell transformation. Other hereditary disorders, including Beckwith-Wiedemann syndrome (BWS), von Hippel-Lindau disease, Rothmund-Thomson syndrome, and the multiple endocrine neoplasias types 1 and 2, are associated with their respective tumor spectra through constitutional activation of molecular pathways of deregulated cellular growth and proliferation. The cancers that occur in these syndromes are generally secondary phenotypic manifestations of disorders that have distinctive recognizable physical stigmata. On the other hand, some cancer predisposition syndromes are recognized only by their malignant manifestations, with nonmalignant characteristics being virtually absent. These include hereditary retinoblastoma, Li-Fraumeni syndrome (LFS), familial Wilms tumor, and familial adenomatous polyposis coli. Each of these presents with distinct cancer phenotypes and unique molecular defects (Table 98.1). Careful attention to detailed cancer family histories continues to lead to the discovery of new cancer predisposition syndromes and the coincident identification of novel cancer genes.²

The study of pediatric cancer and rare hereditary cancer syndromes and associations has led to the identification of numerous cancer genes, including dominant oncogenes, DNA repair genes, and tumor suppressor genes. These genes are important not only in hereditary predisposition, but also in the normal growth, differentiation, and proliferation pathways of all cells. Alterations of these genes have been consistently found in numerous sporadic tumors of childhood and led to studies of their functional role in carcinogenesis. The numerous properties of transformed malignant cells in culture or in vivo can be explained by the complex abnormal interaction of numerous positive and negative growth-regulatory genes. Pediatric cancers offer unique models in which to study these pathways in that they are less likely to be disrupted by nongenetic factors. The embryonic ontogeny of many childhood cancers suggests that better understanding of the nature of

the genetic events leading to these cancers will also augment the understanding of normal embryologic growth and development.

This chapter begins with an outline of tumor suppressor genes—the most frequently implicated class of cancer genes in childhood malignancy. This leads into a discussion of molecular features of retinoblastoma, the paradigm of cancer genetics, followed by an analysis of the molecular pathways associated with other common pediatric cancers. Evaluations of the importance of molecular alterations in familial cancers, as well as new approaches in molecular therapeutics are also addressed.

TUMOR SUPPRESSOR GENES

Faulty regulation of cellular growth and differentiation leads to neoplastic transformation and tumor initiation. Many inappropriately activated growth-potentiating genes, or *oncogenes*, have been identified through the study of RNA tumor viruses and the transforming effects of DNA isolated from malignant cells. However, activated dominant oncogenes themselves do not readily explain a variety of phenomena related to transformation and tumor formation. Among these is the suppression of tumorigenicity by the fusion of malignant cells with their normal counterparts. If these malignant cells carried an activated dominant oncogene, it would be expected that such a gene would initiate transformation of the normal cells, likely leading to either embryonic or fetal death. The observation is more readily explained by postulating the existence of a factor in the normal cell that acts to suppress growth of the fused malignant cells. Malignant cells commonly exhibit specific chromosomal deletions (Table 98.2). The best example of this occurs in retinoblastoma, a rare pediatric eye tumor in which a small region of the long arm of chromosome 13 is frequently missing. The presumed loss of genes in specific chromosomal regions argues strongly against the concept of a dominantly acting gene being implicated in the development of the tumor. Comparisons between the frequencies of familial tumors and their sporadic counterparts led Knudson³ to suggest that the familial forms of some tumors could be explained by constitutional mutations in growth-limiting genes. The resulting inactivation of these genes would facilitate cellular transformation.⁴ Such growth-limiting genes were termed *tumor suppressor genes*.

Whereas acquired alterations of dominant oncogenes most commonly occur in somatic cells, mutant tumor suppressor genes may be found either in germ cells or somatic cells. In the former, they may arise de novo or be transmitted from generation to generation within a family. The diversity of functions, cellular locations, and tissue-specific expression of the tumor suppressor genes suggest the existence of a complex, yet coordinated, cellular pathway that limits cell growth by linking nuclear processes with the intra- and extracytoplasmic environment. This discussion is limited to those genes for which pediatric tumors are frequently associated.

TABLE 98.1

Hereditary Syndromes Associated with Childhood Cancer Predisposition

Syndrome	OMIM Entry ^a	Major Tumor Types	Mode of Inheritance	Genes
<i>Hereditary Gastrointestinal Malignancies</i>				
Adenomatous polyposis of the colon	175100	Colon, thyroid, stomach, intestine, hepatoblastoma	Dominant	APC
Juvenile polyposis	174900	Gastrointestinal	Dominant	SMAD4/DPC4
Peutz-Jeghers syndrome	175200	Intestinal, ovarian, pancreatic	Dominant	STK11
<i>Genodermatoses with Cancer Predisposition</i>				
Nevoid basal cell carcinoma syndrome	109400	Skin, medulloblastoma	Dominant	PTCH
Neurofibromatosis type 1	162200	Neurofibroma, optic pathway glioma, peripheral nerve sheath tumor	Dominant	NF1
Neurofibromatosis type 2	101000	Vestibular schwannoma	Dominant	NF2
Tuberous sclerosis	191100	Hamartoma, renal angiomyolipoma, renal cell carcinoma	Dominant	TSC1/TSC2
Xeroderma pigmentosum	278730, 278700, 278720, 278760, 278740, 278780, 278750, 133510	Skin, melanoma, leukemia	Recessive	XPA, B, C, D, E, F, G, POLH
Rothmund-Thomson syndrome	268400	Skin, bone	Recessive	RECQL4
<i>Leukemia/Lymphoma Predisposition Syndromes</i>				
Bloom syndrome	210900	Leukemia, lymphoma, skin	Recessive	BLM
Fanconi anemia	227650	Leukemia, squamous cell carcinoma, gynecologic system	Recessive	FANCA, B, C, D ₂ , E, F, G
Shwachman-Diamond syndrome	260400	Leukemia/myelodysplasia	Recessive	SBDS
Nijmegen breakage syndrome	251260	Lymphoma, medulloblastoma, glioma	Recessive	NBS1
Ataxia telangiectasia	208900	Leukemia, lymphoma	Recessive	ATM
<i>Genitourinary Cancer Predisposition Syndromes</i>				
Simpson-Golabi-Behmel syndrome	312870	Embryonal tumors, Wilms tumor	X-linked	GPC3
Von Hippel-Lindau syndrome	193300	Retinal and central nervous hemangioblastoma, pheochromocytoma, renal cell carcinoma	Dominant	VHL
Beckwith-Wiedemann syndrome	130650	Wilms tumor, hepatoblastoma, adrenal carcinoma, rhabdomyosarcoma	Dominant	CDKN1C/NSD1
Wilms tumor syndrome	194070	Wilms tumor	Dominant	WT1
WAGR syndrome	194072	Wilms tumor, gonadoblastoma	Dominant	WT1
Costello syndrome	218040	Neuroblastoma, rhabdomyosarcoma, bladder carcinoma	Dominant	H-Ras
<i>Central Nervous System Predisposition Syndromes</i>				
Retinoblastoma	180200	Retinoblastoma, osteosarcoma	Dominant	RB1
Rhabdoid predisposition syndrome	601607	Rhabdoid tumor, medulloblastoma, choroid plexus tumor		SNF5/INI1
Medulloblastoma predisposition	607035	Medulloblastoma	Dominant	SUFU
<i>Sarcoma/Bone Cancer Predisposition Syndromes</i>				
Li-Fraumeni syndrome	151623	Soft tissue sarcoma, osteosarcoma, breast, adrenocortical carcinoma, leukemia, brain tumor	Dominant	TP53
Multiple exostoses	133700, 133701	Chondrosarcoma	Dominant	EXT1/EXT2
Werner syndrome	277700	Osteosarcoma, meningioma	Recessive	WRN
<i>Endocrine Cancer Predisposition Syndromes</i>				
MEN1	131000	Pancreatic islet cell tumor, pituitary adenoma, parathyroid adenoma	Dominant	MEN1
MEN2	171400	Medullary thyroid carcinoma, pheochromocytoma, parathyroid hyperplasia	Dominant	RET

RETINOBLASTOMA: THE PARADIGM

Retinoblastoma is the prototype cancer caused by mutations of a tumor suppressor gene. It is a malignant tumor of the retina that occurs in infants and young children, with an incidence of approximately 1:20,000.⁵ Approximately 40% of retinoblastoma cases are of the heritable form in which the child inherits one mutant allele at the retinoblastoma susceptibility locus (*Rb1*) through the germ line, and a somatic mutation in a single retinal cell causes loss of function of the remaining normal allele, leading to tumor formation. Tumors are often bilateral and multifocal. The disease is inherited as an autosomal-dominant trait, with a penetrance approaching 100%.⁶ The remaining 60% of retinoblastoma cases are sporadic (nonheritable), in which both *Rb1* alleles in a single retinal cell are inactivated by somatic mutations. As one can imagine, such an event is rare, and these patients usually have only one tumor that presents itself later than in infants with the heritable form. Fifteen percent of unilateral retinoblastoma is heritable⁶ but by chance develops in only one eye. Survivors of heritable retinoblastoma have a several 100-fold increased risk of developing mesenchymal tumors such as osteogenic sarcoma, fibrosarcomas, and melanomas later in life.⁷ Several genetic mechanisms have been implicated in elimination of the second wild-type *Rb1* allele in an evolving tumor. These include chromosomal duplication or nondisjunction, mitotic recombination, or gene conversion.⁸

The *Rb1* gene maps to chromosome 13q14 and encodes a 105kD phosphoprotein.^{9,10} The second target gene that led to disease was actually the second copy of the *Rb1* locus. Reduction to homozygosity of the mutant allele (or loss of heterozygosity [LOH] of the wild-type allele) would lead to the loss of functional *Rb1* and account for tumor development. As well as being altered in retinoblastoma, *Rb1* and its protein product are altered in osteosarcomas, small cell lung carcinomas, and bladder, breast, and prostate carcinomas.^{10,11} *Rb1* plays a central role in the control of cell-cycle regulation, particularly in determining transition from G1 through S (the DNA synthesis) phase in virtually all cell types.

Although it is clear that *Rb1* and its protein product play some role in growth regulation, the precise nature of this role remains obscure. In the developing retina, inactivation of the *Rb1* gene is necessary but not sufficient for tumor formation.¹² Retinoblastomas develop as a result of a complex interplay of aberrant expression of other cell-cycle control genes. In particular, a tumor

surveillance pathway mediated by Arf, MDM2, MDMX, and p53 (see later discussion) is activated after a loss of *Rb1* during development of the retina. *Rb1*-deficient retinoblasts undergo p53-mediated apoptosis and exit the cell cycle. Subsequently, amplification of the *MDMX* gene and increased expression of *MDMX* protein are strongly selected for during tumor progression as a mechanism to suppress the p53 response in *Rb1*-deficient retinal cells.¹³ Not only do these observations provide a provocative biologic mechanism for tumor formation in retinoblastoma, but it also offers potential molecular targets for novel therapeutic approaches to this tumor.^{14,15} Some *Rb1* mutations appear to lead to an attenuated form of the disease, an observation that highlights the variable penetrance in families.^{16,17} Outside the retina, *Rb1* inactivation is often a rate-limiting step in tumorigenesis generated by multiple genetic events. The molecular characteristics and potential functional activities of *Rb1* are outlined in detail elsewhere in this volume.

The patterns of inheritance and presentation of retinoblastoma have been well described and the responsible gene has been identified. The basic mechanisms by which the gene is inactivated are understood, and provocative evidence indicates that the intricate functional interactions of pRB with its binding partners and other cell cycle targets will provide targets for development of novel small molecule therapies.

SDH DEFICIENT GIST

Gastrointestinal stromal tumors (GIST) are the most common mesenchymal tumors found in the gastrointestinal (GI) tract, and occur in both adults and children. Strikingly, unlike most adult GIST tumors that harbor either *KIT* or platelet-derived growth factor receptor A (*PDGFRA*) mutations and are susceptible to tyrosine kinase (TK) inhibitors directed against these kinases, 85% of pediatric GIST tumors do not harbor such mutations, and not surprisingly are much less responsive to TK inhibitors. Thus, it appears that a histologically similar tumor in a pediatric population is remarkably biologically distinct from the same tumor in the adult population. It was recently demonstrated that the pediatric-type GIST tumor is characterized by metabolic derangement of the mitochondrial enzyme, succinate dehydrogenase (SDH).¹⁸ Many of these patients have been found to carry germ-line mutations of SDH subunits B, C, or D (SDH_B, SDH_C, or SDH_D) mutations. These germ-line

mutations were first described in Carney-Stratakis syndrome, an inherited predisposition to GIST and paragangliomas.¹⁹ It is noteworthy that these SDH-deficient pediatric predominant GISTs have a marked predilection for gastric location and are more frequent in the female population.²⁰

Further characterization of molecular differences between the typical adult GIST, *KIT*, or *PDGFRA* activated tumors and SDH-deficient, pediatric-type GIST tumors revealed marked epigenetic distinctions between these two types of GISTs. Specifically, the SDH-deficient tumors were found to have marked global hypermethylation compared to the TK-mutant GISTs. Of specific note was enrichment for hypermethylation within DNase hypersensitivity sites.²¹

Thus it is clear that most pediatric GISTs are driven by a distinct mechanism related to SDH-deficient function compared to the adult GISTs, which are driven by the mutation activation of *KIT* or *PDGFRA* kinases. Furthermore, many of these tumors are associated with germ-line mutations of SDH_x, and may or may not be associated with paragangliomas. The finding of global hypermethylation in the pediatric-type GISTs was associated with very stable genomes, suggesting these tumors are epigenetically driven tumors.²¹ Overall, these data clearly suggest that despite histologically similar tumors, the GISTs that occur in the younger population have a distinct behavior that will require management that is quite different than the management of adult, TK-mutating GISTs.

NEUROFIBROMATOSIS

The neurofibromatoses comprise two similar entities. Neurofibromatosis type 1 (NF1) is one of the most common autosomal-dominantly inherited disorders, affecting about 1 in 3,500 people,²² half of which arise from new spontaneous mutations. Carriers of mutant NF1 are predisposed to a variety of tumors, including Schwann cell-derived tumors (neurofibromas and malignant peripheral nerve sheath tumors, gliomas including optic nerve gliomas and malignant gliomas, and pheochromocytomas).^{23,24} Occurring with less frequency are leukemias, osteosarcomas, rhabdomyosarcomas, GISTs, and Wilms tumors.

Using a standard linkage analysis, the neurofibromatosis type 1 (NF1) gene was mapped to chromosomal band 17q11, and subsequently cloned.^{25,26} The NF1 gene is unusual in that it contains three embedded genes, *OMGP*, *EV12A*, and *EV12B*, in a single intron.²⁷ This gene encodes a 2818 amino acid protein, termed *neurofibromin*, that is ubiquitously expressed. One region of the gene shows extensive structural homology to the GTPase activating domain of mammalian GTPase-activating protein (GAP) proteins: loss of the protein's activity results in failure of hydrolysis of GTP to guanosine diphosphate (GDP) by the ras oncoprotein. Loss of neurofibromin function usually results from mutations in one allele of the gene leading to premature truncation of the protein, followed by absence or mutations of the second allele in tumors. This loss of function is thought to lead to elevated levels of the GTP-bound RAS protein that transduces signals for cell division. Downstream modulators of RAS activation in NF1-associated tumors include activation of mammalian target of rapamycin (mTOR) and mitogen activated protein kinase (MEK).^{28,29} Thus, although targeting RAS remains elusive, mTOR and MEK inhibitors are currently either available or are being tested in the clinic. Neurofibromatosis type 2 (NF2) is much less frequent than NF1, occurring in only 1 in 1 million persons. Although it is also inherited as an autosomal-dominant disorder with high penetrance, the new mutation rate in NF2 is low.³⁰ It is clinically characterized by bilateral vestibular schwannomas, spinal nerve root tumors, meningiomas, and ependymomas.

The NF2 locus was mapped to chromosome 22, band q12,³¹ and its 69-kDa encoded protein, termed merlin, has been shown to be expressed in various tissues, including the brain, although not

as ubiquitously as NF1.^{32,33} The mechanism of tumor formation in NF2 appears to be in concordance with the Knudson two-hit model, although the mechanism of action of the NF2 protein has not yet been elucidated. Merlin is a member of the Band 4.1 family of proteins that link cell surface proteins to the cytoskeleton.³⁴ Merlin has been shown to inhibit the number of signaling pathways critical for normal growth including mTOR, Rac1, and Hippo/YAP, with loss of Merlin leading to activation of these pathways, again suggesting potential therapies aimed at inhibition of these pathways.³⁴

NEUROBLASTOMA

Nonrandom chromosomal abnormalities are observed in more than 75% of neuroblastomas.³⁵ The most common of these is deletion or rearrangement of the short arm of chromosome 1, although loss, gain, and rearrangements of chromosomes 10, 11, 14, 17, and 19 have also been reported. The allelic losses indicate loss of function of as yet unknown tumor suppressor genes in these regions. It is believed that a tumor suppressor gene, such as *CHD5* and the kinesin *KIF1Bbeta* that lies on band p36 of chromosome 1 is critically important in the pathogenesis and aggressive nature of neuroblastoma.^{36,37} It has been shown that the loss of chromosome 1p is a strong prognostic factor in patients with neuroblastoma, independent of age and stage.³⁸ Although it is as yet unclear which gene(s) in this region may be directly implicated in neuroblastoma development, aberrant expression of one candidate—*p73*—which is a member of the *p53* tumor suppressor family, has been suggested to play a role in the neuroblastoma cell growth as well as chemotherapy resistance.³⁹ *p73* gives rise to multiple functionally distinct protein isoforms as a result of alternative promoter utilization and alternative mRNA splicing.^{40,41} Alternative splicing of the *p73* mRNA results in more than seven protein isoforms that differ in the coding sequences of the COOH terminus (TA-*p73* α , β , γ , δ , ϵ , ζ , η).

In addition to these COOH-terminal splice forms, three additional forms, *Np73 α* , Δ *Np73 β* , and Δ *Np73 γ* , are transcribed from an alternative promoter located in intron 3. Higher levels of Δ *Np73* are associated with an overall worse clinical prognosis, presumably because of the *antiapoptotic* properties of Δ *Np73* and its ability to inactivate both *TAp73* and *p53*.^{42,43}

Two other unique cytogenetic rearrangements are highly characteristic of neuroblastomas.⁴⁴ These structures, homogeneous staining regions (HSR) and double-minute chromosomes (DM), contain regions of gene amplification. The *N-myc* gene, an oncogene with considerable homology to the cellular protooncogene *c-myc*, is amplified within HSR and DM. Virtually all neuroblastoma tumor cell lines demonstrate amplified and highly expressed *N-myc*,⁴⁵ and *N-myc* amplification is thought to be associated with rapid tumor progression. Expression of *N-myc* is increased in undifferentiated tumor cells compared with much lower (or single-copy) levels in more differentiated cells (ganglioneuroblastomas and ganglioneuromas). *N-myc* expression is diminished in association with the *in vitro* differentiation of neuroblastoma cell lines.⁴⁶ This observation formed the basis for current therapeutic trials demonstrating a survival advantage to patients treated with *cis-retinoic acid*.⁴⁷ Furthermore, a close correlation exists between *N-myc* amplification and advanced clinical stage.⁴⁸

Neuroblastoma cells that express the high-affinity nerve growth factor receptor *trkA*⁴⁹ can be terminally differentiated by nerve growth factor and may demonstrate morphologic changes typical of ganglionic differentiation. Tumors showing ganglionic differentiation and *trk* gene activation have a favorable prognosis.⁴⁹ In contrast, *trkB* receptor expression is associated with poor-prognosis tumors and appears to mediate resistance to chemotherapy.^{50,51} Resistance to multidrug chemotherapeutic regimens (i.e., multidrug resistance) is characteristic of aggressive, poorly responsive *N-myc*-amplified neuroblastomas. It is interesting to note that expression of the multidrug resistance-associated protein, found

to confer multidrug resistance *in vitro*, is increased in neuroblastomas with *N-myc* amplification, decreased after differentiation of tumor cells *in vitro*, and associated with poor outcome independent of *N-myc* amplification.⁵² Gain of chromosome segment 17q21-qter, in which *BICR5*, which encodes Survivin (a member of the apoptosis inhibiting proteins NM23 and PMMID) has been posited as a neuroblastoma-associated candidate gene, has been shown to be the most powerful prognostic factor yet.⁵³

A small subset of neuroblastomas is inherited in an autosomal-dominant fashion. Until recently, the only gene definitively associated with neuroblastoma risk was *PHOX2B*, also linked to central apnea.⁵⁴ De novo or inherited missense mutations in the TK domain of the anaplastic lymphoma kinase (*ALK*) gene on chromosome 2p23 have been observed in the majority of hereditary neuroblastoma families, as well as in somatic tumor cells.^{55–58} Current phase I/II clinical trials with *ALK* inhibitors substantiate the value of such target identification for novel therapies.⁵⁹ The role of other molecular alterations in neuroblastoma continues to be elucidated. In addition to chromosomal loss on chromosome 1p36, unbalanced LOH at 11q23 is independently associated with decreased event-free survival. Alterations at 11q23 occur in almost one-third of neuroblastomas, being most commonly associated with stage 4 disease and age at diagnosis greater than 2.5 years. Both 1p36 LOH and 11q23 LOH were independently associated with decreased progression-free survival in patients with low- and intermediate-risk disease.⁶⁰

Yet another valuable biologic marker of clinical significance is telomerase expression and telomere length. In particular, short telomere length is predictive of favorable prognosis, irrespective of disease stage, whereas long or unchanged telomeres are predictive of poor outcome.^{61,62} Telomerase expression, as measured by human telomerase reverse transcriptase (hTERT), has been shown to be negative in good-risk neuroblastomas, although it is high in tumors with unfavorable histology.⁶² The combined use of these markers—chromosomes 1p and 11q, *N-Myc* amplification, *trkA*, and telomerase expression—as prognostic indicators provides a powerful armamentarium with which to develop rational stratified treatment programs for neuroblastomas.

EWING SARCOMA FAMILY OF TUMORS

Ewing sarcoma (ES) is one of the first examples in which the application of molecular diagnostics led to improved tumor classification. ES was first described by James Ewing⁶³ as a bone tumor characterized by small, blue, round cells and minimal mitotic activity. Turc-Carel et al.⁶⁴ identified a recurring reciprocal t(11;22) chromosomal translocation in these tumors in 1983. Investigators subsequently demonstrated a cytogenetically identical t(11;22) in adult neuroblastoma or peripheral primitive neuroectodermal tumor (pPNET), so named because of its histologic similarity to neuroblastoma.⁶⁵ Based on the presence of the identical translocation, it was hypothesized that pPNET was related to ES. This translocation breakpoint has been molecularly characterized as an in-frame fusion between a new ES gene, *Ewing's sarcoma breakpoint region 1* (*EWS*), on chromosome 22 and an ETS transcription family member, friend leukemia virus integration 1 (*FLI-1*), on chromosome 22.^{66–68}

In addition to this fusion transcript being identified in pPNET, other variants, notably the chest-wall Askin tumor and soft tissue ES—previously treated as an RMS because of its location in soft tissue—were also shown to bear the identical fusion transcript. In total, five translocations also have been identified, invariably fusing the *EWS* gene to an ETS family member.^{69–72} More than 90% of the ES family of tumors (ESFT) carry the *EWS-ETS* fusion gene, and a search for *EWS-ETS* by either reverse transcriptase-polymerase chain reaction or fluorescence *in situ* hybridization should be considered standard practice in the diagnostic evaluation of suspected ESFTs. Interestingly, although it was suggested that the specific fusion protein expressed in ESFT has prognostic

significance,⁷³ several prospective studies in the United States and Europe demonstrated no prognostic impact.^{74,75} The nature of the novel fusion transcription factor and its downstream targets is currently under intense investigation. One target of the *EWS-ETS* fusion is repression of the transforming growth factor- β type II receptor,⁷⁶ a putative tumor suppressor gene.

Expression profiling analysis has also revealed that p53 is transcriptionally upregulated by the *EWS-ETS* fusion gene.⁷⁷ This is of particular interest because it is now known that expression of *EWS-ETS* can lead to apoptosis, and that additional alterations such as loss of p53 or p16 signaling, or both, appear to be necessary components of *EWS-ETS*-induced transformation.⁷⁸ Investigators have now taken advantage of RNA interference technology to inhibit *EWS-FLI-1* in Ewing cell lines to identify genes regulated by the fusion in the proper context. Using this approach, *NKX2.2* and *NR0B1* have been found to be a target gene of *EWS-FLI-1* that is necessary for oncogenic transformation.^{79,80} Recent findings suggest that GGAA microsatellites might mark genes that are upregulated by *EWS-FLI-1* binding.⁸¹

RHABDOMYOSARCOMA

The two major histologic subtypes of RMS, embryonal and alveolar, have both unique histologic appearance as well as distinctive molecular genetic abnormalities, while sharing a common myogenic lineage. Embryonal tumors comprise two-thirds of all RMS, and are histologically characterized by a stroma-rich spindle-cell appearance. Alveolar tumors comprise about one-third of RMS, and are histologically characterized by densely packed small round cells often lining a septation reminiscent of a pulmonary alveolus, giving rise to its name. Both histologic subtypes express muscle-specific proteins, including α -actin, myosin, desmin, and MyoD,^{82–84} and they virtually always express high levels of insulin-like growth factor 2 (IGF2).^{85,86}

At the molecular level, embryonal tumors are characterized by LOH at the 11p15 locus, which is of particular interest because this region harbors the IGF2 gene.^{87,88} The LOH at 11p15 occurs by loss of maternal and duplication of paternal chromosomal material.⁸⁹ Although LOH is normally associated with loss of tumor suppressor gene activity, in this instance, LOH with paternal duplication may result in activation of IGF2. This occurs because IGF2 is now known to be normally imprinted; that is, this gene is normally transcriptionally silent at the maternal allele, with only the paternal allele being transcriptionally active.^{90,91} Thus, LOH with paternal duplication potentially leads to a twofold gene-dosage effect of the IGF2 locus. Furthermore, in alveolar tumors where LOH does not occur, the normally imprinted maternal allele has been shown to be reexpressed.^{92,93} Thus, LOH and loss of imprinting (LOI) may in this case lead to the same functional result—namely, biallelic expression of the normally monoallelically expressed IGF2. However, loss of an as yet unidentified tumor suppressor activity due to LOH also remains a possibility.

Alveolar RMS is characterized by a t(2;13)(q35;q14) chromosomal translocation.⁹⁴ Molecular cloning of this translocation has identified the generation of a fusion transcription factor, fusing the 5' DNA-binding region of *PAX-3* on chromosome 2 to the 3' transactivation domain region of *FOXO1* gene on chromosome 13.^{95,96} A variant t(1;13)(q36;q14) has been identified in a small number of alveolar RMS tumors that fuses the 5' DNA-binding region of the *PAX-7* gene on chromosome 1 with the identical 3' transactivation domain of the *FOXO1* gene.⁹⁷ Fluorescence *in situ* hybridization (FISH) or reverse transcription polymerase chain reaction (RT-PCR) can be used to identify these *PAX3/7-FOXO1* fusions in approximately 90% of tumors, and are diagnostic of alveolar rhabdomyosarcoma (ARMS). As noted previously, the fusion protein generated by the translocation leads to a novel transcription factor.

The recent application of molecular techniques have now clearly shown that *PAX3/7*-mutation positive RMS is clearly distinct from fusion-negative tumors. At the RNA expression level,

fusion-positive tumors cluster together and have an expression profile that is distinct from fusion-negative tumors. Furthermore, the fusion-positive tumors have a much more aggressive clinical behavior.⁹⁸ Using current next-generation sequencing techniques, it has now also been shown that the fusion-negative tumors have significantly more mutations per tumor compared to fusion-positive tumors.^{99,100} Recurrent mutations identified in fusion-negative RMS included both previously identified (*H*, *K* and *NRAS*, *FGFR4*, *phosphatidy-4, 5 bisphosphate 3-kinase catalytic subunit alpha [PIK3CA]*, and *NF1*) as well as a ubiquitin ligase *FBXW7*, and a transcriptional repressor *BCOR*.

Notably, many of the identified mutations in fusion-negative RMS were shown to be transcriptional targets of PAX fusion proteins, suggesting either accumulation of point mutations or upregulation of the same genes by aberrant transcription activation lead to similar tumors. And despite the relative paucity of mutations compared to adult tumors, there is accumulating evidence that targeting members of the RAS/Phosphatidy-4, 5 bisphosphate 3-kinase catalytic subunit alpha (PIK3CA) pathway represents a rational approach to development of new therapeutic approaches to these tumors.¹⁰¹

HEREDITARY SYNDROMES ASSOCIATED WITH TUMORS OF CHILDHOOD LI-FRAUMENI SYNDROME

Although a detailed description of the many syndromes that are associated with the development of childhood cancers are beyond the scope of this chapter, several are discussed here to illustrate the breadth of phenotypes and underlying genetic mechanisms that should be considered in their management. A few hereditary cancer syndromes are associated with the occurrence of childhood as well as adult-onset neoplasms. The paradigm LFS cancer was first described in 1969 from an epidemiologic evaluation of more than 600 medical and family history records of patients with childhood sarcomas.¹⁰² The original description of a kindred with a spectrum of tumors that includes soft tissue sarcomas, osteosarcomas, breast cancer, brain tumors, leukemia, and adrenocortical carcinoma (ACC) has been overwhelmingly substantiated by numerous subsequent studies,¹⁰³ although other cancers, usually of particularly early age of onset, are also observed.¹⁰⁴ Germ-line alterations of the *TP53* tumor suppressor gene are associated with LFS.^{105,106} These are primarily missense mutations that yield a stabilized mutant protein. The spectrum of mutations of *TP53* in the germ line is similar to somatic mutations found in a wide variety of tumors. Carriers are heterozygous for the mutation, and in tumors derived from these individuals, the second (wild-type) allele is frequently deleted or mutated, leading to functional inactivation.¹⁰⁷

Several comprehensive databases document all reported germ-line (and somatic) *TP53* mutations and are of particular value in evaluating novel mutations as well as phenotype-genotype correlations.¹⁰⁸ Only 60% to 80% of classic LFS families have detectable alterations of the gene. It is not yet determined whether the remainder is associated with the presence of modifier genes, promoter defects yielding abnormalities of *TP53* expression, or simply the result of weak genotype-phenotype correlations (i.e., the broad clinical definition encompasses families that are not actual members of LFS). Other candidate predisposition genes, such as *p16*, *p15*, *p21*, *BRCA1*, *BRCA2*, and *PTEN*, associated with multisite cancer associations have generally been ruled out as potential targets. The role of the hCHK2 checkpoint kinase as an alternative mechanism for functional inactivation of *TP53* in LFS has been suggested,¹⁰⁹ although its place as a major contributor to the phenotype has been controversial.¹¹⁰

Germ-line *TP53* alterations have also been reported in some patients with cancer phenotypes that resemble the classic LFS phenotype. Between 3% and 10% of children with apparently sporadic RMS or osteosarcoma have been shown to carry germ-line *TP53*

mutations.^{111,112} These patients tend to be younger than those who harbor wild-type *TP53*. Germ-line *TP53* mutations are observed in more than 60% of children with the anaplastic variant of RMS,¹¹³ and are also overrepresented in children with the Sonic hedgehog (SHH) subgroup of medulloblastomas.¹¹⁴ It appears as well that more than 75% of children with apparently sporadic ACC carry germ-line *TP53* mutations, although in some of these cases, a family history develops that is not substantially distinct from LFS.^{115,116} These important findings indicate a broader spectrum of patients at risk of germ-line *TP53* mutations and refined criteria for *TP53* mutation analyses.^{117,118} A striking genotype-phenotype correlation has been observed in a unique subgroup of ACC patients in Brazil in whom the same germ-line *TP53* mutation at codon 337 has been observed in 35 unrelated kindred.¹¹⁹ The functional integrity of the mutant protein appears to be regulated by alterations in cellular pH,¹²⁰ which suggests potential biologic mechanisms in ACC cells by which the *TP53* mutation leads to malignant transformation. All these observations suggest that germ-line *TP53* alterations may be associated with early-onset development of the childhood component tumors of the syndrome.¹²¹ The variability in age of onset and type of cancer among LFS families suggests modifier effects on the underlying mutant *TP53* genotype. An analysis of mutant genotype-to-phenotype correlations reveals intriguing observations. Nonsense, frameshift, and splice mutations yield a truncated or nonfunctional protein commonly associated with early-onset cancers, particularly brain tumors. Missense mutations in the *TP53* DNA-binding domain are frequently observed in the setting of breast and brain tumors, whereas adrenocortical cancers are the only group that is associated with mutations in the non-DNA-binding loops. Age of onset modifiers have also now been established. The protein murine double-minute-2 (*MDM2*) is a key negative regulator of *TP53* and targets *TP53* toward proteasomal degradation. The *MDM2* single nucleotide polymorphism 309 increases Sp1 transcription factor binding, leading to increased *MDM2* expression levels. Coinheritance of the *MDM2* single nucleotide polymorphism 309 T/G isoform is associated with an earlier onset of cancer.¹²² The earlier age of onset of cancers with subsequent generations in mutant *TP53* LFS families suggests genetic anticipation. This observation can be partially explained by several molecular mechanisms including accelerated telomere attrition from generation to generation, absence of the *PIN3* polymorphism, or excessive DNA copy number variation in *p53* mutation carriers, all of which may be useful predictive markers of tumor age of onset.¹²²⁻¹²⁴ Thus, although germ-line *p53* mutations establish the baseline risk of tumor development in LFS, a complex interplay of modifying genetic cofactors likely defines the specific phenotypes of individual patients.

Beckwith-Wiedemann Syndrome

BWS occurs with a frequency of 1 in 13,700 births. More than 450 cases have been documented since the original reported associations of exomphalos, macroglossia, gigantism, and other congenital anomalies. With increasing age, phenotypic features of BWS become less pronounced. Laboratory findings may include, at birth, hypoglycemia, polycythemia, hypocalcemia, hypertriglyceridemia, hypercholesterolemia, and high serum α -fetoprotein levels. Early diagnosis of the condition is crucial to avoid deleterious neurologic effects of neonatal hypoglycemia and to initiate an appropriate screening protocol for tumor development.¹²⁵ The increased risk for tumor formation in BWS patients is estimated at 7.5% and is further increased to 10% if hemihyperplasia is present. Tumors occurring with the highest frequency include Wilms tumor, hepatoblastoma, neuroblastoma, and ACC.¹²⁶

The genetic basis of BWS is complex. Various 11p15 chromosomal or molecular alterations have been associated with the BWS phenotype and its tumors.¹²⁷ It is unlikely that a single gene is responsible for the BWS phenotype. Because it appears that

abnormalities in the region impact an imprinted domain, it is more likely that normal gene regulation in this part of chromosome 11p15 occurs in a regional manner and may depend on various interdependent factors or genes. These include the paternally expressed genes *IGF2* and *KCNQ10T1* and the maternally expressed genes *H19*, *CDKN1C*, and *KCNQ1*. BWS children who develop rhabdomyosarcoma or hepatoblastoma have epigenetic changes in domain 1, whereas those with Wilms tumor have domain 2 changes or uniparental disomy.¹²⁸

Chromosomal abnormalities associated with BWS are extremely rare, with only 20 cases having been associated with 11p15 translocations or inversions. The chromosomal breakpoint in each of these cases is always found on the maternally derived chromosome 11. This parent-of-origin dependence in BWS suggests that the chromosome translocations disrupt imprinting of a gene in the 11p15 region. On the other hand, BWS-associated 11p15 duplications (approximately 30 reported cases) are always paternally derived, and the duplication breakpoints are heterogeneous.¹²⁹ Paternal uniparental disomy, in which two alleles are inherited from one parent (the father), has been reported in approximately 15% of sporadic BWS patients.¹³⁰ The insulin/*IGF2* region is always represented in the uniparental disomy, although the extent of chromosomal involvement is highly variable. Alterations in allele-specific DNA methylation of *IGF2* and *H19* reflect this paternal imprinting phenomenon.¹³⁰ A minority of BWS patients have demonstrable constitutional DNA sequence alterations, the most common of these being *CDKN1C* mutations.¹³¹ Of BWS patients, 25% to 50% exhibit biallelic rather than monoallelic expression of *IGF2*. Another 50% have epigenetic mutations resulting in LOI of *KCNQ10T0*. Of interest, epigenetic changes, such as methylation and chromatin modification, occur in many pediatric and adult cancers,¹³² indicating the value of the BWS model in understanding the broad scope of molecular changes in cancer. Despite the associated cytogenetic and molecular findings for some patients, no single diagnostic test exists for BWS. This observation is not unlike that described for LFS, or perhaps for other multisite cancer phenotypes, in which the clarity of the phenotype is often weak, making the genetic link cloudy and the likelihood of multiple pathways to tumor formation strong.

Gorlin Syndrome

Nevoid basal cell carcinoma syndrome, or Gorlin syndrome, is a rare autosomal-dominant disorder characterized by multiple basal cell carcinomas; developmental defects, including bifid ribs and other spine and rib abnormalities; palmar and plantar pits; odontogenic keratocysts; and generalized overgrowth.¹³³ The SHH signaling pathway directs embryonic development of a spectrum of organisms. Gorlin syndrome appears to be caused by germ-line mutations of the tumor suppressor gene *PTCH*, a receptor for SHH.^{134,135} Medulloblastomas develop in approximately 5% of patients with Gorlin syndrome. Furthermore, approximately 10% of patients diagnosed with medulloblastoma by the age of 2 years are found to have other phenotypic features consistent with Gorlin syndrome and also harbor germ-line *PTCH* mutations.¹³⁶ Although Gorlin syndrome develops in individuals with germ-line mutations of *PTCH*, a subset of children with medulloblastoma harbor germ-line mutations of another gene, *SUFU*, in the SHH pathway, with accompanying LOH in the tumors. Of further note, mice with heterozygous *PTC* deletions develop RMS.¹³⁷ Although RMS is rarely seen with Gorlin syndrome, the mouse studies suggest a possible link between *PTC* signaling and RMS.¹³⁸

MALIGNANT RHABDOID TUMORS

Malignant rhabdoid tumors are unusual pediatric tumors that occur as primary renal tumors, but have also been described in

lung, liver, soft tissues, and the central nervous system, where they are often termed *atypical* and *teratoid rhabdoid tumors*.¹³⁹ Recurrent chromosomal translocations of chromosome 22 involving a breakpoint at 22q11.2, as well as complete or partial monosomy 22, have been observed, strongly suggesting the presence of a tumor suppressor gene in this area. The *hSNF5/INI1* gene has been isolated and has been shown to be the target for biallelic, recurrent inactivating mutations.¹⁴⁰ The encoded gene product is thought to be involved in chromatin remodeling. Studies have not only demonstrated the presence of inactivating mutations in the majority of malignant rhabdoid tumors (renal or extrarenal), but also in chronic myelogenous leukemia,¹⁴¹ as well as in a wide variety of other childhood and adult-onset malignancies.¹⁴² An intriguing feature in some individuals with malignant rhabdoid tumors is the observation of germ-line mutations, suggesting that this family of tumors may occur as a result of a primary inherited defect in one allele of the *INI1* gene.¹⁴³ Further studies of the function of this gene will be important in determining its role in tumorigenesis of this wide spectrum of neoplasms.

DICER1 SYNDROME

DICER1 syndrome is a very recently characterized phenotype of distinctive dysontogenetic, hyperplastic, or overtly malignant tumors. The most frequent of these is the rare childhood lung malignancy pleuropulmonary blastoma (PPB). Other manifestations include ovarian Sertoli-Leydig cell tumors (SLCT), nodular thyroid hyperplasia, pituitary blastoma, pineoblastoma, papillary and follicular thyroid carcinoma, cervical rhabdomyosarcoma, cystic nephroma, and possibly, Wilms tumor.¹⁴⁴ Germ-line *DICER1* mutations have been identified in children and young adults affected with one or several of these tumors, and somatic *DICER1* mutations have been found in sporadic component tumors. *DICER1* is an endoribonuclease that processes hairpin precursor microRNAs (miRNA) into short, functional miRNAs. Mature 5' miRNAs as well as other components of the RNA-induced silencing complex (RISC) downregulate targeted miRNA.

Unlike the classical Knudson *two-hit* mechanism that inactivates tumor suppressor genes, the effect of *DICER1* loss-of-function appears to result from an initial inactivating mutation that reduces by half the amount of wild-type *DICER1* protein, followed by a second hit that specifically eliminates production of 5' mature miRNAs. Disease penetrance is highly variable. The risk of potentially lethal tumors such as PPB and pineoblastoma in *DICER1*-mutation carriers indicates a need for clinical surveillance, particularly targeting the lungs, abdomen, and brain.

PREDICTIVE TESTING FOR GERM-LINE MUTATIONS AND CHILDHOOD CANCERS

Several important issues have arisen as a result of the identification of germ-line mutations of tumor suppressor genes in cancer-prone individuals and families. These include ethical questions of predictive testing in such families and in unaffected relatives and the selection of patients to be tested, as well as the development of practical and accurate laboratory techniques, the development of pilot testing programs, and the role of clinical interventions based on test results. This chapter was not meant to discuss these problems in detail, but one would be remiss to ignore their significance.

For several reasons, testing cannot as yet be offered to the general pediatric population, particularly in light of the demonstrably low carrier rate of the abnormal tumor suppressor genes and the general lack of standardized methods of preclinical screening of carriers. Exceptions to these limitations include screening of gene carriers in families with retinoblastoma, BWS, multiple

endocrine neoplasia, familial adenomatous polyposis, LFS, hereditary paraganglioma syndromes, and von Hippel-Lindau disease. For some of these diseases, clinical surveillance tools are available, whereas for others, risk-reductive surgery has also been shown to be of value.^{145–148} In general, it has been demonstrated that genetic testing does not lead to clinical levels of anxiety, depression, or other markers of psychological distress in children who are tested or their parents.^{149,150} However, certain circumstances or personality traits are associated with a greater likelihood of an individual experiencing psychological distress after a positive result.¹⁴⁹ Parents now routinely discuss the options of prenatal diagnosis and preimplantation genetic diagnosis. Multidisciplinary teams must be engaged to provide parents and families the necessary tools with which to approach these ethically challenging decisions.^{151,152} The development of screening programs should address aspects of cost, informed consent (particularly where it affects children), socioeconomic impact on the individual tested, consistency in providing results, and counseling. Concerns of risk of employment, health insurance, or life insurance discrimination exist but may be alleviated by congressional legislation to ban such practices.¹⁵³

MOLECULAR THERAPEUTICS

With the identification of alterations in a variety of molecular signaling pathways increasingly identified with application of newer molecular analytic techniques, it has become increasingly apparent that these alterations may potentially represent the *Achilles heel* for these tumors. New agents targeting the TK enzymes as well as agents that alter the epigenetic state of tumors are at various stages of development in early clinical studies of pediatric tumors. A particular issue for the development of targeted therapy for pediatric tumors is the relative effectiveness of standard cytotoxic agents in many tumors. Thus, the identification of single targeted agent activity and the incorporation of such agents into combinations with cytotoxic agents is an important challenge. Ongoing studies incorporating mTOR inhibitors (rhabdomyosarcoma) or IGFIR inhibitors with combination chemotherapy (Ewing sarcoma) will provide important information on whether these approaches will improve outcome. The most important challenge will be to correctly identify the targetable altered pathways that are critical for malignant behavior of specific pediatric tumors and then rapidly test them in a rational approach to improve the outcomes of pediatric cancer patients.

99 Solid Tumors of Childhood

Alberto S. Pappo, Fariba Navid, Rachel C. Brennan, Matthew J. Krasin, Andrew M. Davidoff, and Wayne L. Furman

INTRODUCTION

Solid tumors account for about one-third of the estimated 14,000 cases of cancer diagnosed each year in patients under 20 years in the United States (Fig. 99.1).¹

Since 1975, the overall mortality rates for childhood cancer have decreased by 50% and survival rates for childhood cancer now exceed 80%; however, this progress has been most evident for children with hematologic malignancies, and mortality rates for children affected by some of the most common pediatric solid tumors such as neuroblastoma and sarcomas have remained virtually unchanged over the past 20 years.² The reasons for the lack of progress in patients with solid tumors when compared to those with hematologic malignancies is unclear but might be related to the relatively limited numbers of patients available to conduct randomized trials and the scarcity of recurrent and actionable genetic aberrations reported to date.^{2,3}

MULTIDISCIPLINARY CARE IS ESSENTIAL FOR CHILDREN AND ADOLESCENTS WITH SOLID TUMORS

The management of pediatric solid tumors is complex and requires a coordinated multidisciplinary approach that incorporates multiple subspecialties including surgery, radiology, pathology, radiotherapy, oncology, and physical therapy.⁴

Local control of the tumor may be achieved with the use of surgery, radiation therapy, or both. The use of neoadjuvant chemotherapy offers the theoretical advantage of decreasing the risk of micrometastatic dissemination as well as primary tumor size and, therefore, limiting the extent of surgery and the radiation doses.⁴ In addition, the administration of preoperative chemotherapy facilitates the evaluation of histologic response in the resected surgical specimen providing important prognostic and therapeutic information.⁵

Surgery plays a dual role in the management of pediatric solid tumors because it provides tissue for diagnosis and biologic studies as well as a mechanism for removing the primary tumor. The role of debulking surgery is controversial.^{6,7} Surgery can also be used later in the course of treatment to remove residual tumor, and the results of the surgery may provide important information regarding the need for additional radiotherapy or chemotherapy.⁸⁻¹⁰

The radiation oncologist should evaluate the patient prior to the initiation of any therapy and to help select the radiation plan and optimal treatment modality. The patient's age, extent of disease, and disease status all play a role in selecting the appropriate radiotherapeutic approach from the available techniques including intensity modulated radiation therapy (IMRT), three-dimensional (3D) conformal radiotherapy, proton beam radiation therapy (PBRT), and brachytherapy.

NEUROBLASTOMA

Neuroblastomic tumors comprise a spectrum of tumors that arise from primitive sympathetic ganglion cells and include neuroblastomas, ganglioneuroblastomas, and ganglioneuromas (Fig. 99.2). They can originate anywhere along the sympathetic ganglia; about half arise in the adrenal medulla. This group of tumors is known for a broad spectrum of clinical behaviors ranging from a completely benign mass to spontaneous regression to widely disseminated, aggressive, and often fatal disease.¹¹⁻¹⁴ Tumors can be subdivided into distinct risk categories based on clinical and biologic features.^{11,15} Historically, treatment has been tailored based on determination of the risk of recurrence for a given patient. A combination of clinical and biologic features of disease have been used to classify patients as low, intermediate, and high risk.^{11,15}

Epidemiology

Neuroblastoma is the third most common childhood cancer after leukemia and brain tumors. From 2006 to 2010, the age-adjusted incidence of neuroblastoma was 10.1 per 1 million children aged 0 to 14 years.^{1,16} During the first year of life, neuroblastoma accounts for the majority of cancer cases with an incidence almost double that of leukemia; 16% of infant neuroblastomas are diagnosed during the first month of life.¹⁶

There are approximately 650 children diagnosed each year with neuroblastoma in the United States¹⁶ and their median age at diagnosis is 19.1 months (573 days).¹⁷ Neuroblastoma is slightly more common in Caucasians and males, with the greatest sex-specific incidence difference occurring during infancy.¹⁶

The majority of neuroblastomas are sporadic. About 1% to 2% of cases are associated with a history of neuroblastoma in immediate or extended family members.¹⁸⁻²³ An early analysis of these family pedigrees suggests an autosomal-dominant mode of inheritance with incomplete penetrance.²⁴ Although many of these familial neuroblastoma patients present before 1 year of age, and more frequently have multifocal primaries,^{14,25} there is also great clinical and biologic heterogeneity among patients in the same kindred.^{19-21,26} Recently, germ-line mutations in the anaplastic lymphoma kinase (ALK) gene were identified as the cause of most cases of hereditary neuroblastomas.^{25,27-30} Another less common cause of hereditary neuroblastoma involves germ-line mutations of the pairedlike homeobox 2B (PHOX2B) gene.³¹⁻³³ These children often have concomitant neural crest disorders (neurocristopathies),³⁴ including Hirschsprung disease,^{32,34,35} and congenital hypoventilation syndrome.^{35,34,36} Other genetic conditions that may predispose for the development of neuroblastoma include neurofibromatosis,^{32,37,38} Turner syndrome,³⁹ and Beckwith-Wiedemann syndrome.⁴⁰

Pathology

Neuroblastic tumors, which include ganglioneuromas, ganglioneuroblastomas, and neuroblastomas (see Fig. 99.2), are derived

Figure 99.1 Age adjusted Surveillance, Epidemiology, and End Results (SEER) Cancer Incidence rates by the International Classification of Childhood Cancer category 0–19 years of age, all races, both sexes, SEER 2002–2010. CNS, central nervous system.

from primitive cells involved in the development of the sympathetic nervous system.⁴¹ The most undifferentiated neuroblastic tumors are composed of neuroblasts with very few schwannian (stromal) cells. Immunohistochemistry may be useful in distinguishing neuroblastoma from other small round blue cell tumors, and immunoreactivity is commonly observed to neuron-specific enolase, synaptophysin, chromogranin A, NB84, and S100. As tumors become more differentiated, the ratio of Schwann to neuroblastoma cells increases, and the neuroblasts appear more mature. Ganglioneuroblastoma can be subdivided into either a stroma-rich, intermixed variant, or nodular variant. Ganglioneuroma is predominantly composed of Schwann cells studded with maturing or fully mature ganglion cells and is considered a benign tumor. These tumors were originally classified according to an “age-linked” classification system by Shimada et al.,⁴² which was subsequently clarified and adopted for international use by the International Neuroblastoma Pathology Committee (INPC).^{43–45} These tumors are morphologically classified into four histologic subtypes according to the balance between neural-type cells (primitive neuroblasts, maturing neuroblasts, and ganglion cells) and the Schwann-type cells (Schwannian blasts and mature Schwann cells) and the degree of surrounding Schwannian stroma: (1) neuroblastoma (Schwannian stroma-poor), undifferentiated, poorly differentiated, and differentiating; (2) ganglioneuroblastoma, intermixed (Schwannian stroma-rich); (3) ganglioneuroma (Schwannian stroma dominant), maturing and mature; and (4) ganglioneuroblastoma, nodular (composite Schwannian stroma rich/stroma dominant and stroma poor).⁴³ The grade of neuroblastic differentiation and mitosis-karyorrhexis index (MKI; defined as the number of tumor cells in mitosis and in the process of karyorrhexis) and age of patient are then used to assign to either a *favorable* or *unfavorable* prognostic group (Fig. 99.3).⁴⁴

Neuroblastoma tumors are classified into favorable histology (FH) and unfavorable histology (UH) lesions based on the degree of stromal development, morphology, MKI, and age.

The INPC system’s prognostic significance was confirmed in a retrospective review of two Children’s Cancer Group (CCG) protocols that demonstrated a threefold difference in the 5-year event-free survival (EFS) for patients with FH versus UH features.⁴⁶

Molecular Biology

Amplified segments of DNA in the form of homogeneously staining regions of chromosomes (HSR) or extrachromosomal DNA called double-minute chromosomes (DMs) are often found in neuroblastomas (Fig. 99.4). The gene that was consistently amplified in these segments was identified by Schwab and colleagues⁴⁷ as a *myc*-related gene, which was eventually called MYCN (*v-myc* avian myelocytomatosis viral oncogene neuroblastoma-derived homologue). Amplification of MYCN is predominantly associated with advanced stage disease, rapid tumor progression, and poor prognosis.^{48,49} A 5- to 500-fold amplification of the MYCN gene is found in about 22% of all patients with neuroblastoma,¹¹ and in approximately 30% to 40% of patients with advanced stage disease (see Fig. 99.4).^{48,49} Amplification (increased gene copy number) results in persistently high levels of the MYCN protein, a DNA-binding transcription factor known to cause malignant transformation in tumor models. The negative prognostic significance of MYCN amplification (>10 copies per haploid genome) is independent of age, stage, or other genetic alterations and remains an important part of the current international risk group classification system.^{50,51}

The DNA content (ploidy) of tumors is either near diploid or hyperdiploid.^{50,52} Near-diploid tumors in patients less than 18 to 24 months of age are associated with an adverse prognosis, whereas hyperdiploid tumors in this age group are associated with low-stage disease and a favorable outcome.^{53,54} In the new International Risk Group pretreatment classification system, ploidy is only used to stratify patients less than 18 months old with metastatic disease who do not have MYCN-amplified tumors.⁵¹

Chromosomal deletions or gains are also frequently identified. Loss of heterozygosity (LOH; loss of one allele) at chromosome 1p36 and 11q occurs in 23% and 34% of tumors respectively.⁵⁵ A gain of chromosome 17 or 17q is present in 50% to 60% of neuroblastomas and is associated with an aggressive phenotype.⁵⁶ Trk, a family of neurotrophin receptors, is important in the development of the central and peripheral nervous system. Elevated expression of TrkA or TrkB is seen in favorable, low-stage tumors. Low expression of TrkA or elevated expression of full-length TrkB is seen in advanced-stage MYCN-amplified tumors.⁵⁷ Additionally, TrkB expression has been linked to chemotherapeutic resistance.^{57,58} Among the most common mutations in sporadic neuroblastoma is in the α -thalassemia/mental retardation syndrome X-linked (ATRX) gene, which is seen in children over 12 years of age (44%).⁵⁹ The evaluation of a chromosomal translocation in a neuroblastoma patient led to the identification of a family of genes on chromosome 1, now called neuroblastoma breakpoint family (NBPF).⁶⁰ Copy number variation in this region (1q21.1) has also been shown to be highly associated with neuroblastoma, probably through disruption of one of the NBPF genes, NBPF23.⁶¹ A number of technological advances have enabled the analysis of whole genome or exomes of tumors to provide insight into the pathogenesis of neuroblastoma and are under investigation to refine risk assignment.^{62–68} For example, risk polymorphisms at 6p22, identified by genome-wide association studies (GWAS), have been associated with sporadic neuroblastoma, and homozygosity for any of these alleles is associated with high-risk features.⁶⁹ Similarly, common variations in the BRCA1-associated RING domain 1 (BARD1) gene have been implicated in the development of high-risk disease.⁷⁰ By expanding these GWAS studies, this same group also identified risk alleles within the LMO1 (LIM domain only 1) gene at 11p15.4 that were more common in tumors with high-risk disease ($p < 0.0001$), suggesting that LMO1 may be a neuroblastoma oncogene.⁷¹

Diagnosis

About two-thirds of neuroblastomas originate in the abdomen, with 50% beginning in the adrenal gland. Other common sites include the chest (16%), neck (3%), and pelvic sympathetic ganglia (3%). Approximately 50% of tumors have spread to the bone or bone

Ganglioneuroma

Poorly differentiated neuroblastoma

Ganglioneuroblastoma

marrow at presentation.⁵¹ The pattern of metastatic spread varies with age and histology of the tumor. Infants with favorable histologies are more likely to have liver and skin metastases. Unfavorable histology tumors are more likely to spread to the bone marrow and bones.⁷² At presentation, abdominal tumors can cause increased abdominal girth, a palpable mass, diarrhea, or constipation. Many thoracic tumors are detected incidentally; however, large thoracic or cervical tumors can cause Horner syndrome, superior vena cava syndrome, or mechanical airway obstruction. Children with bone metastases may have a limp, complain of pain, or develop periorbital swelling, ecchymoses, or proptosis. Fever and hypertension are often present.

The evaluation of a child suspected of having neuroblastoma begins with a careful history and physical examination. A detailed head and neck exam, looking for skull metastases; “raccoon eyes,”⁷³ proptosis, or other eye abnormalities; and Horner syndrome should be performed. Attention to neurologic function is critical due to the paraspinous location of many tumors, which can result in spinal cord compression and permanent loss of function if not treated expeditiously.⁷⁴ Similarly, blindness has developed in children with periorbital disease while staging evaluations were being completed.⁷⁵ In infants, the examination must include a search for skin and subcutaneous metastases that appear

as reddish-purple, raised lesions.⁷⁶ Because neuroblastomas produce catecholamine metabolites, the measurement of these can often help narrow the diagnosis.^{77,78} Urine samples for quantitative excretion of vanillylmandelic acid (VMA) and homovanillic acid (HVA) are elevated in more than 80% of patients⁷⁹ and should be part of the diagnostic evaluation for every patient. These markers are also useful to evaluate the effectiveness of therapy and to monitor for disease recurrence.⁸⁰ Ultrasound is often the initial radiologic study to identify the tumor. However, magnetic resonance imaging (MRI) or computerized tomography (CT) of the chest, abdomen, and pelvis is required to clearly define the location and extent of the primary tumor. Radiographically, a neuroblastoma typically appears as a heterogeneous mass with calcifications. Adrenal and retroperitoneal tumors characteristically involve and displace the major vessels.

Patients with paraspinous primary tumors may have asymptomatic extension through the spinal foramina. Due to the increased risk of neurologic compromise, these patients should undergo further imaging of the spinal canal using MRI with contrast. Imaging of the head should be considered in any child with palpable skull lesions, ptosis, or orbital ecchymosis.⁷⁵

Tumors can secrete a vasoactive intestinal polypeptide resulting in intractable diarrhea and abdominal distention that resolves after

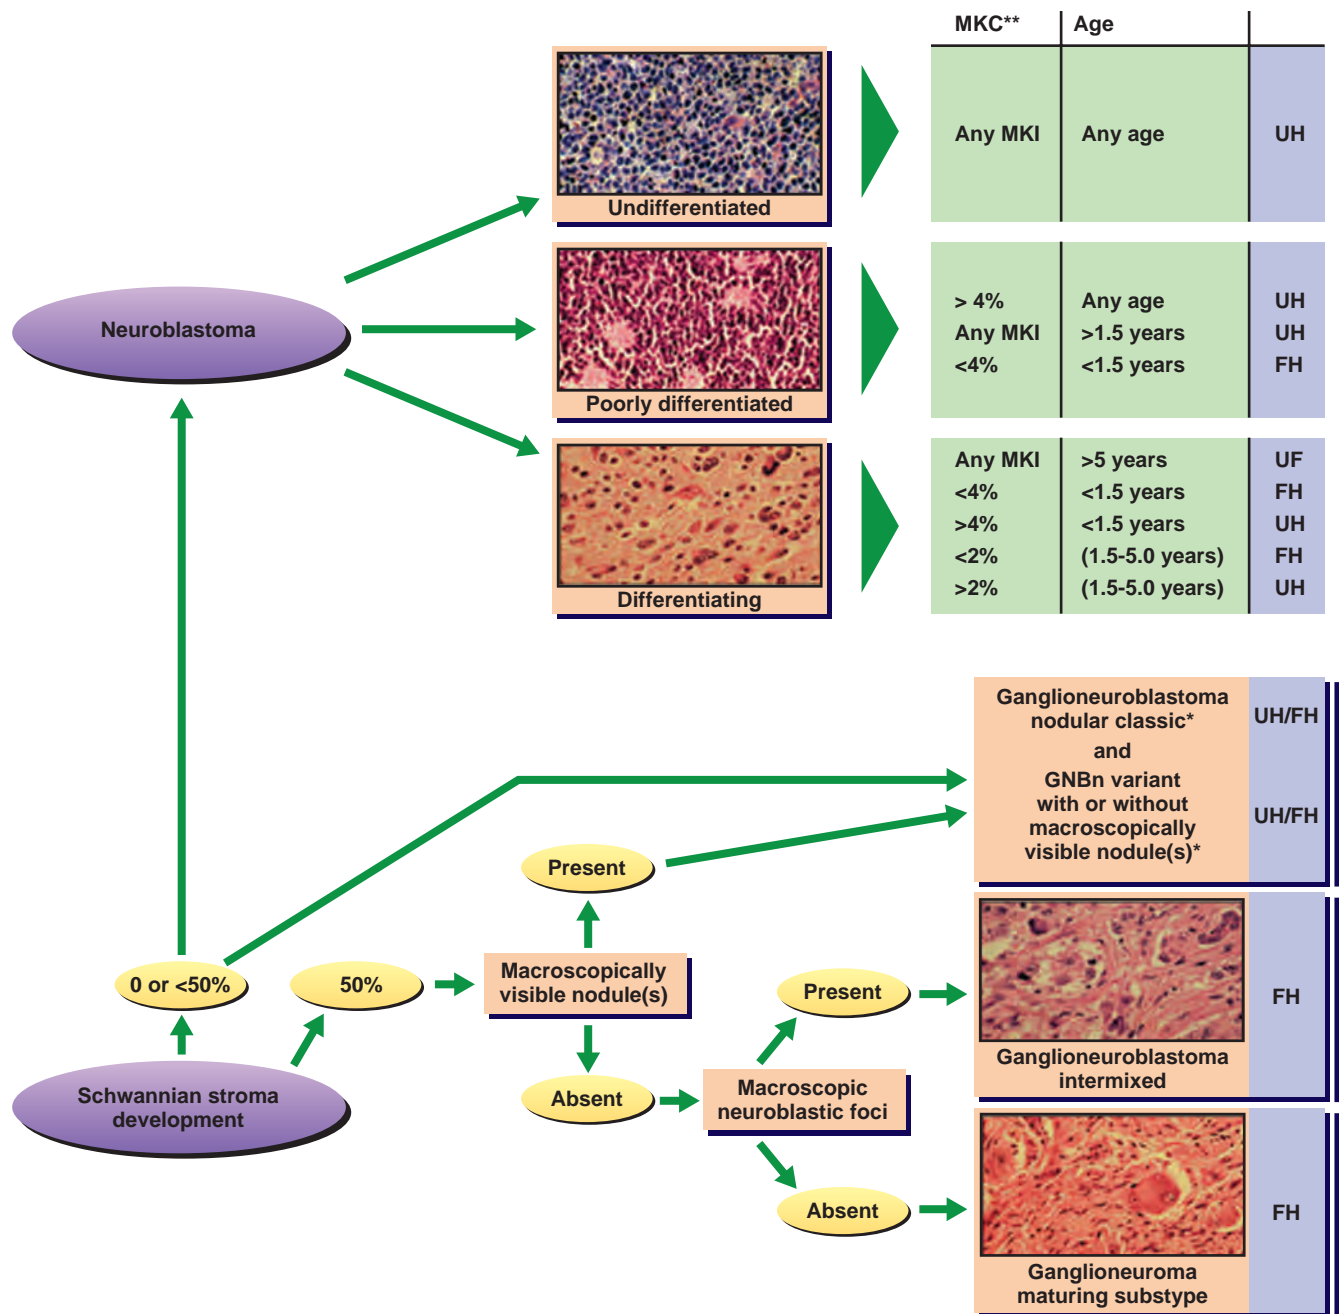

Figure 99.3 The International Neuroblastoma Pathology classification schema. Neuroblastoma tumors are classified into favorable (FH) and unfavorable (UH) histology lesions based on degree of stromal development, morphology, mitosis-karyorrhexis index (MKI), and age. resection. In the largest review of 22 patients, most presented with significant weight loss and metabolic abnormalities, and 16 out of 22 had 1 to 21 months of gastrointestinal (GI) symptoms prior to the diagnosis of neuroblastoma. Although usually associated with differentiating tumors of low stage, 6 of these 22 were high-risk patients who developed diarrhea upon initiation of chemotherapy.⁸¹ Opsoclonus-myoclonus-ataxia (OMA) syndrome, often called *dancing eyes*,⁸² *dancing feet* is seen in up to 3% of children with neuroblastoma and presents with chaotic, multidirectional eye movements, spontaneous limb jerking, and ataxia. Many patients also have significant behavioral problems, sleep disturbances, and learning defects.^{83,84} Although this process is thought to arise as a consequence of immune-mediated cross-reactivity between neuroblasts and the central nervous system, no specific antibody

or lymphocyte marker has been identified.⁸⁵ The tumors associated with OMA patients typically are of favorable biology and limited stage, and thus, patients with this condition have an excellent cancer prognosis.^{86,87} Although the movements may resolve over time, most children have persistent neurologic deficits, including speech and cognitive delays and behavioral problems.^{88,89}

Spinal cord involvement with infiltration of the intervertebral foramina is often seen in the initial evaluation of neuroblastoma⁹⁰; however, only about 5% of children at the time of diagnosis develop symptoms related to spinal cord compression.^{74,91} Spinal cord compression is considered an oncologic emergency because prolonged compression of the spinal cord can lead to irreversible loss of function. This can be treated with urgent radiation therapy, neurosurgery, or chemotherapy. Although there is no current

Figure 99.4 (A) shows upper three cells with MYCN amplification, having likely both, homogeneously stained regions (HSR) and double minutes (DM); the lower cells are normal with two copies each of the MYCN signals. (B) shows a metaphase plate with DM scattered outside the chromosomes. (Courtesy of Dr. Susana Raimondi, Department of Pathology, St. Jude Children's Research Hospital.)

consensus as to the best initial treatment,⁹² a retrospective analysis suggests that each of these modalities are equally effective in the short term. However, there are significant differences in late effects.^{90,93–95} The management of this rare presentation requires an experienced multidisciplinary team and the treatment recommendations should be made on a case-by-case basis specific to the severity and duration of symptoms and an assessment of the anticipated short- and long-term risks of the specific intervention.^{90,92}

Metaiodobenzylguanidine (MIBG) is an analog of norepinephrine and is taken up by tissues that express the norepinephrine transport protein, which includes almost 90% of neuroblastomas.^{96,97} With a sensitivity of about 90% and a specificity of 100%, MIBG has replaced technetium-99m bone scans and has been recommended as a standard agent for staging patients with neuroblastoma^{96,98,99} because of its sensitivity and specificity; all patients should undergo MIBG scans at the time of diagnosis and at subsequent intervals after the start of treatment to assess response. In the 10% of patients who have negative MIBG scans, fludeoxyglucose (¹⁸F-FDG) positron-emission tomography (PET) scans can be considered.⁹⁸ Newer PET agents, such as fluorine-18-L-dihydroxyphenylalanine (¹⁸F-Dopa) are also under investigation.¹⁰⁰ Bone marrow involvement should be further evaluated by bilateral aspiration and a biopsy.^{99,101}

Other malignancies for which neuroblastoma can occasionally be confused include other *small, round, blue cell* tumors such as rhabdomyosarcoma, the Ewing sarcoma family of tumors, non-Hodgkin lymphoma, and acute leukemia. If the diagnosis is to be based on material from bone marrow, it is recommended that these cells be confirmed to be neuroblasts by immunohistochemistry staining with synaptophysin¹⁰² or chromogranin¹⁰³ and that urine HVA and/or VMA be >3.0 SD above mean per milligram creatinine for age.⁹⁹

Screening

Because infants have the best prognosis and because more than 80% of patients with neuroblastoma have elevated catecholamine markers that can be easily measured, screening infants was thought to be a promising approach.¹⁰⁴ Unfortunately, two carefully controlled trials definitively demonstrated that screening did not reduce mortality and, in fact, because many infant neuroblastomas spontaneously regress, led to over diagnosis and treatment of patients that needed no intervention.^{105–108}

Staging

The International Neuroblastoma Staging System (INSS), developed in 1988¹⁰⁹ and revised in 1993⁹⁹ (Table 99.1) was developed to facilitate comparison among trials and is the current staging system used in North American and European cooperative group trials. This system is a postsurgical staging system, in that it uses the extent of initial surgical resection to stage patients. The INSS is significantly affected by the experience of the surgeon, leading to variability in stage assignments. To better define homogenous pretreatment patient cohorts and compare trials conducted in different regions of the world, another staging system, based on preoperative, image-defined risk factors (Tables 99.2A and 99.2B), called the International Risk Group classification system.¹¹⁰ The predictive prognostic significance of this system will be tested in future prospective clinical trials.

Management by Risk Group

The treatment of neuroblastoma incorporates a number of clinical and biologic variables, in addition to the stage of disease, to evaluate the risk of recurrence and to thus determine the intensity of treatment. The Children's Oncology Group's (COG) risk categories incorporate the patient's age at presentation, stage of the tumor, histologic appearance, quantitative DNA content, and presence or absence of MYCN amplification within the tumor cells (Table 99.3).

The age at presentation is an important prognostic factor, because infants tend to have tumors with more favorable features, including stage and histology. A multivariate analysis of 3,666 patients enrolled in cooperative group studies demonstrated 82% 4-year EFS for children less than 18 months versus 42% for those more than 18 months.¹⁷ Adolescents and young adults rarely present with neuroblastoma, but their tumors tend to be indolent and fatal.^{110–112}

The variables selected by other pediatric oncology cooperative groups to define the risk categories have not been uniform. To be able to compare trials worldwide, an international conference developed a consensus approach to pretreatment risk stratification, now called the International Neuroblastoma Risk Group (INRG) Classification System (see Tables 99.2A and 99.2B).⁵¹ This new classification system is different than that of the COG in that it

TABLE 99.1

International Neuroblastoma Staging System Criteria⁹⁹

Stage	Definition
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive)
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor; enlarged contralateral lymph nodes must be negative microscopically
3	Unresectable unilateral tumor infiltrating across the midline ^a with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement ^b
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs (except as defined for stage 4S)
4S	Localized primary tumor (as defined for stage 1, 2A, or 2B), with dissemination limited to skin, liver, and/or bone marrow ^c (<10% involvement) (limited to infants <1 year of age)

Note: Multifocal primary tumors should be staged according to the greatest extent of disease and followed by the subscript "M."

^aThe midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.

^bPatients are upstaged to International Neuroblastoma Staging System stage 3 if there is proven malignant effusion within the abdominal cavity or bilateral thoracic cavity.

^cMarrow involvement in stage 4S should be minimal (i.e., <10%) of total nucleated cells identified as malignant on bone marrow biopsy or on marrow aspirate. More extensive marrow involvement would be considered to be stage 4. The metaiodobenzylguanidine (MIBG) scan, if performed, should be negative in the marrow. From Brodeur GM, Prichard J, Berthold F, et al. Revisions of the international criteria for neuroblastoma diagnosis, staging, and response to treatment. *J Clin Oncol* 1993;11:1466–1477.

uses the new INRG staging system,¹¹³ and adds the presence/absence of 11q aberrations. As new trials are developed, the value of this new risk group classification system will be validated.

Low Risk

Children with low-risk neuroblastomas generally include patients of any age with localized, resectable tumors (Table 99.4). Low-risk tumors comprise about 50% of all neuroblastomas. Surgery is the primary treatment, and overall survival rates are greater than 90%.^{114–116} Recently, a prospective study of 87 infants less than 6 months of age and with small (volume ≤ 16 mL) isolated adrenal masses who were observed only showed that 81% (67 out of 83) were spared surgery with a median follow-up of 3.2 years and an overall survival at 3 years of 100%.¹¹⁷ Thus, expectant observation without surgery in this subgroup of patients should be considered standard treatment and, in fact, the authors recommend extending this approach to "all localized noninfiltrative neuroblastoma tumors [corresponding to the International Neuroblastoma Risk

Group Staging System stage L1; see Table 99.2]¹¹³ in infants less than 1 year of age."¹¹⁷

A 4S neuroblastoma is a *special*¹¹⁸ entity because the high rate of spontaneous regression allows for a delay or elimination of chemotherapy for up to 80% of children.^{119,120} Two subsets are more likely to require chemotherapy: those tumors with unfavorable biologic features (i.e., MYCN amplification) and tumors in infants younger than 2 months who have extensive liver disease. Untreated, the latter case leads to a higher incidence of mortality, because massive hepatomegaly prevents adequate chest wall expansion.^{120,121} These children should receive chemotherapy or low-dose radiation (4.5 to 6 Gy in three to four fractions) to decrease tumor size.

Intermediate Risk

Children with intermediate-risk tumors comprise 10% to 15% of new cases and are defined as: infants (<365 days old) with INSS 3 or 4 tumors without MYCN amplification and favorable histology, children (≥ 365 days old) with INSS 3 tumors without MYCN amplification and favorable histology, or INSS 4 with unfavorable histology and/or diploid DNA (Table 99.5).¹²² Surgery is an important component of treatment, as is the addition of moderately intensive chemotherapy (i.e., carboplatin, etoposide, adriamycin, cyclophosphamide). Radiotherapy is reserved for children with progression or those who have unresectable tumors after chemotherapy. This approach has led to excellent survival of 50% to 100%, depending on the clinical and biologic characteristics.^{123–125} In a recent report from the COG, 479 children were treated according to a biologically based risk assignment system. Of these, 323 with favorable biologic characteristics received four courses of chemotherapy and 141 children with unfavorable biology received eight courses. This approach resulted in a 3-year EFS of 88 \pm 2% and 3-years overall survival of 96 \pm 1%.¹²²

High Risk

Approximately 50% to 60% of children present with metastatic disease at diagnosis and the vast majority of these are classified as

TABLE 99.2A

International Neuroblastoma Risk Group (INRG) Staging System¹¹³

Stage	Description
L1	Localized tumor not involving vital structures as defined by the list of Image Defined Risk Factors and confined to one body compartment
L2	Local-regional tumor with presence of one or more Image Defined Risk Factors
M	Distant metastatic disease (except Stage MS)
MS	Metastatic disease in children <18 months with metastases confined to skin, liver, and/or bone marrow

TABLE 99.2B

International Neuroblastoma Risk Group (INRG) Consensus Pretreatment Classification System.⁵¹

INRG Stage	Age (months)	Histologic Category	Grade of Tumor Differentiation	MYCN	11q Aberration	Ploidy	Pretreatment Risk Group
L1/L2		GN maturing; GNB intermixed					A Very low
L1		Any, except GN maturing or GNB intermixed		N/A Amplified			B Very low K High

MS	<18			NA Amplified	No Yes		C Very low Q High R High

GNB, ganglioneuroblastoma; GN, ganglioneuroma; N/A, not applicable.

high-risk patients.¹²⁶ As seen in Table 99.6, children with high-risk disease predominantly include children more than 18 months of age with INSS 4 disease. Other subsets of high-risk patients include children of any age with INSS 2a/b or 3 disease and *MYCN* amplification, children ≥18 months with INSS 3 and unfavorable histology, and infants (<1 year of age) with *MYCN* amplification. The treatment consists of four general components: (1) induction chemotherapy, (2) surgical resection of all gross disease, (3) consolidation, which generally includes myeloablative chemotherapy with stem-cell rescue and radiation therapy to the tumor bed, and then (4) treatment of minimal residual disease (MRD). Despite this intensive therapy, almost half of all high-risk patients eventually relapse and die of their disease.¹²⁶

Induction Chemotherapy. Standard chemotherapy regimens for high-risk disease include combinations of the epipodophylotoxins etoposide or teniposide, platinum-based agents, cyclophosphamide, and doxorubicin; other active agents such as ifosfamide and topotecan have also been included in some regimens.^{127–134} A retrospective analysis in 1991 of 44 published clinical trials showed a convincing correlation between dose intensity and response and progression-free survival, particularly with cisplatin and teniposide.¹³⁵ Although a later review did not corroborate these findings,¹³⁶ the general approach worldwide has been to increase the intensity of induction chemotherapy. In the only recent randomized trial comparing induction regimens, 262 patients were assigned to either rapid treatment (N = 130) with cisplatin (C), vincristine (O), carboplatin (J), etoposide (E), and cyclophosphamide (C) (COJEC), or standard treatment (N = 132) with vincristine, cisplatin (P), etoposide, cyclophosphamide (OPEC) alternating with vincristine, carboplatin, etoposide, cyclophosphamide (OJEC). The rapid regimen was given every 10 days and the standard regimen was given every 21 days. The same cumulative doses of each drug, except vincristine, were administered and the relative dose-intensity of the rapid regimen was 1.94 compared to the standard regimen.¹³⁷ There was no difference in the overall survival (OS) at 5 and 10 years, although the EFS at 5 years

was significantly better in the rapid group (30.2% versus 18.2%; $p = 0.022$). Also, patients progressed to consolidation a median of 55 days earlier, prompting the authors to speculate that this might have contributed to the better outcome in the rapid group.¹³⁷ The lack of difference in OS and relatively inferior outcomes, compared to other induction regimens,¹³³ make interpretation of these results difficult. What is clear is that response, as measured by MIBG scans at the end of induction, strongly correlate with overall outcome^{138–140} and that further refinement in induction therapy may focus on those *ultra* high-risk patients who have inferior early response as measured by MIBG or more sensitive quantitative methods.^{141,142}

Surgery. The role and timing of surgery in the management of children with high-risk neuroblastoma is uncertain.¹⁴³ Although some reports of patients with stage 3 or 4 disease have found that gross total resection of the primary tumor and metastatic local–regional disease has been associated with improved local tumor control and increased overall patient survival,^{144–147} other reports have not.^{7,148,149} Nevertheless, the COG as well as the major European cooperative group, SIOPEX,¹³⁷ currently recommend gross total resection of the primary tumor and regional disease in patients with high-risk neuroblastoma. The resection is often delayed until near the end of induction, even though tumor volume reduction appears to plateau after the second or third course of chemotherapy,¹⁵⁰ and there are some data that early resection may provide a survival benefit.¹⁵¹ The goal of surgical local control is to remove all visible tumors without jeopardizing vital organs or delaying chemotherapy; however, most primary tumors invade local structures and surround major blood vessels, making resection difficult. Complete removal at the time of diagnosis is possible for less than 20% of patients.^{146,152} Resection of invasive tumor is associated with complications, including the removal of normal organs, hemorrhage, renal injury,¹⁵³ vascular injury, chylous ascites and chronic diarrhea. After treatment with chemotherapy, complete removal becomes possible in more than 50%.⁷

Consolidation. Early studies using high-dose chemotherapy showed a strong correlation of increasing dose intensity with progression-free survival in metastatic neuroblastoma.^{155,154} The critical importance of dose intensity ultimately led to the integration of high-dose chemotherapy and autologous stem cell transplant (ASCT) into modern treatment regimens for high-risk

neuroblastoma.^{155–157} Although with it comes unique challenges and risks, the use of myeloablative ASCT allows for the delivery of chemotherapeutic doses not usually feasible due to the dose-limiting toxicity of myelosuppression. Although there is no consensus on the optimal conditioning regimen, many nonrandomized studies supported the use of ASCT as consolidation¹⁵⁸ and several randomized trials have subsequently made ASCT following intensive induction chemotherapy part of the *standard of care* in the treatment of children with high-risk neuroblastoma.^{129,158–160}

One of the most common myeloablative regimens used worldwide is a combination of busulfan and melphalan (BuMel). A recent retrospective analysis of nearly 3 decades of European experience with ASCT for neuroblastoma revealed a survival benefit for BuMel over other melphalan-based conditioning regimens.¹⁶¹ The 343 patients treated with this regimen in first remission had a 5-year OS rate of 48%.¹⁶² Specifics regarding transplant-related complications were not reported. A recent, smaller retrospective study from Spain using a BuMel conditioning reported a progression-free survival of 57% among 36 patients at a mean follow-up of 55 months.¹⁶² There were no toxic deaths reported and no reported veno-occlusive disease (VOD). Risk of complications from this regimen may be age dependent; a report of infants treated with a busulfan-melphalan regimen (with or

DI, DNA Index.

without cyclophosphamide) reported VOD in 9 of 12 children treated, including one death.¹⁶⁵ However, this regimen utilized oral busulfan, which has been shown to have a higher risk of complications.

Another common myeloablative regimen is a combination of carboplatin or cisplatin, etoposide, and melphalan (CEM), and it has been used in some of the largest reported US trials.¹⁶⁰ The SIOP Europe Neuroblastoma Group (SIOPEN) randomized patients to receive BuMel or CEM in the HR-NBL1 trial with the primary aim to demonstrate superiority based on EFS. This randomization was closed early due to superiority of the BuMel regimen. A significant difference in EFS in favor of BuMel (3-years EFS 49% versus 33%) was observed as well as for OS (3-years OS 60% versus 48%; $p = 0.004$). This difference was mainly related to the relapse and progression incidence, which was significantly ($p = 0.001$) lower with BuMel (48% versus 60%).¹⁶⁴ Although these data clearly show the superiority of the BuMel conditioning regimen over CEM when used with the Rapid COJEC induction regimen of HR-NBL1,¹³⁷ it remains to be demonstrated if this would hold true if BuMel were used after other induction regimens.

Because undetected neuroblastoma cells present in autologous bone marrow can contribute to relapse,¹⁶⁵ the COG evaluated the role of purging stem cell products with a cocktail of five monoclonal antibodies targeting neuroblasts, attached to magnetic beads. All children received identical induction chemotherapy and myeloablation. Enrollees were randomly assigned to receive non-purged peripheral blood stem cells (PBSC; $N = 243$) or purged PBSC ($N = 243$); 192 from the nonpurged and 180 from the purged group received ASCT. The 5-year EFS was 36% in the unpurged group (95% confidence interval [CI] 30 to 42) and 40% (33 to 46) in the group who received purged PBSCs ($p = 0.77$).¹⁶⁶ Thus nonpurged PBSCs are acceptable for support of children receiving myeloablation during consolidation.

Based on improvements in EFS seen in patients treated with myeloablative consolidation and ASCT, several nonrandomized studies, which were further dose intensified using tandem, non-overlapping myeloablative conditioning regimens, suggested this approach may further improve outcome.^{167–172} A pilot study of tandem transplant following intensive induction chemotherapy was developed by COG (ANBL00P1) to test the feasibility and toxicity for use as one of the arms of a randomized phase III study.¹⁷² Patients received the first consolidation with thioTEPA and cyclophosphamide and, upon recovery, received a second ABMT with carboplatin, etoposide phosphate, and melphalan. Forty-one patients were enrolled; eight did not receive any ASCT. Of the 33 who received the first ASCT, 26 went on to receive the second. The 3-year EFS was $44.8 \pm 9.5\%$ and this tandem ASCT combination was used as the experimental arm in a randomized phase III trial comparing single versus tandem ASCT (ANBL0532).¹⁷² This trial completed accrual in February of 2012 and results are still pending.

Radiation Therapy. ASCT for neuroblastoma has been performed using various combinations of chemotherapy with and without total body irradiation (TBI). Although the optimum chemotherapeutic combination has not been conclusively demonstrated, the incorporation of TBI has not improved survival, but rather increases transplant-related complications.^{161,173} However, because primary site failure persists as a component of tumor progression, primary site irradiation has been used as part of consolidation therapy for patients with high-risk neuroblastoma,^{129,174–177} including those enrolled on the recent COG ANBL0532 study.¹⁷⁸ In the setting of recurrent or incurable disease, radiotherapy can

also be used to treat bone and soft tissue metastasis to control pain and to prevent a loss of organ function.¹⁷⁹

Treatment of Minimal Residual Disease. Finally, additional treatment with biologics (i.e., 13-*cis*-retinoic acid) in the setting of minimal residual disease appears to improve survival. CCG randomized children after consolidation with high-dose chemotherapy and ASCT to receive 6 months of *cis*-retinoic acid. The 3-year EFS was significantly better among those who received *cis*-retinoic acid than those assigned to receive no further therapy (46% versus 29%, respectively; $p = 0.027$).¹²⁹ Targeted immunotherapy, using a chimeric monoclonal antibody, ch14.18, against the tumor-associated disialoganglioside, GD2, has been ongoing for more than 2 decades. A recent randomized study from the COG found that the administration of ch14.18, in combination with interleukin-2, granulocyte macrophage colony stimulating factor, and *cis*-retinoic acid following recovery from consolidation was associated with an improved 2-year EFS ($66 \pm 5\%$ versus $46 \pm 5\%$) and OS ($86 \pm 4\%$ versus $75 \pm 5\%$) ($p = 0.02$).¹⁸⁰ This study has established a new standard of care for all children with high-risk disease in the future.

WILMS TUMOR

Wilms tumor is the most common primary malignant renal tumor of childhood. Advances in therapy since the inception of the prospective randomized trials conducted by various multi-institutional cooperative groups have led to an OS rate of 90%, although success has been achieved at a cost of serious chronic health conditions 25 years after diagnosis in 25% of survivors.¹⁸¹

Epidemiology and Genetics

Among North American children less than 15 years of age, the incidence of Wilms tumor is 1 in 10,000 children, or approximately 500 new cases per year.¹⁸² Wilms tumor accounts for 6% of all childhood tumors, but more than 90% of all renal cancers in patients under the age of 20 years.¹⁸³ The risk for developing Wilms tumor is higher in African Americans and lower among Asian populations.¹⁸³ Although unilateral disease is more common, with males presenting at a slightly earlier age (37 months) than females (43 months), approximately 6% of patients harbor bilateral disease at diagnosis, with males presenting slightly earlier (24 months) than females (31 months).¹⁸⁴

A variety of syndromes and congenital abnormalities are associated with the development of Wilms tumor. A deletion of chromosome 11p13 that encompasses the *WT1* and *PAX6* gene results in Wilms tumor, aniridia, genitourinary anomalies, and mental retardation (WAGR syndrome), whereas *WT1* point mutations at 11p13 are implicated in Denys-Drash syndrome (DDS), and Frasier syndrome.¹⁸⁵⁻¹⁸⁷ A second Wilms tumor locus, *WT2*, is located at 11p15 and has been linked to an increased incidence of Wilms tumor in Beckwith-Wiedemann syndrome (BWS).^{186,188} Specific to the *WT2* locus, at least 10 imprinted genes that have preferential expression by the maternal or paternal allele have been identified, including *IGF2*, *H19*, *p57*, and *LIT1*.¹⁸⁶ Other overgrowth syndromes associated with an increased susceptibility for the development of Wilms tumor include Simpson-Golabi-Behmel syndrome, Sotos syndrome, and Perlman syndrome. Patients with isolated hemihypertrophy, aniridia, Bloom syndrome, Alagille syndrome, trisomy 18, or Li-Fraumeni syndrome are also at risk for developing Wilms tumor.^{186,189,190} Familial predisposition accounts for 1% to 2% of cases, and putative familial Wilms tumor genes have been mapped to 17q12-21 (*FWT1*) and 19q13.4 (*FWT2*).¹⁸⁵ Children with hereditary syndromes that predispose to the development of Wilms tumor should receive abdominal screening ultrasounds every 3 months until 8 years of age.¹⁹⁰ Although they

appear to respond to treatment similarly as other children, patients with a predisposition (*WT1* mutation) and Wilms tumor have a higher incidence of bilateral disease, intralobar nephrogenic rests, and end-stage renal disease.¹⁸⁷

Pathology

Most Wilms tumors are solitary and composed of varying proportions of blastemal, stromal, and epithelial cells that recapitulate normal kidney development. Anaplasia, either *focal* or *diffuse*, is characterized by the presence of large nuclei, irregular mitotic features, and hyperplasia and is associated with adverse clinical outcomes.^{191,192} In focal anaplasia, cells with anaplastic nuclear changes are confined to sharply restricted foci within the primary tumor.¹⁹² A recent analysis has demonstrated that the presence of anaplasia even in stage I disease adversely affects clinical outcome.¹⁹³

Wilms tumor must be distinguished histologically from other pediatric renal tumors, including renal cell carcinoma,¹⁹⁴ clear cell sarcoma,¹⁹⁵ and rhabdoid tumor of the kidney,¹⁹⁶ as well as neuroblastoma. Clear cell sarcoma and malignant rhabdoid tumor of the kidney were previously considered to belong to the *unfavorable histology* group of Wilms tumors, but are now considered to be distinct categories of renal tumors. Rhabdoid tumor of the kidney tends to metastasize to the lung and brain. Primary rhabdoid tumors of the kidney and brain (atypical teratoid or rhabdoid tumors) share deletions of chromosome band 22q11.2, the site of *SMARCB1* (also known as *INI1*, *BAF47*, and *SNF5*), a putative tumor suppressor gene.^{197,198} Another important renal neoplasm, congenital mesoblastic nephroma, is important to recognize because it is usually curable by nephrectomy alone. These tumors are typically identified in the first months of life, with a median age at diagnosis of 2 months.¹⁹⁹ They are associated with the t(12;15) translocation that produces the *ETV6-NTRK3* fusion gene product.²⁰⁰

Precursor lesions, or nephrogenic rests, have been identified in the renal parenchyma of approximately 36% of patients with Wilms tumor.^{201,202} Nephroblastomatosis is a term that describes kidneys with multifocal or diffuse nephrogenic rests. Perilobar rests, located along the perimeter of a renal lobe, are strongly associated with synchronous bilateral Wilms tumors, BWS, and hemihyperplasia, whereas intralobar rests (within the renal lobe) show a strong association with metachronous tumors and WAGR and DDS.²⁰³ Children with nephroblastomatosis have an increased risk of developing Wilms tumor and require close monitoring.²⁰⁴

Biologic prognostic factors, such as gain of 1q, LOH at chromosomal regions 1p and 16q, supplement stage, and histology when assigning risk. Gain of 1q is associated with increased risk of relapse in patients with favorable histology Wilms tumor.²⁰⁵ LOH of chromosomes 1p and 16q is present in approximately 5% of favorable histology tumors and is associated with increased risk of relapse and mortality.²⁰⁶ The recently closed COG trial incorporated these factors prospectively into treatment decisions with augmented therapy for patients with LOH and favorable histology; a data analysis is pending. In a retrospective analysis of patients with very low risk disease (stage 1, FH, <550 g, <24 months of age) who were treated with surgery alone, *WT1* mutations, and 11p15 LOH were associated with a higher risk of relapse.²⁰⁷

Clinical Presentation and Natural History

Most children with Wilms tumor come to medical attention because of abdominal swelling or the presence of an abdominal mass that may be noted by the caregiver during bathing or dressing the child. Abdominal pain, gross hematuria, and fever may be present at diagnosis.²⁰⁸ Hypertension is present in approximately 20% of cases.²⁰⁹

Clinical Evaluation and Staging

With gentle palpation to maintain tumor capsule integrity, location and size of the abdominal mass and its movement with respiration should be noted. A varicocele may be associated with the presence of a tumor thrombus in the renal vein or inferior vena cava.²¹⁰ An evaluation for signs of associated syndromes, such as aniridia, hemihypertrophy, and genitourinary abnormalities, is mandatory. Laboratory studies should include a complete blood cell count, liver function tests, renal function tests, serum chemistries including calcium, and a urinalysis.

Diagnostic Imaging

Imaging should define the local and distant extent of the tumor, evaluate the renal veins and surrounding vessels to detect the presence of a tumor thrombus, and assess the contralateral kidney to rule out bilateral lesions, all of which are important prior to surgery.

The initial radiographic study is often an abdominal ultrasound examination to determine the consistency of the mass and the organ of origin, and to assess patency of the inferior vena cava. CT or MRI is appropriate for imaging of the primary tumor and to provide adequate visualization of the contralateral kidney, liver, and abdomen to define metachronous and metastatic tumors in the abdomen and pelvis. MRI may be superior to other imaging modalities in delineating nephroblastomatosis.²¹¹

Both plain radiographs of the chest (chest x-ray) and a chest CT should be performed to determine the presence of pulmonary metastases. In many cases, nodules detected by more sensitive CT scans do not necessarily represent a metastatic tumor, and current studies focused on determining which patients truly require intensified therapy with radiation.²¹² Imaging of the brain or skeleton is usually reserved for patients with rhabdoid tumors of the kidney and clear cell sarcoma of the kidney.

Staging

The staging criteria developed by the National Wilms Tumor Study Group (NWTSG) is shown in Table 99.7. The NWTSG approach allows for an adequate assessment of the extent of disease and histologic characteristics of the tumor and facilitates the collection of tumor tissue for biologic studies prior to therapy. In contrast, the SIOP approach (staging not shown) uses preoperative chemotherapy, decreasing the volume of tumor, and thereby decreasing the perioperative risk of tumor spillage. As a result of these treatment philosophies, children enrolled on NWTSG trials receive radiation therapy more often, whereas patients on the SIOP trials receive more cumulative doses of anthracyclines.^{213–215}

Treatment

Tumor stage and histology are the main prognostic indicators that determine the treatment regimen for Wilms tumor, whereas patient age at presentation and biologic factors (LOH 1p and 16q) were tested prospectively in the most recent COG (NWTSG) trials (results pending). Surgery and chemotherapy comprise the main therapy for Wilms tumors, with the addition of radiation for metastatic or histologically aggressive tumors.

Surgery

Surgical resection is the primary method for achieving local control and is usually performed at the time of diagnosis in North American studies (COG/NWTSG). A review of children treated on the NWTSG-IV demonstrated an increased incidence of local recurrence in those cases in which lymph node biopsies were not

TABLE 99.7
National Wilms Tumor Study Group Staging for Renal Tumors

Stage	Description
I	<ul style="list-style-type: none"> a. Tumor is limited to the kidney and completely excised b. The tumor was not ruptured before or during removal c. The vessels of the renal sinus are not involved beyond 2 mm d. There is no residual tumor apparent beyond the margins of excision
II	<ul style="list-style-type: none"> a. Tumor extends beyond the kidney but is completely excised b. No residual tumor is apparent at or beyond the margins of excision c. Tumor thrombus in vessels outside the kidney is stage II if the thrombus is removed en bloc with the tumor
III	Residual tumor confined to the abdomen: <ul style="list-style-type: none"> a. Lymph nodes in the renal hilum, the periaortic chains, or beyond are found to contain tumor b. Diffuse peritoneal contamination by the tumor c. Implants are found in the peritoneal surfaces d. Tumor extends beyond the surgical margins either microscopically or grossly e. obtained.²¹⁶ Presumably, these children were understaged and thus undertreated. Additionally, this review clearly demonstrated that operative rupture, whether localized to the renal fossa or diffusely spread within the peritoneal cavity, was associated with an increased incidence of local recurrence.²¹⁶

Routine exploration of the contralateral kidney is not necessary if imaging is satisfactory and does not suggest a bilateral process.^{217,218} Nephrectomy alone followed by observation for patients less than 2 years of age with stage I favorable histology tumors that weigh less than 550 g resulted in only an 85% EFS, and even though the study was stopped early, the OS was still 100% for this group of patients.^{219,220} Further analysis identified a *WT1* mutation and an 11p15 LOH as risk factors associated with relapse in this patient group.²⁰⁷ Prenephrectomy chemotherapy and nephron sparing techniques may benefit patients with bilateral disease at diagnosis.²²¹ Children with syndromic, unilateral Wilms tumor who have an increased risk of late renal failure (i.e., DDS or WAGR) may also benefit from partial nephrectomy or nephron sparing surgery.^{222,223} Preoperative treatment of Wilms tumor should be considered in children with a solitary kidney, bilateral renal tumors, tumor in a horseshoe kidney, tumor thrombus in the inferior vena cava above the level of the hepatic veins,^{224,225} and respiratory distress as a result of extensive metastatic disease.²²⁶ In children with bilateral disease or involvement of a solitary kidney, preoperative chemotherapy is intended to permit maximal conservation of uninvolved renal parenchyma. In the current COG renal tumor protocol, children who present with bilateral renal masses receive two to four cycles of chemotherapy without biopsy

(COG-AREN0534, NCT00945009). A biopsy is reserved for those patients whose tumors do not show appropriate volume reduction. Definitive surgery should be performed by week 12.

The role of surgical resection in the management of solitary pulmonary metastases was evaluated by the NWTSG in 211 patients with no therapeutic benefit identified when surgical resection was added to pulmonary radiotherapy and chemotherapy.²²⁷ Four-year survival rates were identical in the two groups.

Chemotherapy

Vincristine and dactinomycin, with the addition of doxorubicin for more advanced disease, form the backbone of most combinations for the treatment of Wilms tumor.²¹³ The recommended standard drug regimens and duration of therapy according to stage and intergroup studies are listed in Table 99.8. The five consecutive NWTSG studies have provided the foundation for current care in North America and the results of various US and European trials are depicted in Table 99.9.^{222,228–233,236,237}

NWTS-1 documented that postoperative radiation therapy is not required for children with stage I/II favorable histology or stage I anaplastic histology tumors when postnephrectomy chemotherapy with vincristine and dactinomycin is administered; NWTS-2 showed that doxorubicin improved relapse-free survival for group II through IV patients, NWTS-3 upstaged all patients with lymph node involvement to stage III, and provided evidence that patients with stage III favorable histology who receive adjuvant chemotherapy and radiation require augmented therapy with either doxorubicin or higher radiation therapy dose (20 Gy) for successful outcomes. Concerns about late effects of radiation resulted in the selection of the three-drug regimen (vincristine, dactinomycin, and doxorubicin) with lower radiation therapy dose (10 Gy) as standard therapy in this group.^{234,235} Furthermore, this trial showed that the addition of cyclophosphamide to the standard three-drug regimen (vincristine, dactinomycin, and doxorubicin) does not improve the outcome of patients with stage IV/favorable histology tumors, but was potentially useful in patients with anaplastic tumors. In NWTS-4, the addition of cyclophosphamide proved to benefit patients with stage II through IV anaplastic tumors. In addition, therapy was reduced for low-risk patients, and *pulse-intensive* regimens were shown to maintain excellent survival with less toxicity than previous regimens.²³⁶ Anaplasia, either diffuse or focal, adversely affects the outcome even after the administration of conventional chemotherapy with vincristine, dactinomycin, and doxorubicin. Cyclophosphamide and etoposide, when added to vincristine, dactinomycin, and doxorubicin, improved the survival of patients

with stage II through IV diffuse anaplasia in NWTS-5.¹⁹³ A trial incorporating carboplatin to improve outcomes was stopped early due to toxicity of this regimen (UH1). Results of NWTS-5 indicate that patients with stage I anaplasia had lower than expected survival and will require augmented therapy in upcoming studies.

Salvage therapy is successful in up to 80% of patients with low-stage favorable histology tumors initially treated with vincristine, dactinomycin, and no radiotherapy.²³⁷ Late recurrence more than 5 years after the diagnosis is rare, but is associated with a similar outcome to earlier recurrence.²³⁸ At the time of relapse, approximately 50% of unilateral Wilms tumor patients who have received standard chemotherapy, three-drug chemotherapy, and radiation can be successfully re-treated.^{239–241} Alternating cyclophosphamide/etoposide and carboplatin/etoposide, surgery and radiation led to 48% OS in high-risk patients with 53% OS in high-risk patients with lung-only relapse on the NWTS-5 relapse protocol.²³⁹ The benefit of high-dose chemotherapy with autologous stem cell rescue (single or tandem transplants) is uncertain,²⁴² although it has been shown that patients with residual disease do not do as well.²⁴³ Alternative agents, including topotecan²⁴⁴ and irinotecan,²⁴⁵ have shown some promising antitumor activity in phase I/2 studies and require further evaluation in clinical trials.

Radiation Therapy

Successive NWTSG trials refined the dosages and indications to decrease radiation exposure while maintaining local control and control of metastatic pulmonary lesions (see Table 99.7). Patients with stage I and II favorable histology tumors do not require abdominal radiotherapy, whereas those with stage III favorable histology or stages I to III focal or diffuse anaplastic disease require adjuvant radiotherapy to the flank or abdomen. The tumor and renal beds with a 1- to 2-cm margin are treated in cases of positive resection margins, nodal involvement, or local spillage during surgery. Care must be taken to provide a uniform dosage to the vertebral column to limit the risk of scoliosis. Whole-abdominal radiotherapy is used for patients with preoperative rupture, diffuse spill during surgery, or when peritoneal metastasis is present. A dose of 10.8 Gy is sufficient for local control in stage III favorable histology patients if they also received chemotherapy with vincristine, dactinomycin, and doxorubicin.²⁴⁶ Most patients receive radiotherapy within 8 to 12 days of nephrectomy without compromise in local-regional control.²⁴⁷ Currently, it is recommended that radiotherapy start within 14 days of a nephrectomy.

Whole-lung irradiation (12 Gy) has been recommended for patients who present with pulmonary metastases, which has

historically been defined by the presence of nodules on chest x-ray. However, CT now allows for the identification of much smaller lesions. Ehrlich et al.²¹² found that, in those patients whose pulmonary lesions were biopsied, only 82% of isolated lesions and 69% of multiple pulmonary lesions were actually tumor. Review of NWTS-4 and -5 identified patients with favorable histology and CT-only pulmonary lesions treated with standard three-drug therapy demonstrated no difference in EFS with or without the addition of radiation.²⁴⁸ For the SIOP 93-01 study, pulmonary radiation was successfully limited to those patients with unresectable, persistent nodules or high-risk primary tumor histology after receiving pre-nephrectomy chemotherapy for 6 weeks and postnephrectomy chemotherapy for 9 weeks.²⁴⁹ To develop a response-based approach to

pulmonary radiation therapy, a recently closed COG trial evaluated the feasibility of eliminating radiotherapy in children whose chest CT scans demonstrated complete resolution of pulmonary nodules at week 6 of therapy. The results of this strategy are pending.

RETINOBLASTOMA

Retinoblastoma is a rare childhood cancer of the developing retina that often presents with leukocoria and is fatal if untreated. Early detection and judicious therapy based on laterality and stage of disease has resulted in survival rates exceeding 90% in the United States for localized (intraocular) disease.

Epidemiology

The incidence rate in the United States for the period 1975 to 1995 is estimated at 3.7 cases per million (about 300 new cases per year) with no racial predilection or significant difference between males and females.¹⁸³ Worldwide, approximately 9,000 new cases are diagnosed each year.²⁵⁰ Over 85% of patients in the United States present with localized intraocular disease at diagnosis. Two-thirds of cases are diagnosed before 2 years of age and 95% before age 5 years. For unilateral disease, the median age at diagnosis is 2 years; for bilateral disease, the median age at diagnosis is less than 12 months. Approximately one-quarter of cases are bilateral and, therefore, have the heritable form of the disease (either sporadic or familial). In the remaining 75% of cases (unilateral), 10% to 15% of patients are found to have the heritable form of the disease. Parents and siblings of patients with retinoblastoma should undergo a thorough ophthalmoscopic examination while genetic testing is pending.

Biology and Genetics

Retinoblastoma is caused by the biallelic inactivation of the retinoblastoma gene, *RB1*, a tumor suppressor gene that is located on the long arm of chromosome 13 (13q14).²⁵¹ Mutations in the *RB1* gene are transmitted as a highly penetrant, autosomal-dominant trait.²⁵² Patients with 13q- syndrome may have other associated abnormalities, such as distinct facial features, mental retardation, and growth failure.²⁵³ Additionally, these patients have more episodes of neutropenia and GI toxicity than other children with retinoblastoma when receiving systemic chemotherapy (Brennan, unpublished). Recently, rare cases of MYCN-amplified retinoblastoma without *RB1* mutation have been reported.²⁵⁴ Despite the loss of a tumor suppressor gene, the retinoblastoma genome is relatively stable, with epigenetic dysregulation of cancer pathways, including upregulation of the proto-oncogene *SYK*, driving further tumorigenesis.²⁵⁵ Regardless of therapy, patients with heritable retinoblastoma are at an increased risk of developing secondary malignancies, particularly sarcomas, brain cancer, and melanoma^{256,257}; those with familial, heritable retinoblastoma may be at an even higher risk.²⁵⁸ The cumulative incidence of secondary malignancies 50 years after diagnosis in a large US cohort was 36% for hereditary retinoblastoma survivors and 5.7% for nonhereditary survivors; however, the mortality was 25.5% for hereditary retinoblastoma survivors and 1.0% for nonhereditary survivors.²⁵⁹

Pathology

Retinoblastoma is composed of uniform small, round, or polygonal cells, which have a scanty, poorly staining cytoplasm. The sparse cytoplasm is located at one side of the cell, suggesting the appearance of an embryonal retinal cell. The nucleus is large and deeply staining, giving the characteristic *small, round, blue cell* appearance. Three types of cellular arrangements may be identified: the Homer-Wright rosette, the Flexner-Wintersteiner rosette, and the fleurette. Calcification and necrosis are often observed.²⁶⁰

Clinical Presentation

Leukocoria, an abnormal white reflection from the retina compared with the normal *red reflex*, is the most common presenting sign of retinoblastoma.²⁶¹ Strabismus, conjunctival erythema, and decreased visual acuity are other common presenting complaints. Esotropia or exotropia may be present on examination, with decreased visual acuity as a result of involvement of the macula by the tumor or the presence of tumor cells and debris in the vitreous.²⁶² The eye may be red and painful because of uveitis after spontaneous necrosis of a retinal tumor or from neovascular glaucoma.

Evaluation

The diagnosis of retinoblastoma is based on clinical history (including family history) and results of examination of both eyes under general anesthesia. Once confirmed, the staging evaluation of a child with retinoblastoma should include an ultrasound of the orbits and MRI of the brain and orbits.^{263,264} An MRI is useful to evaluate the extent of extraocular (orbital or pineal gland) disease. Although optic nerve enhancement may be concerning for the extraorbital spread of disease, pathology (enucleation) remains the gold standard.²⁶⁵ Retinoblastoma may metastasize to the central nervous system, bones, or bone marrow.^{266,267} A further evaluation for metastatic disease with lumbar puncture, bone marrow aspiration/biopsy, and bone scan is reserved for patients with involvement of extraretinal structures, including the orbit or optic nerve, or when symptoms, signs, pathology, or diagnostic imaging studies suggest the involvement of distant sites.^{268,269}

Staging

The patient is staged according to the burden of local and metastatic disease, whereas the eye is *grouped* according to the extent of intraocular disease present. Martin and Reese²⁷⁰ first proposed a staging system for patients with retinoblastoma in 1942. Two decades later, the Reese and Ellsworth²⁷¹ grouping (R-E) attempted to predict the risk of enucleation with external-beam radiotherapy alone (Group Ia through Vb; Table 99.10). Although the R-E group (per eye) is still widely referenced today, the clinical value of utilizing a radiation-based system in an era of multimodal therapy that does not account for the presence of subretinal seeds and was developed before the introduction of indirect ophthalmoscopy is unclear. In 2001, the COG incorporated a new classification system (Group A through E) for grouping intraocular retinoblastoma that could be utilized among all institutions participating

TABLE 99.10

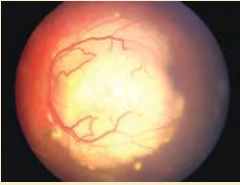

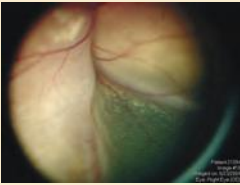

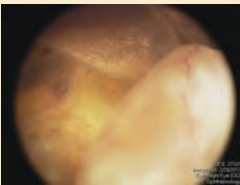

Reese-Ellsworth Grouping System for Retinoblastoma

Group	Description
Group I	
A	Solitary tumor, <4 disc diameters in size, at or behind the equator
B	Multiple tumors, <4 disc diameters in size, all at or behind the equator
Group II	
A	Solitary tumor, 4–10 disc diameters in size, at or behind the equator
B	Multiple tumors, 4–10 disc diameters in size, behind the equator
Group III	
A	Any lesion anterior to the equator
B	Solitary tumors >10 disc diameters behind the equator
Group IV	
A	Multiple tumors, some >10 disc diameters
B	Any lesion extending anteriorly to the ora serrata
Group V	
A	Massive tumors involving more than one-half the retina
B	Vitreous seeding

in clinical trials (Table 99.11). This classification system, which identifies the likelihood of treatment failure requiring enucleation or EBRT (group A = very low risk; group E = very high risk), was originally developed at Children's Hospital Los Angeles and is now used internationally.²⁷² The St. Jude Children's Research Hospital developed a staging system that is defined by the extent of tumor involving the retina and globe, or by the presence of extrachoroidal disease.²⁷³ Another staging system developed by Chantada et al.²⁷⁴ provides a common international classification for patients with extraocular retinoblastoma.

Treatment

Patients with suspected retinoblastoma should be referred to a pediatric ophthalmologist with expertise in the management of intraocular tumors and a pediatric oncologist experienced in the treatment of retinoblastoma. Treatment aims to preserve life and useful vision and is based on laterality and the stage of disease. Protective eyewear is recommended for all patients. With the high percentage of survivors, treatment decisions must carefully weigh

the functional outcome and potential long-term sequelae of local and systemic therapies.²⁷⁵

Enucleation

In view of the excellent response of this tumor to globe-sparing interventions, enucleation is considered in selective situations. Recently, more aggressive attempts at ocular salvage, regardless of visual potential, are being attempted (see the following). However, the most strongly considered indications for enucleation include (1) a unilateral retinoblastoma that completely fills the globe or that has damaged and disrupted the retina or vitreous so extensively that restoration of useful vision is not possible (and attempts at ocular salvage may place the patient at risk for metastatic disease); (2) a tumor that is present in the anterior chamber; (3) a painful glaucoma with a loss of vision after rubeosis iridis; (4) a progressive retinoblastoma disease unresponsive to all other forms of local therapy; and (5) cases with permanent vision loss in which extraocular tumor is suspected. The standard surgical technique is modified to allow excision of the longest possible segment of optic nerve in continuity with the globe.²⁷⁶ After removal, the globe and

optic nerve are inspected for evidence of extraocular extension of the tumor. A hydroxyapatite implant is placed in the muscle funnel, which improves the cosmetic result and the promotion of normal development of the bony orbit.²⁷⁷

Local Therapies

When combined with chemoreduction, local therapies, including laser, cryotherapy, and radioactive plaque brachytherapy, consolidate treatment and improve disease control for patients with R-E group I through IV disease.^{278,279} Patients with R-E group V disease may require additional therapy, including external-beam radiation.²⁸⁰

Laser is useful for tumors ≤ 2.5 mm in thickness and ≤ 4.5 mm in diameter (< 4 disc diameters).²⁷⁸ Like laser therapy, cryotherapy produces an avascular scar, but is more often utilized for tumors 2.5 mm in diameter and 1.0 mm thick located anterior to the equator and confined to the sensory retina.²⁸¹ Radioactive plaque brachytherapy using iodine-125 radiation may be utilized for tumor consolidation, but is more commonly used in the setting of localized recurrence for tumor control or for salvage.^{282,283} Plaque brachytherapy does not appear to have the risk of secondary malignancies seen in external-beam radiation.²⁸³

Radiation Therapy

External-beam radiation therapy is indicated for patients with advanced disease that has not responded adequately to chemotherapy and local treatments but who has useful vision, or patients with extraorbital extension of disease, usually after enucleation. Patients requiring radiation receive doses between 40 and 45 Gy, depending on tumor size, patient age, and the presence of vitreous seeding.²⁸⁴ Modern radiotherapy uses megavoltage accelerators and CT- and MRI-based treatment planning to allow for sparing of the lens and bony orbits. Together with daily image guidance for field placement, these techniques may further reduce known radiotherapy-related late effects to surrounding structures.²⁸⁵ Proton therapy can potentially decrease dosage to the surrounding bony orbits by more than 60% and avoid significant dosage to the hypothalamus compared with intensity-modulated radiotherapy, with equivalent target coverage.²⁸⁶

The preservation of some useful vision in these patients is an obvious advantage of such a treatment approach, but the risk of secondary malignancies after external-beam radiation in young children is well defined.^{259,287} Kleinerman et al.²⁸⁸ published long-term results of 1,601 survivors of retinoblastoma and reported a 3.1-fold increase in the risk of secondary cancers for hereditary retinoblastoma survivors who received radiation therapy. Among hereditary retinoblastoma survivors, radiation therapy increased the cumulative incidence of second malignancies to 38% in patients who received radiation compared with 21% of hereditary patients without radiation. The authors also found the risk of osteosarcomas was higher in patients who received chemotherapy with radiation, compared with radiation alone.

After enucleation, local irradiation to include the orbit and the optic nerve up the chiasm is recommended for all patients with extension of retinoblastoma into the orbit. Presentation with exophthalmos, inability to retain the prosthesis, or a palpable mass through the eyelids suggests the presence of orbital extension of the tumor. The identification of an extraocular mass, histologic confirmation of tumor cells at the cut end of the optic nerve at the time of enucleation, or rupture of the globe during removal is associated with orbital contamination with the tumor.

Chemotherapy

The use of neoadjuvant chemotherapy in treating retinoblastoma was prompted by success in salvaging patients with recurrent extraocular disease.^{289,290} Since the 1990s, there have been a series of studies documenting promising rates of vision-sparing therapy

without external-beam radiotherapy in intraocular disease.^{280,291,292}

Most chemoreduction regimens are platinum based and utilize carboplatin over cisplatin (due to reduced ototoxicity). Other active agents include vincristine, etoposide, cyclophosphamide, doxorubicin, and topotecan.^{291,293–297} Cyclosporin A has also been used as a multidrug-resistant reversal agent.²⁹⁸ Despite the initial response, which is most pronounced in patients with R-E group I through IV tumors, chemotherapy alone rarely achieves durable disease control and is, therefore, paired with local therapies, as described previously. Patients with R-E group V disease, especially those with vitreous seeds, are at highest risk for chemoreduction failure and tumor recurrence/resistance.

Because tumor shrinkage may prevent enucleation, patients with bilateral disease are candidates for conservative treatment with chemoreduction. Indeed, in bilateral retinoblastoma cases, the assessment of which eye is most likely to be capable of functional vision is difficult until a response to chemotherapy is determined. Adjuvant chemotherapy is utilized after enucleation in patients who have high-risk histologic features, including invasion of the choroid (massive), anterior chamber, or ciliary body/iris, postlaminar optic nerve involvement with concomitant invasion of the choroid, or involvement of sclera or tumor present at the cut end of the optic nerve.^{295,299}

Other recent areas of clinical investigation include locally delivered chemotherapeutic agents to increase drug concentration within the eye such as periocular chemotherapy (subconjunctival or subtenon injection),³⁰⁰ supraselective intra-arterial chemotherapy,^{301,302} and intravitreal chemotherapy.³⁰³ Because several reports have shown promising results, the techniques of intra-arterial and intravitreal chemotherapy will be prospectively evaluated in upcoming COG clinical trials to carefully evaluate the feasibility and toxicity of each regimen. At the same time, preclinical retinoblastoma research is providing novel therapies that target key pathways in retinoblastoma tumorigenesis.^{255,304,305} Pairing the right drug and delivery technique will translate into therapy that can save globes and vision while reducing the long-term effects of radiation and chemotherapy.

Metastatic Disease

Although most patients in the United States present with localized (intraocular) disease, 10% to 15% of patients will have evidence of extraocular spread at diagnosis. Patients with heritable disease (RBI mutation) have a 3% to 9% risk of developing trilateral disease, or disease invading the pineal gland, although this may be lower in this era of improved MRI (tumor versus cyst of pineal gland) and systemic chemotherapy.²⁶⁴

Therapy for patients with metastatic disease requires a multimodal approach with intensive systemic chemotherapy, external beam radiation, and, for patients with distant systemic or central nervous system (CNS) metastatic disease, autologous bone marrow transplantation.^{289,306–308} Despite aggressive therapy, survival for patients with metastatic retinoblastoma outside of the CNS is 50%, with survival decreasing to $< 10\%$ for those with CNS metastatic disease.

Late Effects and Long Term Follow-Up

Although patients treated for intraocular retinoblastomas have an excellent prognosis, those with germ-line RBI mutations remain at risk for secondary malignancies. Patients treated with chemotherapy are at risk for late effects, including secondary leukemia with exposure to etoposide^{309,310} and ototoxicity with exposure to carboplatin.^{311,312} There is also a growing awareness of the other long-term consequences that reach beyond the genetic and physical effects of therapy, such as health-related quality of life and neurocognitive and psychosocial outcomes.^{313,314} Further investigation through COG and other large retinoblastoma treatment centers is underway.

PEDIATRIC BONE SARCOMAS: OSTEOSARCOMA AND EWING SARCOMA

Osteosarcoma and Ewing sarcoma account for approximately 5% of all pediatric malignancies.^{183,315,316} Although the biologic properties of these tumors are distinct, their treatment principles are quite similar.³¹⁷ Osteosarcoma has a bimodal age distribution, with the first peak in the 2nd decade of life and the second peak occurring in older adults over the age of 65 years. A comprehensive discussion of osteosarcoma is provided in Chapter 91. This section will focus on the main features of osteosarcoma in the younger population, including its unique molecular, genetic, and cytogenetic features.

Osteosarcoma

Epidemiology

Osteosarcoma is the most common primary, malignant bone tumor in children and adolescents, accounting for 4% of all childhood cancers. In the United States, approximately 400 new cases are diagnosed in those younger than 20 years of age.¹⁸³ The peak age of incidence corresponds with the time of most rapid bone growth, 16 years in boys and 12 years in girls.³¹⁸ The disease is slightly more prevalent in males and in African Americans.³¹⁸

Biology and Molecular Genetics

The majority of osteosarcomas are sporadic. However, certain conditions, such as previous exposure to ionizing radiation³¹⁹ and alkylating agents,³²⁰ predispose individuals to the development of osteosarcoma. Additionally, a large proportion of patients older than 40 years who develop osteosarcoma also have Paget disease of bone.³²¹ Osteosarcoma is also associated with several cancer-predisposition syndromes, including hereditary retinoblastoma, Li-Fraumeni syndrome (LFS), and Rothmund-Thomson syndrome (RTS).

Patients with hereditary retinoblastoma have germ-line mutations in the *RB1* gene and somatic mutations in retinal cells, resulting in retinoblastoma. The majority of secondary nonocular malignancies in these patients are sarcomas, and more than a third of these are osteosarcomas, half of which occur within a previously irradiated field.^{257,287,322} LFS is a familial cancer syndrome in which affected family members have a wide spectrum of cancers, including osteosarcoma.³²³ Many of these patients carry germ-line mutations in the *p53* tumor suppressor gene.^{324,325} Screening of a large series of children with osteosarcoma showed that approximately 3% to 4% carried constitutional germ-line mutations in *p53*.³²⁶ RTS is an autosomal-recessive condition characterized by a distinctive rash (poikiloderma), small stature, skeletal anomalies, sparse hair, and increased risk for OS. In a cross-sectional study of 41 patients with RTS, 13 patients (30%) had osteosarcoma.³²⁷ Two-thirds of patients had constitutional mutations in the *RECQL4* gene, and the presence of mutations correlated with osteosarcoma risk.³²⁸ Because these genetic conditions are known to predispose individuals to osteosarcoma, careful detailing of family history in a patient with newly diagnosed osteosarcoma is important to identify underlying genetic risk and for genetic counseling of family members.

In view of these genetic predisposition syndromes, it is not surprising that the *RB1* and *p53* genes are also frequently altered in sporadic osteosarcoma tumors. Approximately 70% of primary osteosarcoma tumors have alterations in the *RB1* gene.^{329–331} Regulators of the *RB1* pathway, including cyclin-dependent kinases 4 and 6, cyclin D1, and p16^{INK4a}, are also altered in some cases of osteosarcoma.^{332–334} Inactivating mutations of the *p53* gene occur in approximately 50% of all sporadic cancers. The overall frequency of *p53* mutations in osteosarcoma ranges from 15% to 30% depending on the detection methods used.³³⁵ Other members of the *p53* pathway, including p14^{ARF} and MDM2, are altered in

some cases of sporadic osteosarcoma.^{336,337} Unlike *p53* and *RB1*, the *RECQL4* gene has not been found to be mutated in cases of sporadic osteosarcoma.³³⁸

Clinical Presentation and Natural History

Most patients with osteosarcoma present with pain and soft-tissue swelling. Approximately 5% to 10% may present with a pathologic fracture of the affected bone.^{339,340} Systemic symptoms such as fever, weight loss, and malaise are generally absent. A physical examination usually demonstrates a firm, tender mass and restricted range of motion in the affected extremity. Laboratory evaluation results are usually normal except for elevated alkaline phosphatase (in approximately 40%),³⁴¹ elevated lactate dehydrogenase (in approximately 30%),³⁴² and elevated erythrocyte sedimentation rate, none of which are specific for osteosarcoma.

Osteosarcoma in the pediatric population preferentially involves the metaphyseal region of the long bones, in contrast to Ewing sarcoma, which typically arises in the diaphyseal region of the long bones. The primary site of disease in 80% of patients with osteosarcoma is an extremity, most commonly (in descending order) the distal femur, proximal tibia, and proximal humerus. Unlike Ewing sarcoma, osteosarcoma rarely affects the axial skeleton.³⁴³ Approximately 20% of patients with osteosarcoma present with clinically detectable metastatic disease, most frequently to the lungs and less often to bones.

Diagnostic and Staging Evaluation

The initial evaluation of a suspected bone tumor involves obtaining a patient's complete history and performing a physical examination. Radiographic studies allow for an assessment of the anatomic site, the extent of local invasion, and the pattern of extension.³⁴⁴ If the tumor involves an extremity, then plain radiographs should encompass both proximal and distal joint regions, and they should be taken in two planes. Characteristic findings suggestive of osteosarcoma on a radiograph include a mixed lytic and sclerotic appearance, periosteal new bone formation with lifting of the cortex and the formation of the Codman triangle, and ossification of the soft tissue in a radial or *sunburst* pattern (Fig. 99.5).³⁴³ Even if the plain radiographs are classic for osteosarcoma, further imaging of the primary tumor by MRI or CT is required to evaluate the extent of the tumor for surgery-planning purposes. The imaging should include the entire tumor-bearing bone in order to assess for skip metastases (i.e., isolated tumor foci within the same bone as the primary tumor). Although both CT and MRI are equally accurate for local staging of tumors, an MRI is preferable for evaluating soft-tissue extension and joint and marrow involvement.³⁴⁴

Because patients with metastatic disease at presentation have a significantly worse outcome than do patients with localized disease, a thorough search for sites of metastases is imperative. Staging workup for osteosarcoma includes a technetium-99 bone scan to evaluate the involvement of other bones and a chest CT to detect pulmonary metastases. Studies evaluating the utility of FDG PET/CT in osteosarcoma staging show that FDG PET/CT may be more sensitive and accurate than a bone scan in detecting bone metastases.^{345,346} Furthermore, the results of several studies suggest that changes in the metabolic tumor activity as assessed by PET/CT during therapy correlate with the percentage of tumor necrosis at the time of definitive surgery.^{347,348} A histologic confirmation is indicated in pulmonary lesion(s) that cannot be unequivocally defined as being a metastatic disease. Finding one or more pulmonary (or pleural) nodules of at least 1-cm diameter or three or more nodules of at least 0.5-cm diameter generally indicates definite pulmonary metastases and may not require a biopsy. Fewer or smaller lesions may or may not represent metastatic disease; therefore, confirmation by resection may be indicated.³⁴⁴ There are no laboratory studies that are diagnostic or prognostic

Figure 99.5 Radiographic appearance of osteosarcoma involving the distal femoral diaphysis and metaphysis, with Codman triangles at the proximal end of the tumor (*white arrows*) and an associated sunburst periosteal reaction (*curved arrows*). Skip metastases are suggested by the presence of round sclerotic foci abutting the growth plate (*black arrows*).

for osteosarcoma.³⁴⁹ General laboratory tests such as a complete blood count; electrolyte counts including calcium, magnesium, and phosphorus; liver and renal function tests; and alkaline phosphatase and lactate dehydrogenase (LDH) measurements should be performed to obtain baseline values.³⁴⁹

Pathology

None of the radiographic features described previously are pathognomonic for osteosarcoma; therefore, a tissue biopsy is required to make a definitive diagnosis. The differential diagnosis for a bone lesion with aggressive features (e.g., the presence of a Codman triangle, associated soft-tissue mass, permeative appearance) on imaging studies includes Ewing sarcoma, lymphoma, and metastatic tumor. It may also occasionally include benign bone lesions, such as osteochondroma and giant cell tumor, and nonneoplastic

conditions, such as osteomyelitis, eosinophilic granuloma, and aneurysmal bone cyst. The biopsy should be performed by an orthopedic surgeon experienced in the management of malignant bone tumors, ideally by the same surgeon who will perform the definitive surgery. Proper planning of the biopsy with careful consideration of the future definitive surgery is important so as not to jeopardize the subsequent treatment, particularly in the case of a limb-salvage procedure.³⁵⁰

Osteosarcoma is thought to be derived from primitive bone-forming mesenchymal cells.¹³⁵ The histologic diagnosis is based on the presence of a malignant sarcomatous stroma associated with the production of *tumor* osteoid or immature bone.³⁵¹ Several types of osteosarcomas have been identified based on histologic, clinical, and radiographic features including conventional osteosarcoma (80%), which is the type most frequently encountered in children and adolescents. Conventional osteosarcomas are further subdivided into osteoblastic (50% of conventional OS), fibroblastic (25%), and chondroblastic (25%) variants depending on the presence of the predominant type of matrix.³⁵² The main feature that distinguishes these tumors from the malignant fibrosarcomas and chondrosarcomas, which also arise from primitive mesenchymal cells, is the production of osteoid.³⁵¹

Other variants of osteosarcoma include parosteal, telangiectatic, small-cell, periosteal, low-grade central, and high-grade surface.^{353,354} All variants are considered to be high-grade tumors except for low-grade central and parosteal osteosarcomas, which are considered to be low-grade tumors, and periosteal osteosarcoma, which is thought to be intermediate grade.^{354,355} Small-cell osteosarcoma can be histologically confused with other small, round cell tumors, especially Ewing sarcoma.³⁵⁶ The tumors may stain positive for CD99 and may contain the Ewing sarcoma breakpoint region 1 (EWSR1) gene rearrangement.³⁵⁷ Two other distinct variants of osteosarcoma have been described, osteosarcoma of the jaw and extrasosseous osteosarcoma. Osteosarcoma of the jaw tends to occur in older patients, has an indolent course, and is more often associated with local recurrences than with distant metastases. Extrasosseous osteosarcoma is rarely encountered and usually occurs after exposure to radiation.³⁵⁸

In contrast to other pediatric sarcomas, osteosarcomas do not have any specific translocations or other molecular genetic abnormalities that can serve as diagnostic or tumor-specific markers of disease. Cytogenetically, osteosarcoma tumors have complex numerical and structural chromosomal abnormalities with significant cell-to-cell variation and heterogeneity, highlighting the complexity and instability of the genetic makeup of osteosarcoma.³⁵⁹⁻³⁶³

Treatment

The mainstays of therapy for osteosarcoma are surgery and chemotherapy. The outcome of patients with nonmetastatic osteosarcoma has improved dramatically during the past 3 to 4 decades from an EFS rate of 10% to 20% to one of 65% to 70%, mostly because of the addition of adjuvant chemotherapy as well as improvements in surgical and diagnostic imaging techniques.^{343,364-366} The care of patients with osteosarcoma requires a team approach involving oncologists, orthopedic surgeons, pathologists, oncology nurses, physical therapists, social workers, and child life specialists.

Chemotherapy

Localized Disease. Because of current combinations of surgery and chemotherapy, long-term disease-free survival and OS rates for osteosarcoma are greater than 60%. Based on the results of cooperative group trials over the past years (Table 99.12), the current standard three-drug chemotherapy regimen for patients with localized disease includes doxorubicin, cisplatin, and high-dose methotrexate (MAP). Patients receive neoadjuvant chemotherapy with these drugs for approximately 10 weeks and then undergo

definitive surgery, which is followed by adjuvant chemotherapy for approximately 20 weeks. The exceptions to this therapy scheme in localized disease are low-grade central and parosteal osteosarcomas and some periosteal osteosarcomas without high-grade features; these variants are traditionally treated with surgery alone.³⁵⁴

The benefit of adjuvant chemotherapy in the treatment of osteosarcoma was clearly demonstrated in two prospective trials that randomly assigned patients to observation or chemotherapy following surgery.^{342,365,367} The concept of *neoadjuvant* or *induction* chemotherapy (i.e., chemotherapy given before definitive surgical resection) was prompted by the development of techniques for limb-sparing procedures and the need to control disease while the prosthesis was being constructed.³⁶⁸ In a prospective randomized trial by the Pediatric Oncology Group (POG) of neoadjuvant chemotherapy versus primary surgery followed by adjuvant chemotherapy³⁶⁹ outcomes were similar between the two groups, with 5-year EFS rates of approximately 61% and 69% ($p = 0.8$), respectively. Subsequent trials examining whether intensifying or adding other chemotherapy agents have not resulted in substantial improvements in OS for patients with osteosarcoma.^{370,371}

The use of immunostimulatory agents in the treatment of osteosarcoma was tested in a joint POG and CCG randomized study (INT-0133).⁵ The aim of this study was to determine whether adding the macrophage-activating agent MTP-PE (muramyl tripeptide phosphatidylethanolamine; mifamurtide) to chemotherapy would enhance survival in patients with newly diagnosed osteosarcoma. The study also evaluated whether adding ifosfamide to the standard three-drug MAP regimen improved survival. Initial results suggested that there may be some modest benefit to patients treated with MTP-PE, and with additional follow-up of patients treated on this study show that adding MTP-PE had an improved 6-year OS rate from 70% to 78%. The drug is not available in the United States for clinical use.

The most recent study, an international trial (EURAMOS 1) for patients with resectable localized or metastatic osteosarcoma,

has completed accrual. All patients were initially treated with standard three-drug induction with MAP. Those whose disease was classified as having a good response (>90% tumor necrosis) after induction chemotherapy continued with the same chemotherapy but were randomized to receive pegylated interferon α -2b, an immune-modulating cytokine that some Scandinavian studies have shown to have activity against osteosarcoma.^{372,373} Patients whose disease had poor histologic responses were randomized to receive high-dose ifosfamide and etoposide in addition to the standard three drugs. Preliminary results of the cohort of patients who experienced good responses to induction MAP chemotherapy showed no improvement in EFS rates of patients who received interferon α -2b versus those that received MAP alone; however, only 75% of patients who were randomized to receive interferon actually started the drug, and of those, only 55% completed all specified therapies.³⁷⁴

Metastatic Disease. The presence of metastatic disease at presentation is associated with a poor prognosis. In the absence of an available clinical trial, most patients with metastatic disease receive MAP chemotherapy with high-dose ifosfamide with or without etoposide.^{369,375,376}

The ability to control all foci of macroscopic disease is essential in managing metastatic osteosarcoma. Patients with pulmonary metastatic disease have a survival rate of 30% to 50%, whereas patients with bone metastases have a worse prognosis.^{377,378} Similarly, patients with multifocal osteosarcoma have a dismal prognosis.

Multiple studies have demonstrated that the removal of all sites of metastatic or recurrent disease (e.g., pulmonary lesions), even after completion of chemotherapy, can result in long-term survival.^{379–381} In a large analysis of the Cooperative Osteosarcoma Study Group, which included more than 1,700 consecutively treated patients, the 10-year survival probability was 40%

for metastatic patients who had all sites of metastatic disease resected.³⁸² However, patients with extrapulmonary metastases (e.g., bone metastases) are less likely to be cured, particularly those with multifocal disease.³⁸³ Ongoing strategies to improve the outcome of patients with metastatic osteosarcoma include the use of MTP-PE,³⁸⁴ bisphosphonates,^{385,386} and molecularly targeted agents such as those against vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) receptors, mammalian target of rapamycin (mTOR), and Src kinase.³⁸⁷

Local Control. Osteosarcoma is relatively radioresistant; therefore, surgery alone is the mainstay of local control. The choice of limb salvage versus amputation for extremity tumors depends on the location and extent of the tumor, the ability to achieve good surgical margins, and proximity to the joints and neurovascular bundle. As long as the tumor is removed in its entirety with disease-free margins, then the type of surgery—limb salvage versus amputation—does not seem to influence outcome.³⁸⁸ On the basis of the results of studies assessing quality of life and functional measures, most patients who undergo limb salvage procedures report an improved quality of life and demonstrate better functional ability than do those who have amputations.^{389,390}

Pelvic Tumors and Unresectable Disease. Patients with primary tumors of the axial skeleton generally have poor outcomes because surgery does not provide adequate local control. In some pelvic and most vertebral primary tumors, complete resection often is not possible. Most pelvic osteosarcomas can be treated by hemipelvectomy; however, more centrally located pelvic tumors, especially those involving the sacrum, are unresectable. Only a few pelvic osteosarcomas can be treated by limb-sparing resection (i.e., internal hemipelvectomy). Contraindications to resection are unusually large extraosseous extensions with sacral plexus or major vascular involvement. In general, these tumors cannot be resected with negative margins and are best treated by chemotherapy and radiotherapy.

Radiation Therapy. Historically, osteosarcoma has been considered to be relatively radioresistant; therefore, radiation therapy is generally not used as a definitive primary treatment of this disease. Radiation may be used in patients with microscopic positive margins of resection in doses of 55 to 68 Gy with local control rates ranging between 67% and 78%.³⁹¹ Patients with gross residual or unresected disease have been treated to doses of 70 Gy or higher. Treatment volumes have consisted of the gross residual disease or tumor bed plus a 1- to 2-cm clinical margin. In the setting of metastatic or unresectable osteosarcoma, radiotherapy may also be of benefit by improving pain in up to 76% of cases.³⁹² Despite the relative rarity of patients with osteosarcomas requiring radiation, its use can be of benefit in the management of both local and metastatic sites of disease.

Recurrent Disease. Outcomes for patients with local or distant relapse are poor.^{393–395} Effective therapy for these patients is challenging and is limited by the paucity of salvage chemotherapeutic agents active against this disease. Chemotherapy agents that have been used in the relapse setting include high-dose ifosfamide,³⁹⁶ gemcitabine and docetaxel,^{397–399} cyclophosphamide, and etoposide.⁴⁰⁰ More recently, targeted agents such as sorafenib have been used.⁴⁰¹ Isolated pulmonary disease with a single unilateral lung lesion is more likely to result in long-term disease-free survival than is bilateral pulmonary disease or bony metastasis. A longer disease-free interval (>12 to 24 months) from initial therapy is associated with longer disease-free survival.^{394,402,403}

Prognostic Factors

The most important prognostic factors for survival in patients with osteosarcoma are the presence of metastatic disease and the extent

of tumor necrosis following induction chemotherapy, with more than 90% necrosis (i.e., grades 3 or 4) being favorable and less than 90% (i.e., grades 1 or 2) necrosis being less favorable.^{370,404–407} Other prognostic variables have been less definitive in predicting outcomes. Some of these factors include age, tumor size, and tumor location.³⁸² Location is important because axial tumors, such as those of the pelvis, skull, or vertebrae, fare worse because of the difficulty in achieving a complete surgical resection with disease-free margins.

Ewing Sarcoma

Epidemiology

The term Ewing sarcoma was previously used to refer to the least-differentiated of a group of small, round cell tumors that share a recurring chromosomal translocation (discussed in detail in the following paragraphs). Over the years, this group of tumors became designated as the Ewing sarcoma family of tumors and includes Askin tumors (Ewing sarcoma arising in the chest wall) and the more histologically differentiated peripheral primitive neuroectodermal tumors. The 2013 World Health Organization classification proposed that the phrase *Ewing sarcoma* be used to refer to this family of tumors.⁴⁰⁸ We will follow this recommendation in this section.

Ewing sarcoma is the second most common primary bone tumor in pediatric patients after osteosarcoma, accounting for approximately 2% of childhood malignancies. About 200 cases of Ewing sarcoma are diagnosed in the United States per year.¹⁸³ Most of these tumors arise in the 2nd decade of life. There is a slight male predominance, and African and Asian children are rarely affected by this cancer.¹⁸³ Ewing sarcoma can arise in bone and, less commonly (about 30%), in the soft tissue (i.e., extraosseous) anywhere in the body.⁴⁰⁹

Biology and Molecular Genetics

The cell-of-origin of Ewing sarcoma is unknown but is presumed to arise from a mesenchymal stem cell.^{410–413} These tumors characteristically have recurrent chromosomal translocations that, in almost all cases, involve the *EWSR1* gene on chromosome 22 and a member of the ETS family of transcription factors.^{414,415} Of Ewing sarcoma tumors, 85% harbor t(11;22) (q24;q12), resulting in the fusion of the *EWSR1* and *FLI1* genes. Another 10% to 15% of tumors are associated with t(21;22) (q22;q12), which generates the *EWSR1-ERG* fusion gene. Less commonly, *EWS*, or the related protein *FUS*, is fused to another ETS family transcription factor (i.e., *ETV1*, *EIAF*, *FEV*, or *ETV4*), resulting in the same Ewing phenotype.⁴¹⁶

Heterogeneity in the *EWSR1-FLI1* fusion gene is based on the location of the chromosomal breakpoint. The most common rearrangement, designated type 1, consists of the first seven exons of *EWSR1* fused to exons six to nine of *FLI1*. This fusion gene accounts for over half of all cases. The type 2 rearrangement, accounting for about 25% of cases, fuses *EWSR1* to exon 5 of *FLI1*. There is no prognostic significance based on the type of fusion protein.^{417,418} As a chimeric transcription factor, *EWS-FLI1* is believed to regulate a number of critical downstream target genes that have been implicated in tumor biology, including members of the Sonic Hedgehog and *GLI1* pathways.^{419,420}

Evidence shows that directly inhibiting *EWS-FLI1*'s oncogenic activity by altering its interaction with critical binding partners such as RNA helicase A (RHA) significantly alters tumor biology. A small-molecule inhibitor that disrupts the *EWS-FLI1/RHA* interaction decreases xenograft growth and increases tumor cell apoptosis.⁴²¹ Additional evidence suggests that several intracellular signal transduction pathways are significantly altered in these tumors, including insulin-like growth factor receptor 1 (IGF-1R)

and the phosphatidylinositol-3 kinase (PI3K)–mTOR pathway.⁴²² Drugs targeting these pathways are being explored as possible new therapeutic agents for Ewing sarcoma, including anti-IGF-1R antibodies and mTOR inhibitors.^{423–426}

Clinical Presentation and Natural History

Patients with osseous Ewing sarcoma typically present with localized pain and swelling in the affected bone and may have other nonspecific symptoms such as fever, decreased appetite, and weight loss, which are usually seen in advanced disease.^{427,428} In contrast to osteosarcoma, Ewing sarcoma is equally distributed between extremity and axial sites. The lower extremity—primarily, the femur—is the most common site of disease, followed by the pelvis and the chest wall.⁴²⁹ Ewing sarcoma can also affect nonosseous structures, and this usually occurs in the soft tissues, but it can also arise in the GI tract, the kidneys, the adrenal gland, the lung, and other rare sites. The presenting symptom in these cases is site specific.

Metastatic disease is present in approximately 25% of patients at the initial diagnosis.⁴³⁰ The most frequent site of metastases is the lungs, followed by the bones, and bone marrow.⁴²⁹ Other sites of metastases, such as the lymph nodes, the liver, or the brain, are relatively rare unless in end-stage disease.

There is no specific blood or urine test to diagnose Ewing sarcoma. Abnormal laboratory findings at the time of diagnosis may include elevated LDH and alkaline phosphatase levels. LDH is useful as a gauge of tumor burden and usually falls with effective therapy and rises with disease recurrence.⁴³¹

Diagnostic Staging Evaluation

An evaluation of suspected Ewing sarcoma includes a radiographic examination of the primary tumor site and documentation of the presence or absence of distant metastases. Plain radiographs and MRI or CT scans should be initially obtained to characterize and define the local extent of the primary tumor. An MRI provides the most precise definition of the extent of the tumor and its relation to nearby nerves and vessels. Lesions that originate in the long bones characteristically involve the diaphyses, with extension toward the metaphyses. On plain films, a lytic or mixed lytic–sclerotic lesion is usually identified in the bone. A multilamellar periosteal reaction (i.e., onion skin appearance [Fig. 99.6]) and lifting of the periosteum (i.e., Codman triangle), or less frequently, radiating bone spicules, may be present. The lesion is usually poorly marginated and has a permeative and destructive pattern.

CT scans of the chest should be obtained to evaluate for pulmonary metastases. A biopsy of solitary pulmonary nodules should be strongly considered before classifying the disease as being metastatic. A technetium-99m whole-body radionuclide bone scan should be obtained to detect bone metastases. FDG PET/CT is highly sensitive in screening for bone metastases Ewing sarcoma^{432–434} and may be a useful predictor of outcome, similar to histologic response, after induction chemotherapy.⁴³⁵ Bilateral bone marrow sampling is required to complete the staging of all patients regardless of primary site or tumor size. Microscopically detectable bone marrow metastases occur in less than 10% of patients and are associated with a poor prognosis.⁴³⁶

Pathology

A biopsy of the tumor and an histopathologic examination are required for diagnosis. It is critical for the surgeon performing the diagnostic biopsy to place the incision appropriately to avoid complicating future resection. Under light microscopy, Ewing sarcoma falls under the category of small, round, blue cell tumors that includes neuroblastomas, rhabdomyosarcomas, lymphoblastic

Figure 99.6 Multilamellar periosteal reaction (arrows) in a plain radiograph (A) and MRI axial T2-weighted image (B) of the femur of a young girl who presented with intermittent leg pain. Diagnostic considerations included Ewing sarcoma, osteomyelitis, osteosarcoma, and Langerhans cell histiocytosis. Open biopsy of the lesion revealed Ewing sarcoma.

lymphomas, and, less commonly, histiocytosis and small-cell osteosarcomas. Ewing cells have a high nuclear-to-cytoplasmic ratio and appear homogenous, with uniform round nuclei that contain evenly distributed chromatin and little mitotic activity.⁴¹⁵ The cytoplasm is typically scant and weakly eosinophilic; however, intracellular accumulation of glycogen may confer a positive periodic acid–Schiff test. Some tumors may demonstrate neuroectodermal differentiation. These tumors typically have Homer-Wright pseudorosettes on light microscopy and positive immunohistochemical staining for synaptophysin, neuron-specific enolase, S100, and CD57.⁴¹⁵ More than 95% of Ewing sarcomas express CD99 (encoded by the *MIC2* gene) on their cell membranes.⁴²⁹ Although CD99 staining of the cell membranes in a honeycomb pattern is suggestive of Ewing sarcoma, it is not pathognomonic and may be seen in a variety of tumors, including synovial sarcoma, mesenchymal chondrosarcoma, and B-cell and T-cell leukemia/lymphoma.^{437–440}

The rapid identification of *EWSRI* gene rearrangements by performing reverse transcription–polymerase chain reaction assays or fluorescence in situ hybridization assays on fresh, frozen, or paraffin-embedded specimens is useful for expeditiously discriminating between Ewing sarcoma and other morphologically similar small round cell tumors.⁴¹⁴

Treatment

Chemotherapy. Ewing sarcoma is a very chemotherapy-sensitive tumor, and the outcome of patients with this disease has greatly improved as a result of intensifying systemic multiagent chemotherapy, particularly that of anthracycline and alkylating agents, as well as improvements in surgical and radiation techniques and supportive care (e.g., use of hematopoietic growth factors). Using current treatment strategies, over 70% of patients who present with localized disease are cured of their disease. However, the prognosis

of patients with metastatic or recurrent disease remains poor, with a long-term survival rate of less than 30%.⁴⁴¹

Localized Disease. Results of the major treatment trials for localized Ewing sarcoma are summarized in Table 99.13.^{411,442-454} Early cooperative group studies using adjuvant chemotherapy documented the efficacy of a four-drug regimen with vincristine (V), actinomycin D (A), cyclophosphamide (C), and doxorubicin (D) in combination with local control measures. By using these strategies, survival rates were improved from less than 20% to more than 40%.^{448,449} The next generation of studies confirmed the benefit of the addition of ifosfamide and etoposide in the treatment of Ewing sarcoma. A randomized phase III study conducted by the first American Intergroup Ewing trial (INT-0091/POG-8850/CCG-7881) demonstrated a superior outcome in patients with localized disease treated with VD(A)C alternating with ifosfamide (I) and etoposide (E) compared to VD(A)C alone (5-year EFS, 69% ± 3% versus 54% ± 4% respectively, $p = 0.005$).⁴⁴⁷ Similar improvements in survival with the addition of ifosfamide have been reported in studies by the National Cancer Institute and multiple European cooperative groups.^{444,455,456}

Dose intensification of the VDC-IE regimen in a second intergroup POG-CCG study (CCG-7942/POG-9354) of nonmetastatic Ewing sarcoma showed that a dose-intensified 30-week treatment schedule did not improve EFS beyond that of the standard 48-week schedule.⁴⁴⁶ However, a strategy of interval compression delivering the five-drug standard therapy (VDC-IE) in 30 weeks (chemotherapy every 14 days versus every 21 days) led to improved survival rates, with a median 5-year EFS rate of 73% for the compressed cohort and 65% for the patients treated every 21 days (see Table 99.13).⁴⁵⁴

In Europe, the collaborative study EURO-Ewing 99 is using risk-based stratification to assign patients into three risk groups based on tumor volume, presence, and pattern of metastatic disease, and histologic response to six cycles of four-drug induction chemotherapy (VIDE).^{429,457} After induction therapy, the study includes two randomized comparisons: patients with localized disease having a good response (i.e., less than 10% viable tumor after VIDE) continue therapy with either VAC or VAI; patients with either large tumors (i.e., more than 200 mL) or tumors having a poor response (i.e., more than 10% viable tumor after VIDE) receive VAI or busulfan–melphalan megatherapy. This study is nearing completion of accrual (see Table 99.13).

Metastatic Disease. The treatment for patients who present with metastatic Ewing sarcoma is challenging. In contrast to the improvement in survival for patients with nonmetastatic disease, no comparable benefit from the addition of IE has been demonstrated for patients who present with metastatic disease. In the first CCG-POG intergroup study (INT-0091), 120 patients with metastatic disease were evaluated using treatment regimens similar to those previously described for nonmetastatic patients. The addition of ifosfamide and etoposide in the metastatic group provided no survival advantage for those who did or did not receive IE.⁴⁵⁸ Results of studies testing dose-intensification strategies, including the use of total body irradiation and myeloablative chemotherapy followed by autologous stem cell rescue, have been disappointing.^{436,459-463} The EURO-Ewing 99 study described previously had an additional arm (R3) for patients with newly diagnosed primary disseminated disease. Two-hundred and eighty-one patients were treated with six cycles of VIDE, one cycle of VAI, and then surgery and/or radiation followed by high-dose busulfan–melphalan and autologous stem cell transplant. The 3-year EFS rate of these patients was 27% ± 3%.⁴⁶¹ Poor prognostic factors included age of 14 years or older, tumor volume of 200 mL or more, increased number of bone metastases, and bone marrow and bone involvement.

Recurrent Disease. Although most patients with Ewing sarcoma can experience a complete response to multimodal therapy,

about 30% of patients with localized disease and more than 70% of those with metastatic disease at initial presentation experience recurrent disease. The median time to relapse in most studies is approximately 16 to 21 months from diagnosis.⁴⁶⁴⁻⁴⁶⁶ The overall prognosis for these patients is dismal, with less than 20% survival. However, patients with early relapse (i.e., less than 2 years from diagnosis) fare worse than do those with late relapse (i.e., less than 10% survival).⁴⁶⁴⁻⁴⁶⁶ In terms of long-term follow-up surveillance and counseling, it is important to recognize that recurrences of Ewing sarcoma can occur very late, more than 5 years from diagnosis.⁴⁶⁷

There is no established salvage regimen for patients with recurrent disease. Combination chemotherapy regimens of cyclophosphamide and topotecan⁴⁶⁸⁻⁴⁷⁰; irinotecan and temozolomide^{471,472}; ifosfamide, carboplatin, and etoposide⁴⁷³⁻⁴⁷⁵; and gemcitabine and docetaxel⁴⁷⁶ have demonstrated antitumor activity in the relapse setting. Myeloablative chemotherapy and, in some cases, total body irradiation have been attempted in an effort to improve the prognosis for patients with high-risk or relapsed disease, with only modest improvement in outcome and at the cost of significant toxicity.^{477,478}

Local Control. Local control with surgical resection or high-dose radiotherapy in addition to chemotherapy is imperative for curative therapy in Ewing sarcoma. The inclusion of 12 to 15 weeks of systemic chemotherapy before the introduction of local control measures has become standard practice, regardless of tumor size, location, or stage, unless the tumor causes an immediate threat to survival, such as spinal cord compression or cardiopulmonary compromise. As of 2013, there has been no randomized trial to determine whether surgery or radiotherapy is superior in achieving local control. For decades, radiotherapy was the standard local treatment modality, but surgery is now the preferred modality if a complete resection is feasible.⁴⁷⁹ In prospective but nonrandomized trials, the improved survival in the surgical resection group has generally been attributed to the allocation of larger tumors with a correspondingly poorer prognosis to the radiation group. In some situations, particularly in patients who are at high risk for local treatment failure after resection, a combination of surgery and radiation is warranted. Decisions about local control should take into account resectability, functional outcome, long-term morbidity, the risk of late-onset secondary malignancies in tissues exposed to high-dose radiotherapy, and patient preference. Factors that influence the success of local control include the initial location of the primary tumor, with central disease having a poorer prognosis, and initial tumor response to chemotherapy as shown by the percentage of tumor necrosis.²³⁷

Surgery. In general, patients with resectable primary tumors receive induction chemotherapy followed by definitive surgery alone. For extremity tumors, limb salvage is preferred; however, if limb salvage or irradiation are not feasible, then amputation is warranted. Central pelvic or spinal lesions are frequently treated with radiation alone because surgery with negative margins is often not feasible. Chest wall lesions often present as large tumors extending into the thoracic cavity. Preoperative chemotherapy can greatly reduce the size, vascularity, and friability of the tumor, facilitating resection and decreasing the risk of intraoperative tumor rupture.⁴⁸⁰⁻⁴⁸² Because surgical outcome is improved in patients receiving preoperative chemotherapy, they are less likely to require postoperative chest wall radiotherapy, which has well-established risks of cardiac and pulmonary damage and radiation-induced second malignancies.⁴⁸³

Radiation Therapy. Radiation therapy is delivered in either the adjuvant or definitive setting based on the finding of involved surgical margins or unresectable disease. The selection of patients for radiation therapy should be made by a multidisciplinary team involving orthopedic oncologists, pediatric oncologists, and pediatric

radiation oncologists in order to best select a local control approach that maximizes the potential for high rates of local control with minimal toxicity. Modern radiation treatment techniques are now used that rely on CT simulation, target delineation, and treatment techniques, including conformal radiation therapy, intensity modulated radiation therapy, and proton beam radiation therapy.

The dose of radiation prescribed is dependent on the volume of the disease. Patients undergoing surgical resection with microscopically involved surgical margins (either after induction chemotherapy or at diagnosis) should receive adjuvant radiation therapy to the tumor bed to a dose of 50.4 Gy at 1.8 Gy per treatment fraction daily. Patients with gross disease present at the time of radiation therapy should be treated to doses of 55.8 Gy at 1.8 Gy per treatment fraction. Patients with no tumor present at the surgical margin but a poor histologic response to preoperative chemotherapy may also benefit from adjuvant radiation therapy.⁴⁸⁴ Other primary site prognostic factors that negatively impact local or overall disease control include the size of the tumor (≥ 8 cm) and the pelvic site of the disease.⁴⁸⁵⁻⁴⁸⁷ Patients with these prognostic factors that place them at high risk for local failure are candidates for more aggressive surgical resections and radiation dose escalation on clinical trials.

Ewing sarcoma was historically treated with large radiation portals and POG prospectively evaluated whole-bone (i.e., conventional) irradiation compared with tailored treatment fields, and a published analysis of this trial supports the efficacy of a more limited treatment volume as defined by prechemotherapy tumor extent.⁴⁸⁸ Modern treatment volumes for patients requiring radiation include all areas of gross disease, including areas the tumor initially infiltrated at diagnosis and the initially involved bone. Patients undergoing surgical resection, but still requiring adjuvant radiation should have the tumor bed or surgical cavity targeted. These target volumes should be expanded by 1 to 1.5 cm to account for microscopic spread of disease and treated to the doses indicated previously. The timing of radiation therapy usually occurs after the initial 12 weeks of chemotherapy. The risk of secondary sarcomas arising in irradiated bone is reported as being from 5% to 10% at 20 years from diagnosis. In patients treated with doses of 60 Gy or more, a significant excess risk of secondary bone sarcomas has been reported compared to the risk in those patients treated with doses below 48 Gy.⁴⁸⁹

Ewing sarcoma is one of few diseases in which radiation therapy is used curatively for metastatic disease. Whole-lung irradiation has proven effective for the consolidation of lung metastases after chemotherapy. Multiple trials have demonstrated superior EFS and OS rates when whole-lung radiation is given.⁴⁷⁹ Paulussen et al.⁴⁹⁰ analyzed patients in three cooperative Ewing sarcoma studies and found that the EFS rate was significantly higher for patients who received whole-lung irradiation. Whole-lung doses between 15 and 18 Gy are used with minimal acute toxicity to treat patients after initial chemotherapy.

Prognostic Factors

The most important prognostic factor for outcome still remains the presence of metastatic disease at diagnosis. Patients with isolated pulmonary metastases do better (about 30% disease-free survival) than those with bone or bone marrow metastases (about 20% disease-free survival), but all fare worse than patients with non-metastatic disease.^{447,491,492} Large tumor size and volume and high serum LDH levels at diagnosis correlate with an adverse outcome in some studies.^{430,431,487} Children with nonmetastatic pelvic primary sites also have a poorer prognosis than children with primary tumors of the extremities, although this difference may be related to the larger size and more difficult resectability of pelvic tumors.⁴⁹¹

Although not a prognostic factor assessable at the time of diagnosis, the histologic response to chemotherapy appears to be a strong predictor of treatment outcome. Poor histologic response (<90% tumor necrosis) correlates with a poor prognosis, whereas

complete or near complete tumor necrosis correlates with good outcome, with a 5-year EFS rate of 84% to 95%.^{493,494}

As understanding of the molecular pathogenesis of Ewing sarcoma continues to increase, other prognostic markers, such as those derived from genetic expression analyses of primary and metastatic tumors, may identify genetic signatures that allow for the stratification of disease into low- and high-risk subgroups.^{495,496} These studies may also provide clues as to which patients may benefit from various targeted therapies.

RHABDOMYOSARCOMA

Epidemiology and Genetics

Rhabdomyosarcoma is the most common soft tissue sarcoma in children, accounting for 3% to 4% of all cases of childhood cancer and for approximately 350 new cancer cases each year in patients younger than 20 years of age.^{1,182,183} Rhabdomyosarcoma is more common in males and Caucasians, and two-thirds of cases occur in patients under the age of 10 years with a median age at diagnosis of 5 years.⁴⁹⁷ Although most cases of rhabdomyosarcoma are sporadic, there are several genetic and environmental factors that have been associated with a heightened risk of developing the disease, including:

- Germ-line P53 mutations⁴⁹⁸
- Costello syndrome⁴⁹⁹
- Beckwith-Wiedemann syndrome⁵⁰⁰
- Neurofibromatosis type 1⁵⁰¹
- Germ-line DICER1 mutations⁵⁰²
- Parental use of cocaine and marijuana⁵⁰³
- Birthing order and accelerated in utero growth^{504,505}

Although rhabdomyosarcoma can arise in multiple sites of the body, the most common sites in decreasing order of frequency include the head and neck (including the orbit and paranasal areas [35%]), the genitourinary tract (including the bladder, prostate, vagina, vulva, uterus, and paratesticular area [26%]), and extremities (19%).¹⁰ Only about 20% of children with rhabdomyosarcoma present with disseminated disease, which most commonly involves the lung.⁵⁰⁶

Pathology and Molecular Biology

The International Classification of Rhabdomyosarcoma recognizes three main categories of rhabdomyosarcoma:⁵⁰⁷

1. Superior prognosis (both are variants of embryonal rhabdomyosarcoma):
 - a. Botryoid
 - b. Spindle cell
2. Intermediate prognosis
 - a. Embryonal rhabdomyosarcoma
3. Poorer prognosis
 - a. Alveolar rhabdomyosarcoma
 - b. Undifferentiated sarcoma

In contrast, the World Health Organization recognizes four variants of rhabdomyosarcoma and these subtypes, including embryonal, alveolar, pleomorphic, and spindle cell/sclerosing rhabdomyosarcoma.⁵⁰⁸ The presence of focal and diffuse anaplasia can be documented in about 13% of cases of rhabdomyosarcoma, and its presence may be of prognostic significance in patients with intermediate-risk embryonal rhabdomyosarcoma.⁵⁰⁹ In children and adolescents, the two most common types of rhabdomyosarcoma are the embryonal (65%) and alveolar (25%) subtypes and each of these entities have unique clinical and biologic features that will be described in more detail.^{510,511}

Embryonal tumors have a more favorable clinical outcome, often affect younger male patients, and most commonly arise in the head, neck, and genitourinary regions (Fig. 99.7).^{497,507,512} The botryoid variant of rhabdomyosarcoma resembles a bunch of grapes and characteristically arises in hollow organs such as the bladder, the biliary tract, the vagina, and occasionally, the conjunctiva and ear.^{507,513} In children, spindle cell tumors most commonly arise in the paratesticular area, whereas the sclerosing variant has been reported to more commonly affect the extremities and the head and neck region.^{508,514} Embryonal tumors are characterized by a loss of heterozygosity at the imprinted 11p15 locus, resulting in a loss of the maternal allele and duplication of the paternal allele that encodes the IGF-2 growth factor and is believed to participate in rhabdomyosarcoma tumorigenesis. This loss of imprinting also suggest that inactivation of a tumor suppressor gene at the maternal locus may promote tumorigenesis.^{515,516} Embryonal tumors are characterized by a high background mutation rate and overall number of single-nucleotide variants (see Fig. 99.7) as well a multiple chromosomal gains and losses most often involving chromosome 8 gains (74% of cases). Gains of chromosomes 2, 7, 11, 12, 13q21, and 20 as well as losses of 1p36, 6, 9q22, 14q21, and 17 have been reported.^{517,518} Activating RAS pathway mutations involving KRAS, NRAS, and HRAS have been documented in 42% of cases of embryonal rhabdomyosarcoma.⁵¹⁹ Mutations involving the *FGFR4*, *ALK*, *BRAF*, *CTNNB1*, *PIK3CA*, and *PTPN11* genes have been described less frequently.^{520,521} Embryonal tumors have also been reported to have *MDM2* amplification,⁵¹⁷ loss of *PTEN*, *BCL2L1* amplification, homozygous deletions of *CDKN2B*, increased *GLI* expression, *NF1* deletions, and *ALK* copy number gains.^{519,521} In contrast to patients with embryonal tumors, children with alveolar tumors have a worse clinical outcome and their tumors more commonly arise in the trunk and extremities (see Fig. 99.7).^{512,522} Genomically, these tumors are characterized by a t(2;13) (q35;q14) or t(1;13) (p36;q14), in which the *PAX3* gene on the long arm of chromosome 2 or the *PAX7* gene in chromosome

1 is fused with the *FOXO1* gene on the long arm of chromosome 13 (see Fig. 99.7).⁵²³ In addition, *ALK* gene copy number gains are seen in the majority of cases of alveolar rhabdomyosarcoma, and copy number gains and overexpression of *MYCN* have been associated with an adverse clinical outcome in this disease.^{521,524} Approximately 18% of alveolar rhabdomyosarcomas lack *FOXO1* rearrangements⁵¹⁰ and are termed fusion-negative alveolar rhabdomyosarcomas. These patients clinically behave more like patients with embryonal tumors, suggesting that the presence of a PAX/FOXO1 fusion is a key determinant of clinical behavior and should be incorporated into the risk stratification of the disease.^{517,525}

Diagnosis and Staging

Given the heterogeneous location of this tumor, rhabdomyosarcoma can cause a variety of signs and symptoms. Head and neck tumors, which comprise about one-third of all cases of rhabdomyosarcoma, can present with proptosis, ophthalmoplegia, nasal drainage, and obstruction, headache, cranial nerve palsies, dysphonia, dysphagia, and palpable adenopathy.⁵²⁶ Patients with genitourinary tumors, which account for 25% of cases of rhabdomyosarcoma, can present with hematuria, dysuria, hydronephrosis palpable abdominal mass, vaginal discharge, and palpable painless masses.⁵²⁶ Tumors in the extremities, which account for about 20% of cases of rhabdomyosarcoma, can present with swelling, palpable adenopathy, and pain.⁵²⁶ Tumors on the trunk, pelvis, and abdomen can present with nerve root compression, palpable mass or adenopathy, jaundice (biliary tract tumors), and perirectal pain and swelling.^{526,527}

A staging evaluation should include a complete blood count, serum chemistries, bone or PET scan, bilateral bone marrow aspirates and biopsies, CT of the chest, CT or MRI of the primary tumor, and CT or MRI of abdomen and pelvis for abdominal, pelvic, and lower extremity tumors. A recent report from the COG

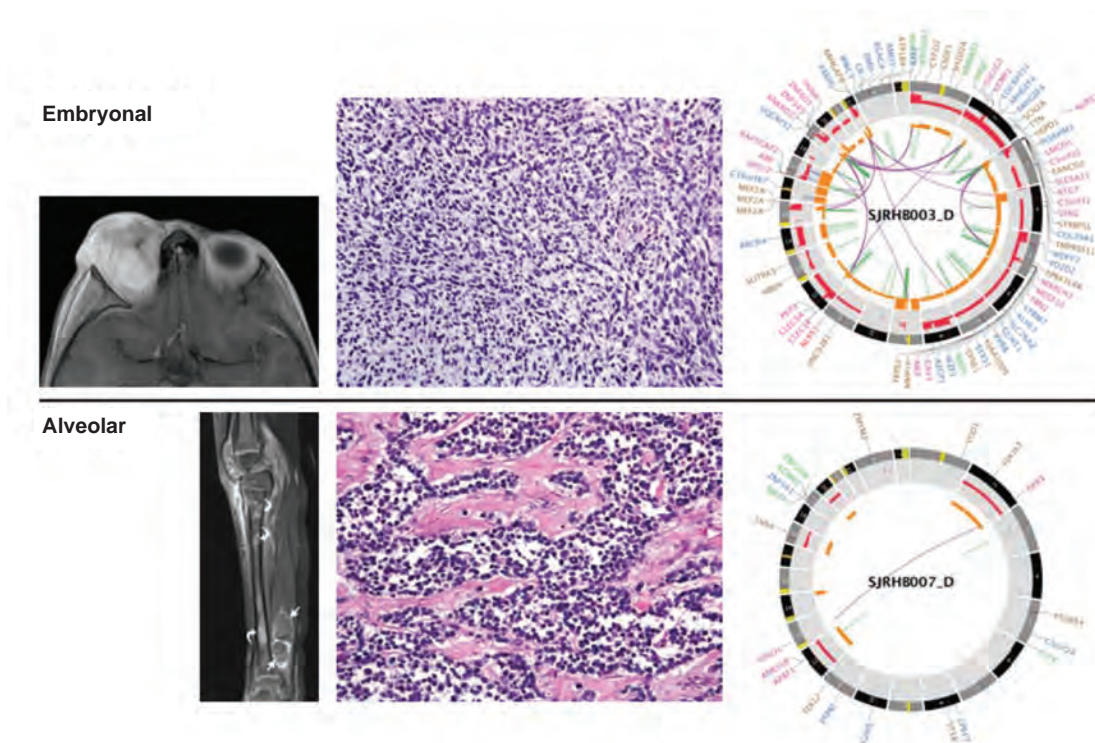

Figure 99.7 Clinical, histologic, and genomic features of embryonal and alveolar rhabdomyosarcoma.

suggests that up to one-third of patients with rhabdomyosarcoma, specifically those with embryonal noninvasive node-negative disease can be spared an extensive metastatic evaluation that includes a bone marrow examination and a bone scan.⁵²⁸ Studies investigating the role of PET scan in initial staging and as a predictor of clinical outcome in pediatric rhabdomyosarcoma are ongoing.^{529,530} Routine cranial imaging is not indicated unless there is evidence of spinal involvement and cerebrospinal fluid examination should be reserved for patients with parameningeal primaries.⁵³¹ Following a biopsy, a routine evaluation of regional nodes should be reserved for patients with extremity tumors and those with paratesticular tumors who are older than 10 years of age.⁵³² Sentinel node biopsy is increasingly being used to assess nodal involvement in patients with extremity tumors.⁵³³

Patients with rhabdomyosarcoma are staged using a surgical-pathologic grouping system as well as a pretreatment staging system as shown in Tables 99.14 and 99.15.^{534,535} About 16% of patients have group I disease (completely resected), 20% have group II disease (microscopic residual), 48% have group III disease (incompletely resected), and 16% present with group IV disease (metastatic).⁵³⁶ In addition, all patients should be staged using the pretreatment tumor, regional nodes, metastasis (TNM) staging system, which stratifies patients into four different categories based on the site of the primary tumor, tumor size, presence or absence of nodal and distant disease, and invasiveness. Using both

systems in addition to histologic subtype, pediatric rhabdomyosarcoma can be classified into three distinct risk groups (Table 99.16). Patients with low-risk disease, which account for about one-third of cases can be further subdivided into two subsets as shown in Table 99.16.⁵³⁷ Patients with intermediate risk account for about 50% of cases, and those with high-risk disease account for about 16% of cases (see Table 99.16).

Prognostic Factors

Clinical group, stage, histologic subtype, age, and treatment (see Table 99.16) are the most important predictors of outcome in childhood rhabdomyosarcoma.⁵³⁸ Patients with low-risk disease (embryonal tumors stage 1 through 3 group I, II and stage 1 group III) are expected to have a 5-year OS rate in excess of 95%.⁵³⁹ Patients with intermediate-risk disease (stage 2, 3 group III embryonal and stage 1 through 3 group I through III alveolar) have an estimated 4-year EFS of about 70% and the outcome of these patients has not changed significantly over time.⁵⁴⁰ Certain subsets of patients with intermediate-risk embryonal tumors such as those with T2 tumors, extremity primaries, and age <1 year and ≥10 years have a poorer clinical outcome.⁵³⁸ Similarly, patients with intermediate-risk alveolar tumors who present with stage 3 group III N1 disease have a particularly poor prognosis.⁵³⁸ Patients with high-risk disease

TABLE 99.14

Intergroup Rhabdomyosarcoma Study (IRS) Clinical Grouping Classification

Group I: Localized disease, completely resected

(Regional nodes not involved: Lymph node biopsy or dissection is required except for head and neck lesions)

(a) Confined to muscle or organ of origin.

(b) Contiguous involvement; infiltration outside the muscle or organ of origin, as through fascial planes.

NOTATION: This includes both gross inspection and microscopic confirmation of complete resection. Any nodes that may be inadvertently taken with the specimen must be negative. If the latter should be involved microscopically, then the patient is placed in the Group IIb or IIc (see the following).

Group II: Total gross resection with evidence of regional spread

(a) Grossly resected tumor with microscopic residual disease.

(Surgeon believes that he has removed all of the tumor, but the pathologist finds tumor at the margin of resection and additional resection to achieve clean margin is not feasible.) No evidence of gross residual tumor. No evidence of regional node involvement. Once radiotherapy and/or chemotherapy have been started, reexploration and removal of the area of microscopic residual does not change the patient's group.

(b) Regional disease with involved nodes, completely resected with no microscopic residual.

NOTATION: Complete resection with microscopic confirmation of no residual disease makes this different from Groups IIa and IIc. Additionally, in contrast to Group IIa, regional nodes (which are completely resected, however) are involved, but the most distal node is histologically negative.

(c) Regional disease with involved nodes, grossly resected, but with evidence of microscopic residual and/or histologic involvement of the most distal regional node (from the primary site) in the dissection.

NOTATION: The presence of microscopic residual disease makes this group different from 2b, and nodal involvement makes this group different from Group 2a.

Group III: Incomplete resection with gross residual disease

(a) After biopsy only

(b) After gross or major resection of the primary (>50%)

Group IV: Distant metastatic disease present at onset

(Lung, liver, bones, bone marrow, brain, and distant muscle and nodes)

NOTATION: The previous excludes regional nodes and adjacent organ infiltration which places the patient in a more favorable grouping (as noted under Group II).

Note: The presence of positive cytology in cerebrospinal fluid (CSF), pleural or abdominal fluids, as well as implants on pleural or peritoneal surfaces are regarded as indications for placing the patient in Group IV.

TABLE 99.15

Tumor, Regional Nodes, Metastasis Pretreatment Staging Classification for Rhabdomyosarcoma

Stage	Sites	Tumor	Size	Node	Metastasis
1	Orbit Head and neck (excluding parameningeal) GU, nonbladder/nonprostate biliary tract	T ₁ or T ₂	a or b	N ₀ or N ₁ or N _x	M ₀
2	Bladder/prostate, extremity, cranial parameningeal, other (includes trunk, retroperitoneum, etc.) (excludes biliary tract)	T ₁ or T ₂	a	N ₀ or N _x	M ₀
3	Bladder/prostate, extremity, cranial parameningeal, other (includes trunk, retroperitoneum, etc.) (excludes biliary tract)	T ₁ or T ₂	a b	N ₁ N ₀ or N ₁ or N _x	M ₀ M ₀
4	All	T ₁ or T ₂	a or b	N ₀ or N ₁	M ₁

Definitions:

Tumor	T(site) ₁	Confirmed to anatomic site of origin (a) ≤5 cm in diameter in size (b) >5 cm in diameter in size
	T(site) ₂	Extension and/or fixative to surrounding tissue (a) ≤5 cm in diameter in size (b) >5 cm in diameter in size
Regional Nodes	N ₀	Regional nodes not clinically involved
	N ₁	Regional nodes clinically involved by neoplasm
	N _x	Clinical status of regional nodes unknown (especially sites that preclude lymph node evaluation)
Metastasis	M ₀	No distant metastasis
	M ₁	Metastasis present

GU, Genitourinary.

continue to fare poorly with less than 30% of patients expected to be disease-free at 3 years following diagnosis.⁵⁴¹ Children with high-risk disease who are between 1 and 9 years of age, present with a favorable primary tumor, have less than three metastatic sites, and no evidence of bone or bone marrow disease have an expected 5-year failure-free survival of about 50%.⁵⁴¹ Recent studies have confirmed that the presence of PAX/FOXO1 fusions are the main determinant of clinical outcome and that previously identified metagene sets derived from gene-expression profiles were largely dominated by the effect of fusion status.⁵²⁵ Several reports suggest that the presence of a PAX7/FOXO1 rearrangement is associated with a better clinical outcome, but these findings need to be confirmed in larger prospective studies.^{525,542}

Management

Principles of Therapy

As previously mentioned, the management of rhabdomyosarcoma requires a multidisciplinary team, and current therapy is assigned

according to three distinct risk groups (low, intermediate, and high) that incorporate information regarding stage, clinical group, and histology of the tumor (see Table 99.16)⁵³⁷.

Local Therapy

Surgical considerations for the treatment of rhabdomyosarcoma are site specific, and given the high degree of chemosensitivity of these tumors, extensive surgeries in certain sites such as the orbit, the bladder, the vagina, and the biliary tract are unwarranted.⁵²⁷ When feasible, reexcision of positive margins in patients with extremity and trunk primaries is associated with improved survival.⁵⁴³ Second-look surgeries in selected patients may help identify and resect the residual viable tumor and convert patients with a partial or minor radiographic response into a complete response either reducing or eliminating the need for radiotherapy.^{8,537,544} It is estimated that about 60% of patients with residual radiographic abnormalities will have evidence of a viable tumor at the time of second-look surgery, and this finding is associated with an inferior failure-free survival, particularly if microscopic or gross residual disease is left behind.⁸ In addition, the results of second-look procedures can

TABLE 99.16

Risk Subgroups of Rhabdomyosarcoma

Risk	Proportion of Patients	Stage	Group	Histology	5-Year Event-Free Survival	Therapy
Low subset 1	30%	1,2	I-II III orbit	Embryonal	90%	VA ± C ± RT
Low subset 2	30%	1 3	III nonorbit I,II	Embryonal	87%	VA ± C ± RT
Intermediate	55%	2,3 1,2,3	III I-III	Embryonal Alveolar	65%–73%	VAC ± other agent + RT
High	15%	4	IV	Embryonal and alveolar	<30%	VAC ± other agents + RT

V, vincristine; A, actinomycin D; C, cyclophosphamide; RT, Radiotherapy.

help tailor the dose or eliminate the use of radiotherapy in selected cases.^{8,537,542} The use of debulking procedures has a very limited role in the management of rhabdomyosarcoma, although one report suggests that patients with debulking may improve the survival of patients with embryonal retroperitoneal tumors.^{6,545}

Radiotherapy should be administered to all children with the exception of those with group I embryonal tumors. A recent report also suggests that patients with stage 1, 2 group I alveolar tumors can be spared the use of radiotherapy.⁵⁴⁶ The use of conformal radiotherapy or hyperfractionated radiotherapy does not improve local control.^{547,548} The recommended doses for node-negative microscopic residual disease are 36 Gy and 41.4 Gy for those with microscopic disease and pathologically proven but grossly negative nodal disease. For a gross residual tumor, the recommended dose is 45 Gy for orbital and 50.4 Gy for nonorbital primary sites. The selection of reduced doses of radiation for patients with orbital sites of involvement is supported by the D9602 trial where the use of reduced doses of radiotherapy without an alkylating agent in patients with embryonal group IIA and orbital group III tumors did not compromise local control rates (~15% local failure).⁵⁴⁹ The treatment volumes for patients requiring radiation include all areas of gross disease, including areas the tumor initially infiltrated at diagnosis. Patients undergoing surgical resection, but still necessitating adjuvant radiation should have the tumor bed or surgical cavity targeted. These target volumes should be expanded by 1 cm to account for the microscopic spread of disease and treated to the doses indicated previously. The timing of radiation therapy usually occurs after the initial 12 or 18 weeks of chemotherapy based on whether that patient has localized or metastatic disease. Several attempts have been made to eliminate the need for radiation therapy in very young patients due to the risks of late toxicity from radiation. Although a delay of radiation therapy in very young patients may be considered if the patient's clinical response is acceptable (both maximizing the age of the patient at the time of radiation and minimizing the volume of the radiation targets), the elimination of radiation altogether based on a complete chemotherapeutic response should not be considered outside of a clinical trial. In the D9602 trial, patients with group III vaginal tumors experienced unacceptably high local failure rates in excess of 60% when they followed a response-based approach that attempted to eliminate radiation therapy without the use of higher dose cyclophosphamide.⁵⁵⁰

Systemic Therapy

Chemotherapy

All children with rhabdomyosarcoma should receive chemotherapy. The most common regimen used in North America consists of vincristine, actinomycin D, and cyclophosphamide (VAC); ifosfamide is preferentially used in the European trials.^{512,551} Other agents such as topotecan, melphalan, methotrexate, ifosfamide, etoposide, irinotecan, and doxorubicin have also proven active, but their addition to VAC regimens failed to improve outcomes in intermediate and high risk patients.⁵⁵² See Table 99.16 for the current outcomes and treatment recommendations for patients with low-, intermediate-, and high-risk tumors.⁵³⁷ For low-risk patients, who account for one-third of all cases of rhabdomyosarcoma, the administration of VA or VAC with or without radiotherapy is associated with survival rates in excess of 90%. Because of the excellent prognosis, the recently completed trial ARST 0331 for low-risk patients examined the feasibility of limiting the duration of therapy and the exposure to alkylating agents; preliminary results are only available in abstract form. Patients with intermediate-risk disease comprise about half of all patients with rhabdomyosarcoma and their survival depending on stage, group, and histology ranges from 59% to 83%.⁵⁴⁰ The use of alternating drug combinations with VAC and irinotecan is currently being investigated in the D9803 COG trial. Despite marked improvements in survival of nonmetastatic patients, survival for the remaining 16% of high-risk patients who

present with metastatic disease has remained unchanged during the past 30 years. End intensification with high-dose chemotherapy, dose intensification of alkylating agents, and integration of novel agents has failed to improve survival in these patients.^{552,553} The Soft Tissue Sarcoma Committee of COG has relied on pre-clinical xenograft models to identify potentially active agents and to translate these findings into frontline window studies for children with previously untreated poor prognosis rhabdomyosarcoma, and the current high-risk trial is investigating the addition of temozolomide and IGF-1R inhibitors to standard chemotherapy.^{554,555}

Less than one-third of children who develop a recurrence of rhabdomyosarcoma are expected to survive long term; however, patients who had stage 1 group I embryonal tumors at diagnosis and experienced a localized relapse >18 months from diagnosis have a higher likelihood of cure.^{556,557}

HEPATOBLASTOMA

Epidemiology

Approximately two-thirds of primary liver tumors in children are malignant, and they account for 1.1% of all cancers in children less than 20 years old (see Fig. 99.1).¹⁸³

Hepatoblastoma is the most common, accounting for two-thirds of all pediatric liver cancers, with hepatocellular carcinoma accounting for the vast majority of the remaining cases.⁵⁵⁸ The incidence rates for hepatoblastoma have steadily increased over time, doubling from 0.8 per million from 1975 to 1979 to 1.5 per million from 1990 to 1995, and more recently, increasing at a rate of 4.3% (95% CI, 0.2% to 8.7%) annually.^{558,559} In contrast, the incidence of hepatocellular carcinoma (HCC) has decreased from 0.6 per million to 0.2 per million.¹

Hepatoblastoma accounts for over 90% of all malignant liver tumors in children under the age of 5 years, and is slightly more common in males (1.2:1) and Caucasian children.^{558,560,561} The median age at presentation is 16 to 18 months.^{562,563} The most common risk factors for the development of hepatoblastoma include low birth weight,^{564,565} familial adenomatous polyposis coli (FAP),^{566,567} BWS,⁴⁰ and hemihypertrophy.⁵⁶⁸ There are also several case reports suggesting a predisposition for hepatoblastoma in children with trisomy 18.^{569,570}

Genetic Abnormalities

Most cases of hepatoblastoma are sporadic. Only about 15% of hepatoblastoma patients have genetic syndromes, the most common of these being FAP.⁵⁷¹ The risk for developing hepatoblastoma in FAP families is up to 800 times higher than that of the general population^{566,572} and, in two studies, up to 10% of patients with sporadic hepatoblastoma had germ-line mutations of the APC gene.^{566,573} Thus, screening of all families of hepatoblastoma patients for FAP may be appropriate.^{567,573} Other common recurring genetic changes in hepatoblastoma include gains of whole chromosomes, particularly 2, 8 and 20,^{571,574} and up to 18% have unbalanced translocations involving chromosome 1.⁵⁷⁴⁻⁵⁷⁶

Prematurity has been increasingly recognized as a risk factor for the development of hepatoblastoma, and in one Japanese study, hepatoblastoma accounted for nearly 60% of all cancers seen in premature babies weighing less than 1,000 g at birth.⁵⁷⁷ In another study, a clear correlation between a rising rate in hepatoblastoma and the percentage of low- and very low-birth-weight newborns was documented.⁵⁷⁸ A case-controlled study is currently being conducted by the COG to better delineate the role of prematurity and other factors in the development of hepatoblastoma.

Pathology

Hepatoblastoma is an embryonal tumor that is thought to arise from a liver stem cell.^{579,580} Thus, tumors have various combinations of

epithelial, mesenchymal, embryonal, macrotrabecular, and undifferentiated cells.⁵⁸¹ Although there is no consensus classification system, two pathologic subtypes have been identified with very different prognoses: (1) pure fetal histology and (2) small cell undifferentiated (SCU). Pure fetal tumors are composed of sheets of cells that resemble fetal hepatocytes, have minimal mitotic activity (<2/10 high-power \times 400 microscopic fields) and commonly contain clusters of hematopoietic precursors.⁵⁸¹ These tumors are curable with surgery alone.⁵⁸² At the other end of the spectrum are SCU tumors, accounting for less than 5% of all hepatoblastomas.⁵⁸¹ These tumors are often associated with low alpha-fetoprotein (AFP) at diagnosis (<100 ng/mL)⁵⁸³ and may lack SMARCB1/INI1 nuclear expression,⁵⁸⁴ suggesting that a subset of these tumors may be malignant rhabdoid tumors, rather than hepatoblastomas.

Clinical Presentation

Patients most commonly present with a palpable asymptomatic abdominal mass. Other common symptoms include nausea, vomiting, anorexia, and weight loss; jaundice is uncommon. Patients presenting with fatigue may also be anemic, and acute abdominal pain may indicate tumor rupture. Hepatoblastoma patients can present with isosexual precocity, as a consequence of elevations of β -human chorionic gonadotropin (HCG), and hemihypertrophy can be seen in up to 10% of patients.⁵⁸⁵ The presenting physical findings in children with HCC are similar to those encountered in patients with hepatoblastoma.

Evaluation and Staging

A laboratory evaluation should include a complete blood count, tests of renal and hepatic function, and urinalysis. Thrombocytosis is not uncommon in children presenting with hepatoblastoma, presumably a result of thrombopoietin production by the tumor.^{586,587} The serum levels of total bilirubin, alkaline phosphatase, and alanine aminotransferase and aspartate aminotransferase are not generally useful for the differential diagnosis of malignant hepatic tumors in children. Serum levels of AFP are elevated in approximately 90% of patients with hepatoblastoma and in 67% (29 out of 43) of children with HCC in the last COG trial⁵⁸⁸ and 70% (28 out of 40) of children with HCC in SIOPEL.^{563,589} A very low or high value (<100 ng/L or >1,000,000 ng/L) at diagnosis as well as a low early decline (<1 log) prior to definitive surgery has been associated with poor prognosis in hepatoblastoma.^{590,591} If the diagnosis of HCC is established, testing for hepatitis B surface antigen, hepatitis B antibody, serum iron, total iron-binding capacity, serum ferritin, and α_1 -antitrypsin should be performed. The initial radiographic evaluation often is with an abdominal ultrasound. However, a CT and/or an MRI are required for a definitive evaluation of the mass. A multiphase CT may ultimately be obtained to further define the anatomic relationship of the tumor to adjacent blood vessels—information that may be critical in surgical planning. In addition, this type of study may further suggest the most likely tumor histology. PET/CT may also be a useful modality.⁵⁹² The evaluation should also include a CT of the chest to search for metastases.⁵⁹³

The staging system used in therapeutic studies of hepatic tumors conducted by the COG segregates patients according to the resectability of the primary tumor and the presence or absence of metastatic disease.^{594,595}

The European SIOPEL Liver Tumor Study Group (SIOPEL) uses a pretreatment extent of disease (PRETEXT) staging system (Fig. 99.8).^{596,597}

This preoperative classification scheme identifies four PRETEXT categories reflecting the number of sections of the liver free of tumor and describes extension of disease into portal and hepatic veins, the vena cava, or intra-abdominal extrahepatic sites. A recent study comparing both staging systems suggests that the PRETEXT and COG systems can accurately predict survival in patients who might benefit from upfront surgical resection and reduced therapy

Figure 99.8 Liver resection of a patient with pretreatment extent of disease (PRETEXT) stage IV disease who underwent a successful liver transplant. The resected specimen shows multiple areas of viable tumor.

as well as patients with unresectable disease who are at increased risk of death.⁵⁹⁵

Prognostic Factors

The initial extent of disease (Staging; COG or SIOPEL)^{595,598} and tumor resectability⁵⁹⁹ as well as AFP values at diagnosis (less than 100 ng/L^{583,600} or >1,000,000 ng/mL⁵⁹¹), histology (pure fetal⁵⁸² or small cell undifferentiated histology⁶⁰¹) are the main predictors of outcome in hepatoblastomas.⁵⁹⁵ The presence of vascular involvement by the tumor is an additional adverse factor that has been used by the SIOPEL to classify patients as high risk. However, in a multivariate analysis, this did not hold up, perhaps because these patients often also have higher PRETEXT stage and/or metastatic disease.⁶⁰⁰ In children with HCC, tumor resectability is essentially the only prognostic factor.^{588,589} In adult patients, other important prognostic factors include cirrhosis, tumor size, the presence of metastases, satellite lesions, vascular invasion, or invasion of the tumor capsule.^{602,603}

Treatment

Surgery

Complete tumor resection is essential for a cure.^{599,604–607} Unfortunately, fewer than half of patients with hepatoblastoma⁵⁹⁴ and less than 20% of children with HCC have resectable disease at the time of diagnosis.^{588,589,608} Among the factors that render a liver tumor unresectable include invasion or close proximity to major vessels or involvement of both lobes.⁶⁰⁴ Treatment with chemotherapy before definitive surgery has allowed for complete tumor resection in more than two-thirds of children whose hepatoblastomas were initially deemed unresectable.^{594,609,610} In contrast, HCC is much less responsive to chemotherapy, limiting the effectiveness of preoperative pharmacologic intervention. In the SIOPEL report, all but two patients received preoperative chemotherapy and 36% (14 out of 40) eventually had gross total resection.⁵⁸⁹ When feasible, aggressive attempts at the initial resection of HCC should be pursued.

Liver transplantation has been used by several centers for children with unresectable hepatoblastoma, with 10-year survival rates in excess of 80% for those who underwent this procedure as “primary” surgical therapy.^{611–613}

This approach has also been used for patients with HCC.^{589,614–619} Chemoembolization and/or radiofrequency ablation of hepatic malignancies has been increasingly used in adults with HCC.⁶²⁰ Their overall role in the treatment of pediatric HCC remains to be defined.^{621–623}

Radiation Therapy

Traditionally, radiation therapy has had a limited role in the treatment of hepatoblastoma or HCC given the low tolerance that the normal liver has for radiation. In the era of image-guided radiotherapy, radiation may be delivered to liver tumors with less hepatotoxicity.^{624,625} Not much information is available in children regarding the use of radiotherapy in hepatoblastoma or HCC. In one report, doses of 25 to 45 Gy were associated with six of eight children with incompletely resected hepatoblastomas surviving after multimodality treatment.⁶²⁶

Chemotherapy

Before the identification of active chemotherapy, more than half of all children with hepatoblastoma were not amenable to surgical resection because of either extensive intrahepatic disease or the presence of extrahepatic metastases. Chemotherapy has enabled the successful surgical resection of many of these patients, resulting in cure rates approaching 80% in patients who have successful complete resections.⁶²⁷⁻⁶²⁹ Thus, the role of chemotherapy in the treatment of hepatoblastoma is well established.^{594,627,629-632} The most active agent is cisplatin.⁶²⁷ Other active agents include doxorubicin, vincristine, 5-fluorouracil, carboplatin, etoposide and ifosfamide,^{594,632-636} and more recently, irinotecan.^{637,638} A randomized study using cisplatin-based chemotherapy demonstrated that the combination of doxorubicin and cisplatin was equivalent to the combination of cisplatin, vincristine, and 5-fluorouracil (CFV),

but the latter triplet was associated with less myelosuppression, toxic deaths, and a decreased need for prolonged hyperalimentation.⁵⁹⁴ Thus, the latter regimen has become the standard for treating patients in North America. In Europe, SIOPEL preferentially used a cisplatin–doxorubicin-containing regimen (Table 99.17).⁵⁹⁸

A recent SIOPEL prospective randomized trial suggests, however, that patients with localized hepatoblastoma who have three or less liver sectors involved can be successfully treated with single-agent cisplatin.⁶²⁷ A significantly worse outcome was recently reported by investigators of the COG when carboplatin and cisplatin were alternated in newly diagnosed patients with advanced-stage disease (see Table 99.17), suggesting that platinum intensification in this manner was ineffective.⁶³⁹ The primary role of cisplatin in the treatment of hepatoblastoma was further corroborated by the recent SIOPEL report in which dose-intensive single-agent cisplatin (given every 2 weeks) was as effective as the combination of cisplatin and doxorubicin in children younger than 16 years of age with standard-risk hepatoblastoma.⁶²⁷

The 5-year EFS for patients with hepatoblastoma using cisplatin-containing regimens is about 70%, but survival is closely dependent on the tumor stage at diagnosis: 91±4% for stage I, 100% for stage II, 64±5% for stage III, and 25±7% for stage IV.⁵⁹⁴ Similar 5-yr EFS results based on PRETEXT staging have been published by SIOPEL investigators: 100%, 83%, 56%, and 46%, respectively, for patients with PRETEXT stages I through IV.⁶⁰⁹ Patients with metastatic disease continue to fare poorly regardless

TABLE 99.17

Results of Intergroup Studies (Children's Oncology Group and SIOPEL Liver Tumor Study Group) for the Treatment of Hepatoblastoma

Study (Reference)	Number of Patients	Treatment	Outcome	Comments
POG/CCG ⁵⁹⁴	173	CDDP–V–5-FU vs CDDP–Dox	5-yr S 69% 5-yr S 72% (p = 0.88)	Regimen without doxorubicin less toxic with similar survival
COG P 9645 ⁶³⁹	53 56	CDDP–V–5-FU vs CBDCA–CDDP	1-yr EFS 57% 1-yr EFS 37% (p = 0.017)	Intensified platinum regimens increase the probability of adverse outcomes in children with hepatoblastoma
SIOPEL 1 ⁶⁰⁹	154	CDDP–Dox	5-yr S 75%	138 received preoperative chemotherapy only, and of these 72% had a complete resection
SIOPEL 2 ⁶¹⁰	67 58	Standard risk (PRETEXT I, II, III) CDDP only HR–CDDP–CBDCA–Dox	3-yr S 91 ± 7% 3-yr S 53 ± 13%	97% of SR had complete tumor resections Results led to randomized comparison of CDDP vs. PLADO for SR (SIOPEL 3)
SIOPEL 3 ⁶²⁷	126 129	CDDP only CDDP–Dox	3-yr S 95% 3-yr S 93%	Dox can be safely omitted from treatment of SR patients
SIOPEL-3HR ⁶²⁸	151	High risk (PRETEXT IV, P+, V+, E+, metastases, AFP <100 ng/mL) CDDP/Dox/CBDCA	3-yr EFS 65%; 3-yr OS 69%	70% (106/151) achieved complete resection of tumor lesions, including metastases
SIOPEL-4 ⁶²⁹	62	High risk (PRETEXT IV, P+, V+, E+, metastases, AFP <100 ng/mL, or tumor rupture) CDDP/Dox/CBDCA	3-yr EFS 76%; 3-yr OS 83%	Increased dose-intensity of CDDP; GTR of all tumor achieved in 46/62 (74%) high-risk patients
HB 89 ⁶³⁴	72	Ifos–CDDP–Dox	“Long-term” EFS 75%	GTR in 92%
HB 94 ⁵⁹¹	69	Ifos–CDDP–Dox	3-yr S 77%	GTR 86% (54/63) Long-term EFS of 95% in those with GTR
JPLT-1 ⁶⁶⁷	134	CDDP–pirarubicin	3-yr S 77.8%	GTR 72%
JPLT-2 ⁶⁶⁸	212	CDDP–pirarubicin Ifos–pirarubicin–etop–CBDCA	3-yr S 82.4%	GTR 82%; 3-yr S 88%. Macroscopic disease /unresectable 3-yr S 56% (p <0.001)

CDDP, cisplatin; V, vincristine; 5-FU, 5-fluorouracil; S, survival; Dox, doxorubicin; CBDCA, carboplatin; HR, high risk; PLADO, cisplatin + doxorubicin; SR, standard risk; GTR, gross total resection; Ifos, ifosfamide; etop, etoposide.

of the regimen used, and their survival is less than 30%. Nearly one-third of patients who relapse following therapy with CFV can be salvaged with further surgery and a doxorubicin-based regimen.⁶⁴⁰

Currently, the COG study for patients with newly diagnosed hepatoblastoma (AHEP0731) is assigning treatment based on an assessment of risk. The factors incorporated in the risk group assignment include: COG stage, histology (pure fetal or SCU) and AFP. Very low-risk patients are defined as those with stage I tumors, pure fetal histology (PFH), and AFPs >100 ng/mL and are treated with surgery alone; those with low-risk disease are those with grossly resected tumors (stages I or II), AFPs >100 ng/mL, and who do not have SCU histology. These patients are treated with two courses of CFV chemotherapy. Intermediate-risk patients are defined as those with stage III tumors or those with stage I/II tumors with any SCU elements, as long as AFP is greater than 100 ng/mL. These patients receive six cycles of CFV with doxorubicin added to each cycle. Finally high-risk patients, defined as those with metastatic disease or AFP <100 ng/mL, regardless of stage, will receive an initial two courses of irinotecan/vincristine, followed by courses of CFV with doxorubicin.

In conclusion, although hepatoblastoma is a rare childhood cancer, cooperative group trials have enabled significant improvements in treatment. Because of the success of these trials and the rarity of these tumors, additional progress will require further international collaboration. Planning is ongoing for an international trial (Pediatric Hepatoblastoma International Therapeutic Trial [PHITT]), including all of the worldwide pediatric liver tumor cooperative groups from the United States, Europe, and Japan to evaluate what is the best chemotherapy for these children.

GERM CELL TUMORS

Epidemiology

Germ cell tumors account for 3.5% of cases of cancer in children under 15 years of age but for 16% of all cancers in those who are 15 to 19 years of age.¹⁸³ In pediatrics, germ cell tumors have a bimodal age distribution with peaks during infancy and puberty.⁶⁴¹ In boys under 4 years, gonadal and extragonadal tumors are evenly represented and teratomas and yolk sac carcinomas predominate, whereas most of the tumors in patients older than 10 years are located in the testis and are of nonseminomatous histology (teratoma, embryonal carcinoma, mixed). In girls, the majority of tumors in patients younger than 4 years of age are extragonadal, whereas germinomas and teratomas affecting the ovary are most commonly seen in patients over 10 years of age.⁶⁴¹ Sacrococcygeal tumors account for 40% of all childhood germ cell tumors and 78% of all extragonadal tumors⁶⁴²; less common extragonadal sites include the mediastinum, the retroperitoneum, the vagina, and the pineal region. Predisposing conditions for the development of pediatric germ cell tumors include cryptorchidism, Turner syndrome, Klinefelter syndrome, and androgen insensitivity syndromes.^{642,643}

Pathology

Pediatric germ cell tumors comprise a diverse group of histologies reflecting the pluripotent nature of the primordial germ cells. There are several subtypes of germ cell tumors, the most common being teratomas (37%), yolk sac tumors (27%), germinomas (18%), mixed (12%), embryonal carcinomas (2%), and choriocarcinomas (2%).⁶⁴⁴

Laboratory Markers

AFP and the β subunit of HCG (β -HCG) are oncofetoproteins, which are elevated in the serum of patients with a variety of germ cell tumors. AFP reaches peak concentrations at 12 to 14 weeks and declines to levels of less than 10 ng/L by 1 year of age. The

half-life of AFP is 5 to 7 days. AFP is elevated in patients with yolk sac and embryonal carcinomas.⁶⁴²

β -HCG is a glycoprotein secreted by the placenta, and its half-life is only 26 to 36 hours. Elevated levels in patients with germ cell tumors implies the presence of syncytiotrophoblastic cells, which are seen in germinomas, embryonal carcinomas, and choriocarcinomas.⁶⁴²

Clinical Presentation, Staging, and Treatment

The following section briefly summarizes the clinical presentation and treatment recommendations for germ cell tumors in specific anatomic areas. In general, pediatric patients with germ cell tumors can be divided into three risk categories that determine the type of therapy they receive (Table 99.18). A recent study suggests

TABLE 99.18

Staging of Pediatric Germ Cell Tumors

Stage	Extent of Disease
<i>Testicular Germ Cell Tumors</i>	
I	Limited to testis (testes), completely resected by high inguinal orchiectomy; no clinical, radiographic, or histologic evidence of disease beyond the testes. Patients with normal or unknown tumor markers at diagnosis must have a negative ipsilateral retroperitoneal node sampling to confirm stage I disease if radiographic studies demonstrate lymph nodes >2 cm.
II	Transscrotal biopsy; microscopic disease in scrotum or high in spermatic cord (≤ 5 cm from proximal end). Failure of tumor markers to normalize or decrease with an appropriate half-life.
III	Retroperitoneal lymph node involvement, but no visceral or extra-abdominal involvement. Lymph nodes >4 cm by CT or >2 cm, and <4 cm with biopsy proof.
IV	Distant metastases, including liver.
<i>Ovarian Germ Cell Tumors</i>	
I	Limited to ovary (peritoneal evaluation should be negative). No clinical, radiographic, or histologic evidence of disease beyond the ovaries. (Note: The presence of gliomatosis peritonei does not result in changing stage I disease to a higher stage).
II	Microscopic residual; peritoneal evaluation negative. (Note: The presence of gliomatosis peritonei does not result in changing stage II disease to a higher stage). Failure of tumor markers to normalize or decrease with an appropriate half-life.
III	Lymph node involvement (metastatic nodule); gross residual or biopsy only; contiguous visceral involvement (omentum, intestine, bladder); peritoneal evaluation positive for malignancy.
IV	Distant metastases, including liver.
<i>Extragenital Germ Cell Tumors</i>	
I	Complete resection at any site, coccygectomy for sacrococcygeal site, negative tumor margins.
II	Microscopic residual; lymph nodes negative.
III	Lymph node involvement with metastatic disease. Gross residual or biopsy only; retroperitoneal nodes negative or positive.
IV	Distant metastases, including liver.

that the addition of other prognostic factors that include age, LDH and AFP levels, and the presence of a mediastinal primary tumor may help refine the risk stratification of patients with pediatric germ cell tumors.⁶⁴⁵

In general, following surgical resection, patients with mature and immature teratomas as well as patients with stage I gonadal tumors (see the following section) can be observed and chemotherapy can be reserved to salvage patients who recur. For patients with more advanced stage disease, the use of cisplatin-based regimens has dramatically improved the outcome of patients with germ cell tumors, and with current regimens, over 80% of children with disseminated disease and over 90% of those with localized disease can be cured.⁶⁴⁶⁻⁶⁴⁸ The administration of higher doses of cisplatin may benefit subsets of patients with stage III/IV extragonadal tumors; however, this treatment is associated with significant ototoxicity.⁶⁴⁸ Attempts to reduce the rates of ototoxicity by adding amifostine to high-dose platinum were unsuccessful in one COG trial.⁶⁴⁹ In another trial, the addition of high-dose cyclophosphamide to standard-dose platinum proved to be feasible, but its benefit could not be adequately assessed given the low numbers of patients enrolled.⁶⁵⁰

Extragonadal Germ Cell Tumors

Sacrococcygeal teratoma occur in 1 in 35,000 live births, are the most common germ cell tumors in infants and newborns, and more commonly affect girls.⁶⁵¹ Approximately 80% of these tumors are diagnosed within the first month of life.

Four types of sacrococcygeal teratomas have been defined on the basis of the abdominopelvic extent and the presence or absence of external extension (Fig. 99.9).⁶⁵¹ The frequency of malignancy is closely associated with the type of teratoma and the age

at presentation; girls and boys older than 2 months of age have a malignancy rate of 48% and 67%, respectively.⁶⁵² Surgery is the mainstay of therapy for sacrococcygeal tumors and should include the removal of the coccyx to minimize local recurrence. Surgical sequelae that affect bowel and bladder control are reported in 11% to 41% of survivors.⁶⁵¹ Children with benign sacrococcygeal tumors have an excellent outcome with surgery alone, but recurrences that often contain a yolk sac component are seen in 11% of patients with mature teratomas and in 4% of patients with immature teratomas.⁶⁵³ This finding argues in favor of close follow-up of these patients for 3 years following resection.⁶⁵¹ Patients with malignant yolk sac tumors located in the abdomen and pelvis are highly responsive to chemotherapy and have an excellent survival (approximately 90%) when treated with platinum-containing regimens.⁶⁵⁴

Mediastinal Germ Cell Tumors

These tumors more commonly affect adolescent males and are associated with Klinefelter syndrome. In the first year of life, teratomas predominate, whereas older patients have yolk sac or mixed germ cell tumors. Patients may be asymptomatic or present with respiratory symptoms such as cough and dyspnea; infants and toddlers more often present with respiratory symptoms that may also include hemoptysis and upper airway obstruction.⁶⁴² The diagnosis is established by biopsy of the primary tumor or an involved supraclavicular lymph node. Staging studies should include serum chemistries; a complete blood count; tumor marker studies; a CT of the chest, abdomen, and pelvis; an MRI of the brain if clinically symptomatic; and a bone scan if metastases are evident at diagnosis in other sites such as the lung.

The use of cisplatin-containing regimens has dramatically improved the outcome for children with malignant mediastinal germ

Figure 99.9 Types of sacrococcygeal teratoma. **A:** Type I predominantly external, **B:** Type II external and intrapelvic, **C:** Type III predominantly pelvic, **D:** Type IV presacral. (From Rescorla FJ, Breitfeld PP. Pediatric germ cell tumors. *Curr Probl Cancer* 1999;23(6):257, with permission from Elsevier.)

cell tumors, but patients who are ≥ 12 years of age have a sixfold increased risk of death (survival $< 50\%$) compared to younger patients with tumors located in other sites.⁶⁵⁵ The use of a high-dose platinum regimen in one trial was not associated with a significant difference in clinical outcome.⁶⁵⁵

Gonadal Tumors

Testicular tumors make up approximately 17% of all pediatric germ cell tumors. About 75% of testicular tumors in children are of germ cell origin; in prepubertal males, teratomas and yolk sac carcinomas are the most common histologies, whereas mixed germ cell tumors are seen in older patients.⁶⁴⁴ Children with primary testicular tumors often present with painless testicular enlargement, and in about 20% of cases, they are associated with hydroceles or inguinal hernias.⁶⁴² The preoperative evaluation should include an ultrasound, a complete blood count, a chest radiograph, and serum chemistries, including AFP and β -HCG levels. After the diagnosis is established, the metastatic evaluation should include CT scans of the chest, abdomen, and pelvis. A bone scintigraphy should be performed in all patients with advanced stage disease, and brain imaging should be obtained when clinically indicated.

All scrotal masses should be explored through an inguinal incision. If the AFP is elevated and a malignancy is suspected, a radical orchiectomy with control of the vessels at the internal ring should be performed. If a benign lesion with a normal AFP is being considered as a diagnostic possibility, an enucleation of the mass following opening of the tunica can be performed after mobilizing the testicle and controlling the cord.⁶⁵¹

Patients with nonseminomatous stage I germ cell tumors (completely resected tumors) can be treated with radical orchiectomy alone, reserving the use of chemotherapy for relapse (Table 99.19).^{656,657} Children with more advanced stage disease (intermediate-risk disease; see Table 99.19) should be treated with standard courses of cisplatin, etoposide, and bleomycin and are expected to have a 6-year survival in excess of 90%.⁶⁴⁸

Ovarian tumors account for approximately 29% of all pediatric germ cell tumors and the incidence of this tumor increases with a peak at 18 years of age. Teratomas are the most common germ cell tumor of the ovary in children and adolescents, and dysgerminoma is the most common malignant germ cell tumor of the ovary in this patient population. Presenting symptoms include pain, abdominal distension, and acute abdomen, which may result from tumor hemorrhage, rupture, or torsion. Other less common symptoms include vaginal bleeding or precocious puberty (mostly in patients with sex-cord stromal tumors).⁶⁵¹ The initial work-up should include a complete blood count and serum chemistries, including

TABLE 99.19

Treatment of Pediatric Germ Cell Tumors

Risk	Treatment	5-Year Survival (%)
Low Risk Stage 1 testicular Stage 1 ovarian	Surgery only	< 95
Intermediate Risk Stage II–IV ovary Stage II–IV testes Stage I–II extragonadal	PEB \times 3 or 4	< 90
High Risk Stage II–IV extragonadal Stage IV ovary	PEB \times 4	70–75

PEB, cisplatin, etoposide, bleomycin.

AFP and β -HCG. The preoperative radiographic evaluation should include an abdominal ultrasonography and CT scans of the abdomen and pelvis. Once the tissue diagnosis is established, a metastatic evaluation that includes a CT of the chest and a bone scintigraphy (for advanced cases) should be performed. Surgical exploration should be performed through a laparotomy, and the following additional samples should be obtained: peritoneal washings, an examination of omentum with resection of adherent or abnormal areas, an exploration of retroperitoneal nodes with resection of abnormal nodes, and an inspection of the contralateral ovary with a biopsy of abnormal areas.⁶⁵⁸ Every attempt should be made to spare uninvolved fallopian tubes and the uterus to preserve fertility. Ovarian tumors are staged using the POG/CCG staging system, which represents a simplified version of the International Federation of Gynecology and Obstetrics staging system.

Surgery alone is sufficient for a cure in patients with mature and immature teratomas, and the presence of gliomatosis elements does not affect the prognosis.^{642,659,660} For patients with stage I seminomatous (dysgerminoma) and nonseminomatous malignant germ cell tumors, European and North American trials including a recently completed COG trial demonstrate that close observation following surgery is a reasonable strategy; although one-third of patients recur, more than 95% can be successfully salvaged and cured with chemotherapy at the time of relapse.^{657,661,662} Current pediatric regimens for the treatment of stages II through IV ovarian germ cell tumors use a combination of standard-dose cisplatin, etoposide, and bleomycin with 6-year event-free survival and OS rates in excess of 86% and 93%, respectively (see Tables 99.18 and 99.19).⁶⁴⁸

100 Leukemias and Lymphomas of Childhood

Karen R. Rabin, Judith F. Margolin, Kala Y. Kamdar, and David G. Poplack

INTRODUCTION

The cure rates seen in pediatric oncology are some of the best in modern oncology. These are largely related to the remarkable progress in the treatment of leukemias and lymphomas, where cure rates have improved from less than 10% to 80% to 95%.¹⁻⁴ Cure rates for pediatric myeloid leukemia are lower, in the 60% to 70% range.^{5,6} The improvement in outcomes for all of pediatric cancer are the result of the successful implementation of cooperative group clinical trials at the national and even international level.⁷ Currently, more than two-thirds of children with cancer in the United States are treated in clinical trials.⁷ Although there are many similarities in treating children and adults with these diseases, there are also differences that pertain to development and growth, drug metabolism, and psychosocial issues.

LEUKEMIAS

Incidence, Histology, and General Outcomes

Acute lymphoblastic leukemia (ALL), the most common malignancy of childhood, accounts for 75% of leukemias and is curable in 80% to 95% of cases.⁸ Figure 100.1 demonstrates the improvement in survival in pediatric ALL on successive cooperative group trials from 1968 to 2005.¹ Although there are variations with age, sex, and ethnicity, the majority of ALL cases have pre-B immunophenotype and FAB L1 histology (80% of cases); 20% are of T-cell origin. The peak incidence of pediatric ALL is between ages 2 and 5 years. ALL is slightly more common in American Caucasians than in African Americans, and there is a slightly increased incidence in male patients.⁹ Approximately 5,000 children are diagnosed with ALL each year in the United States, with an incidence of 29.2 per million.⁹ The Surveillance, Epidemiology, and End Results (SEER) program data show that the incidence of ALL has been climbing slowly. Controversy exists concerning whether and how incidence and outcomes differ between racial and ethnic groups. Studies from the 1990s suggest that Caucasians have slightly higher survival rates than those of African ancestry and Hispanics, although this is confounded in part by the fact that those of African ancestry and Hispanics more often develop high-risk forms of ALL.¹⁰⁻¹² Racial and ethnic disparities in access to care and adherence to treatment may also have an adverse impact on survival.^{13,14}

Acute myeloid leukemia (AML) accounts for approximately 15% to 20% of childhood leukemias, chronic myelogenous leukemia (CML) accounts for 3% to 4%, and juvenile myelomonocytic leukemia (JMML) and other rarer histologies account for less than 1%. The incidence of AML is currently estimated to be 5 to 7 cases per million in the United States.¹⁵ Myelodysplastic syndrome (MDS) is a relatively rare diagnosis in childhood, generally progresses to AML, and is treated with similar regimens (including bone marrow transplant) as AML.¹⁶ AML incidence is slightly higher in African Americans and Hispanics in the United States,

and survival is slightly lower.^{17,18} Because of intrinsic differences in drug sensitivity between ALL and AML cells, progress in treating AML has been less dramatic than that of ALL. Nevertheless, current cure rates in AML have risen to approximately 45% to 65% with the advent of more intensive conventional chemotherapy and bone marrow transplant (BMT) (Fig. 100.2).^{19,20}

Etiology

Environmental Factors

There is extensive literature and a continued interest in exploring possible relationships between infectious or environmental exposures and increased risk of childhood leukemia. However, most studies show weak or no correlation of these factors with the incidence of leukemia.²¹⁻²³ Electromagnetic fields have not been found to be significant in pediatric malignancies.²⁴⁻²⁶ There is an emerging body of evidence from population-based studies of polymorphisms of drug-metabolizing genes, such as *NQO1* and *GST* polymorphisms, that may be associated with an increase or decrease in an individual's risk for developing leukemia based on exposures to particular environmental toxins like benzene and other organic solvents, quinine-containing substances, and flavonoids.²⁷

Genetics

There is significant evidence that genetic factors play a role in the etiology of pediatric leukemia. Within the leukemic blasts themselves, there are characteristic cytogenetic changes (Table 100.1), many of which have prognostic significance (see later discussion). Key genetic changes found in childhood leukemia (especially in younger patients) may occur in utero or very early in life.^{28,29} Evidence includes the detection of cells bearing these changes in neonatal blood spots³⁰ and transmission of leukemia by twin-twin transfusion.³¹ The *delayed infection* hypothesis holds that children in developed countries are spared the frequent early infections that are necessary for normal development of the immune system. An infection occurring at a later time is then hypothesized to elicit a pathologic, myelosuppressive response, providing a selective growth advantage to the preleukemic clone, leading to development of overt leukemia.³²

In most cases, leukemia appears to result from a complex interplay between environmental and genetic factors. Recently, genome-wide association studies have identified several constitutional genetic variations with moderate but statistically significant effects on the relative risk of ALL.³³⁻³⁶ Collectively, variants in *IKZF1*, *ARID5B*, *CEBPE*, and *CDKN2A* may account for up to 80% of the attributable risk of developing ALL in Europeans.³⁵ *ARID5B* and *GATA3* polymorphisms have been identified as associated with both ALL susceptibility and relapse hazard, and may contribute to racial disparities in outcome, because high-risk alleles occurred more frequently in subjects with a greater degree of Native American ancestry.³⁷

In addition to somatic and germ-line genetic changes associated with leukemia, there are well-described cases of familial

Figure 100.1 Improvement in survival of children with acute lymphoblastic leukemia. Overall survival probability by treatment era for 29,287 children with ALL who enrolled in trials from 1968 to 2005 conducted by the Children's Oncology Group (COG), the Pediatric Oncology Group (POG), and the Children's Cancer Group (CCG). The 2000 to 2005 curve includes CCG, POG, and COG. The 1995 to 1999 curve includes CCG and POG. All other curves are CCG. (Adapted from Hunger SP, Lu X, Devidas M, et al. Improved survival for children and adolescents with acute lymphoblastic leukemia between 1990 and 2005: a report from the children's oncology group. *J Clin Oncol* 2012;30:1663–1669.)

leukemia, including recently described mutations in the hematopoietic transcription factor *PAX5*,³⁸ as well as strong associations between leukemia risk and immunodeficiency and several somatic genetic disorders (e.g., Down syndrome [DS], Bloom syndrome, ataxia telangiectasia, Shwachman-Diamond syndrome, Noonan syndrome, neurofibromatosis).⁸ Recently, a new association has been described between Li-Fraumeni syndrome, a well-known cancer predisposition syndrome, and hypodiploid ALL.³⁹

Patients with DS have a 10- to 20-fold increased risk of developing leukemia.⁴⁰ The occurrence of leukemia in DS patients appears to be unrelated to the other congenital abnormalities and

Figure 100.2 Improvement in survival of children with acute myeloid leukemia. Incremental improvements in overall survival in Children's Oncology Group and legacy trials in de novo childhood AML during the years indicated. (From Gamis AS, Alonzo TA, Perentesis JP, et al. Children's Oncology Group's 2013 blueprint for research: acute myeloid leukemia. *Pediatr Blood Cancer* 2013;60:964–971.)

TABLE 100.1

Acute Leukemia: Favorable and Unfavorable Prognostic Factors

Acute Lymphoblastic Leukemia

Favorable

- Age, 1–9 years
- White blood cell count <50,000/mcL
- High hyperdiploidy (DNA index >1.16; and especially trisomies of chromosomes 4 and 10)
- Chromosomal translocation t(12;21) or *ETV6-RUNX1*
- CNS-1
- Rapid response to induction chemotherapy

Unfavorable

- Age, <1 or ≥10 years
- White blood cell count ≥50,000/mcL
- Hypodiploidy (DNA index <0.81 or <44 chromosomes)
- Chromosomal alterations
 - t(9;22) or *BCR-ABL1*
 - *MLL* gene rearrangement
 - iAMP21 (intrachromosomal amplification of chromosome 21)
 - *IKZF1* gene deletion or mutation
 - Ph-like gene expression profile
- Extramedullary disease
- Slow response to induction chemotherapy

Acute Myeloid Leukemia

Favorable

- Core binding factor transcription complex, t(8;21) or inv(16)
- Acute promyelocytic leukemia t(15;17)
- Down syndrome
- Rapid response to induction chemotherapy

Unfavorable

- Monosomy 5, 5q deletion
- Monosomy 7
- FLT3 internal tandem duplication
- Secondary AML/myelodysplastic syndrome
- Slow response to induction chemotherapy

CNS, central nervous system.

medical problems of DS.⁴¹ The cytogenetic changes common in ALL occur less frequently in DS-ALL,⁴²⁻⁴⁵ but two alterations are markedly enriched: (1) Janus kinase 2 (*JAK2*) activating mutations in approximately 20% of DS-ALL, and (2) rearrangements leading to overexpression of cytokine receptor-like factor 2 (*CRLF2*) in up to 50% of DS-ALL.⁴⁶⁻⁴⁸

In the neonatal period, DS patients have a propensity for developing a nonneoplastic entity known as *transient myeloproliferative disease* (TMD) of DS, which at presentation, can appear very similar to AML (i.e., very high white blood cell counts with peripheral myeloblasts), but usually resolves spontaneously.⁴⁹ TMD may be difficult to distinguish from AML. Although TMD itself is not a form of malignancy or leukemia, approximately 30% of the DS patients with TMD will develop AML later in childhood.⁴⁹

When patients with DS do develop AML (especially those younger than age 2 years), they tend to develop acute megakaryoblastic leukemia (AMKL), display particular mutations in the *GATA-1* hematopoietic transcription factor, and have an excellent prognosis compared to other adult and pediatric AML subgroups. The disease-free survival (DFS) for DS patients with *GATA-1*+ AMKL is over 90%, with regimens significantly less intensive than those required for other AML cases.⁵⁰ The reasons behind the increased risk of leukemia in DS remain unknown.

Clonal Nature of Lymphoid Cancers

Lymphoid malignancies appear to have derived from an original abnormal progenitor that lost the ability to fully differentiate and formed a *clone* of leukemic blast cells. ALL blasts are characterized by early cytoplasmic and surface lymphoid antigens (detectable by flow cytometry), as well as incomplete immunoglobulin (Ig) and T-cell receptor (TCR) gene rearrangements, suggesting they arise from a precursor T- or B-lymphoid progenitor. AML may arise from a multipotent or committed myeloid progenitor. Persistence of subclinical amounts of leukemia during or after therapy is called minimal residual disease (MRD).⁵¹ MRD may be detected by flow cytometry or polymerase chain reaction (PCR)-based detection of Ig/TCR rearrangements or chromosomal translocations.⁵² Use of high-throughput sequencing technologies for MRD detection is being undertaken on a research basis and may hold promise as a future clinical test with even higher sensitivity and precision.⁵³

Diagnosis

The presenting signs and symptoms of a child with leukemia reflect the impact of bone marrow infiltration, the extent of extramedullary disease spread, and problems arising from changes in blood viscosity and chemistry related to the size, number, and breakdown products of leukemic blasts (tumor lysis).¹² Leukostasis from high white blood cell (WBC) counts may cause signs and symptoms ranging from mild respiratory symptoms and pulmonary infiltrates, to stroke, cranial or peripheral neuropathies, hematuria, renal failure, and ocular findings.⁸ AML blasts are larger, less flexible, and contain granules that can cause inflammation and clotting. Thus, AML has a higher risk of serious systemic problems than ALL for a given high WBC (e.g., >100,000/mm³). Gingival infiltration and orbital and periorbital soft tissue masses (chloromas) are often seen in AML.⁵⁴ AML FAB subtypes 4 and 5 have a tendency to present with chloromas.

Central nervous system (CNS) involvement is more common in ALL but is also possible with AML.^{55,56} CNS involvement is most often meningeal involvement, but may manifest as cranial nerve involvement, and occasionally, frank leukemic infiltrates in the parenchyma of the brain. CNS involvement may be asymptomatic or manifest as cranial nerve palsies, seizures, or focal neurologic findings. Testicular involvement generally manifests as a painless, palpable mass. Hepatosplenomegaly is common in both ALL and AML, and may compromise respiration in small children. Lymphomatous involvement of nodes or extranodal tissue

can cause superior mediastinal or superior vena cava syndromes, and bowel wall or mesenteric node infiltrations can cause intussusception or bowel perforation.

Tables 100.2 and 100.3 summarize the clinical and laboratory findings and differential diagnosis, respectively, for pediatric patients presenting with ALL. Infection and bleeding are significant risks. Fever should be managed aggressively with intravenous broad-spectrum antibiotics. Bleeding risk should be addressed by prompt transfusions of packed red blood cells, platelets, and/or plasma, as clinically indicated.

A definitive diagnosis of leukemia requires that the bone marrow has more than 20% to 25% leukemic blasts (depending on the pathologic classification system used).⁵⁷ Traditionally, the diagnosis depended on bone marrow aspirate and biopsy morphology and immunohistochemical staining patterns. The cornerstone of modern diagnosis is immunophenotyping, using flow cytometry antibody panels (see Chapter 107) to define the lineage of the leukemic clone. Cytogenetics also play a critical role.

Other diagnostic approaches that have become standard in many centers include fluorescent in situ hybridization (FISH), and PCR (to identify specific fusion proteins arising from chromosomal rearrangements). Finally, several techniques are used primarily on a research basis, such as RNA expression arrays, DNA copy number and single-nucleotide polymorphism (SNP) arrays, and whole-genome and whole-exome sequencing.⁵⁸⁻⁶¹ These techniques will be used increasingly for clinical decision making as well, such as to identify cryptic, actionable mutations⁶² or to predict susceptibility to targeted therapy.^{63,64}

TABLE 100.2

Clinical and Laboratory Features at Diagnosis in Children with Acute Lymphoblastic Leukemia

Clinical and Laboratory Features	Percentage of Patients
<i>Symptoms and Physical Findings</i>	
Fever	61
Bleeding (e.g., petechiae or purpura)	48
Bone pain	23
Lymphadenopathy	50
Splenomegaly	63
Hepatosplenomegaly	68
<i>Laboratory Features</i>	
Leukocyte count (mm ³)

TABLE 100.3

Differential Diagnosis in Childhood Acute Lymphoblastic Leukemia

- Nonmalignant conditions
 - Juvenile rheumatoid arthritis
 - Infectious mononucleosis
 - Idiopathic thrombocytopenic purpura
 - Pertussis; parapertussis
 - Aplastic anemia
 - Acute infectious lymphocytosis
- Malignancies
 - Neuroblastoma
 - Retinoblastoma
 - Rhabdomyosarcoma
- Unusual presentations
 - Hypereosinophilic syndrome

Management

Prognostic Factors in Management of Pediatric Acute Lymphoblastic Leukemia

As outcomes with modern therapy in pediatric ALL have improved, many factors previously shown to be important for predicting a prognosis have lost statistical significance. Five factors have retained prognostic significance and constitute the basis on which patients are stratified in most treatment protocols. These factors are (1) age at presentation, (2) WBC at presentation, (3) specific cytogenetic abnormalities, (4) presence or absence of CNS involvement (Table 100.4), and (5) rapidity of initial response to chemotherapy.⁸ The 1996 National Cancer Institute (NCI) consensus criteria standardized definitions of age, initial WBC, and CNS involvement to facilitate a comparison of clinical trial results between groups.⁶⁵ Cooperative groups differ in incorporation of cytogenetics and response to therapy. General principles of

TABLE 100.4

Definitions of Central Nervous System Disease Status at Diagnosis of Acute Lymphoblastic Leukemia Based on Cerebrospinal Fluid Findings⁶⁵

Status	Cerebrospinal Fluid Findings
CNS-1	No lymphoblasts
CNS-2	<5 WBCs/mcL with definable blasts on cytocentrifuge examination
CNS-3	≥5 WBCs/mcL with blast cells (or cranial nerve palsy)

modern ALL protocols include treatment of low-risk disease with less-intensive chemotherapy to minimize toxicity while maintaining excellent overall survival (OS) (90% to 95%), whereas high-risk disease (OS, 40% to 85%) is treated with more intensive therapy.⁸

The age-determined risk groups are less than 1 year (infant ALL), 1.0 to 9.99 years (standard risk ALL), and ≥10 years (high-risk ALL). Infants constitute a very high-risk group. *MLL* (11q23) rearrangements are frequent, especially t(4;11)(q21;q23), and are associated with hyperleukocytosis, extramedullary disease, and common acute lymphoblastic leukemia antigen (CALLA) (CD10) negativity.^{66,67} Cure rates on current infant protocols have improved modestly to approximately 50%.^{68,69} Results are poorest in infants under 3 months of age with *MLL* rearrangement. Unlike for some other high-risk ALL subgroups, current evidence does not suggest a benefit of stem cell transplant.⁶⁹

Adolescents and young adults have also traditionally demonstrated lower cure rates, although survival has improved significantly with early intensive postinduction therapy.^{12,70} In B-lineage ALL, presenting with a WBC count more than 50,000/mcL, and particularly over 100,000/mcL, is associated with a high risk of relapse.

Blast cell cytogenetics and ploidy have a significant prognostic impact in ALL (Fig. 100.3). High hyperdiploidy (≥50 chromosomes or DNA index >1.16) is associated with good prognosis, particularly with trisomies of chromosomes 4 and 10.⁷¹⁻⁷³ Hypodiploidy (<45 chromosomes) and especially haploidy

Number at risk	0	2	4	6	8	10	12	14	16
Hyperdiploidy	205	190	144	108	80	52	25	10	1
E2A-PBX1	40	36	27	19	14	9	6	0	0
TEL-AML1	163	144	105	83	60	46	30	10	0
Other B-lineage	261	221	161	130	92	50	28	13	3
T cell	138	112	75	60	36	22	8	3	1
BCR-ABL	22	15	7	5	3	2	0	0	0
MLL-AF4	15	9	6	4	4	2	1	1	0

Figure 100.3 Kaplan-Meier analysis of event-free survival according to biologic subtype of leukemia. (From Pui CH, Robison LL, Look AT. Acute lymphoblastic leukaemia. *Lancet* 2008;371:1030-1043.)

(23 chromosomes) are associated with a poor prognosis.^{72,74} Two other recently identified unfavorable abnormalities are *IKZF1* alterations⁷⁵ and intrachromosomal amplification of chromosome 21 (iAMP21).⁷⁶ *CRLF2* overexpression has been found to have an independent adverse prognostic impact in some studies, but not others.^{77,78}

The most common translocation in pediatric ALL is t(12;21) (p12;q22), forming the *ETV6-RUNX1* (also known as *TEL-AML1*) fusion. This cryptic translocation occurs in 25% of US pediatric ALL cases, less frequently in other geographic and ethnically defined populations, and is associated with a favorable prognosis.^{79,80} The Philadelphia chromosome (Ph+) refers to the t(9;22) (q34;q11) translocation, forming the *BCR-ABL1* fusion. Ph+ ALL is less prevalent in children than adults and was historically associated with a dismal prognosis. Treatment of Ph+ ALL and CML were revolutionized by imatinib mesylate, a selective tyrosine kinase inhibitor active against the *BCR-ABL1* fusion. The addition of imatinib to conventional chemotherapy has improved survival from approximately 30% to 40% to 80%, and hematopoietic stem cell transplant (HSCT) in first remission is no longer considered as the standard of care.⁸¹⁻⁸³ Ongoing studies are investigating the efficacy of later generation tyrosine kinase inhibitors such as dasatinib.⁸⁴

Numerous translocations occur in T-lineage ALL, but they are not generally associated with a prognosis. Activating *NOTCH1* mutations occur in over 50% of T-ALL cases, and are associated with a favorable prognosis.^{85,86} Because mutated *NOTCH1* activity depends on γ -secretase activity, γ -secretase inhibitors are being investigated as a novel therapeutic approach. Early T-cell precursor (ETP) is a very unfavorable prognostic subgroup identified based on a distinctive immunophenotype, constituting approximately 10% of T-lineage ALL, which bears a gene expression signature and mutational profile similar to myeloid leukemia.^{61,87}

CNS and testicular involvement are unfavorable prognostic signs, for which therapy is intensified.⁵⁶ The CNS is considered a sanctuary site because many systemic treatments do not adequately penetrate the blood-brain barrier, so CNS preventive therapy is required in all patients to prevent eventual CNS relapse. CNS prophylaxis is usually achieved through systemic and intrathecal chemotherapy. Although CNS involvement at diagnosis has generally been treated in the past with the addition of radiation to intensive chemotherapy, some advocate for reserving CNS radiation for use only in the case of CNS relapse.⁸⁸ Both testicular and CNS relapses require site-directed radiation as well as systemic reinduction due to increased risk of subsequent bone marrow relapse.^{12,89}

All modern pediatric ALL treatment protocols use the prognostic factors outlined here, in varying ways, to stratify patients into different risk groups that receive treatment of different intensity. The first phase of treatment (*induction*) lasts 4 to 6 weeks and includes a glucocorticoid, vincristine (VCR), asparaginase, and for high-risk patients, an anthracycline (usually daunomycin).¹² The Berlin-Frankfurt-Munster group begins induction with a *steroid window*, and the degree of cyto-reduction during this window is used in risk assessments.⁹⁰ Some groups intensify induction with additional medications. Rapid response to induction is an important prognostic variable (Fig. 100.4).^{8,73} Induction failure ($\geq 25\%$ marrow blasts at the end of induction) is rare (2% to 5% of cases) and generally associated with a poor prognosis, although a recent large retrospective analysis reported an unexpected heterogeneity in survival, ranging from 10% to 70%, depending on age, cytogenetics, and B- versus T-lineage disease.⁹¹

Induction is usually followed by a *consolidation phase* to reinforce the bone marrow remission and to administer CNS prophylaxis. Subsequent intensive phases may be termed *intensification*, *delayed intensification*, or *reinduction/reconsolidation*, with the intensity depending on the risk group.^{12,92,93} These intensive courses are generally delivered within the first 6 to 12 months of treatment, followed by a *maintenance* or *continuation* phase lasting 2 to 3 years, which consists of antimetabolite treatment (usually consisting of methotrexate weekly and 6-mercaptopurine daily), periodic intrathecal (IT) treatments, and periodic *pulses* of VCR and oral glucocorticoids with the frequency of these pulses varying by protocol and treatment group. To minimize and avoid treatment-related toxicities, strict supportive care guidelines are employed. Therapy-related mortality on frontline pediatric ALL protocols is generally under 2% to 3%. Overall treatment duration is usually between 2 and 3.5 years. On current Children's Oncology Group regimens, boys receive an additional year of maintenance, but many other cooperative study groups treat both genders for approximately 2 years.

CNS-directed therapy is usually present in all phases, but is most intensive during the first several months. CNS therapy uses intrathecal chemotherapy, high-dose systemic chemotherapy (principally, higher dose methotrexate or cytarabine), and/or cranial radiation.^{56,94} Because it is often associated with neurocognitive deficits, endocrine, and growth abnormalities, cranial radiation has generally been reserved only for patients at highest risk of CNS relapse (i.e., approximately 5% of patients who present with initial CNS involvement or T-cell disease), but at least one treatment group currently reserves the use of cranial irradiation only for CNS-relapsed cases.⁸⁸ Through the years, the doses of

Figure 100.4 Effect of minimal residual disease (MRD) on prognosis. Event-free survival (EFS) of all patients enrolled on the Pediatric Oncology Group 9900 series therapeutic studies with satisfactory end-induction MRD. The 5-year EFS values plus or minus standard error are shown for patients with varying levels of MRD. The outcome of those with high levels of MRD is very poor, but even those with 0.01% to 0.1% MRD have only a 59% \pm 5% 5-year EFS. (From Borowitz MJ, Devidas M, Hunger SP, et al. Clinical significance of minimal residual disease in childhood acute lymphoblastic leukemia and its relationship to other prognostic factors: a Children's Oncology Group study. *Blood* 2008;111:5477-5485.)

cranial radiation have decreased from the 24- to 36-Gy range that was used on early protocols to 18 Gy for treatment and 12 Gy on some CNS preventive therapy regimens.⁵⁶

Therapy for relapsed ALL depends on the location of relapse (isolated extramedullary, bone marrow, or combined) and the duration of initial remission. Extramedullary relapse generally has a better prognosis than bone marrow relapse, but requires localized in addition to systemic chemotherapy.¹² For testicular relapse, local therapy involves orchiectomy, followed by irradiation of the remaining testicle and scrotal area.^{12,95} Fertility will be compromised (so postpubertal males should be offered sperm banking), and hormonal supplements should be offered as needed. Prognosis after a testicular relapse remains quite good. For CNS relapse, local therapy involves intensified intrathecal therapy, varying regimens of high-dose systemic therapy, and the addition of cranial and/or craniospinal radiation.

All relapse types have a worse prognosis if they occur during therapy or within 6 months of completing therapy.⁹⁶ Interestingly, a recent study indicated that postrelapse survival does not differ according to the intensity of chemotherapy received prior to relapse.⁹⁷ Multiple medications and regimens are being tested for induction in relapsed and refractory leukemia. A common approach is to administer several intensive blocks of conventional chemotherapy agents, with or without a concomitant novel investigational agent.⁹⁸ Promising results have been recently obtained with clofarabine and clofarabine-containing regimens.⁹⁹⁻¹⁰¹ Blinatumomab, a CD19/CD3-bispecific T-cell engaging (BiTE) antibody, has shown promising response rates and prolonged survival in relapsed B-lineage ALL in adults, and is currently in a phase II international trial in pediatrics.^{102,103} Promising recent results have been obtained using chimeric antigen receptor-modified T cells with specificity for CD19, termed CTL019 cells.¹⁰⁴ The most recent update on this trial reported that among 20 patients (including 16 pediatric) with treatment refractory CD19+ ALL, 14 patients (82%) achieved complete remission, with robust in vivo expansion of CTL019 cells, and 11 of 17 evaluable patients maintained an ongoing CR during median follow-up of 2.6 months.¹⁰⁵

The decision between chemotherapy and HSCT for second complete remission has been controversial. HSCT is usually used for relapse within 6 months of the completion of initial treatment (CR1 <30 months), but the decision also depends on suitable donor availability, the difficulty (number and intensity of induction attempts needed to achieve CR2), and the overall health of the recipient.¹⁰⁶ Prior to HSCT, patients with relapsed ALL typically receive induction and consolidative chemotherapy, because the chances of success with HSCT are extremely low in the setting of continued active disease. Autologous BMT in ALL is no longer recommended.

Prognostic Factors and Management of Pediatric Acute Myeloid Leukemia

In contrast with ALL, there are fewer standard clinical or laboratory-based factors in AML that consistently relate to prognosis. Table 100.1 reviews prognostic factors in pediatric ALL and AML. Poor prognostic factors that predict lower remission rates and/or decreased event-free survival (EFS) include blast cytogenetics with monosomy 5 or 7, 5q deletion, FLT3/ITD, and secondary AML/MDS.^{19,107-109} Adolescents and young adults have an increased risk of treatment-related mortality, but no significant difference in OS.¹¹⁰ A swift response to induction chemotherapy (i.e., remission after one cycle of chemotherapy), favorable cytogenetics, and DS (with FAB M7) are predictive of better outcomes.¹⁰⁸ Favorable cytogenetics in AML include core binding factor alterations (the t[8;21] *AML1/ETO* fusion and inv[16]), and the t(15;17) *PML/RAR α* fusion seen in acute promyelocytic leukemia (APL) (see Chapter 107). Two other recently identified favorable cytogenetic alterations (CCAAT) are mutations in *NPM1*¹¹¹ and CCAAT/enhancer-binding protein alpha (*CEBP*).¹¹² In addition to genetic

alterations, MRD is being integrated into current AML studies as an important prognostic marker.¹¹³ Although many findings in AML are similar between adults and children, important biologic and therapeutic differences are emerging. An example of this is that mutations of the *KIT* receptor tyrosine kinase have a similar frequency in pediatric core binding factor AML as those found in adult AML, but lack the poor prognosis seen in adults.¹⁰⁹

There have been incremental improvements in AML outcomes over recent decades, with current overall survival in the 60% to 70% range (see Fig. 100.2). These improvements have come through increased intensity of therapy and improved supportive care.^{114,115} The inherent drug resistance of AML cells poses challenges because the intensification of therapy required is associated with significant treatment-related toxicity, particularly infections.¹⁹

With the exception of DS patients with FAB M7 AML and patients with APL, most pediatric AML induction therapies include two cycles of ara-C and daunomycin, with or without thioguanine and/or etoposide. Studies have shown that the intensity of induction therapy is important for OS.¹⁹ In the Children's Cancer Group 2891 protocol, intensively timed induction (starting the second cycle on day 14 regardless of count recovery) did not change the induction (CR1) rate, but it did have a profound effect on eventual cure rate.¹¹⁶ Although fewer than 5% of pediatric AML patients present with CNS disease, as many as 20% will suffer an isolated CNS relapse.⁵⁵ Intrathecal chemotherapy (usually ara-C) has been found by several groups to effectively reduce the risk of CNS relapse.¹⁹

Conventional postinduction consolidative chemotherapy in pediatric AML usually involves two to three cycles of high-dose ara-C–based combinations, to which anthracycline, etoposide, or ifosfamide/cyclophosphamide may be added. There is no proven benefit to maintenance chemotherapy, so conventional treatment is rarely more than four to eight cycles.^{19,117}
