Axitinib is a potent and selective second-generation inhibitor of VEGFR-1, -2, and -3. The *in vitro* half-maximal inhibitory concentration (IC₅₀) of axitinib is 10-fold lower for the VEGF family of receptors than for other TKIs such as pazopanib, sunitinib, or sorafenib.¹¹⁶ In January 2012, axitinib received approval for the treatment of advanced RCC after the failure of one prior systemic therapy based on a phase III trial (AXIS) comparing the efficacy and safety of axitinib versus sorafenib as a second-line treatment for metastatic RCC.^{117,118} The median PFS was 6.7 months with axitinib compared to 4.7 months with sorafenib (HR, 0.67; 95% CI, 0.54, 0.81; one-sided *p* < 0.0001). This improvement in PFS was greater in the cytokine-pretreated subgroup in comparison with the sunitinib-pretreated subgroup. The most frequent adverse events with axitinib were diarrhea (all grade), hypertension (all grade), fatigue, decreased appetite, nausea, and dysphonia. Moreover, hypertension, nausea, dysphonia, and hypothyroidism were more common with axitinib, whereas palmar-plantar erythrodysesthesia, alopecia, and rash were more frequent with sorafenib. A phase III trial (AGILE) comparing axitinib with sorafenib as first-line therapy in patients with treatment-naïve metastatic RCC demonstrated no significant difference in median PFS between patients treated with axitinib or sorafenib.¹¹⁹ Additionally, axitinib is being studied as a single agent as well as in combination with chemotherapy across several tumor types including HCC, NSCLC, and pancreatic and thyroid cancers.

Cabozantinib

Cabozantinib (XL184) is a small-molecule TKI with potent activity toward the MET receptor and VEGFR2, as well as a number of other receptor tyrosine kinases, including RET, KIT, AXL, and FLT-3. MET is the only known receptor for hepatocyte growth factor (HGF), and its signaling activity plays a key role in tumorigenic growth, metastasis, and therapeutic resistance. The dysregulated expression and/or activation of MET and HGF have been implicated in the development of numerous human cancers including glioma; melanoma; and hepatocellular, renal, gastric, pancreatic, prostate, ovarian, breast, and lung cancers, and is often correlated with poor prognosis.¹²⁰ Recent studies have determined that the MET pathway plays an important role in the development of resistance to VEGF pathway inhibition and that the use of VEGFR inhibitors, such as sunitinib, sorafenib, or a VEGFR2-targeting antibody, can result in the development of an aggressive tumor phenotype characterized by increased invasiveness and metastasis.¹²¹⁻¹²⁵ Thus, there is an advantage to targeting both the MET and VEGF pathways to disrupt angiogenesis, tumorigenesis, and cancer progression. In November 2012, cabozantinib received U.S. regulatory approval for progressive metastatic MTC based on the phase III trial that demonstrated a statistically significant PFS prolongation for the cabozantinib-treatment arm.¹²⁴ The estimated median PFS was 11.2 months for cabozantinib versus 4.0 months for placebo (HR, 0.28; 95% CI, 0.19 to 0.40; *p* < 0.001). Manageable toxicities included diarrhea, palmar-plantar erythrodysesthesia, decreased weight and appetite, nausea, and fatigue. Cabozantinib has been effective against several solid cancers, including MTC, breast, NSCLC, melanoma, and liver cancer, and is currently being studied in clinical trials in a number of tumor types, with the most significant results observed in the reduction of bone metastatic lesions in castration-resistant prostate cancer.¹²⁵

Regorafenib

Regorafenib is a small-molecule TKI of multiple membrane-bound and intracellular kinases including RET, VEGFR1, VEGFR2, VEGFR3, KIT, PDGFR- α , PDGFR- β , FGFR1, FGFR2, TIE2, DDR2, TrkA, Eph2A, RAF-1, BRAF, BRAFV600E, SAPK2, PTK5, and Abl pathways.¹²⁶ Regorafenib is structurally related to

sorafenib and differs from the latter by the presence of a fluorine atom in the center phenyl ring, resulting in higher inhibitory potency against various proangiogenic receptors than sorafenib, including VEGFR2 and FGFR1. In September 2012, regorafenib was approved for the treatment of patients with mCRC who have been previously treated with fluoropyrimidine-, oxaliplatin-, and irinotecan-based chemotherapy, with an anti-VEGF therapy, and if KRAS wild type, with an anti-EGFR therapy. The phase III CORRECT trial that resulted in approval of the drug demonstrated a median OS of 6.4 months in the regorafenib group versus 5.0 months in the placebo group (HR, 0.77; 95% CI, 0.64 to 0.94; one-sided *p* = 0.0052).¹²⁷ Regorafenib is the first TKI with survival benefits in mCRC that has progressed after all standard therapies. In February 2013, it received another indication for the treatment of patients with locally advanced, unresectable, or metastatic GIST who have been previously treated with imatinib and sunitinib. This was based on positive findings of the phase III GRID trial that demonstrated a median PFS of 4.8 months for regorafenib and 0.9 months for placebo (HR, 0.27, 95% CI, 0.19 to 0.39; *p* < 0.0001).¹²⁸ In both studies, regorafenib provided significant improvements in PFS to highly refractory patient populations who have progressed on standard treatments. The most common adverse events that were grade 3 or higher and related to regorafenib were hand-foot skin reaction, fatigue, diarrhea, hypertension, and rash or desquamation. Its clinical development as a single agent or in combination with standard chemotherapeutic agents in various malignant tumors is ongoing and includes a phase III trial in patients with HCC whose disease has progressed after treatment with sorafenib.

mTOR Inhibitors

The mTOR pathway is a central component of the PI3K/Akt signaling pathway and a regulator of many biologic processes that are essential for angiogenesis, cell proliferation, and metabolism.¹²⁹ Inhibition of the mTOR kinase prevents downstream signaling via the Akt pathway, resulting in inhibition of protein translation and cell growth. mTOR plays a key role in angiogenesis and specifically regulates the expression of HIF-1, which is upregulated by the loss of the von Hippel-Lindau gene in RCC. In May 2007, temsirolimus was approved for the treatment of advanced RCC. Efficacy and safety were demonstrated in a phase III study in previously untreated patients (*n* = 626) with poor risk features of metastatic RCC assigned to one of three treatment arms: IFN- α alone, temsirolimus 25 mg alone, or the combination of temsirolimus (15 mg) and IFN- α .¹³⁰ Single-agent temsirolimus was associated with a statistically significant improvement in OS when compared with IFN; the addition of temsirolimus to IFN did not improve OS. The results of the phase III INTORSECT trial compared the efficacy of temsirolimus and sorafenib in the second-line treatment of metastatic RCC after disease progression on sunitinib demonstrated that temsirolimus did not improve survival over sorafenib in the second-line setting.¹³¹ The significant OS difference in favor of sorafenib (stratified HR, 1.31; 95% CI, 1.05 to 1.63; two-sided *p* = 0.01) suggested that VEGFR inhibition may be a better option than mTOR inhibitors for patients progressing on sunitinib. The most common adverse reactions that occurred were rash, asthenia, mucositis, nausea, edema, and anorexia. Rare, but serious adverse reactions associated with temsirolimus included interstitial lung disease, bowel perforation, and acute renal failure.

Everolimus (RAD001) was approved in March 2009 for patients with advanced RCC whose disease had progressed on VEGFR-targeted therapy (sunitinib or sorafenib). Efficacy was demonstrated in a phase 3 trial that study met its primary endpoint with a median PFS of 4.9 and 1.9 months in the everolimus and placebo arms, respectively (HR, 0.33; *p* < 0.0001).¹³² Everolimus is also indicated for

subependymal giant cell astrocytoma (SEGA) associated with tuberous sclerosis complex (TSC), renal angiomyolipoma with TSC, progressive neuroendocrine tumors of pancreatic origin, and advanced hormone receptor-positive, HER2-negative breast cancer in combination with exemestane.¹³³ The most common adverse reactions were stomatitis, infections, asthenia, fatigue, cough, and diarrhea. The most common grade 3/4 adverse reactions were infections, dyspnea, fatigue, stomatitis, dehydration, pneumonitis, abdominal pain, and asthenia. Both temsirolimus and everolimus are currently being evaluated in phase I through III studies of various cancer types. By downregulating HIF-1 in the tumor cell, mTOR inhibitors may complement the effects of TKIs at the level of the EC; thus, the combination of mTOR inhibitors with other targeted agents such as bevacizumab or sorafenib/sunitinib are also being investigated.

On the Horizon: Anti-VEGFR2 Monoclonal Antibody

Ramucirumab (IMC-1121B) is a fully human IgG1 monoclonal antibody that binds with high affinity to the extracellular VEGF-binding domain of VEGFR-2. In a phase III trial (REGARD), ramucirumab monotherapy conferred a statistically significant benefit in OS and PFS compared to placebo in patients with advanced gastric or gastroesophageal junction adenocarcinoma in the second-line setting with an acceptable safety profile.¹³⁴ The survival advantage is the first to be elicited by a single-agent biologic treatment in this setting and, based on these findings, the FDA has assigned a priority review designation for ramucirumab. An ongoing phase III trial (RAINBOW) of ramucirumab in combination with chemotherapy as second-line treatment for patients with advanced gastric cancer is currently underway, and preliminary results demonstrated the trial met both its primary (OS) and secondary (PFS) endpoints. In April 2014, the U.S. FDA approved ramucirumab for use as a single agent for the treatment of patients with advanced or metastatic, gastric or gastroesophageal junction adenocarcinoma with disease progression on or after prior treatment with fluoropyrimidine- or platinum-containing chemotherapy. The recommended ramucirumab dose and schedule is 8 mg/kg administered as a 60-minute intravenous infusion every 2 weeks. The drug also marginally improved survival in the second-line treatment of NSCLC in an ongoing phase III (REVEL) trial.

COMBINATION THERAPIES

Tumor angiogenesis is a highly complex process involving multiple growth factors and their receptor signaling pathways. Based on current evidence, with a few exceptions, effective therapy will probably rely on a combinatorial approach that involves targeting multiple pathways simultaneously. However, a recent study has demonstrated that simultaneous inhibition of the VEGF and EGF pathways in combination with chemotherapy shortens rather than prolongs PFS as compared to inhibition of the VEGF pathway alone in combination with chemotherapy.¹³⁵ Whether other targeted agents exhibit beneficial effects when combined with VEGF inhibitors remains to be investigated. Moreover, a number of studies have shown that antiangiogenic agents in combination with chemotherapy or radiotherapy result in additive or synergistic effects. Several models have been proposed to explain the mechanism responsible for this potentiation, keying in on the chemosensitizing effects of antiangiogenic therapy.¹³⁶ One hypothesis is that antiangiogenic therapy may normalize the tumor vasculature, thus resulting in improved oxygenation, better blood perfusion, and consequently, improved delivery of chemotherapeutic drugs.¹³⁷ A second model suggests that chemotherapy delivered at low doses and at close, regular intervals with no extended drug-free break periods preferentially damages ECs in the tumor neovasculature,^{138,139} and suppresses circulating endothelial progenitor cells.^{140,141} This regimen, also called metronomic

chemotherapy, sustains antiangiogenic activity and reduces acute toxicity.¹⁴² Thus, the efficacy of metronomic chemotherapy may increase when administered in combination with specific antiangiogenic drugs. Another model addresses the use of antiangiogenic drugs to slow down tumor cell repopulation between successive cycles of cytotoxic chemotherapy.¹⁴³ This model underscores the importance of timing and sequence in achieving the maximal therapeutic benefit from combination therapies. In fact, a preclinical study in murine tumor models demonstrated that the administration of sunitinib markedly reduced chemotherapy-induced bone marrow toxicity, suggesting that the sequential treatment regimen (delivery of antiangiogenics followed by chemotherapy) showed superior survival benefits compared with the simultaneous administration of two drugs.¹⁴⁴ Finally, other mechanisms that might also contribute to the synergism include angiogenesis inhibitor–induced tumor blood vessel regression, the prevention of tumor coopting of vessels from surrounding healthy tissues, and the formation of abnormal vessels in the tumor microenvironment.¹⁴⁵ Nevertheless, it remains a challenge to determine why bevacizumab has proved largely ineffective as a single agent, whereas VEGF RTK inhibitors have repeatedly failed in randomized phase III trials when used in combination with chemotherapy. Furthermore, an additional challenge is to determine the optimal dose and duration of antiangiogenic drugs as well as the impact of drug sequencing in combination regimens. Studies are warranted to delineate the discrepancy of bevacizumab's efficacy in the macrometastatic versus micrometastatic disease settings.^{146,147}

BIOMARKERS OF ANTIANGIOGENIC THERAPY

Antiangiogenic therapy has created a need to develop effective biomarkers to assess the activity of these inhibitors. Biomarkers of tumor angiogenesis activity are important to guide clinical development of these agents and to select patients most likely to benefit from this approach. Although there are currently no validated biomarkers for clinically assessing the efficacy of or selecting patients who will respond to antiangiogenic therapies, a number of candidate markers, including tissue, imaging, and circulating biomarkers, are emerging that need to be prospectively validated.^{148,149} Several avenues are currently being investigated and include tumor biopsy analysis, microvessel density, noninvasive vascular imaging modalities (positron-emission tomography, dynamic contrast-enhanced magnetic resonance imaging), and measuring circulating biomarkers (levels of angiogenic factors in serum, plasma, urine, or circulating ECs and their precursors).^{150–152} Recent research efforts have focused on identifying genetic and toxicity biomarkers to predict which patients will benefit from anti-VEGF/VEGFR therapy and identify patients at risk of adverse events. The existence of VEGF single-nucleotide polymorphisms (SNP) and their association with clinical outcomes may be predictive of patient response to bevacizumab. A recent study identified a locus in VEGFR1 that correlated with increased VEGFR1 expression and poor bevacizumab treatment outcomes.¹⁵³ Moreover, a breast cancer study (E2100) reported the VEGF-2578 AA and VEGF-1154 AA genotypes predicted an improved median OS, whereas the VEGF-634 CC and VEGF-1498 TT genotypes predicted protection from grade 3/4 hypertension in the combination-treatment arm.¹⁵⁴ The degree of hypertension can serve as a predictive biomarker of survival in patients after bevacizumab or TKI treatment. Although an association between hypertension and anti-VEGF therapy has been described, the clinical implications of this association and the predictive value of hypertension remains to be validated prospectively. A retrospective analysis of hypertension and efficacy outcomes was conducted in seven large phase III trials (n = 6,486 patients) and, in six of seven studies, early treatment-related blood pressure increase was neither predictive of clinical benefit from bevacizumab nor prognostic for the course of the disease.¹⁵⁵ However, one study (AVF2107g) showed early increased blood pressure

was associated with longer PFS and OS. Because genetics play a significant role in modifying the risk of hypertension,¹⁵⁶ it remains to be determined whether polymorphisms in the VEGF/VEGFR pathway may function as potential biomarkers to predict the association between treatment-related hypertension and response to anti-VEGF therapy, as previously implicated in the E2100 trial.¹⁵⁴ Other biomarkers of response include elevated VEGF and placental growth factor levels,^{148,152} whereas biomarkers of resistance, including circulating basic fibroblast growth factor, stromal cell-derived factor 1 α , and viable circulating endothelial cells, increased when tumors escaped treatment.¹⁵⁷ A first prospective biomarker study (MERiDiAN) in metastatic breast cancer is currently underway to evaluate the impact of bevacizumab in patients stratified for plasma short VEGF-A isoforms. If validated, these findings could help identify which subgroup of patients should receive antiangiogenic therapy and could lead the way to possible future tailoring of individualized antiangiogenic therapy.

RESISTANCE TO ANTIANGIOGENIC THERAPY

Despite a decade of trials with angiogenesis inhibitors, clinical experience reveals that VEGF-targeted therapy often prolongs the survival of cancer patients by only months because tumors elicit evasive resistance.^{145,158} Resistance to VEGF inhibitors may be observed in late-stage tumors when tumors regrow during treatment after an initial period of growth suppression from these antiangiogenic agents. This resistance involves the reactivation of tumor angiogenesis and increased expression of other proangiogenic factors. As the disease progresses, it is possible that redundant pathways might be implicated, with VEGF being replaced by other angiogenic pathways, warranting the addition of a second angiogenesis inhibitor that would target these secondary growth factors and/or their activated receptor pathways, or the use of a multitargeted TKI antiangiogenic drug (e.g., sunitinib, sorafenib).

However, resistance to these drugs eventually occurs, implicating the existence of additional pathways mediating resistance to antiangiogenic therapies. Moreover, tumor cells bearing genetic alterations of the *p53* gene may display a lower apoptosis rate under hypoxic conditions, which might reduce their reliance on vascular supply and, therefore, their responsiveness to antiangiogenic therapy.¹⁵⁹ The selection and overgrowth of tumor-variant cells that are hypoxia resistant and, thus, less dependent¹⁵⁹ on angiogenesis and vasculature remodeling, resulting in vessel stabilization,¹⁶⁰ could also explain the resistance to antiangiogenic drugs. Other possible mechanisms for acquired resistance include tumor vessels becoming less sensitive to antiangiogenic agents, tumor regrowth via rebound revascularization, and vessel cooption.^{161–166} Perhaps one of the most intriguing findings is that, although ECs are assumed to be genetically stable, they may under some circumstances harbor genetic abnormalities and thus acquire resistance as well.^{167,168}

Recent studies report that VEGF-targeted therapies not only induce primary tumor shrinkage and inhibit tumor progression, but can also initiate mechanisms that increase malignancy to promote tumor invasiveness and metastasis.^{122,123,169} These mechanisms of resistance to antiangiogenic therapy involve tumor- and host-mediated pathways and may allow for differential efficacy in different stages of disease progression.¹⁶³ Specifically, antiangiogenic drug-resistance mechanisms involve pathways mediated by the tumor, whether intrinsic or acquired in response to therapy or by the host, which is either responding directly to therapy or indirectly to tumoral cues. Taken together, antiangiogenic therapy can enhance tumor invasiveness and metastasis to facilitate and/or accelerate disease in microscopic tumors and, hence, reduce OS benefit. Understanding the mechanisms of resistance, whether intrinsic or acquired, after exposure to antiangiogenic drug treatment is essential for developing strategies that will allow for optimal exploitation of VEGF inhibitors. It is equally important to identify biomarkers of drug resistance and factors mediating this resistance because the development of reliable biomarkers can be invaluable to monitor the development of evasive resistance to angiogenesis inhibitors.

29 Monoclonal Antibodies

Hossein Borghaei, Matthew K. Robinson, Gregory P. Adams,
and Louis M. Weiner

INTRODUCTION

Antibody-based therapeutics are important components of the cancer therapeutic armamentarium. Early antibody therapy studies attempted to explicitly target cancers based on the structural and biologic properties that distinguish neoplastic cells from their normal counterparts. The immunogenicity and inefficient effector functions of the first-generation murine monoclonal antibodies (MAb) that were evaluated in clinical trials limited their effectiveness.¹⁻³ Patients developed human antimouse antibody (HAMA) responses against the therapeutic agents that rapidly cleared it from the body and limited the number of times the therapy could be administered. The development of engineered chimeric, humanized, and fully human MAbs has identified a number of important and useful applications for antibody-based cancer therapy. Currently, the U.S. Food and Drug Administration (FDA) has approved 14 MAbs and MAb-conjugates for the treatment of cancer (Table 29.1) and many more are under evaluation in late-stage clinical trials.⁴ Antibodies provide an important means by which to exploit the immune system by specifically recognizing and directing antitumor responses.

Antibodies are produced by B cells and arise in response to exposures to a variety of structures, termed antigens, as a result of a series of recombinations of V, D, and J germline genes. Immunoglobulin-G (IgG) molecules are most commonly employed as the working backbones of current therapeutic monoclonal antibodies, although various other isotypes of antibodies have specialized functions (e.g., IgA molecules play important roles in mucosal immunity, IgE molecules are involved in anaphylaxis). The advent of hybridoma technology by Kohler and Milstein⁵ made it possible to produce large quantities of antibodies with high purity and monospecificity for a single binding region (epitope) on an antigen.

The mechanisms that antibody-based therapeutics employ to elicit antitumor effects include focusing components of the patient's immune system to attack tumor cells^{6,7} and methods to alter signal transduction pathways that drive tumor progression.^{8,9} Antibody-based conjugates employ the targeting specificity of antibodies to deliver toxic compounds, such as chemotherapeutics, specifically to the tumor sites.

IMMUNOGLOBULIN STRUCTURE

Structural and Functional Domains

An IgG molecule is typically divided into three domains consisting of two identical antigen-binding (Fab) domains connected to an effector or Fc domain by a flexible hinge sequence. Figure 29.1 shows the structure of an IgG molecule. IgG antibodies are comprised of two identical light chains and two identical heavy chains, with the chains joined by disulfide bonds, resulting in a bilaterally symmetrical complex. The Fab domains mediate the binding of

IgG molecules to their cognate antigens and are composed of an intact light chain and half of a heavy chain. Each chain in the Fab domain is further divided into variable and constant regions, with the variable region containing hypervariable, or complementarity determining regions (CDR) in which the antigen-contact residues reside. The light and heavy chain variable regions each contain three CDRs (CDR1, CDR2, and CDR3). All six CDRs form the antigen-binding pocket and are collectively defined in immunologic terms as the idiotype of the antibody. In the majority of cases, the variable heavy chain CDR3 plays a dominant role in binding.¹⁰

The different isotypes of immunoglobulins are defined by the structure and function of their Fc domains. The Fc domain, composed of the CH2 and CH3 regions of the antibody's heavy chains, is the critical determinant of how an antibody mediates effector functions, transports across cellular barriers, and persists in circulation.^{7,11}

MODIFIED ANTIBODY-BASED MOLECULES

Advances in antibody engineering and molecular biology have facilitated the development of many novel antibody-based structures with unique physical and pharmacokinetic properties (see Fig. 29.1). These include chimeric human-murine antibodies with human-constant regions and murine-variable regions,¹² humanized antibodies in which murine CDR sequences have been grafted into human IgG molecules, and entirely human antibodies derived from human hybridomas and, more recently, from transgenic mice expressing human immunoglobulin genes.¹³ An accepted naming scheme based on "stems" was developed by the World Health Organization's International Nonproprietary Names (INN) for pharmaceuticals and is employed in the United States (Table 29.2). Engineering has also facilitated the development of antibody-based fragments. In addition to the classic, enzymatically derived Fab and F(ab')₂ molecules, a plethora of promising IgG-derivatives have been developed that retain antigen-binding properties of intact antibodies (see Fig. 29.1; for review see Robinson et al.¹⁴). The basic building block for these molecules is the 25 kDa, monovalent single-chain Fv (scFv) that is comprised of the variable domains (V_H and V_L) of an antibody fused together with a short peptide linker. Novel, bispecific antibody-based structures can facilitate binding to two tumor antigens or bridge tumor cells with immune effector cells to focus antibody-dependent cell-mediated cytotoxicity (ADCC) or killing by T cells. An example of the former is MM-111, a bispecific gene-fused molecule composed of an anti-HER2 scFv connected to an anti-HER3 scFv via a modified form of human serum albumin.¹⁵ Examples of the latter mechanism include small scFv-based bispecific T-cell engagers (BiTE) such as the anti-CD3/anti-CD19 molecule blinatumomab¹⁶ and larger MAb-based antibodies such as catumaxomab, a rat/mouse anti-CD3/EpCAM bispecific MAb produced via quadroma technology.¹⁷ Both classes of bispecifics endow selectivity and targeting properties that are not obtainable with natural antibody formats.

TABLE 29.1

FDA Approved Antibodies for the Treatment of Cancer

Generic Name (Trade Name)	Origin	Isotype (Conjugate)	Indication	Target	Initial Approval
Unconjugated MAbs					
Rituximab (Rituxan)	Chimeric	IgG1	NHL	CD20	1997
Trastuzumab (Herceptin)	Humanized	IgG1	BrCa	HER2	1998
Alemtuzumab (Campath-1H)	Humanized	IgG1	CLL	CD52	2001
Cetuximab (Erbix)	Chimeric	IgG1	CRC, SCCHN	EGFR	2004
Bevacizumab (Avastin)	Humanized	IgG1	CRC, NSCLC, RCC, GBM	VEGF	2004
Panitumumab (Vectibix)	Human (XenoMouse)	IgG2	CRC	EGFR	2006
Ofatumumab (Arzerra)	Human (XenoMouse)	IgG1	CLL	CD20	2009
Denosumab (Prolia/Xgeva)	Human	IgG2	Metastasis-related SREs, ADT/AI-associated osteoporosis, GCT	RANKL	2010
Pertuzumab (Perjeta)	Humanized	IgG1	BrCa	HER2	2012
Immunoconjugates					
Gemtuzumab ozogamicin (Mylotarg)	Humanized	IgG4 (calicheamicin)	AML	CD33	2000 ^a
Ibritumomab tiuxetan (Zevalin)	Murine	IgG1 (⁹⁰ Y)	NHL	CD20	2002
Tositumomab (Bexxar)	Murine	IgG2A (¹³¹ I)	NHL	CD20	2003
Brentuximab vedotin (Adcetris)	Chimeric	IgG1 (MMAE)	HL, sALCL	CD30	2011
Ado-trastuzumab emtansine (Kadcyla)	Humanized	IgG1 (DM1)	BrCa	HER2	2013

^aWithdrawn from the US market in June 2010.

NHL, non-Hodgkin lymphoma; BrCa, breast cancer; CLL, chronic lymphocytic leukemia; CRC, colorectal cancer; SCCHN, squamous cell carcinoma of head and neck; EGFR, epidermal growth factor receptor; NSCLC, non-small-cell lung cancer; RCC, renal cell carcinoma; GBM, glioblastoma multiforme; VEGF, vascular endothelial growth factor; SREs, skeletal-related events; ADT, androgen deprivation therapy; AI, aromatase inhibitor; GCT, giant cell tumor; RANKL, RANK ligand; AML, acute myelogenous leukemia; ⁹⁰Y, yttrium-90; ¹³¹I, iodine-131; MMAE, Monomethyl auristatin E; HL, Hodgkin lymphoma; sALCL, systemic anaplastic large-cell lymphoma.

TABLE 29.2

Rules for Naming MAb for the Treatment of Cancer

The International Nonproprietary Names (INN) for monoclonal antibodies (MAbs) are composed of “stems” that indicate their origin, specificity, and modifications. The names include a random prefix to provide distinction from other names, a substem indicating the target specificity (*-t[u]-* for tumor), a substem indicating the species of origin (see the following) and a suffix (*-mab*), which indicates the presence of an immunoglobulin variable domain.

Substem Indication of the Species on Which the Immunoglobulin Sequence Is Based

-o-	mouse
-xi-	chimeric
-zu-	humanized
-xizu-	chimeric/humanized
-u-	human

FACTORS REGULATING ANTIBODY-BASED TUMOR TARGETING

Antibody Size

Nonuniform distribution of systemically administered antibody is generally observed in biopsied specimens of solid tumors. Heterogeneous tumor blood supply limits uniform antibody delivery to tumors, and elevated interstitial pressures in the center of tumors oppose inward diffusion.¹⁸ This high interstitial pressure slows the diffusion of molecules from their vascular extravasation site in a size-dependent manner.^{19,20} The relatively large transport distances in the tumor interstitium also substantially increase the time required for large IgG macromolecules to reach target cells.²¹

Tumor Antigens

Access to the target antigen is undoubtedly a critical determinant of therapeutic effect of antibody-based applications. Such access is regulated by the heterogeneity of antigen expression by tumor cells. Shed antigen in the serum, tumor microenvironment, or both may saturate the antibody's binding sites and prevent binding to the cell surface. Alternatively, a rapid internalization of an antibody/antigen complex, although critical for antibody–drug conjugates (ADC), may deplete the quantity of cell surface MAb capable of initiating ADCC or cytotoxic signal transduction events. Finally, target antigens are normally *tumor associated* rather than *tumor specific*. Tumor-specific antigens are both highly desirable and rare. Typically, such antigens arise as a result of unique tumor-based genetic recombinations, such as clonal immunoglobulin idiotypes expressed on the surface of B-cell lymphomas.²²

Antibody affinity for its target antigen has complex effects on tumor targeting. The *binding-site barrier* hypothesis postulates that antibodies with extremely high affinity for target antigen would bind irreversibly to the first antigen encountered upon entering the tumor, which would limit the diffusion of the antibody into the tumor and accumulate instead in regions surrounding the tumor vasculature.^{23,24} Similarly, in tumor spheroids, the in vitro penetration of engineered antibodies is primarily limited by internalization and degradation.²⁵ The valence of an antibody molecule can increase the functional affinity of the antibody through an avidity effect.^{26–28}

Half-Life/Clearance Rate

The concentration of intact IgG in mammalian serum is maintained at constant levels with half-lives of IgGs measured in days. This homeostasis is regulated in part by the major histocompatibility complex (MHC)-class I-related Fc receptor, FcRn (n = neonatal), a saturable, pH-dependent salvage mechanism that regulates quality and quantity of IgG in serum. This mechanism can be exploited via mutations in the Fc portion of an IgG to modulate IgGs pharmacokinetics.^{29,30} Indeed, multiple strategies have been developed to increase the serum persistence of antibody-based fragments and other classes of protein therapeutics.^{14,31}

Glycosylation

IgGs undergo N-linked glycosylation at the conserved Asn residue at position 297 within the C_H2 domain of the constant region. Glycosylation status of the residue has long been known to impact the ability of IgGs to bind effector ligands such as Fc γ R and C1q, which, in turn, affects their ability to participate in Fc-mediated functions such as ADCC and complement-dependent cytotoxicity (CDC).^{32–34} The glycosylation of MAbs can be altered to increase ADCC by producing them in a cell line engineered to express β (1,4)-N-acetylglucosaminyltransferase III (GnTIII), the enzyme

required to add the bisecting GlcNAc residues.³³ Defucosylation of antibody Fc domains is also associated with enhanced ADCC, and in a recently completed multicenter phase II trial of a defucosylated anti-CC chemokine receptor 4 (CCR4), MAb was associated with meaningful antitumor activity, including complete responses and enhanced progression-free survival (PFS).³⁵

UNCONJUGATED ANTIBODIES

The majority of monoclonal antibodies approved for clinical use display intrinsic antitumor effects that are mediated by one or more of the following mechanisms.

Cell-Mediated Cytotoxicity

As components of the immune system, effector cells such as natural killer (NK) cells and monocytes/macrophages represent natural lines of defense against oncologically transformed cells. These effector cells express Fc γ receptors (Fc γ R) on their cell surfaces, which interact with the Fc domain of IgG molecules. This family is comprised of three classes (type I, II, and III) that are further divided into subclasses (IIa/IIb and IIIa/IIIb).³⁶ Recognition of transformed cells by immune effector cells leads to cell-mediated killing through processes such as ADCC and phagocytosis, as shown in Figure 29.2, and can be mediated by Fc γ RI (CD64), a high affinity receptor capable of binding to monomeric IgG, or Fc γ RII (CD32) and Fc γ RIII (CD16), which are low affinity receptors that preferentially bind multimeric complexes of IgG. Signaling through type I, IIa, and IIIa receptors results in the activation of effector cells due to associated immunoreceptor tyrosine-based activation motifs (ITAM), whereas the engagement of type IIb receptors inhibits cell activation through associated immunoreceptor tyrosine-based inhibitory motifs (ITIM).³⁶ Clinical results support the idea that ADCC can play a role in the efficacy of antibody-based therapies. Naturally occurring polymorphisms in Fc γ Rs alter their affinity for human IgG1 and have been linked to clinical response.^{37,38} A polymorphism in the FCGR3A gene results in either a valine or phenylalanine at position 158 of Fc γ RIIIa. Human IgG1 binds more strongly to Fc γ RIIIa-158V than Fc γ RIIIa-158F, and likewise to NK cells from individuals that are either homozygous for 158F or heterozygous for this polymorphism.³⁹ The Fc γ RIIIa-158v was a predictor of early response and was associated with improved PFS.

Figure 29.2 Antibody-dependent cellular cytotoxicity. The antibody engages the tumor antigen and the Fc domain binds to cellular Fc receptors to bridge effector and target cells. This bridging induces effector cell activation, resulting in natural killer cell cytotoxicity or phagocytosis by neutrophils, monocytes, or macrophages.

A second polymorphism, FcγRIIIa-131H/R, did not predict early response but was an independent predictor of time to progression (TTP).³⁸ Taken together, these data suggest that modulating the affinity of MABs for FcγRIIIa, FcγRIIIa, or both may increase the efficacy of therapeutic MABs.

Each class of FcγR exhibits a characteristic specificity for IgG subclasses.⁴⁰ Many groups have focused on modifying the Fc domain of IgGs to optimize the engagement of subclasses of FcγR and the induction of ADCC, based on the findings of Shields et al.,²⁹ who performed a series of mutagenesis experiments to map the residues required for IgG1-FcγR interaction. Antibodies such as ocrelizumab, a humanized version of rituximab, have increased binding to low affinity FcγRIIIa variants and are now in clinical trials.

An alternative to modifying the Fc region of MABs is to create bispecific antibodies (bsAbs) that recognize both a tumor-associated antigen and a *trigger antigen* present on the surface of an immune effector cell.⁴³ Simultaneous engagement of both antigens can redirect the cytotoxic potential of the effector cell against the tumor.^{41–43} Such antibodies are capable of eliciting effector function against tumor cell lines *in vitro* and in animal models. Two HER-2 directed bispecific antibodies, 2B1 and MDX-H210, have been tested in phase I clinical trials.^{44,45}

Bispecific antibodies have a number of distinctive properties, including flexible choices of cytotoxic trigger molecules,⁴⁶ recruitment of effector function in the presence of excess IgG,⁴² and custom tailoring of the affinity of the bsAb to match effector cell characteristics. These advantages have been facilitated by improved methods of bsAb production.⁴⁷ BiTE antibodies represent a novel class of bispecific, single-chain Fv antibodies.⁴⁸ Promising results have been seen in early phase clinical trials with at least two BiTE antibodies, one of which, blinatumomab, targets CD19/CD3.⁴⁹ Promising phase I results have also been reported in an interim analysis of an anti-EpCAM/anti-CD3 MT110 BiTE in the setting of advanced lung and gastrointestinal tumors.⁵⁰

Complement-Dependent Cytotoxicity

In addition to cell-mediated killing (see previous), MABs can recruit the complement cascade to kill cells via CDC. Although IgM is the most effective isotype for complement activation, it is not widely used in clinical oncology. Similar to ADCC, the human IgG subclass used to construct a therapeutic MAB dictates its ability to elicit CDC; IgG1 is extremely efficient at fixing complement, in contrast to IgG2 and IgG4.⁵¹ Antibodies activate complement through the classical pathway, by engaging multiple C1q to trigger activation of a cascade of serum proteases, which kill the antibody-bound cells.^{52,53} The anti-CD20 MAB rituximab has been found to depend in part on CDC for its *in vivo* efficacy.⁵⁴ Antibody engineering approaches have identified residues in the C_H2 domain of the Fc region that either suppress or enhance the ability of rituximab to bind C1q and activate CDC.⁵⁵ The ability to manipulate complement fixation through engineering approaches warrants *in vivo* testing to determine the impact of these changes on the efficacy and toxicity of MABs.

ALTERING SIGNAL TRANSDUCTION

Growth factor receptors represent a well-established class of targets for therapeutic intervention. Normal signaling through these receptors often leads to mitogenic and prosurvival responses. Unregulated signaling, as seen in a number of common cancers due to receptor overexpression, promotes tumor cell growth and insensitivity to chemotherapeutic agents. Clinically relevant MABs can modulate signaling through their target receptors to normalize cell growth rates and sensitize tumor cells to cytotoxic agents. The binding of cetuximab or panitumumab to the epidermal growth factor receptor (EGFR) physically blocks ligand binding⁵⁶ and

prevents the receptor from assuming the extended conformation required for dimerization.⁵⁷ Pertuzumab binds to the dimerization domain of HER-2, thereby sterically inhibiting subsequent receptor heterodimerization with other ligand-bound family members.⁵⁸ Alternatively, signaling through growth factor receptors can be indirectly modified by MABs that bind to activating ligands, as is seen with the anti-vascular endothelial growth factor (VEGF) MAB, bevacizumab.⁵⁹

IMMUNOCONJUGATES

MABs that are not capable of directly eliciting antitumor effects, either by altering signal transduction or directing immune system cells, can still be effective against tumors by delivering cytotoxic payloads. MABs have been employed to deliver a wide variety of agents, including chemotherapy, toxins, radioisotopes, and cytokines (for review see Adams and Weiner⁶⁰). In theory, the appropriate combination of toxic agents and MABs could lead to a synergistic effect. For example, delivery of a therapeutic radioisotope by a MAB would be significantly enhanced if, by binding to its target antigen, the MAB also activated a signaling event that increased the target cell's sensitivity to ionizing radiation.

Catalytic toxins derived from plants catalytic toxins derived from plants (e.g., ricin) and microorganisms (e.g., *Pseudomonas*) represent two classes of cytotoxic agent that have been investigated for their utility in immunoconjugate strategies.⁶¹ Although there are promising preclinical studies,⁶² few successful clinical trials have been reported using this approach. In a phase I clinical trial in hairy cell leukemia patients who were resistant to cladribine, 11 of 16 patients exhibited complete remissions with minimal side effects with an anti-CD22 immunotoxin with a truncated form of *Pseudomonas exotoxin*.⁶³ Clinical trials with other immunotoxins have been associated with unacceptable neurotoxicity⁶⁴ and life-threatening vascular leak syndrome.⁶⁵

Immunocytokine fusions have also been investigated as an approach to direct the patient's immune response to his or her own tumor.⁶⁶ A number of cytokines have been incorporated into antibody-based constructs, including interleukin-2 (IL-2),^{67,68} interferon γ (IFN- γ),⁶⁹ tumor necrosis factor α (TNF- α),⁶⁹ VEGF,⁷⁰ and IL-12.⁷¹

Antibody–Drug Conjugates

The first ADC, gemtuzumab ozogamicin (Mylotarg), was approved by the FDA in 2000 for the treatment of patients with relapsed CD33-positive acute myeloid leukemia, but was voluntarily withdrawn from the US market by its manufacturer in 2010 after a confirmatory phase III trial (SWOG S0106) recommended, based on results of a planned interim analysis, that Mylotarg randomizations be terminated due to a lack of efficacy in the presence of enhanced toxicity.⁷² Although two additional randomized trials^{73,74} suggested that some patient populations may benefit from Mylotarg therapy, the drug remains off the market in the United States.

The majority of ADCs under development employ potent cytotoxic agents that block the polymerization of tubulin (e.g., auristatins or maytansines) or damage DNA (e.g., calicheamicins or pyrrolobenzodiazepines) by employing a variety of linkers and conjugation strategies.⁷⁵

A variety of ADCs specific for a wide range of oncology targets are currently in clinical evaluation, with the majority of the more advanced agents being tested in the setting of diffuse malignancies.⁷⁶ The majority of these employ auristatins or maytansines as their payloads. Early observations suggest that cumulative, dose-related peripheral sensory neuropathy can result when auristatins are conjugated to an antibody via a cleavable linker, and dose-limiting thrombocytopenia can result when auristatins and maytansinoids are conjugated to the antibody via an uncleavable linker.^{76,77}

Two ADCs are now approved for use in clinical practice. Ado-trastuzumab emtansine (T-DM1, Kadcyla), an ADC composed of the anti-HER2 MAb trastuzumab linked to DM1,⁷⁸ is now approved for the treatment of patients with refractory HER2/neu expressing breast cancers. The other, brentuximab vedotin (SGN-35, Adcetris), is an ADC consisting of the anti-CD30 chimeric MAb cAC10 that is linked to three to five molecules of the microtubule-disrupting agent Monomethyl auristatin E. At this point, this drug is approved for use in patients with recurrent systemic anaplastic large cell lymphoma. The clinical data associated with both of these ADCs will be discussed in subsequent sections of this chapter.

Antibodies also can be used to target liposome-encapsulated drugs⁷⁹ and other cytotoxic agents, such as antisense RNA⁸⁰ or radionuclides to tumors.

Radioimmunoconjugates

Two anti-CD20 radioimmunoconjugates have been FDA approved for radioimmunotherapy (RIT) of non-Hodgkin lymphoma (NHL). Ibritumomab (Zevalin) and tositumomab (Bexxar) are murine MABs labeled with yttrium-90 (⁹⁰Y) and iodine-131 (¹³¹I), respectively. Both are associated with impressive clinical efficacy.^{81,82} Although these radioimmunoconjugates are effective therapeutics, cumbersome logistics surrounding their administration have significantly limited their use. Despite significant preclinical evidence supporting the use of RIT for solid malignancies, clinical results have not demonstrated consistent antitumor activity.⁶⁰

ANTIBODIES APPROVED FOR USE IN SOLID TUMORS

Trastuzumab

Trastuzumab (Herceptin) is a humanized IgG1⁸³ that targets domain IV of the HER2/ErbB2 member of the EGFR/ErbB family of receptor tyrosine kinases. Gene amplification as judged by fluorescence in situ hybridization (FISH) with concomitant overexpression of HER2 protein measured by immunohistochemistry (IHC) is seen in approximately 25% of breast cancers.^{84,85} HER2 amplification and overexpression is now recognized to also be a critical driver in a subset (7% to 34%) of gastric cancers.⁸⁶ Trastuzumab inhibits tumor cell growth by binding to HER2 and blocking the unregulated HER2 signaling that is associated with its high level overexpression.

Trastuzumab became the first FDA-approved monoclonal antibody for the treatment of solid tumors based on a series of studies carried out in the setting of HER2-positive metastatic breast cancer.^{87,88} A subsequent phase III trial investigating trastuzumab in combination with cytotoxic chemotherapy demonstrated an improved response rate compared to chemotherapy alone, from 25.0% to 57.3% with a taxane regimen.⁸⁹

Trastuzumab is also approved for use in the adjuvant setting based on an approximately 50% reduction in recurrence after 1 year in multiple phase III trials.^{90–92} Myocardial dysfunction, seen with anthracycline therapy, was observed with increased frequency in patients receiving antibody alone⁹³ or with doxorubicin or epirubicin.

Recognition of HER2 as a driver in a subset of gastric cancers led to an open-label, randomized, phase III trial (ToGA) that investigated the addition of trastuzumab to standard of care chemotherapy⁹⁴ and showed increased median overall survival with higher levels of HER2 expression. A study by Gomez-Martin et al.⁹⁵ in 99 patients with metastatic gastric cancer being treated with first-line trastuzumab plus chemotherapy identified a mean HER2/CEP17 ratio of 4.7 to be an optimal cut-off to discriminate between trastuzumab-sensitive and refractory patients.

Pertuzumab

Pertuzumab (Perjeta) is a humanized IgG1 MAB that binds to domain II of HER2 and blocks ligand-dependent dimerization of HER2 with other members of the EGFR family.⁹⁶ Pertuzumab, in combination with trastuzumab and docetaxel, is approved for use as first-line therapy in HER2-positive metastatic breast cancer patients. Use of the combination is also approved for the treatment of HER2-positive, locally advanced, inflammatory, or high-risk early breast cancer (>2 cm node negative or node positive) in the neoadjuvant setting.

FDA-approval of pertuzumab was based on results of a phase III trial (CLEOPATRA) of 808 patients with locally recurrent, unresectable, or metastatic breast cancer randomized to receive trastuzumab plus docetaxel with or without the addition of pertuzumab. Inclusion of pertuzumab increased the independently assessed PFS by 6.1 months from 12.4 to 18.5 (hazard ratio [HR], 0.62 [95% confidence interval [CI], 0.51, 0.75], $p < 0.0001$), with a trend toward improved overall survival⁹⁷ that reached statistical significance ($p = 0.0008$) after an additional year of follow-up.⁹⁸ The addition of pertuzumab did increase rates of grade 3 adverse events (AE), but it did not adversely affect cardiac function. Accelerated approval was granted for use of pertuzumab in combination with trastuzumab and docetaxel for the neoadjuvant treatment of high-risk early-stage breast cancer. This approval was based on results from a four-arm, open-label phase II study of 417 patients randomized to receive trastuzumab plus docetaxel, pertuzumab plus docetaxel, pertuzumab plus trastuzumab, or the triple combination. The triple combination improved the pathologic complete response (pCR) rate by 17.8% over the trastuzumab plus docetaxel arm (39.3% versus 21.5%) in the pertuzumab arm.⁹⁹ Follow-up studies to confirm a correlation between pCR and long-term clinical benefit are ongoing.

Cetuximab

Cetuximab (Erbix) targets the EGFR. This chimeric IgG1 binds to domain III of the EGFR, with roughly a tenfold higher affinity than either EGF or transforming growth factor α (TGF- α) ligands and thereby inhibits ligand-induced activation of this tyrosine kinase receptor. Cetuximab may also function to downregulate EGFR-dependent signaling by stimulating EGFR internalization.¹⁰⁰ Cetuximab is approved for the treatment of colorectal cancer (CRC) and, more recently, for the treatment of squamous cell cancer of the head and neck (SCCHN).

The efficacy and safety of cetuximab against CRC was demonstrated alone and in combination with irinotecan in a phase II, multicenter, randomized, and controlled trial of 329 patients.¹⁰¹ The combination of irinotecan plus cetuximab increased both the overall response and the median duration of response as compared to cetuximab alone. Additionally, patients with irinotecan refractory disease responded to treatment with the combination regimen. Recent studies in patients with colorectal cancers have indicated that patients with KRAS mutations in codon 12 or 13 should not receive anti-EGFR therapy.^{101,102}

An international, multicenter, phase III trial comparing definitive radiotherapy to radiotherapy plus cetuximab in SCCHN demonstrated that EGFR blockade with radiotherapy significantly reduced the risk of locoregional failure by 32% and the risk of death by 26%. In advanced stage non-small-cell lung cancer (NSCLC) expressing EGFR, the combination of cetuximab and standard doublet chemotherapy (cisplatin plus vinorelbine) was studied in a prospective randomized phase III trial.¹⁰³ The addition of cetuximab was associated with a slight, but statistically significant, benefit in overall survival over chemotherapy alone (median overall survival 10.1 versus 11.3 months). A similar study using the carboplatin plus paclitaxel backbone in combination with cetuximab did not meet its primary endpoint of improved PFS,

although cetuximab-treated patients exhibited higher objective response rates.¹⁰⁴ Therefore, the benefit of adding cetuximab to standard chemotherapy for patients with advanced NSCLC is unclear.

Panitumumab

Panitumumab (Vectibix) is a fully human IgG2 monoclonal antibody that binds to EGFR. Similar to cetuximab, panitumumab inhibits EGFR activation by blocking the binding of EGF and TGF- α . However, it does so by binding to EGFR with a higher affinity than cetuximab (5×10^{-11} M versus 1×10^{-10} M). As previously mentioned, the IgG2 class of antibodies does not induce activation of the immune system cell via the Fc-receptor mechanism, so panitumumab's primary action appears to be interference with EGFR–ligand interactions.

A phase III trial of 463 patients with metastatic colorectal cancer compared panitumumab plus best supportive care (BSC) to BSC alone.¹⁰⁵ A partial-response rate of 8% and a stable-disease rate of 28% were reported for the panitumumab arm compared with a 10% stable-disease rate in the best supportive care arm of the study. As with cetuximab, patients with metastatic colorectal cancers who have KRAS mutations in codons 12 or 13 are not routinely offered therapy with panitumumab.¹⁰⁶

Bevacizumab

Bevacizumab (Avastin or rhuMab VEGF) is a humanized monoclonal antibody targeting VEGF. VEGF is a critical determinant of tumor angiogenesis, a process that is a necessary component of tumor invasion, growth, and metastasis. VEGF expression by invasive tumors has been shown to correlate with vascularity and cellular proliferation and is prognostic for several human cancers.^{107–109} Interestingly, the inhibition of VEGF signaling via bevacizumab treatment may normalize tumor vasculature, promoting a more effective delivery of chemotherapy agents.¹¹⁰ Bevacizumab is approved for use as a first-line therapy for metastatic colorectal cancer and NSCLC when given in combination with appropriate cytotoxic chemotherapy regimens. Phase III clinical trials leading to the approval of bevacizumab for the treatment of colorectal cancer demonstrated improved response rates from 35% to 45% compared to fluorouracil (5-FU)–based chemotherapy alone. Enhanced response durations and improved patient survival were seen in patients treated with chemotherapy plus bevacizumab as compared to patients receiving chemotherapy alone.¹¹¹ A survival benefit was also seen in the setting of NSCLC. A randomized phase III trial (ECOG 4599) of paclitaxel and carboplatin with or without bevacizumab in patients with advanced nonsquamous NSCLC led to a significant improvement in median survival (12.5 months versus 10.2 months; $p = 0.0075$) for patients in the bevacizumab arm,¹¹² with significantly higher response rates. A higher incidence of bleeding was associated with bevacizumab (4.5% versus 0.7%). Five of 10 treatment-related deaths occurred as a result of hemoptysis, all in the bevacizumab arm.

A phase III trial randomized 722 patients with metastatic breast cancer with no prior chemotherapy for advanced disease to either paclitaxel or paclitaxel and bevacizumab.¹¹³ PFS was significantly better in the paclitaxel plus bevacizumab arm (median, 11.8 versus 5.9 months; HR for progression, 0.60; $p < 0.001$) with an increased response rate (36.9% versus 21.2%, $p < 0.001$). Overall survival, however, was similar.

In contrast,¹¹⁴ in a randomized phase III trial, capecitabine/bevacizumab increased response rates compared with capecitabine alone in 462 anthracycline and taxane pretreated metastatic breast cancer patients but did not meet its primary endpoint of improved PFS. Overall survival and time to deterioration in quality of life were comparable in both treatment groups.

Bevacizumab has not demonstrated activity in the adjuvant colorectal and breast cancer settings.^{115,116} There was no

improvement in overall survival between the two groups and the rate of invasive disease-free survival was also not significantly different between the treatment groups.

Bevacizumab is also approved for the management of recurrent glioblastomas based on results of phase II studies.¹¹⁷

Ado-Trastuzumab Emtansine

Ado-trastuzumab emtansine (T-DM1, Kadcyla) is an ADC composed of the anti-HER2 MAb trastuzumab linked to DM1, a highly potent derivative of maytansine, through a stable thioether linker.⁷⁸

Based on two single-agent phase II trials of T-DM1^{118,119} that demonstrated single-agent activity in the setting of metastatic breast cancer, two separate phase III studies were conducted. The 991 patient EMILIA trial demonstrated that T-DM1 significantly prolongs both PFS and overall survival as compared to a regimen of lapatinib plus capecitabine when used in the setting of metastatic breast cancer that had progressed after treatment with trastuzumab plus a taxane.¹²⁰ Grade 3 and worse AEs were lower in the T-DM1 arm (200, 40.8%) as compared to the lapatinib plus capecitabine arm (278, 57%). Results are still awaited from the ongoing MARIANNE trial that is assessing first-line efficacy and safety of T-DM1 alone and T-DM1 plus pertuzumab versus trastuzumab plus taxane (NCT01120184).

Denosumab

Denosumab (Xgeva) is a fully human IgG2 RANK ligand (RANKL) neutralizing antibody. Denosumab is FDA-approved for use in adults and skeletally mature adolescents who have either surgically unsalvageable giant cell tumors of the bone (GCTB) or where resection is anticipated to result in severe morbidity. Approval was based in part on two open-label, phase II trials examining subcutaneous administration of 120 mg q4 week with additional loading doses on days 8 and 15 of the first cycle.^{121,122} Serious adverse events were seen in 9% of patients ($n = 25$). Of 187 patients, 47 (25%) exhibited partial objective responses based on modified Response Evaluation Criteria in Solid Tumors (RECIST) criteria.

Denosumab is also approved in for use in two supportive care settings based on three randomized, double-blind, placebo-controlled phase III trials evaluating its efficacy versus zoledronic acid^{123–125} to reduce bone metastasis-related skeletal-related events (SRE). Based on data from two phase III trials, a second formulation and dosing schedule of denosumab is approved to increase bone mass in prostate cancer¹²⁶ and breast cancer¹²⁷ patients at high risk for bone fracture due to hormone-ablation therapies.

ANTIBODIES USED IN HEMATOLOGIC MALIGNANCIES

Rituximab

Rituximab (Rituxan) is a chimeric anti-CD20 monoclonal antibody that was the first MAb to be approved by the FDA for use in human malignancy.^{128,129} Studies have shown that multiple doses can be safely administered, and *in vitro* studies have demonstrated multiple mechanisms by which anti-CD20 antibodies can lead to cell death.¹³⁰ Efficacy of rituximab monotherapy is well established.¹³¹

Rituximab has been tested in conjunction with chemotherapy based on supportive preclinical data.^{132,133} The combination of rituximab with cyclophosphamide, doxorubicin, vincristine, and prednisolone (CHOP) resulted in a 95% overall response rate (55% complete response, 40% partial response) among 40 patients with low-grade or follicular B-cell non-Hodgkin lymphoma, with molecular complete remissions observed.¹³⁴ A long-term study of elderly patients with previously untreated diffuse large-cell lymphoma randomized to either CHOP chemotherapy plus rituximab (R-CHOP) or CHOP alone

demonstrated a significant improvement in event-free survival, PFS, disease-free survival, and overall survival for the combination arm.¹³⁵ No significant differences in long-term toxicity were noted.

Low-grade B-cell lymphoma patients possessing the 158V/V polymorphism in FcγRIII experience superior response rates and outcomes when treated with rituximab.^{37,38} These findings signify that antibody Fc domain::Fc receptor interactions underlie at least some of the clinical benefit of rituximab, and indicate a possible role for ADCC that depends on such interactions.

A combination of active agents (such as lenalidomide and thalidomide) that are also immune modulating may be additive with rituximab,¹³⁶ and perhaps synergize by increasing ADCC.¹³⁷ Cytokines such as interleukin-2 (IL-2), IL-12, or IL-15 and myeloid growth factors may also enhance therapeutic antibody activity as suggested by preclinical data demonstrating that IL-2 can promote NK cell proliferation and activation and can enhance rituximab activity¹³⁸ and clinical efficacy.^{139,140} Myeloid growth factors, in combination with rituximab, may also activate ADCC.¹⁴¹ Alternative approaches to induce effector cell activity by combining Toll-like receptors (TLR) agonists, such as CpG oligonucleotides, have been investigated.¹⁴² Altering the balance of proapoptotic and antiapoptotic signals could generate more rituximab-induced cytotoxicity. BCL-2 downregulation by antisense oligonucleotides was found to enhance rituximab efficacy in preclinical testing.^{143,144} However, small molecules that bind to the BH-3 domain common to many members of the BCL-2 family of proteins may be better therapeutic agents.¹⁴⁵⁻¹⁴⁷

Ofatumumab

The anti-CD20 ofatumumab¹⁴⁸ is a fully human antibody that binds an epitope on CD20 distinct from that bound by rituximab and is engineered for better complement activation, although it induces less ADCC. Ofatumumab has received regulatory approval for the treatment of patients with fludarabine-refractory chronic lymphocytic leukemia (CLL). In a recently reported, planned interim analysis that included 138 CLL patients with treatment-refractory disease or bulky (>5 cm) lymphadenopathy, treatment with ofatumumab led to an overall response rate (primary endpoint) of 47% in patients with bulky disease and 5% in patients refractory to both alemtuzumab and fludarabine.¹⁴⁹

Additional humanized anti-CD20 antibodies (veltuzumab¹⁵⁰ and ocrelizumab) are under development.

Alemtuzumab

Alemtuzumab (Campath-1H) targets the CD52 glycopeptide, which is highly expressed on T and B lymphocytes. It has been

tested as a therapeutic agent for CLL and promyelocytic leukemias, as well as other non-Hodgkin lymphomas.

Brentuximab Vedotin

Brentuximab vedotin (SGN-35, Adcetris) is an ADC consisting of the anti-CD30 chimeric MAb cAC10 that is linked to three to five molecules of the microtubule-disrupting agent Monomethyl auristatin E (MMAE). MMAE is a highly potent derivative of dolastatin. Linkage of MMAE to cAC10 occurs through a protease-cleavable linker.¹⁵¹ Brentuximab vedotin is approved for treating systemic, chemotherapy-refractory anaplastic large-cell lymphomas (sALCL). It is also approved to treat patients with Hodgkin lymphoma who have progressed after an autologous stem cell transplant (ASCT). Patients ineligible for ASCT must have failed two prior multidrug chemotherapy regimens.

Brentuximab vedotin received accelerated approval in 2011 based in part on the results of two phase II trials. In a multicenter trial conducted by Pro et al.,¹⁵² 58 patients with relapsed or refractory sALCL received brentuximab vedotin (1.8 mg per kilogram per week), and 86% of patients achieved objective response. Complete responses occurred in 57% of patients, with a median duration of 13.2 months. An additional 17 patients (29%) had partial responses. Median overall response was 12.6 months. Most common grade 3 and 4 adverse events (AE) were neutropenia (21%), thrombocytopenia (14%), and peripheral sensory neuropathy (12%). A similar trial, in Hodgkin lymphoma, was reported by Younes et al.¹⁵³ Patients (n = 102) that had failed ASCT received brentuximab vedotin on the same schedule as listed previously and were assessed for the objective response rate. In this setting, 75% of patients had objective responses, with 34% being complete remissions. The median duration of complete responses was 20.5 months, and 31 patients were progression free after a median follow-up of 1.5 years. Phase III trials to assess the known risk of neuropathy (AETHERA) and to confirm overall clinical benefit seen in the phase II trials (ECHELON-2, or ClinicalTrials.gov Identifier NCT01712490) are ongoing.

CONCLUSION

In the 35 years since Kohler and Milstein first developed the hybridoma technology that enabled antibody-based therapeutics, the field has made remarkable progress. Numerous antibody-based molecules are currently in clinical trials and many more are in development. Multiple therapeutic antibodies have a proven clinical benefit and have been licensed by the FDA. The thoughtful application of advances in cancer biology and antibody engineering suggest that this progress will continue.

30 Assessment of Clinical Response

Antonio Tito Fojo and Susan E. Bates

INTRODUCTION

Approaches to response assessments have become increasingly important over the past decade as the drug development pipeline has steadily increased in volume. In 2012, an estimated 981 medicines were in development for cancer, and the number is certainly higher today.¹ The challenge is, first, how to measure the activity of an agent in the research setting, and, second, how to measure activity in the standard of care setting.

The “modern era” of drug development began in 1976 when 16 experienced oncologists treating lymphoma gathered to decide what would be considered a reliable measure of response to a therapy.² Each oncologist measured 12 *simulated tumor masses* employing *usual clinical methods* (i.e., calipers or rulers). A principal goal was to identify the amount of shrinkage that *could not* be ascribed to operator error and that *would not* be found if a *placebo* was administered. Moertel and Hanley recommended that *to avoid error, a 50% reduction in the product of perpendicular diameters be employed as the criterion for efficacy.*² It was from this beginning that our current methodologies of response assessment evolved. The important point to note is that the decision to use a 50% reduction in the product of perpendicular diameters as a measure of efficacy was made so as to reduce error and *not because it represented a value that conferred clinical benefit.*

From Calipers and Rulers in Lymphoma to the Bidimensional World Health Organization Criteria

In 1981, five years after the Moertel and Hanley report,² a World Health Organization (WHO) initiative developed standardized approaches for the “reporting of response, recurrence and disease-free interval.”³ The WHO criteria, like Moertel and Hanley, recommended that malignant disease be measured in two dimensions. Complete response (CR) was defined as the disappearance of all known disease, and a partial response (PR) was scored if there occurred a “50% decrease in the sum of the products of the perpendicular diameters of the multiple lesions.” Thus, the 50% reduction initially chosen as an operationally optimal value became institutionalized as the threshold for declaring efficacy in the majority of cancers. This measure of efficacy was perpetuated in 2000 with the now widely used Response Evaluation Criteria in Solid Tumors (RECIST), but shifting to one dimension.⁴ The authors noted “the definition of a partial response, in particular, is an arbitrary convention—there is no inherent meaning for an individual patient of a 50% decrease in overall tumor load.” Nevertheless, the threshold chosen—a 30% reduction in one dimension—was comparable in volume to the 50% decrease in the sum of the products of the perpendicular diameters and thus perpetuated the 1976 standard. In spite of its arbitrary origins, the 50% reduction has held up over time. But the major impact of the WHO criteria was that it marked the beginning of a common language of response. These criteria have been revisited and refined over time, as technology

and medicine advanced. Table 30.1 compares the WHO criteria with those of RECIST 1.0 and RECIST 1.1 and three modifications of RECIST, whereas Figure 30.1 provides a visual presentation of the RECIST threshold required to qualify as response or progression.³⁻⁹

ASSESSING RESPONSE

RECIST 1.1

The RECIST 1.0 guidelines were updated as RECIST 1.1 in 2009, with a number of differences between the two response criteria highlighted. RECIST 1.1 preserves the same categories of response found in RECIST 1.0:

- Complete response: Complete disappearance of all disease
- Partial response: $\geq 30\%$ reduction in the sum of the longest diameter of target lesions
- Stable disease: Change not meeting criteria for response or progression
- Progression: $\geq 20\%$ increase in the sum of the longest diameter of target lesions

However, a decade of experience with RECIST identified several problems with the criteria, some of which could be corrected. In RECIST 1.0, minimum size varied between 1 and 2 cm depending on technique; in RECIST 1.1, a 1-cm lesion is the minimum measurable. In RECIST 1.0, 10 lesions were to be measured, 5 per organ; RECIST 1.1 reduced that to 5 lesions, 2 per organ. Response criteria in RECIST 1.0 did not address lymph nodes; in RECIST 1.1, lymph nodes decreasing to < 1 cm in their short axis could constitute a complete response. Disease progression in nontarget disease was further defined to indicate that in addition to a 20% increase in target lesions over the smallest sum on study, there must be an absolute increase of 5 mm, and that an increase of a single nontarget lesion should not trump an overall disease status assessment based on target lesions.

Variations of the RECIST Criteria

The RECIST criteria have been widely used for standardizing the reporting of clinical trial results and have improved reproducibility. However, the increasing precision and codification of RECIST has led to recognition of its limitations. For example, there are unique challenges in central nervous system (CNS) disease, relating response to tumor size measurements based on contrast enhancement. Pseudoprogression refers to an increase in contrast enhancement due to a transient increase in vascular permeability after irradiation, whereas pseudoresponse is a decrease in contrast enhancement that may occur due to a reduction in vascular permeability following corticosteroids or an antiangiogenic agent such as bevacizumab.¹⁰⁻¹² The McDonald criteria, traditionally used in determining glioma response based

TABLE 30.1

Key Features of Response Criteria

	WHO ³	RECIST 1.0 ⁴	RECIST 1.1 ⁵	CNS RANO Criteria ⁷	RECIST Mesothelioma ⁸	RECIST Immunotherapy ⁹
Dimension	Uni- and bidimensional	Unidimensional	Unidimensional	Bidimensional	Unidimensional	Bidimensional
Measurable Lesion	Not defined	Longest diameter, ≥ 20 mm with most modalities; ≥ 10 mm with spiral CT	Longest diameter ≥ 10 mm on CT or on skin if using calipers; ≥ 20 mm if using CXR	Two perpendicular diameters of contrast enhancing lesions ≥ 10 mm	Tumor thickness perpendicular to chest wall or mediastinum, measured in two positions at three levels on transverse cuts of CT scan	Longest perpendicular diameters
Measurable Lymph Nodes	Not defined	Not defined	≥ 15 mm short axis	—	—	—
Disease Burden to be Assessed at Baseline	All (not specified)	Measurable target lesions up to 10 total (5 per organ); other lesions nontarget	Measurable target lesions up to 5 total (2 per organ); other lesions nontarget	Two to five lesions in patients with several lesions	Pleural disease in perpendicular diameter; nodal, subcutaneous, and other bidimensional lesions measured unidimensionally as per the RECIST criteria	5 lesions per organ, up to 10 visceral lesions and five cutaneous lesions
Sum	Sum of the products of bidimensional diameters or sum of linear unidimensional diameters	Sum of longest diameters of all measurable lesions	Sum of the longest diameters of target lesions with only exception use of short axis for lymph nodes	Sum of the products of perpendicular diameters of all measurable enhancing target lesions	Sum of the six measurements defines a pleural unidimensional measure	SPD with new lesions incorporated into baseline; tumor burden = $SPD_{\text{index lesions}} + SPD_{\text{new lesions}}$
Complete Response	Disappearance all known disease	Disappearance all known disease	Disappearance all known disease; lymph nodes < 10 mm	—	Disappearance all target lesions with no evidence of tumor elsewhere	Disappearance all lesions in two consecutive observations
Partial Response	$\geq 50\%$ decrease	$\geq 30\%$ decrease; all other no evidence of progression	$\geq 30\%$ decrease; all other disease, no evidence of progression	$\geq 50\%$ reduction; stable or decreased steroid use compared to baseline	$\geq 30\%$ reduction in total tumor measurement	$\geq 50\%$ decrease compared with baseline in two observations
Response Confirmation?	≥ 4 weeks apart	≥ 4 weeks apart	≥ 4 weeks apart (if response primary end point); no, if secondary endpoint	≥ 4 weeks apart	Repeat on two occasions ≥ 4 weeks apart	≥ 4 weeks apart

(continued)

TABLE 30.1

Key Features of Response Criteria (continued)

	WHO ³	RECIST 1.0 ⁴	RECIST 1.1 ⁵	CNS RANO Criteria ⁷	RECIST Mesothelioma ⁸	RECIST Immunotherapy ⁹
Progressive Disease	≥25% increase in size of one or more measurable lesions or appearance of new lesions	≥20% increase, taking as reference smallest sum in study; or appearance of new lesions	≥20% increase, with absolute increase ≥5 mm, taking as reference smallest sum in study; or appearance of new lesions	≥25%, or any new lesions	≥20% increase in the total tumor measurement over the nadir measurement, or the appearance of one or more new lesions	≥25% increase compared with nadir confirmed ≥4 weeks apart; up to five new lesions (≥5 × 5 mm) per organ incorporated into tumor burden
	Nonmeasurable disease: Estimated increase of ≥25%	Nonmeasurable disease: unequivocal progression	Nonmeasurable disease: unequivocal progression	Nonmeasurable disease: >5 mm increase in maximal diameter; ≥25% increase in SPD; or significant increase in nonenhancing lesions on same or lower dose of corticosteroids	—	New, nonmeasurable lesions (i.e., <5 × 5 mm) do not define progression
Stable Disease	Stable disease or non-PR and non-PD ≥4 weeks	Non-PR, non-PD; minimum time defined by protocol	Non-PR, non-PD; minimum time defined by protocol	—	Non-PR, non-PD	Non-irPR, non-irPD

CXR, Chest X-ray; SPD, sum of products of two largest perpendicular diameters; PD, progressive disease; irPR, immune-related partial response; irPD, immune-related progressive disease.

on two-dimensional measurements, have been recently updated as part of the Response Assessment in Neuro-Oncology (RANO) response criteria and extended to include a response assessment for metastatic CNS disease.^{7,13}

Other examples where RECIST is limited include mesothelioma, gastrointestinal stromal tumors (GIST), hepatocellular cancers, among others. The pleural disease of mesothelioma increases in depth while following the pleural surface. GIST tumors may remain unchanged in size after treatment, whereas the center of the tumor mass undergoes necrosis, and progression may occur in the remaining rim.¹⁴ Hepatocellular cancers are often treated with local-regional therapy in which the goal is tumor necrosis and treatment failure occurs in surviving viable tumor.¹⁵ Different

strategies have emerged to quantify these diseases, including modifications of RECIST, quantifying positron-emission tomography (PET) imaging, and biomarker criteria, as will be discussed. The RECIST adaptation for mesothelioma, growing along the pleural surface, is to measure the diameter perpendicular to the chest wall or mediastinum, and to measure at three levels.⁸ The adaptation for hepatocellular cancer following local therapy is measurement of the longest diameter of the tumor that shows enhancement on the arterial phase of the scan, bypassing the dense, homogeneous Lipiodol-containing necrotic area.¹⁵

Investigators have also observed that following immunotherapy, tumor lesions may increase in size due to the increased infiltration of T cells, even meeting criteria for RECIST-defined progressive

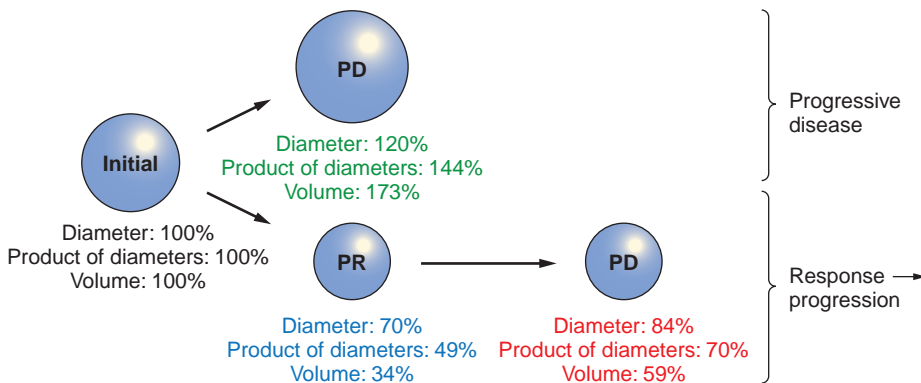

Figure 30.1 RECIST thresholds in three parameters: diameter, product of diameters, and volume. In the figure, spheres meeting RECIST criteria for progressive disease (PD) and for PR are shown with the percentage relative to the baseline calculated for each parameter. To meet the threshold for PD, the longest diameter must increase to 120%, which is equivalent to a 144% increase in the product of the perpendicular diameters and a 173% increase in the volume of a sphere. Although PR definitions are almost identical to those employed with WHO, RECIST has a higher threshold to meet PD.⁶

disease (PD). Previously radiographically undetectable lesions may appear. Departing from conventional RECIST, which defines any new lesion as PD, the immune response criteria allow the appearance of new lesions, adding them to the total tumor burden.⁹ An increase in total tumor burden of >25% relative to baseline or nadir is required to define PD.

International Working Group Criteria for Lymphoma

Revised guidelines for lymphoma assessment were promulgated by the International Working Group (IWG) in 2007.¹⁶ These guidelines incorporated 18F-fluorodeoxyglucose (FDG)-PET assessments in metabolically active lymphomas.¹⁶ Although a CR requires the complete disappearance of detectable disease, a post-treatment residual mass is permitted if it is negative on FDG-PET and was positive at baseline. For lymphomas that are not consistently FDG avid, or if FDG avidity is unknown, a CR requires that nodes >1.5 cm before therapy regress to <1.5 cm, and nodes that were 1.1 to 1.5 cm in long axis and >1.0 cm in the short axis shrink to ≤1.0 cm in short axis. The definition of PR resembles the WHO criteria, in that a ≥50% decrease in the sum of the product of the diameters in up to six nodal masses or in hepatic or splenic nodules must be documented. Although RECIST 1.1 now includes lymph node assessment, the IWG criteria remain the assessment method typically used in lymphoma clinical trials.

ALTERNATE RESPONSE CRITERIA

The previous examples represent attempts to more accurately measure tumor burden. Evolving imaging technology enabling volumetric measurements of tumor masses may eventually resolve some of these problems, but effective therapeutic agents are required to enable validation and utilization of response assessment tools. The lack of an agent that can mediate substantial tumor shrinkage underlies the concept of *clinical benefit response* (CBR) as an endpoint in pancreatic cancer. Clinical benefit was defined as a combination of improvement in pain, performance status, and weight; the assessment of CBR supported the U.S. Food and Drug Administration (FDA) approval of gemcitabine in pancreatic cancer.^{17,18} Better therapies for pancreatic cancer that result in tumor shrinkage or eradication should include and then eclipse clinical benefit.

Response criteria may be specific to a particular disease or clinical setting. Some diseases by their nature require specific strategies for response assessment.

Severity-Weighted Assessment Tool Score in Cutaneous T-Cell Lymphoma

Cutaneous T-cell lymphoma (CTCL) is a disease that can involve the entire epidermis, or comprise individual skin lesions varying widely in severity rather than size. The severity-weighted assessment tool (SWAT) assigns a factor for skin lesion severity—patch, plaque, or tumor—multiplies this factor by the percent of skin involved with each lesion type and then adds these together. This complex system formed the basis of the FDA approval of vorinostat for CTCL.¹⁹

Pathologic Complete Response in Breast Cancer

One unique response endpoint is the assessment of breast cancer treated in the neoadjuvant setting. The purpose of neoadjuvant therapy is to improve survival, render locally advanced cancer amenable to surgery, or to aid in breast conservation. In that setting, the absence of cancer cells in resected breast tissue has been used to define a pathologic complete response (pCR). The rate of pCR has been proposed as a surrogate endpoint for event-free survival (EFS) or overall survival (OS) to support approval of new agents or combinations of agents tested in clinical trials.²⁰ In a

pooled analysis of 11,955 patients enrolled on 12 neoadjuvant trials, individual patients with pCR had improved EFS and OS.²¹ However, at the trial level, pCR rates did not correlate with EFS or OS, a problem likely due to heterogeneity of breast cancer subtypes among the trials. Despite this, pCR rates were recently used to support the approval of pertuzumab and trastuzumab in the neoadjuvant setting.^{21,22}

Computed Tomography-Based Tumor Density

One approach, often called the Choi criteria, advocates assessing tumor response in GIST, renal cell cancer, or hepatocellular cancer based on density on computed tomography (CT) scans (Table 30.2). This variation was prompted by the evident response to treatment with imatinib but with minimal tumor shrinkage.²³ The Choi criteria are still considered exploratory in GIST,^{24,25} and it is too soon to know of benefits in other histologies.^{26,27} Further study should determine its utility, although it will likely be confined to specific tumor types with specific drugs.

FDG-PET

Although widely used in clinical practice, FDG-PET has become part of standardized response criteria for clinical trials only in lymphoma (see Table 30.2). In solid tumors, FDG-PET can aid in the detection of new or recurrent sites of disease, and can be used as an adjunct during assessments for disease progression when using RECIST criteria.⁷ Although FDG uptake is a powerful diagnostic tool and its uptake reflects a tumor's metabolic activity, it has some limitations: Some tumors have variable FDG avidity; differences can occur due to variations in patient activity, carbohydrate intake, blood glucose, and timing; and there are several benign sources of uptake, including inflammatory and postsurgical sites. Multiple methods of quantitating FDG-PET and assessing response have been proposed, but to date there is no consensus, particularly regarding the definition of a metabolic response.²⁸⁻³³

The two most widely used response criteria—the European Organisation for the Research and Treatment of Cancer (EORTC) criteria and PET Response Criteria in Solid Tumors (PERCIST) (see Table 30.2)—have been evaluated in specific disease types, but unifying FDG-PET response criteria remains a challenge in anticancer drug development.^{28,30} We would note that, as shown in Figure 30.1, a 30% reduction in the diameter of a sphere—the magnitude of change required to score a response according to RECIST—represents a 65% decrease in volume. If an standardized uptake value (SUV) decrease is directly equated to a volume decrease, a reduction of 25% translates to a 10% reduction in diameter, a value that likely constitutes an insufficient response.

Serum Biomarkers of Response

The ideal response assessment method is an assay that could measure tumor quantity by a simple blood test (see Table 30.2). Circulating protein biomarkers have been identified and studied for several decades for screening, early detection of recurrent disease, determining prognosis, selecting therapy, and monitoring response to therapy. These serum tumor markers are to be distinguished from the assays determining the presence of an overexpressed or mutated molecular target. With the successful launch of therapies against such molecular targets, there has been increased interest in the assays needed to select therapy for individual patients (predictive biomarkers). The analytical and clinical validation of such assays, along with determination of their clinical utility, has created a new regulatory paradigm known as *companion diagnostics*.^{34,35} This investment in the development of predictive markers for companion diagnostics has reduced the focus on protein biomarkers of treatment response relative to older literature.

As a result, there are few clinically validated biomarkers of response.³⁶ In addition to issues regarding sensitivity and specificity, their use and development has also been hindered by the often

TABLE 30.2

Alternate Response Criteria: Biomarkers

Criterion	Baseline	Response	Progression
CA-125 in ovarian cancer (GCIG criteria) ⁴³	CA 125 >2× ULN	CA 125 decline ≥50% confirmed at 28 days	2× nadir OR 2× ULN if normalized on therapy on two occasions 1 wk apart
PSA in prostate cancer (PSA WG1) ^{45,a}	PSA ≥5 ng/mL and documentation of two consecutive increases in PSA 1 wk apart	PSA decline of 50% from baseline (measured twice 3–4 wks apart)	After decrease from baseline, a 50% increase AND an increase ≥5 ng/mL, or back to baseline, whichever is lower
PSA in prostate cancer (PCWG2) ^{46,a}	PSA ≥2.0 ng/mL; estimate pretreatment PSA-DT: Need ≥3 values ≥4 wks apart	Report percent change from baseline (rise or fall) at 12 weeks, and separately, the maximal change (rise or fall) at any time using a waterfall plot	PSA increase ≥25% and absolute increase by ≥2 ng/mL above the nadir, confirmed by a second value ≥3 wks later (i.e., confirmed rising trend) OR PSA increase ≥25% and ≥2 ng/mL above baseline >12 wks
hCG and AFP in testicular cancer ^{50–51}		Decrease consistent with marker half-life: 2–3 d for hCG, 5–7 d for AFP	Rising levels usually indicate need to change therapy
Choi Criteria for CT Imaging			
Choi criteria ^{24–27}		≥10% decrease in tumor size OR ≥15% reduction in tumor density	An increase in tumor size ≥10% and does not meet criteria of PR by tumor attenuation on CT
FDG-PET Criteria			
EORTC criteria ^{29–31}	ROI should be drawn, SUV calculated	CMR: Complete resolution of uptake PMR: SUV reduction ≥25% SMD: SUV increase <25% and decrease <15%	PMD: SUV increase >25% in regions defined on baseline, or appearance of new FDG-avid lesions
PERCIST criteria ²⁹	SUL peak >1.5× normal liver	CMR: Complete resolution of uptake PMR: SUL reduction ≥30%	PMD: SUL increase >30% in regions defined on baseline, or appearance of new FDG avid lesions

^a Guidelines for PSA assessment have evolved from those of the PSAWG1, where responses were dichotomized based on the percent decline, to those in the PCWG2 where PSA response is considered a continuous variable. Recently, emphasis has shifted to assessing PSA doubling time. CA-125, cancer antigen 125; GCIG, Gynecologic Cancer InterGroup; ULN, upper limit of normal; PSA, prostate-specific antigen; PSAWG1, PSA Working Group 1; PCWG2, Prostate Cancer Working Group 2; PSA-DT, PSA-doubling time; hCG, human chorionic gonadotropin; AFP, alpha-fetoprotein; EORTC, European Organisation for the Research and Treatment of Cancer; ROI, regions of interest; SUV, standardized uptake value; CMR, complete metabolic response; PMR, partial metabolic response; SMD, stable metabolic disease; PMD, progressive metabolic disease; PERCIST, PET response criteria in solid tumors; SUL, SUV normalized to lean body mass.

limited efficacy of therapies; response biomarkers are of little value without highly effective primary and salvage therapies. For example, a recent clinical trial indicates that in *asymptomatic patients* with ovarian cancer whose only evidence of disease progression is an isolated rising CA-125, nothing is gained by instituting treatment before there is other evidence of progression.^{37,38}

- **Cancer Antigen 125 (CA-125):** Despite recognized limitations, CA-125 is widely used. For example, the Gynecologic Cancer InterGroup (GCIG) criteria have evolved to help determine whether a patient's tumor has responded to therapy.^{39–41} Response is defined as a 50% decline from an elevated baseline value, whereas progression is defined as a doubling over the nadir or the upper limit of normal.⁴² In clinical practice, CA-125 levels are followed as part of standard management, but making clinical decisions on marker changes alone is not recommended.⁴³
- **Prostate-Specific Antigen (PSA):** Similar issues have confronted investigators caring for patients with prostate cancer. The PSA Working Group 1 (PCWG1) guidelines, first published in

1999, established PSA criteria, particularly for use in patients with disease that was difficult to quantify.⁴⁴ There followed a second working group (PCWG2) that recommended plotting the percent PSA change for each patient in a waterfall plot so as to avoid creating a dichotomous variable from the changes in PSA.⁴⁵ PCWG2 also recommended keeping patients on trial until evidence of a change in clinical status—either symptomatic or radiographic progression. The latter addressed concerns with patients in whom PSA changes did not reflect clinical status, particularly those with transient increases in the first 12 weeks of a new therapy.

- **Human Chorionic Gonadotropin (hCG) and alpha fetoprotein (AFP):** Because testicular cancer is a highly curable disease with validated biomarkers, outcome assessment has focused on the rapid detection of patients whose tumors have a poor response to therapy. Because both markers have relatively short half-lives—2 to 3 days for hCG and 5 to 7 days for serum AFP—the rate of decline can be determined. Various methods have demonstrated that a rapid decline or early normalization of marker levels is indicative of a good

outcome, without any one method achieving widespread acceptance.⁴⁶⁻⁴⁸ Nonetheless, the 2010 American Society of Clinical Oncology (ASCO) guidelines on serum tumor markers concluded there was still insufficient evidence to recommend changing therapy solely on the basis of a slow marker decline.⁴⁹ Rising levels after two cycles of therapy (outside the first week of treatment when rises can be due to tumor lysis) can be considered an indication to change the treatment plan.^{49,50}

Circulating Tumor Cells and Circulating Tumor DNA

Two response endpoints under recent investigation show a potential to detect the impact of therapy. One is the measurement of circulating tumor cells (CTC) in the bloodstream, enriched by one or more capture strategies, including one that has received FDA approval.⁵¹ The number of CTCs in the blood has been shown to be prognostic, with higher levels conferring a poor prognosis, and to correlate with a response to therapy. A second approach is the determination of levels of circulating tumor DNA (ctDNA) in the blood. This is detected by quantitating the number of DNA molecules carrying a given mutation or gene rearrangement in the blood, typically detected through targeted sequencing of common mutations, or of a previously identified *mutation signature* or gene rearrangement. The amount of ctDNA appears to correlate with tumor burden, increases with stage, and in one study, was deemed more sensitive than CTC detection.⁵²⁻⁵⁴ Whether these tests will ultimately prove to be more sensitive and accurate than the serum biomarkers discussed previously remains to be determined. Because targeted sequencing can be very sensitive, one concern is that false-positive ctDNA detection may occur after treatment, or intermittently in the setting of enlarging tumor masses. At the least, detection of CTCs and ctDNA is advancing our understanding of cancer biology, as studies reveal evidence of metastatic heterogeneity, clonal heterogeneity, and emergence of resistance mutations in clinical samples.

DETERMINING OUTCOME

The response measures described previously represent different approaches to quantitate tumor burden. What happens after those data are obtained varies depending on the clinical setting. In the community, less emphasis is placed on strict criteria. In the setting of a clinical trial, tumor size is measured and the response categorized. For FDA submission, these are but factors in the risk-benefit equation needed for drug approvals. The FDA conveys full approval to new agents based on true *clinical benefit* (i.e., an improvement in a *survival* endpoint or symptom relief).⁵⁵ Surrogates for clinical benefit, such as response rate, may support either regular approval or accelerated approval, depending on the setting.

Overall Response Rate, Duration of Response, and Stable Disease

Overall response rate (ORR) is the proportion of patients with a tumor size reduction of a predefined amount for a minimum time period. The FDA has generally defined ORR as the sum of PRs and CRs. Although OS remains the gold standard, ORR is often used both in drug development and in clinical practice to indicate antitumor efficacy of a given therapy. Table 30.3 summarizes the attributes and drawbacks of using ORR as a method of assessment. Using standardized definitions of response, it has been shown that ORR often correlates with OS, although ORR usually explains only a fraction of the variability of the survival

benefits.⁵⁶⁻⁵⁸ Equally important, however, is the duration of response, a value that is measured from the time of initial response until documented tumor progression, and which assumes added importance when ORR is the endpoint for regulatory approval.

Unlike PR and CR, the FDA has generally not been willing to include *stable disease* (SD), defined as shrinkage that qualifies as neither response nor progression, as part of the ORR, feeling it is often indicative of the underlying disease biology rather than a drug's therapeutic effect.^{55,59} Nevertheless, in reporting data, investigators are increasingly using the term *CBR*, which includes CR + PR + SD and which is a misuse of the term *clinical benefit* because neither CR, PR, or SD are *objective tumor findings* that address the true *clinical benefit* of a therapy.^{58,60} In the absence of standardized definitions for SD that are shown to effect meaningful changes in a clinical outcome, SD should not be used as a response endpoint. A better approach is to use nondichotomized response assessments, such as the waterfall plot or one of the kinetic analyses, discussed later.

Progression-Free Survival, Time to Progression, and Time to Treatment Failure

In cancer drug development, one usually finds ORR assessed as an indicator of activity in phase II trials, whereas randomized phase III trials rely on other endpoints such as progression-free survival (PFS) and time to progression (TTP) (see Table 30.3). Although PFS and TTP attempt to assess efficacy in close proximity to a therapy, they score outcomes differently and are not interchangeable. TTP is defined as the time from randomization to *the time of disease progression*.⁵⁵ In *TTP analyses*, deaths are censored either at *the time of death or at an earlier visit*. In contrast, PFS is defined from the time of randomization to the time of *disease progression or death*. Although patients who discontinue trial participation for adverse events might be censored in both analyses, patients who die while on study are censored only in the TTP analysis. Those who favor TTP argue that if a patient dies without their tumor meeting criteria for progression, one cannot accurately estimate when progression might have occurred, so the data should be censored. However, those who favor PFS argue that, in some cases, death might be an adverse effect of the therapy. High-dose therapies represent an example of why PFS might be a preferable (regulatory) endpoint. If in a given tumor there is evidence of a dose-response relationship for an active drug, then high doses may have a greater response. However, such high doses may also be responsible for a greater number of deaths. Assessing only those who survive the high dose therapy and ignoring those who die (i.e., TTP) may lead to the conclusion that the high-dose therapy is more effective. The balance sheet that includes death (i.e., PFS) would clearly demonstrate this efficacy came at too great a price.

Although many have argued that PFS and TTP should be acceptable endpoints for cancer clinical trials, in the majority of tumors there is no convincing evidence PFS is a surrogate for OS, and in those where there is some evidence, its value is arguable.⁶¹ Table 30.3 presents the attributes and drawbacks of PFS and TTP. Note that the definition of progression is often difficult, particularly in some tumor types, and that investigator bias can influence PFS and TTP. Problems with ascertainment bias and censoring, depicted in Figure 30.2, can also impact outcomes.

Alternate endpoints include time to treatment failure (TTF), defined as a composite endpoint measuring time from randomization to discontinuation of treatment for any reason, including disease progression, treatment toxicity, and death. The FDA has not recommended TTF as a regulatory endpoint for drug approval. However, the high rates of censoring due to toxicity seen in phase III clinical trials may lead to a reassessment of this position given that most can agree that not only is efficacy important, but so too is tolerability, and TTF can capture both of these attributes.

TABLE 30.3

A Comparison of Important Cancer Approval Endpoints

Regulatory Evidence	Endpoints	Advantages	Disadvantages
Clinical benefit used for regular approvals	Overall survival (OS)	<ul style="list-style-type: none"> Universally accepted direct measure of clinical benefit Easily measured Includes treatment-related mortality that can obscure benefit in a subset Precisely measured; unambiguous Not dependent on assessment intervals 	<ul style="list-style-type: none"> May involve larger studies May require long follow-up May be affected by crossover and/or sequential therapies Includes noncancer deaths
	Symptom endpoints (patient-reported outcomes)	<ul style="list-style-type: none"> Patient perspective of direct clinical benefit 	<ul style="list-style-type: none"> Blinding is often difficult Data are frequently missing or incomplete Clinical significance of small changes is unknown Multiple analyses Lack of validated instruments
Surrogates used for accelerated approvals or regular approvals	Disease-free survival (DFS)	<ul style="list-style-type: none"> Smaller sample size and shorter follow-up necessary compared with survival studies 	<ul style="list-style-type: none"> Not statistically validated as surrogate for survival in all settings Not precisely measured; subject to assessment bias, particularly in open-label studies Definitions vary among studies
	Objective response rate (ORR)	<ul style="list-style-type: none"> Can be assessed in single-arm studies Assessed earlier and in smaller studies compared with survival studies Effect attributable to drug, not natural history 	<ul style="list-style-type: none"> Not a direct measure of benefit Not a comprehensive measure of drug activity Only a subset of patients who benefit
	Complete response (CR)	<ul style="list-style-type: none"> Can be assessed in single-arm studies Durable complete responses can represent clinical benefit Assessed earlier and in smaller studies compared with survival studies Definition of progressive disease (PD) identifies uniform time to end treatment and data capture 	<ul style="list-style-type: none"> Not a direct measure of benefit in all cases Not a comprehensive measure of drug activity Small subset of patients with benefit Requires prospective, consistent definition. Meaningful response durations not standardized Definition of PD is arbitrary without evidence it actually represents end of benefit period
	Progression-free survival (PFS) or time to progression (TTP) ^a	<ul style="list-style-type: none"> Smaller sample size and shorter follow-up necessary compared with survival studies Measurement of stable disease included Not confounded by crossover or subsequent therapies Generally based on objective and quantitative assessment 	<ul style="list-style-type: none"> Statistically validated as surrogate for survival only in some settings Not precisely measured; subject to assessment bias particularly in open-label studies Definitions vary among studies; little agreement on magnitude of difference that constitutes clinical benefit Requires frequent and consistent radiological or other assessments Involves balanced timing of assessments among treatment arms

^a Progression-free survival includes all deaths; time to progression censors deaths that occur before progression.

Adapted from U.S. Department of Health and Human Services, Food and Drug Administration, Center for Drug Evaluation and Research (CDER), Center for Biologics Evaluation and Research (CBER). *Guidance from Industry. Clinical Trial Endpoints for the Approval of Cancer Drugs and Biologics*. 2007. <http://www.fda.gov/downloads/Drugs/.../Guidances/ucm071590.pdf>.

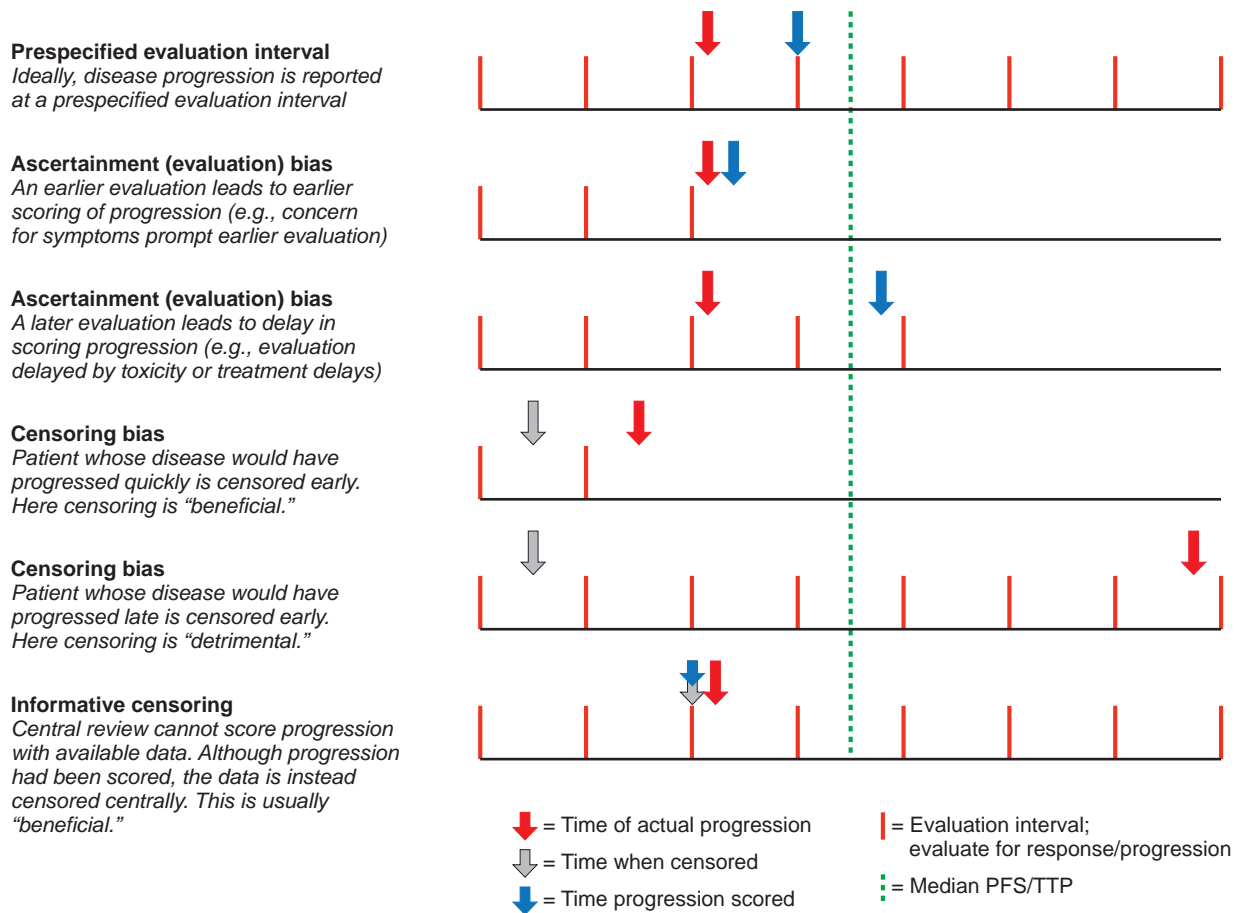

Figure 30.2 The potential problems encountered when PFS is used as an endpoint. Ideally, as depicted at the *top*, response assessment will be conducted at a prespecified time. However, the date at which progression is scored may suffer from either ascertainment or censoring bias. Ascertainment bias can occur if either an evaluation occurs before the prespecified date or if it is delayed. For example, a clinician concerned about a patient who is not experiencing side effects and has likely been randomized to placebo may be more inclined to investigate symptoms early and document progression before the prespecified time, while delaying the evaluation of a patient randomized to the experimental arm who experiences some toxicity. Similarly, censoring—an increasing problem in randomized trials—may impact the outcome of a given study arm by either censoring patients who would experience early progression (beneficial impact) or censoring those who would have remained progression free for a long time (detrimental impact). Finally, informative censoring can occur when independent radiologic review cannot concur with an investigator’s assessment of progression and censors the patient. This outcome is usually beneficial, because a patient who is very close to experiencing progression is censored. (Adapted from Villaruz LC, Socinski MA. The clinical viewpoint: definitions, limitations of RECIST, practical considerations of measurement. *Clin Cancer Res* 2013;19:2629–2636.)

Overall Survival

Defined as the time from randomization to death, OS has been considered the gold standard of clinical trial endpoints (see Table 30.3). In part, this is so because it is unambiguous and does not suffer from interpretation bias. An additional advantage of the survival endpoint is that it can balance the effect of therapies with high treatment-related mortality even if tumor control is substantially better with the new treatment. However, some worry that because patients may receive multiple lines of therapy following the clinical trial, the results may be confounded by those subsequent therapies. The latter concern is often cited as the reason why an advantage in PFS/TTP *disappears* when one looks to OS. But as a review of clinical trials confirms,⁶² the magnitude of the difference does not disappear, only the statistical validity (Fig. 30.3).^{63,64}

When evaluating a randomized controlled trial, it is important that the OS as well as the PFS analyses are always by intention to treat (ITT). In an ITT analysis, often described as *once randomized, always analyzed*, all patients assigned to a group at the time of randomization are analyzed regardless of what occurred

subsequently.⁶⁵ An ITT analysis avoids the bias introduced by omitting dropouts and noncompliant patients that can negate randomization and overestimate clinical effectiveness.

Kaplan–Meier Plots

In a typical clinical trial, data are often presented as a Kaplan–Meier plots. In discrete time intervals, the number of patients in each group who are progression free and alive (PFS analysis) or alive (OS analysis) at the end of the interval are counted and divided by the total number of patients in that group at the beginning of the time interval. One excludes from this calculation patients censored for a reason other than progressive disease or death during the same interval. This has the advantage that it allows one to include censored patients in estimates of the probability of PFS or OS up to the point when they were censored (i.e., they are excluded only beyond the point of censoring). In most clinical trials, a fraction of patients are typically censored.

In constructing the Kaplan–Meier plot, probabilities are calculated for each interval of time. The probability of surviving

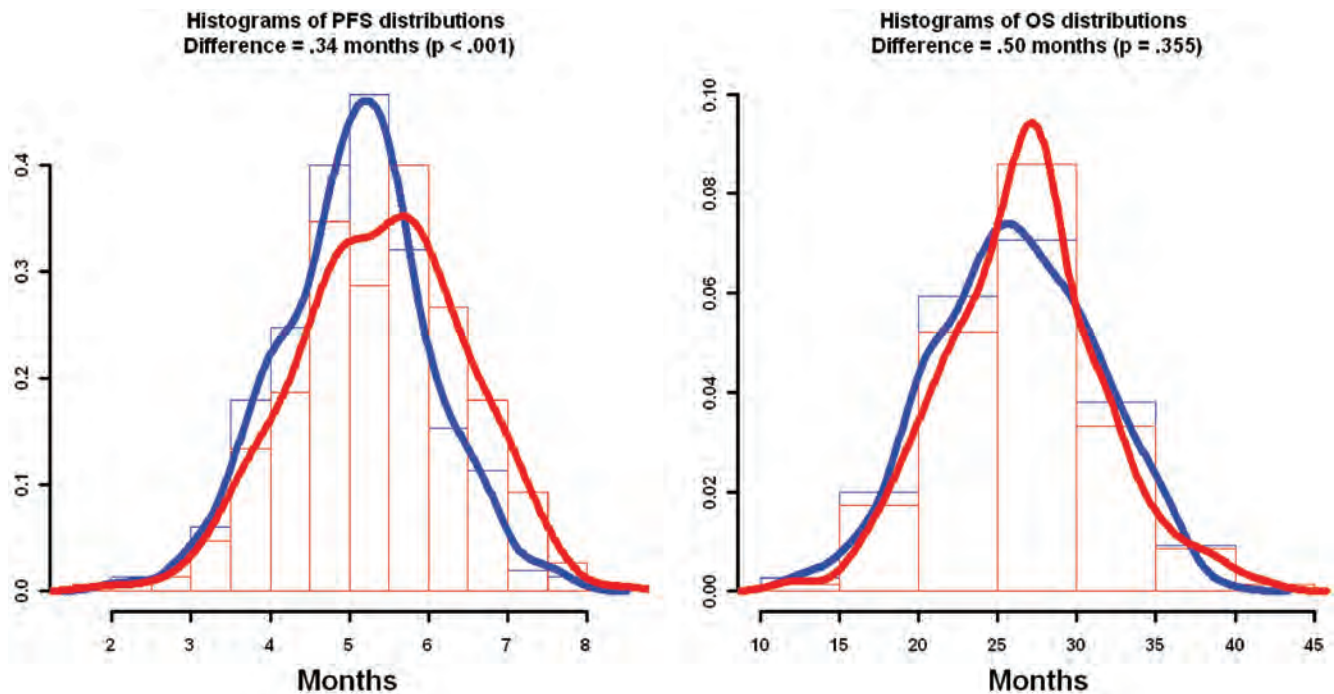

Figure 30.3 Hypothetical distribution of PFS and OS data demonstrating the *disappearance of PFS benefit*. Because chemotherapy does not exert a lasting effect on the underlying tumor biology and because PFS is a shorter interval (measured in increments, not daily as is OS) PFS differences often disappear. The *hypothetical example* shown illustrates this phenomenon. The *left panel* shows a histogram of PFS distributions with a difference of 0.34 months that nevertheless achieves statistical significance over the short interval when PFS is measured. The *right panel* depicts similar histograms for OS captured over a longer time period. Despite a larger absolute difference of 0.5 months, the OS difference does not reach statistical significance. For these hypothetical curves, random number generated data sets (with normal distribution), histograms, and density plots were generated using R version 2.11.1 (2010-05-31).⁷⁹ The differences were deliberately chosen to be small, but a similar disappearance can also occur with larger differences. As can be seen, what disappears is not the absolute benefit, but the statistical validity.

progression free or being counted as a survivor to the end of any interval of assessment is the product of the probabilities of surviving in all the preceding assessment intervals multiplied by the probability for the interval of interest. One might ask to what extent the two curves in each study differ. One measure that is of value is the median PFS or OS—a value calculated in most studies from a Kaplan–Meier plot.

Hazard Ratios

Increasingly, however, hazard ratios are cited in preference to the more traditional measures of efficacy such as the median PFS and median OS. *However, because a hazard ratio is a value that has no dimensions, it has very limited value, informing the reader only with regard to the reliability and uniformity of the data.* It does not quantify the magnitude of the benefit. A physician and, especially, a patient want to know the magnitude of the benefit (i.e., the extent to which a life will be prolonged), not what a dimensionless hazard ratio is. By definition, the *hazard ratio* is a ratio of the *hazard rates*. The hazard rate quantifies the likelihood that a patient will experience a *hazardous event* or a hazard during a defined interval of observation, and this is expressed as a rate or percent. For example, if during a given period of observation 20 of 100 patients receiving a reference or control therapy experience progression or death, their hazard rate during this interval is 0.2 (20/100). If during this same interval, only 10 of the 100 patients receiving the experimental therapy experience progression or death, their hazard rate is 0.1 (10/100). In this simple example, the hazard ratio for the interval, calculated as *the ratio of the hazard rates* is 0.5 (0.1/0.2) and indicates the likelihood of experiencing a hazardous event is reduced by 50% in the experimental arm. As commonly presented, and as this simple example illustrates, the lower the

hazard ratio, the better the experimental therapy. To determine whether the hazard ratio has statistical significance, one can (1) use a log-rank test to show that the null hypothesis that the two treatments lead to the same survival probabilities is wrong, or (2) use a parametric approach writing a regression model and fitting the data to the model so that one can establish the hazard ratio for the whole trial and its statistical significance. In many cases, the Cox proportional hazard model is used. Although the ideal hazard ratio would capture the differential benefit throughout the period of study, in practice, the extremes depicted in a Kaplan–Meier plot may not be analyzed.

Forest Plots

Interest in determining whether there is heterogeneity in a treatment effect, such that better outcomes occur in some subgroups, has led to the use of Forest plots to display treatment effects across subgroups. Although simple in concept, these plots are subject to error because subgroups are composed of smaller numbers and the confidence intervals are therefore wider than those for the entire group. The most common presentation includes a vertical line at the *no effect point* (e.g., a hazard ratio of 1.0), with symbols of varying size representing the subgroups, each with its confidence interval depicted by a line that stretches from the symbol to both sides (the symbol size is usually proportional to the size of the subgroup). If the confidence interval for a subgroup crosses the no effect point, this is commonly interpreted (not necessarily correctly) as a lack of effect in the subgroup. *The information one seeks from a Forest plot is whether the effect size for different subgroups varies significantly from the main effect, which is determined by a test for heterogeneity.*⁶⁶

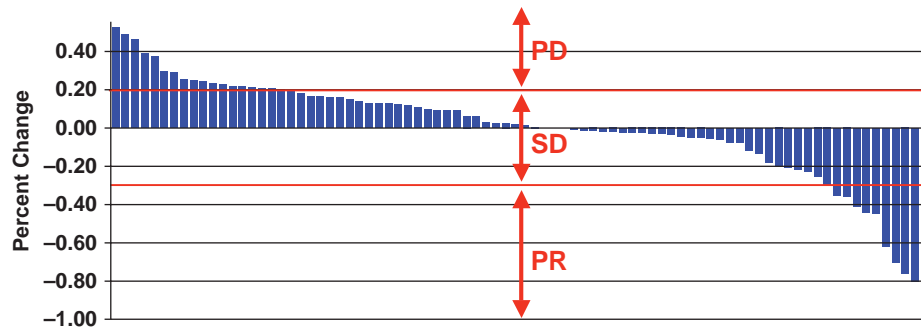

Figure 30.4 Example of a waterfall plot demonstrating for each patient the maximum benefit obtained with the study therapy. Those to the *left* represent patients whose tumors increased, and those on the *right* represent patients whose tumors regressed. The *vertical red lines* at +20% and -30% define the boundaries of stable disease according to RECIST. Ideally, all responses should be confirmed after a period of at least 4 weeks. The example shown is of patients with renal cell carcinoma treated with the microtubule targeting agent ixabepilone. (From Huang H, Menefee M, Edgerly M, et al. A phase II clinical trial of ixabepilone [Ixempra; BMS-247550; NSC 710428], an epothilone B analog, in patients with metastatic renal cell carcinoma. *Clin Cancer Res* 2010;16:1634–1641.)

Beyond Dichotomized Data

Quality of Life

The assessment of cancer patients enrolled on a clinical trial can be said to consist of two sets of endpoints: cancer outcomes and patient outcomes. Cancer outcomes measure the response of the tumor to treatment, the duration of the response, the symptom-free period, and the early recognition of relapse. In contrast, patient outcomes assess the benefit achieved with a given therapy by measuring the increase in survival and the quality of life (QOL) before and after therapy. Unfortunately, physicians tend to concentrate on cancer-

related outcomes, often neglecting assessments of QOL. Although a QOL assessment in clinical settings is possible with currently available instruments, there must be continued development and refinement of these instruments. Such development must focus not only on extracting valuable information in an unbiased manner, but also and equally important, developing an instrument that is user friendly and will be completed in a high percentage of encounters.

Waterfall Plots

The arbitrary nature of the 50% cutoff set by Moertel and Hanley and its evolution to the current RECIST threshold of 30%

Figure 30.5 The effect of the growth rate constant, g , on two commonly reported clinical values: maximum tumor shrinkage and PFS. Tumor measurements obtained in patients can be analyzed mathematically. (A–E) The *black line* depicts idealized clinical data using tumor quantities measured as patients received chemotherapy. Actually, clinical measurements comprise concurrent tumor regression (*dashed red line*) and growth (*dashed blue line*) that can be described by a rate constant and a first order kinetic equation, $f(t) = \exp^{-d \cdot t} + \exp^{g \cdot t} - 1$, where \exp is the base of the natural logarithm, $e = 2.7182 \dots$, and f is the percent change in tumor measurement at time t , normalized to the value when treatment began. The rate constant d accounts for exponential decrease, whereas the rate constant g accounts for exponential growth occurring during treatment.^{68,69} To demonstrate the correlation between the growth rate, tumor shrinkage and PFS, the *same* regression rate (d) has been modeled in panels A through E, whereas the growth rate constant, g , *increases* in each successive panel. The *black triangles* depict the point at which tumor size is 20% above the nadir (RECIST definition of PD). As the growth rate increases (i.e., faster tumor growth) from A to E, the nadir is reached sooner, and the depth of the nadir is less. (F) The correlation between PFS and maximum tumor shrinkage (nadir) is shown, plotting the correlation between PFS and response fraction, which is defined as the ratio of nadir to initial value.^{68,69} Although idealized plots are given, the curves are based firmly on data obtained from patients enrolled on clinical trials.

reduction in the size of the maximum diameter raises valid queries as to why 30% is valuable and not 29% or 25%. On this background, waterfall plots such as the one shown in Figure 30.4 have become increasingly popular because they depict the benefit or lack thereof in all patients as a continuum of response, rather than a dichotomized response rate.⁶⁷ Waterfall plots can be generated from any quantitative assessment. If ctDNA or tumor cells prove to be as quantitative as hoped, the maximum decline could be plotted as a waterfall plot.

Growth Kinetics

Efforts to quantify tumor kinetic parameters from clinical data have been investigated in recent years. Different equations have been applied to describe the two-phase curve based on tumor size as observed in most solid tumor trials, where there is first shrinkage followed by regrowth (Fig. 30.5). These models show

exponential tumor shrinkage after treatment, followed by tumor regrowth that is either exponential or linear and have been shown to correlate with OS and to discriminate effective therapies as well as individual patients within trials.^{68–73} A major advantage is that more of the data are used, relative to dichotomized response assessment, and regression or growth rates can be determined even in patients who are censored in a Kaplan–Meier analysis. Equations that model both regression and growth rates confirm the clinical intuition that resistant disease is emerging even as overall tumor volume is reduced. Further, “the strategy of studying tumor growth kinetics circumvents one weakness of ‘progression criteria,’ which is that they inherently dichotomize a complex biological process that may be better characterized using a continuous function.”⁷⁴ As shown in Figure 30.5, the response of a tumor to a therapy is exemplified by the nadir, the time to the nadir, and the time to progression or PFS, and these are all dependent on the growth rate.

Cancer Prevention and Screening

31 Tobacco Use and the Cancer Patient

Graham W. Warren, Benjamin A. Toll, Irene M. Tamí-Maury, and Ellen R. Gritz

INTRODUCTION

Tobacco is commonly described as the largest preventable cause of cancer. Over 50 years ago, tobacco was increasingly recognized as the primary cause of lung cancer, with definitive recognition for tobacco use as a causative factor in the seminal 1964 U.S. Surgeon General's Report (SGR) on Smoking and Health.¹ Recent editions of the SGR have described the widespread adverse health effects of tobacco on a spectrum of diseases, including as a causative agent for a spectrum of cancers.^{2,3} Tobacco use is an addiction usually initiated in youth prior to the age of 18 and is driven by the highly addictive drug, nicotine.⁴ As related to the cancer patient, considerable work has been conducted to associate tobacco use with the risk of developing cancer and how tobacco cessation can substantially reduce cancer risks. However, there is a relative paucity of effort that has been put forth to identify the effects of smoking on outcomes for cancer patients or to establish methods to help cancer patients quit smoking. Fortunately, in recent years, the importance of tobacco use by the cancer patient has been increasingly recognized as an important health behavior, including a National Cancer Institute (NCI)-sponsored conference on tobacco use in 2010, a joint sponsored NCI-American Association of Cancer Research (AACR)-sponsored workshop at the Institute of Medicine in 2012, and recent recommendations by the AACR and the American Society of Clinical Oncology (ASCO) to address tobacco use in cancer patients.^{5,6} The recently released 2014 SGR now provides substantial evidence behind the effects of smoking by cancer patients with the following conclusions:⁷

1. In cancer patients and survivors, the evidence is sufficient to infer a causal relationship between cigarette smoking and adverse health outcomes. Quitting smoking improves the prognosis of cancer patients.
2. In cancer patients and survivors, the evidence is sufficient to infer a causal relationship between cigarette smoking and increased all-cause mortality and cancer-specific mortality.
3. In cancer patients and survivors, the evidence is sufficient to infer a causal relationship between cigarette smoking and increased risk for second primary cancers known to be caused by cigarette smoking, such as lung cancer.
4. In cancer patients and survivors, the evidence is suggestive but not sufficient to infer a causal relationship between cigarette smoking and the risk of recurrence, poorer response to treatment, and increased treatment-related toxicity.

The overall objective of this chapter is to discuss tobacco use by cancer patients, the clinical effects of smoking in cancer patients, methods to address tobacco use by cancer patients, and areas of needed research.

NEUROBIOLOGY OF TOBACCO DEPENDENCE

Nicotine is the primary addictive component of tobacco that increases extracellular concentrations of dopamine in the nucleus accumbens and stimulates the mesolimbic dopaminergic

system,^{8,9} resulting in nicotine's rewarding effect experienced by tobacco users.¹⁰⁻¹² Dopaminergic neurotransmission may also be involved in the assignment of incentive salience, or stimulus for a pleasure based reward, to tobacco use-related environmental cues^{13,14} that may become conditioned reinforcers of tobacco use behaviors. For example, an individual who smokes while drinking their morning coffee may associate coffee, or even holding a coffee cup in their hand, with the reward from smoking. Thus, cigarette smoking is directly linked to external nontobacco-based behavioral stimuli. Activation of the nucleus accumbens has further been implicated in drug reinstatement or relapse.^{15,16} Individuals who have quit tobacco use for years have restarted a tobacco habit simply by sitting next to a smoker and being exposed to secondhand smoke. Substantial work has been conducted on the addictive nature of tobacco and nicotine, and readers are referred to several comprehensive reviews on this topic.^{9,12,17}

TOBACCO USE PREVALENCE AND THE EVOLUTION OF TOBACCO PRODUCTS

Much of the discussion on tobacco use epidemiology and carcinogenesis is presented in Chapter 4. In brief, the prevalence of cigarette smoking among adults in the United States decreased to 19.0% as compared with 22.8% in 2001, but it did not meet the *Healthy People 2010* objective to reduce smoking prevalence to 12%.^{18,19} There have been substantial changes in the landscape of tobacco use over time as a direct consequence of cigarette-centered policies and regulations aiming to reduce the harmful effects and number of deaths caused by smoking.²⁰⁻²² Under this new landscape, novel and reemergent noncigarette tobacco products such as cigars, cigarillos, snuff, chewing tobacco, water pipes (hookahs), and other forms of tobacco consumption have been growing in demand as a consequence of aggressive and sophisticated marketing by the tobacco industry.²³ Consumption patterns have also changed due to efforts by the tobacco industry to make cigarettes appear safer, such as low tar or filtered cigarettes, and the inclusion of flavoring (menthol, vanilla, fruits, etc.).²⁴ Although these efforts may have changed consumption patterns, they have not reduced cancer risk. Large patient cohorts demonstrate that the introduction of low tar and filtered cigarettes actually increased risk by promoting deeper inhalation and higher rates of addiction with no reductions in cancer risk,^{24,25} resulting in subsequent changes in lung cancer from centrally located squamous cell cancers to peripherally located nonsquamous cell cancers.

The relatively recent introduction of electronic cigarettes (i.e., e-cigarettes, e-cigs, nicotine vaporizers, or electronic nicotine delivery systems [ENDS]) is noteworthy. These electronic or battery-powered devices activate a heating element that vaporizes a liquid solution contained in a cartridge, and then the user inhales this vapor. Levels of nicotine as well as other chemical additives and flavors in the cartridge are uncertain and vary according to the brand.²⁶ Although there are no research studies that have evaluated the potential harmful effects of the use of e-cigarettes for

cancer patients,²⁷ organizations such as the World Health Organization have already expressed concerns about the safety of these increasingly popular products.^{28,29} To date, e-cigarettes have not been approved by the U.S. Food and Drug Administration (FDA) as therapeutic devices to aid in quitting smoking.²⁶ Readers are referred to a recent editorial on the use of e-cigarettes by cancer patients²⁷; however, it will likely be several years before evidence-based health information is available.

TOBACCO USE BY THE CANCER PATIENT

The prevalence of current smoking among long-term adult cancer survivors appears to have declined in the past decade,³⁰ but data suggest higher rates of smoking among cancer survivors than in the general population.^{30–32} These data are often biased by the fact that assessments in cancer patients may not include cancer patients who were current smokers at the time of death. As a result, estimates of smoking rates in cancer survivors may be misleading and may underestimate true tobacco use patterns for cancer patients. Furthermore, alternative tobacco products are often not assessed in cancer patients. Data from the Childhood Cancer Survivor Study and the 2009 Behavioral Risk Factor Surveillance System indicate that approximately 3% to 8% of cancer survivors use smokeless tobacco products.^{33,34} Patients may be attracted to these alternative products due to less social stigma and the nonevidence-based perception that these products are healthier alternatives compared to cigarette smoking.

Continued tobacco use by cancer patients often represents a combined failure by the patient to recognize the need to stop smoking even after a cancer diagnosis and the effort by health-care providers to address tobacco use with evidence-based assessments and tobacco cessation support. Approximately 30% of all cancer patients use tobacco at the time of cancer diagnosis with higher rates in traditionally tobacco-related disease sites, such as head and neck or lung cancers, and lower rates in traditionally nontobacco-related disease sites, such as breast or prostate cancers.^{35–44} However, findings from several studies indicate that cancer patients are receptive to smoking cessation interventions even as they continue to smoke.^{35,38,45–50}

A cancer diagnosis can be used as a window of opportunity, or *teachable moment*, to intervene and provide assistance in the quitting process.⁵¹ A recent study in 12,000 cancer patients, including 2,700 patients who smoked, capitalized on the teachable moment and demonstrated that less than 3% of patients who were contacted by the cessation program rejected tobacco cessation assistance.⁴⁵ However, only 1.2% of patients who received a mailed invitation participated in the program. This highlights the idea that patients may be interested in quitting, but methods such as mailed tobacco cessation information may not yield effective participation by cancer patients. Once enrolled, patients and clinicians must realize that although relapses in the general population usually occur within 1 week of cessation, relapses in cancer patients may be delayed due to cancer treatment–related variables such as surgical or other posttreatment healing.⁵² Consequently, it is important to continue offering tobacco assessments and cessation support for cancer survivorship efforts.

Defining Tobacco Use by the Cancer Patient

In dealing with tobacco use by cancer patients, it is important to note that virtually all of the evidence associating tobacco with cancer treatment outcomes deals with smoking. Few studies report associations between other forms of tobacco use (e.g., smokeless, cigars, cigarillos) and outcomes in cancer patients. Furthermore, the definition of smoking across published studies varies substantially.⁵³ In studies of cancer patients, smoking has been defined as current (e.g., smoking after diagnosis, at diagnosis, in the weeks

before diagnosis, within the 12 months prior to diagnosis, after diagnosis, within the past 10 years), former (e.g., recent, intermediate-, or long-term quit for 1 month, 3 month, 6 month, 12 month, 2 years, 5 years, 10 years), never, quitting after diagnosis, and according to exposure (e.g., multiple pack year cutoffs, Brinkman index, years of smoking, years of smoking within a predefined period of time such as 5 years prior to diagnosis). Though the non-standard method of addressing tobacco use in cancer patients has been observed in several reports,^{54–57} there are no current standard recommendations for the definition of tobacco use by any national organization. There are four primary categories for smoking status:

1. **Never smoking** is typically defined as having smoked less than 100 cigarettes in a person's lifetime and no current cigarette use. These patients are generally considered as a reference group in many studies. Categories 2 through 4 require that a person has smoked at least 100 cigarettes in their lifetime.
2. **Former smoking** is typically defined as no current cigarette use, usually within the past year.
3. **Recent smoking** (or recent quit) is generally defined as having stopped smoking within the recent past, typically for a period of 1 week to 1 year.
4. **Current smoking** is typically defined as smoking one or more cigarettes per day every day or some days.

Ever smoking is a combination of categories 2 through 4 (i.e., former, recent, and current smokers) that has been used to report negative associations between smoking and cancer outcomes in a number of studies.^{58–70} Defining smoking according to *ever* smoking status limits the ability to interpret the effects of current smoking on a clinical outcome, and nothing can be done to address a prior tobacco use history. However, defining exposure according to *current* smoking status allows for the analysis of potentially reversible effects as well as for the potential implementation of smoking cessation to prevent the adverse outcomes of smoking on cancer patients. The primary focus for the remainder of this chapter will be on *current* smoking and will include a discussion of methods to address tobacco use with the cancer patient through accurate assessments and structured tobacco cessation support.

THE CLINICAL EFFECTS OF SMOKING ON THE CANCER PATIENT

Cancer treatment is generally defined according to disease site, stage, treatment type (e.g., surgery, chemotherapy [CT], radiotherapy [RT], or biologic therapy), and primary treatment objective, such as cure or palliation. A comprehensive discussion of the effects of smoking on cancer patients is beyond the scope of a single chapter, but the 2014 SGR provides an excellent evidence base, concluding that “the evidence is sufficient to infer a causal relationship between cigarette smoking and adverse health outcomes.”⁷ Overall, approximately 75% to 80% of studies in the SGR demonstrated a negative association between smoking and outcome, with approximately 65% to 70% of studies demonstrating statistically significant negative associations. This chapter will provide an illustrative review of studies that demonstrate the adverse effects of tobacco across disease sites and treatment modalities (e.g., surgery, CT, RT), and effects will be discussed across the categories of *mortality, recurrence and cancer-related mortality, toxicity, and risk of a second primary cancer*. Evidence for the benefits of smoking cessation will also be presented within each section.

The Effect of Smoking on Overall Mortality

Substantial evidence demonstrates that current smoking by cancer patients increases the risk of overall mortality across virtually all cancer disease sites and for all treatment modalities. Currently smoking significantly increased the risk of overall mortality by

between 17% to 38% as compared with never, former, and recent quit smokers in a large cohort of patients across 13 disease sites.⁷¹ Similar but larger observations were noted in elderly current smokers from a separate cohort (hazard ratio [HR], 1.72, 95% confidence interval [CI], 1.23 to 2.42).⁷² A large analysis of over 20,000 patients treated with surgery demonstrated that current smoking increased mortality by 62% in gastrointestinal cancer patients and by 50% in thoracic cancer patients with a nonsignificant trend in urologic cancer patients.⁷³ Several larger studies with at least 500 patients demonstrated that current smoking increases mortality in head and neck cancer,⁷⁴⁻⁷⁷ breast cancer,⁷⁸⁻⁸¹ gastrointestinal cancers,^{82,83} prostate cancer,⁸⁴⁻⁸⁷ renal cancer,⁸⁸ gynecologic cancers,^{89,90} and lung cancer.⁹¹⁻¹⁰² Smaller studies demonstrate similar effects for hematolymphoid cancers such as leukemia and lymphoma.^{103,104} Studies suggest that the effects of current smoking on mortality may be dose and time dependent, with higher risks in heavier smokers^{105,106} and lesser risks in patients whose time since quitting was longer.¹⁰⁵

Whereas many reports rely on retrospective chart reviews, several prospective studies demonstrate that current smoking increases mortality.⁷¹ Browman et al.¹⁰⁷ was one of the first prospective studies to demonstrate that current smoking increased mortality by 2.3-fold in patients who continued to smoke during RT as compared with nonsmokers. Results from Radiation Therapy Oncology Group (RTOG) 9003 and 0129 cooperative group trials demonstrated that current smoking increased mortality in advanced head and neck cancer patients treated with RT or concurrent chemoradiotherapy (CRT),¹⁰⁸ with a similar effect noted in 165 cervical cancer patients treated with CRT.¹⁰⁹ In the randomized retinoid chemoprevention trial of 1,190 early stage head and neck cancer patients, current smoking increased mortality by 2.5-fold.¹¹⁰

Numerous studies have demonstrated that current smoking increases overall mortality as compared with former and never smokers combined.^{72,75,76,101,102,107,108} The adverse effects of smoking compared with former and never smokers not only reflect the negative effects of smoking on mortality as a whole, but also demonstrate that the effects of smoking are reversible. Current smoking increased mortality risk as compared with patients who quit within the year⁷¹ or 1 to 3 months prior to diagnosis.^{111,112} Furthermore, in 284 limited-stage small-cell lung cancer patients, patients who quit smoking at or following a cancer diagnosis had a 45% reduction in mortality as compared with current smokers.¹¹³ These studies suggest that the effects of smoking on mortality are reversible.

Collectively, these studies provide significant data associating current smoking with increased overall mortality across most disease sites, tumor stages, treatment modalities, and in both traditionally tobacco-related as well as nontobacco-related cancers. The potential significance of smoking is perhaps best exemplified by Bittner et al.,¹¹⁴ who analyzed causes of death in prostate cancer patients and demonstrated that more than 90% died of causes other than prostate cancer, but that current smoking increased the risks of non-prostate cancer deaths between 3- and 5.5-fold. As a result, tobacco use and cessation may be of paramount importance to cancers with high cure rates, such as prostate cancer or breast cancer, simply because patients may be at the most risk of death from noncancer-related causes such as heart disease, pulmonary disease, or other diseases related to smoking and tobacco use.

The Effect of Smoking on Cancer Recurrence and Cancer-Related Mortality

The primary objective of cancer therapy is to cure cancer and prevent recurrence. However, smoking has been shown to increase cancer recurrence and cancer-related mortality. Across a broad spectrum of cancer patients, current smoking increased cancer mortality as compared with former and never smokers.⁷¹ Current smoking has been shown to increase cancer mortality in patients with head and neck cancer,^{108,115-118} breast cancer,^{78,119}

gastrointestinal cancers,^{82,120,121} prostate cancer,^{41,84,122} gynecologic cancers,^{89,90,106,123-125} and lung cancer.¹²⁶ Cancer recurrence, whether local or metastatic, is a key driver behind cancer-related mortality. Several studies demonstrate that current smoking increases the risk of recurrence and decreases response across multiple disease sites.^{76,84,107,127,128} The effects of smoking on increasing recurrence or cancer-related mortality have also been reported in several relatively rare cancers.^{120,129} In a remarkable report of patients with recurrent head and neck cancers treated with salvage surgery, continued smoking after salvage treatment continued to increase the risk of yet another recurrence by 42%.¹³⁰ The striking nature of this last study highlights the continued risks even in recurrent cancer patients and the resilience with which some cancer patients will continue to smoke.

The effects of smoking are also noted in premalignant lesions. In patients with high-grade vulvar intraepithelial neoplasia, current smoking increased the risk of persistent disease after therapy by 30-fold.¹³¹ In a prospective trial of progesterone to treat cervical intraepithelial neoplasia (CIN), current smoking increased the risk of progression as compared with former and never smokers combined.¹³² A prospective trial of 516 low-grade cervical intraepithelial neoplasia patients demonstrated that current smoking decreased response by 36%, although a similar effect was also noted in former smokers.¹³³

As noted with overall mortality, several studies demonstrated that the effects of current smoking are worse than the effects of former smoking^{76,86,89,109,127,134-136,137} and that the effects of smoking may be acutely reversible. Several studies also demonstrate that current smoking increases recurrence or cancer mortality, whereas former smoking has no significant effect.^{41,78,82,84,85,119,122-124,138}

The acutely reversible effects of smoking were shown by Browman et al.¹³⁹ who demonstrated that continued smoking increased the risk of cancer-related mortality by 23% as compared with patients who quit within 12 weeks of starting RT. In 284 colorectal cancer patients, smoking at the first postoperative visit increased the risk of cancer mortality by 2.5-fold as compared with all other patients suggesting that smoking after treatment significantly predict for adverse outcome.¹²¹ In a notable study of over 1,400 prostate cancer patients treated with surgery, continued smoking 1 year after treatment increased the risk of recurrence 2.3-fold, but quitting smoking 1 year after treatment did not confer an increased risk of recurrence.¹²⁸ Chen et al.¹³⁸ demonstrate that patients who continue to smoke before and following a bladder cancer diagnosis have an increased risk of recurrence as compared with patients who quit in the year prior to diagnosis or within the first 3 months after diagnosis. The reversible effects of smoking on recurrence and mortality are consistent with observations on overall mortality and continue to emphasize the benefit of tobacco cessation for cancer patients who smoke at diagnosis.

The Effect of Smoking on Cancer Treatment Toxicity

Discussion of the effects of smoking on cancer treatment toxicity is highly dependent upon disease site, treatment modality (e.g., surgery, CT, RT), and timing of toxicity. Across disease sites and treatments, current smoking has been shown to increase complications from surgery,¹⁴⁰⁻¹⁴⁹ pulmonary complications,^{150,151} toxicity from RT,^{117,152-156} mucositis,¹⁵⁷ hospitalization,¹⁵⁸ and vasomotor symptoms.¹⁵⁹ One of the largest recent studies in over 20,000 gastrointestinal, pulmonary, and urologic patients demonstrates that former or current smoking increased the risk of surgical site infection, pulmonary complications, or 30-day mortality in a site-specific manner.⁷³ The effects of current smoking were most significant for pulmonary complications where former smoking had a lesser or nonsignificant effect. In 13,469 lung cancer patients treated with surgery, current smoking increased the risk of postoperative death with no increased risk in former smokers.¹⁶⁰ Current

smoking increased the risk of complications, morbidity, or reoperation following esophagectomy, pancreatectomy, or colorectal surgery.^{161–163} A study of 836 prostate cancer patients treated with RT demonstrated that current smoking increased abdominal cramps, rectal urgency, diarrhea, incomplete emptying, and sudden emptying between two- and nine-fold,¹⁶⁴ with similar effects noted in 3,489 cervical cancer patients who smoked more than 1 pack per day (PPD).¹⁵⁶

Several studies have demonstrated that the effects of smoking on cancer treatment toxicity are reversible. Stopping smoking within 3 weeks of surgery reduced wound healing complications in esophageal cancer patients treated with surgery and reconstruction.¹⁶⁵ In 393 T1 laryngeal cancer patients treated with RT, quitting smoking after diagnosis reduced laryngeal complications as compared with continued smoking.¹⁵² In a large study of 7,990 lung cancer patients from the Society of Thoracic Surgeons Database, current smoking increased the risk of pulmonary complications by 80% and hospital mortality 3.5-fold.¹⁵¹ However, smoking cessation for 2 weeks eliminated the risks for pulmonary complications, and cessation for 1 month eliminated risks for hospital mortality. Vaporciyan et al.¹⁶⁶ also showed that current smoking increased the risk of pulmonary complications 2.7-fold as compared with smoking cessation for at least 1 month prior to surgery. In a striking example of the potentially reversible effects of smoking in 205 head and neck cancer patients treated with RT,¹⁶⁷ 43% of smoking patients treated in the morning experienced Grade 3+ mucositis compared with 72% of smokers treated in the afternoon ($p = 0.04$). These data suggest that reducing smoking overnight may yield a clinical benefit in reduced toxicity. Whereas all toxicity may not be acutely reversed, these encouraging data show that patients can make clinically meaningful improvements in their health and/or cancer treatment within a short time frame by quitting smoking.

The Effect of Smoking on Risk of Second Primary Cancer

Several studies have reported the effects of smoking on the risk of developing a second primary cancer. Park et al.¹⁶⁸ reported on over 14,000 male cancer patients and demonstrated that current smoking increased the risk of developing a second tobacco-related primary cancer twofold, with no increased risk in former smokers. A higher risk was observed in head and neck cancer patients who smoked more than 10 cigarettes per day, with no increased risk in lighter smokers.¹⁶⁹ Kinoshita et al.¹⁷⁰ showed an 82% increased risk of developing a second primary in gastric cancer patients who are current smokers with no increased risk in former smokers. In the phase III randomized trial of isotretinoin for the prevention of a second primary tumor in 1,190 head and neck cancer patients, current smoking increased the risk of a second primary by 2.2-fold with a nonsignificant trend of 1.6-fold in former smokers.¹¹⁰ Notably, 39% of patients who reported quitting within the previous year were biochemically confirmed smokers.¹⁷¹ As a result, these data collectively suggest that some of the increased risk may be biased by continued smoking in patients who deny smoking by self-report.

The effects of smoking on the risk of a second primary cancer are also noted in nontobacco-related cancers and in long-term survivors. In 835 breast cancer patients, smoking increased the risk for the development of lung metastases after breast cancer by more than threefold.¹⁷² Ford et al.¹⁷³ demonstrated that breast cancer patients who were former smokers had a threefold increased risk of developing lung cancer, but that current smokers had a 13-fold increased risk. In nearly 1,100 estrogen receptor (ER)-positive breast cancer patients, current smokers had a 1.8-fold increased risk of developing a second contralateral breast cancer, and current smokers at most recent follow-up had a 2.2-fold increased risk, but former smoking at the diagnosis or most recent follow-up had no increased risk.¹⁷⁴ In 2,700 5-year survivors of testicular cancer,

current smokers had a 1.8-fold increased risk of developing a second primary as compared with all other survivors.¹⁷⁵

There are some studies suggesting that smoking, combined with cytotoxic therapy, may have an additive or synergistic effect on the risk of developing a second primary cancer. In 9,780 prostate cancer patients from the Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) study, RT increased the risk of bladder cancer by 1.6-fold, smoking increased the risk by 2.1-fold, and smoking combined with RT increased risk by 3.7-fold.¹⁷⁶ In ER-positive breast cancer patients, treatment with RT had no significant effect on the risk of developing a contralateral breast cancer, but RT combined with current smoking increased the risk of contralateral cancer by ninefold.¹⁷³ In a detailed analysis of Hodgkin lymphoma patients, nonheavy smokers (defined as never, former, and less than one PPD) had a second primary relative risk of between fourfold and sevenfold when treated with CT or RT as compared with patients who received no RT or CT.¹⁷⁷ However, heavy smokers had a sixfold increased risk in the absence of RT and CT and a 17- to 49-fold increased risk when combined with RT and/or CT. These observations suggest that smoking combined with cytotoxic cancer therapy may complement the risk of developing a second primary cancer perhaps through the promotion of mutations induced by CT and/or RT in the presence of tobacco smoke. The potential mechanisms of this effect have not been tested or defined at this time, but the mechanism of tobacco-induced carcinogenesis in prior reports³ supports these observations.

Human Papilloma Virus, Epidermal Growth Factor Receptor, Anaplastic Lymphoma Kinase, Programmed Cell Death Protein 1, and Smoking

Data over the past decade has shown that head and neck cancers that are human papilloma virus (HPV) positive are known to have an improved prognosis as compared with HPV-negative tumors.¹⁷⁸ Patients who have HPV-positive tumors typically have increased p16 expression and often respond better to conventional cancer therapy, including RT and CT. Many HPV-positive patients are never smokers or have a lighter smoking history. However, smoking was an independent adverse risk factor for both overall and cancer-related mortality with a 1% increase in risk per pack-year smoked.¹⁷⁸ Current smoking increased cancer mortality approximately fivefold even in p16-positive patients treated with surgery.¹¹⁵ Smoking also increased the risk of developing second primary cancer in both HPV-positive and HPV-negative patients.¹⁷⁹ As a consequence, the presence of HPV does not appear to negate the adverse effects of smoking.

A similar effect is noted in lung cancer patients with epidermal growth factor receptor (EGFR)-mutated or anaplastic lymphoma kinase (ALK)-mutated tumors. As with HPV-positive head and neck cancer patients, lung cancer patients who are light or never smokers have a higher rate of EGFR-positive tumors that may respond to biologic therapy using EGFR tyrosine-kinase inhibitors. At this time, most information regarding EGFR-based therapy for lung cancer reports on the effects of ever smoking demonstrating that ever smokers have a decreased response to EGFR therapy. Early, large, randomized trials demonstrate that Tarceva (erlotinib) and Iressa (gefitinib) provide survival and tumor control benefits specifically in never smokers.^{180,181} A very similar pattern is noted for ALK-positive patients with a much higher incidence in never smokers and high response rate to the ALK kinase inhibitor crizotinib.¹⁸² Paik et al.¹⁸³ have described the importance of driver mutations in EGFR, ALK, and KRAS demonstrating that smokers have a higher preponderance for K-ras drivers, whereas nonsmokers tend to have EGFR or ALK driver mutations. In general, patients who are smokers may be best served with conventional cancer treatments rather than these biologic therapies, but randomized controlled trials confirming this suggestion are lacking at this time.

Although there are essentially no biologic therapies that have shown to have a better response in smokers, there are exciting data presented at the 2013 European Cancer Organization (ECCO) annual conference, suggesting that anti-programmed cell death protein 1 (PD-1)-based therapies may have a better response rate in smokers.¹⁸⁴ These very preliminary data have yet to be replicated or expanded into randomized trials, but if expanded trials prove effective, they may represent one of the only cancer treatments that may specifically benefit smokers.

Summarizing the Clinical Effects of Smoking on the Cancer Patient

Smoking by cancer patients increases mortality, toxicity, recurrence, and the risk of a second primary cancer. There are four important conclusions, and a fifth implied conclusion, to the evidence previously presented:

1. One or more adverse effects of smoking affect all cancer disease sites.
2. One or more adverse effects of smoking affect all treatment modalities.
3. The effects of current smoking are distinct from an ever or former smoking history.
4. Several lines of evidence demonstrate that many of the effects of smoking are reversible.

Although substantial data demonstrate that smoking by cancer patients increases the risk for one or more outcomes, the largest limitations are the lack of standard tobacco use definitions, the lack of assessing tobacco use in cancer patients at follow-up, and the lack of structured tobacco cessation for cancer patients. Importantly, patients may further misrepresent tobacco use. Several studies suggest that approximately 30% of cancer patients who smoke deny tobacco use.^{171,185,186} Marin et al.¹⁸⁷ exemplify the importance of an accurate assessment, demonstrating that patients who self-reported smoking had no significant risk associated with surgical complications; however, biochemical confirmation of smoking significantly increased the risk of surgical wound complications. This highlights the potential discrepancy between the effects of smoking based on subjective versus biochemically confirmed assessments. Due to this discrepancy, the *fifth implied conclusion* is that the adverse effects of smoking and the benefits of cessation may be more pronounced than currently reported in the literature.

ADDRESSING TOBACCO USE BY THE CANCER PATIENT

National Oncology Association Statements and Clinical Practice Guidelines

Professional societies are taking leadership roles in recognizing the need to assess patients' tobacco use and to examine the effects of tobacco use in medical treatment, including the important role of tobacco cessation. The American Medical Association (AMA) passed a resolution supporting documentation of smoking behavior in clinical trials, from trial registration through treatment, follow-up, and to end of the study or death.¹⁸⁸ The Oncology Nursing Society (ONS) has also advocated for assessment and cessation.^{189,190} Both the AACR^{3,191} and ASCO^{6,192} have issued policy statements specifically addressing tobacco use in cancer patients, detailing that clinicians have a responsibility to address tobacco use, that all patients should be screened, that all patients who use tobacco should receive evidence-based tobacco cessation support, and that tobacco use should be included in clinical practice and research. These provide strong counsel to address tobacco use in the general population as well as in cancer patients.

Smoking Cessation Guidelines

Overall, the approach to tobacco cessation for the cancer patient is very similar to the approach for the general population. However, there are a few specific details that are important to consider when approaching the cancer patient who smokes. It is important to recognize that virtually all newly diagnosed cancer patients are faced with a life-changing diagnosis that will require intensive treatment approaches. Treatments, toxicity, and outcomes differ according to disease site and treatment modality. Whereas some cancer patients may have a curable cancer, others may have incurable cancer. Smoking in cancer patients is also often associated with comorbid psychiatric diseases, such as depression, that may affect dependence.¹⁹³ The urgency of cessation is also important to consider. If smoking decreases the efficacy of cancer treatment, then every effort should be made to stop tobacco use as soon as possible rather than choosing a quit date several weeks or months after a cancer diagnosis. Patients may also be burdened with a "stigma" associated with certain tobacco-related cancers,¹⁹³⁻¹⁹⁷ where they may be viewed by others, or themselves, as causing their cancer due to tobacco use. As a result, the rationale and motivation for quitting tobacco use likely differs among cancer patients, but there is a consistent theme that exists. (1) All patients should be asked about tobacco use with structured assessments; (2) all patients who use tobacco or are at risk for relapse should be offered evidence-based cessation support; and (3) tobacco assessment and cessation support should occur at the time of diagnosis, during treatment, and during follow-up for all cancer patients.

Empiric treatment of tobacco use by cancer patients is fundamentally supported by Public Health Service (PHS) Guidelines that are based on evidence from tobacco cessation efforts in non-cancer patients. Originally issued in 1996 and renewed in 2008, *The Clinical Practice Guideline: Treating Tobacco Use and Dependence* is a PHS-sponsored, evidence-based guideline designed to assist health-care providers in delivering and supporting effective smoking cessation treatment.^{198,199} The basic recommendation states that clinicians should consistently identify, document, and treat every tobacco user seen in a health-care setting. Details of cessation support range from brief to intensive intervention, but emphasize that consistent repeated cessation support and even brief counseling are effective methods to assist patients with stopping tobacco use. It is important to note that physician-delivered interventions significantly increase long-term abstinence rates.¹⁹⁹ Included are newer effective medication options and strong support for counseling and the use of quit lines as effective intervention strategies. As described in the PHS Guidelines, the principal steps in conducting effective smoking cessation interventions are referred to as The 5 A's:

1. *Ask* about tobacco use for every patient.
2. *Advise* every tobacco user to quit.
3. *Assess* the willingness of patients to quit.
4. *Assist* patients with quitting through counseling and pharmacotherapy.
5. *Arrange* follow-up cessation support, preferably within the first week after the quit date.

There is a strong evidence base for these interventions as documented in the clinical practice guideline.¹⁹⁹

Implementing Smoking Cessation Into Clinical Practice

An algorithm is provided to guide clinicians in implementing the five A's into clinical cancer care (Fig. 31.1).^{5,45,194,199} Included in the algorithm are suggested questions that are useful to accurately assess tobacco use by cancer patients where patients can generally be divided into *current*, *former*, or *never* smokers. The first step (ASK) is to inquire about and document tobacco use behaviors for every

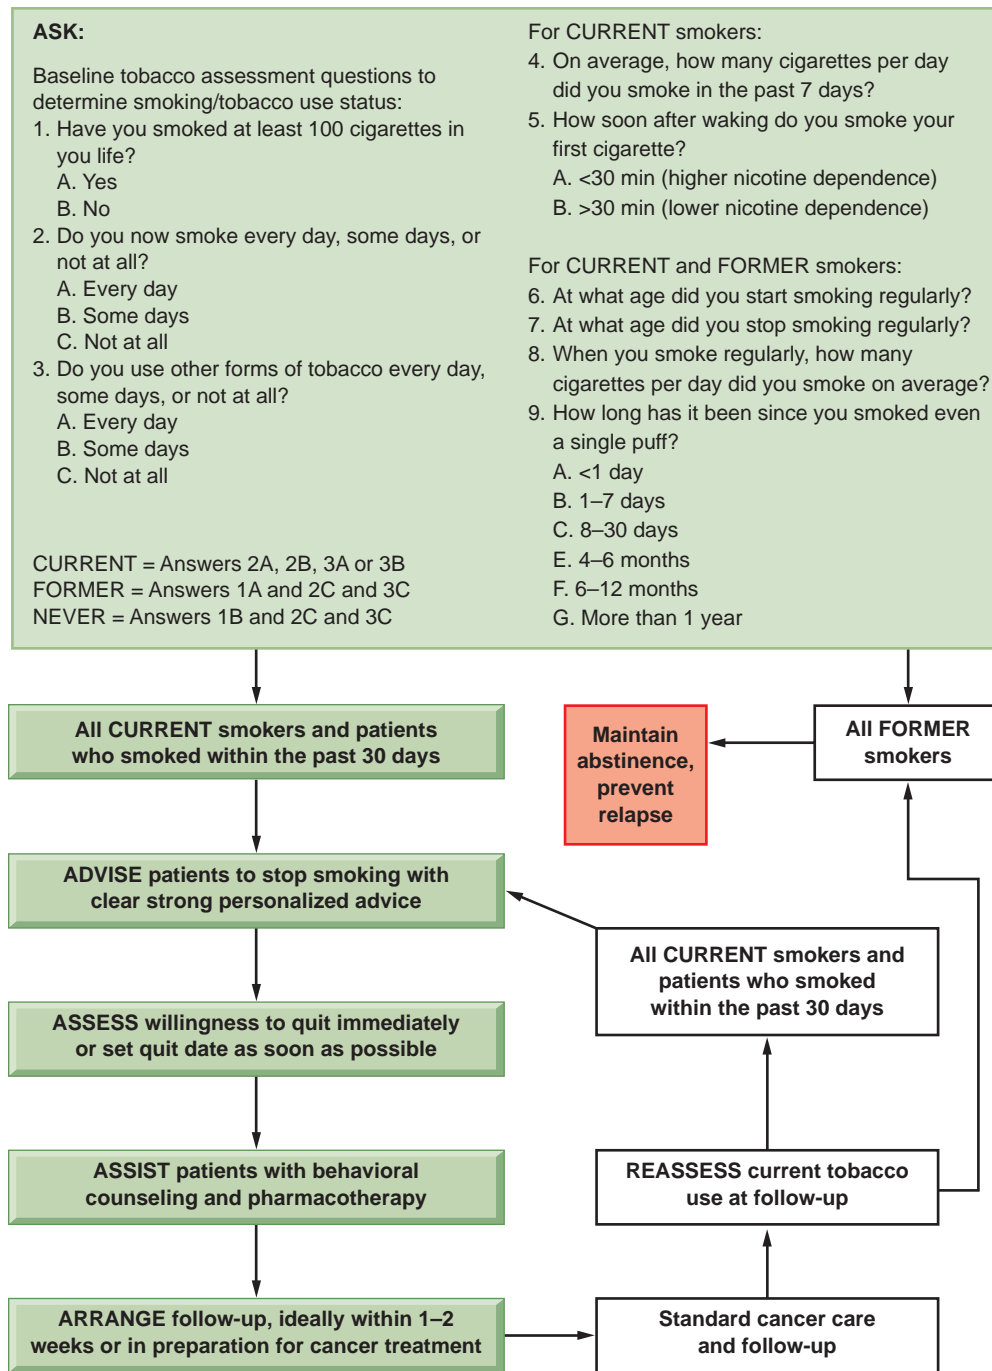

Figure 31.1 This 5 A's screening and smoking cessation treatment schema for cancer patients may be integrated into clinical oncology practice.

patient at every visit including follow-up visits. Whereas a more comprehensive evaluation is necessary at the first consult, only updates to current tobacco use are needed at follow-up. Including smoking status assessments as a “vital sign” for all patients significantly increases the identification and treatment for patients.²⁰⁰ Tobacco-use status stickers on paper charts or an automated reminder system for electronic records can increase compliance with tobacco assessments.⁴⁵ With the recent Meaningful Use standards that were implemented in 2011, hospitals using an electronic medical record (EMR) are essentially required to document tobacco use.²⁰¹ A recent report utilized the EMR to implement mandatory tobacco assessments in cancer patients demonstrating that just a few questions at the initial evaluation and at follow-up could yield high referral.

Less than 1% of referrals were delayed when assessments were repeated on a monthly basis rather than at every clinic visit.⁴⁵ These findings reduce the clinical burden and patient fatigue associated with repeated assessments as frequently as every day such as in patients who are treated with daily RT or CT.

At the time of this chapter release, there were no national guidelines for implementation of specific questions to assess tobacco use in cancer patients. However, Figure 31.1 provides effective questions for assessing tobacco use in cancer patients based on advice from published reports.^{5,45,194,199} Current, former, and never smokers are identified in a structured manner. Patients who use tobacco within the past 30 days should have structured support to quit tobacco use, maintain abstinence, and prevent relapse.

Although not explicitly stated by any specific guidelines, asking about tobacco use in family members of cancer patients may be important because family members often support cancer patients during and following treatment, but continued smoking by family members can make quitting much more difficult.^{202–204}

Advising is the second step in promoting effective tobacco cessation that involves giving clear, strong, and personalized advice to stop tobacco use. This advice should include the importance of quitting smoking, such as explicit information on the risks of continued smoking and the benefits of cessation for cancer treatment outcomes and overall health regardless of cancer diagnosis. This includes a discussion of how it is not “too late” to quit and that quitting will in fact benefit their cancer treatment efficacy and cancer outcome.⁵ Patients can also consider the cost savings of stopping a smoking habit. Clinicians must be particularly sensitive to avoid contributing to any perceived blame for the patient’s illness.^{195–197,205}

Clinicians must remember that most patients started smoking in adolescence and did not completely understand the risks associated with tobacco use. At the same time, the severe addiction associated with chronic tobacco use makes it difficult to stop.

The next step is *assessing* dependence and willingness to quit. Asking “How soon after waking do you smoke your first cigarette?” assesses nicotine dependence, with high dependence associated with a shorter interval between waking and the first cigarette.²⁰⁶ Nicotine dependence is predictive of smoking cessation outcomes and can be used as a good indicator of the intensity of cessation treatment needed, such as the need for pharmacotherapy.^{207,208} Determining the patient’s motivation and interest in quitting are critical parameters that influence the types of intervention strategies to be employed. Different strategies for quitting are based on the transtheoretical model of change and motivational interviewing stance, which recognizes that unique intervention messages and strategies are needed to optimally promote smoking cessation based on a patient’s readiness to quit smoking.^{209,210} In the general population, recommendations encourage that clinicians set a target quit date within 30 days. However, for cancer patients, the reader is encouraged to consider an urgent need to stop smoking immediately. If patients are unable to quit immediately, then patients should be encouraged to immediately reduce tobacco use and to set a quit date as soon as possible based on the typical need to start cancer treatment in the immediate future.

Assisting patients with smoking cessation involves clinicians helping the patient design and implement a specific quit plan or broadly enhancing the motivation to quit tobacco. Promoting an effective quit strategy for cancer patients should consist of (1) setting a quit date (immediately or as soon as possible), (2) removing all tobacco-related products from the environment (e.g., cigarettes, ashtrays, lighters), (3) requesting support from family and friends, (4) discussing challenges to quitting, and (5) discussing or prescribing pharmacotherapy where appropriate. Patients should also be provided information on cessation support services (Table 31.1). In the cancer setting, patients can also be informed that smoking cessation is a critical component of cancer care over which they have complete control, thereby conferring some personal control over their cancer care.

Patients who are unwilling to quit should continue to receive repeated assessments and counseling to help motivate patients to quit smoking. These patients should be encouraged to make immediate reductions in tobacco use and work toward abstinence as soon as possible. Clinician education, reassurance, and gentle encouragement can help them to consider changing their smoking behaviors. Specific strategies include discussing the personal relevance of smoking and benefits to cessation, providing support and acknowledging the difficulty of quitting, educating patients about the positive consequences of quitting smoking, and discussing available pharmacologic methods to assist with quitting.²¹¹ The emphasis should be placed on patient autonomy to quit. Motivational strategies for patients unwilling to quit can be employed (e.g., asking open-ended questions, providing affirmations,

reflective listening, summarizing).^{198,210,212,213} Table 31.2 provides suggested methods to help clinicians promote tobacco cessation.

The final step in a clinician-delivered smoking cessation intervention involves *arranging* a follow-up contact with the patient. Ideally, cancer patients will follow an immediate quit strategy and follow-up should occur preferably within 1 to 2 weeks. However, a short-term follow-up may also benefit patients who are reluctant to quit smoking. The clinician must remember that a new cancer diagnosis is stressful and patients may rely on continued smoking to

TABLE 31.2

Select Treatment Strategies Used for Tobacco Cessation Treatments

Provide and monitor the use of nicotine replacement or other pharmacotherapy.
Provide education regarding the health effects of tobacco use and its addictive and relapsing nature.
Identify and change environmental and psychological cues for tobacco use.
Generate alternative behaviors for tobacco use.
Assist in optimization of social support for cessation efforts and address tobacco use in family members.
Prevent relapse including the identification of future high-risk situations and plans for specific behaviors in those situations.
Provide motivational interventions as needed throughout treatment.
Identify relaxation techniques such as guided imagery and progressive muscle relaxation.
Provide behavioral strategies to address depressed mood (e.g., increasing pleasurable activities).
Provide crisis intervention including appropriate referrals and emergency intervention if indicated.
Recognize and congratulate patients on success with reducing and/or quitting smoking.

relieve stress, but after absorbing the psychological effects of a new cancer diagnosis, patients may be more receptive to smoking cessation. During follow-up, clinicians should congratulate patients on successful cessation efforts, discuss accomplishments and setbacks, and assess pharmacotherapy use and problems. Patients should not be criticized for returning to smoking; rather, it is critical to create a supportive environment for patients to communicate progress, failure, and personal needs. Framing relapses as a learning experience can be helpful, and patients should be encouraged to set another quit date. Referrals to a psychologist or professionally trained smoking cessation counselor should be considered for patients with numerous unsuccessful quit attempts, comorbid depression, anxiety, additional substance abuse disorders, or inadequate social support.

Clinicians who are not well versed in tobacco cessation should realize that smoking is an extremely difficult addiction to overcome and should recognize the clinical pattern associated with cessation. As patients stop smoking, many will experience symptoms of withdrawal, including dry or sore throat, constipation, cravings to smoke, irritability, anxiety, trouble concentrating, restlessness, increased appetite, depression, and insomnia. In the first few weeks, patients may also report an increase in mucous secretions from the airways, a cough, and other upper respiratory tract symptoms. Patients and clinicians should realize that tobacco cessation requires a concerted effort, may require repeated attempts, and symptoms will not resolve immediately. Clinicians should counsel patients on a repeated basis, recognize success, and provide repeated assistance if patients relapse.

Pharmacologic Treatment for Smoking Cessation

The principles of pharmacotherapy to help patients quit smoking are fundamentally based on reducing the craving associated with nicotine withdrawal. Nicotine replacement therapy (NRT), in the

form of patches, lozenges, inhalers, sprays, and gum, varenicline (Chantix), and bupropion (Zyban) are the three principal first-line pharmacotherapies recommended for use either alone or in combination according to PHS Guidelines.¹⁹⁹ Table 31.3 presents information on these first-line agents. Nicotine is the primary addictive substance in tobacco and NRT facilitates smoking cessation by reducing craving and withdrawal that smokers experience during abstinence. NRT also weans smokers off nicotine by providing a lower level and, in some cases, slower infusion of nicotine than smoking.²¹⁴ Strong evidence from over 100 randomized clinical trials support the use of NRT to increase the odds of quitting approximately twofold as compared with placebo.²¹⁵ Pooled analyses demonstrate that 17% of smokers receiving NRT were able to quit versus 10% with placebo after at least 6 months. Recent evidence further shows that combination therapy, or dual NRT (such as a nicotine patch and lozenge), is a very effective smoking cessation therapy that produces high quit rates.^{216,217} Data suggest that activation of the nicotinic acetylcholine receptor (nAChR) may promote tumor development,²¹⁸ but evidence suggests that the negative aspects of smoking outweigh these concerns.^{219,220} Furthermore, there are no clinical trials reporting negative outcomes for NRT in cancer patients as related to mortality or recurrence. Studies also demonstrate that NRT is not associated with an increased risk of carcinogenesis in the general population.^{221,222} As a result, NRT should be used as a clinically proven method to help cancer patients stop smoking.

Antidepressants have been studied as non-nicotine-based pharmacotherapy in part due to depression and psychiatric disease being comorbid conditions in smokers.²²³ Bupropion (Zyban) is currently the only FDA-approved antidepressant for the treatment of tobacco dependence.¹⁹⁹ Bupropion inhibits the reuptake of both dopamine and norepinephrine, thereby increasing dopamine and norepinephrine concentrations in the mesolimbic systems.^{12,224} Bupropion also antagonizes the nAChR, thereby lowering the rewarding effects of nicotine.²²⁵ Should an abstinent smoker relapse, bupropion may function to reduce the pleasure of cigarette smoking experienced by the smoker²²⁶ and help to prevent further relapse. A meta-analysis found that smokers who received bupropion were twice as likely as those who received placebo to have achieved long-term abstinence at either a 6- or 12-month follow-up.²²⁷

Varenicline (Chantix) is a $\alpha 4\beta 2$ nAChR partial agonist that produces sustained dopamine release in the mesolimbic system that received FDA approval for treating tobacco dependence in 2006. Sustained dopamine release maintains a normal systemic level of the neurotransmitter, which helps to reduce craving and withdrawal during abstinence.²²⁸ Varenicline also antagonizes the rewarding effects of nicotine. Because varenicline attenuates the pleasure smokers experience from smoking, it may decrease motivation to smoke and protect them from relapse. One of the initially reported randomized clinical trials that compared varenicline (2 mg), bupropion (300 mg), and placebo showed that varenicline was superior to bupropion and placebo, with overall continuous abstinence rates between 10% to 23%.²²⁹ A meta-analysis demonstrated that the 1-mg daily dose approximately doubled, whereas the 2-mg daily dose approximately tripled the likelihood of long-term abstinence at 6 months as compared to placebo.¹⁹⁹ As a result, the 1-mg daily dose can be considered as an alternative should the patient experience significant dose-related side effects. Several meta-analyses have shown that varenicline is superior to bupropion and placebo in the general population.^{230–233}

In July 2009, the FDA issued a warning after reports that some patients attempting to quit smoking while using varenicline or bupropion experienced unusual changes in behavior, depressed mood, worsening of depression, or had thoughts of suicide. This has prompted recommendations that health-care providers elicit information about a patient's psychiatric history prior to prescribing varenicline or bupropion to closely monitor changes in mood and behavior during the course of treatment. However,

TABLE 31.3

First-Line Pharmacotherapy Agents for the Treatment of Nicotine Dependence

Agent	Dose	Mechanism	Use
Nicotine Replacement			
Transdermal (patches)	16 h or 24 h 7, 14, or 21 mg 1 patch/d	Steady state NRT to reduce craving and withdrawal	6–10 CPD: 14 mg daily × 8 wks then 7 mg daily × 2 wks >10 CPD: 21 mg daily × 6 wks, then 14 mg × 2 wks, then 7 mg × 2 wks
Gum	2 or 4 mg Max: 24 pieces/d	Short-term NRT to reduce craving and withdrawal	First cigarette >30 min after waking: 2 mg PO q1–2 hr First cigarette <30 min after waking: 4 mg PO q1–2 hr
Lozenge	2 or 4 mg Max: 20 lozenges/d	Short-term NRT to reduce craving and withdrawal	1st cigarette >30 min after waking: 2 mg PO q1–2 hr 1st cigarette <30 min after waking: 4 mg PO q1–2 hr
Nasal spray	0.5 mg/spray Max: 10 sprays/hr or 80 sprays/d	Short-term NRT to reduce craving and withdrawal	1 spray/nostril q1–5 hr
Inhaler	4 mg/cartridge Max: 16 cartridges/d	Short-term NRT to reduce craving and withdrawal	1 cartridge inhaled over 20 min q1.5–6 hr
Bupropion (Zyban)	150 mg	Block nicotinic receptors and reduces reward	1 tablet daily × 3 d, then 1 tablet twice daily for 7–12 wks
Varenicline (Chantix)	0.5 or 1 mg	Dopaminergic reward and partial nicotinic receptor antagonist	0.5 mg daily × 3 d, then 0.5 mg twice daily × 3 d, then 1 mg twice daily

CPD, cigarettes per day; PO, by mouth; NRT, nicotine replacement therapy.

updated recent safety studies examining very large databases (one database of N = 119,546, one database of N = 35,800) regarding safety have shown no difference in neuropsychiatric side effects between varenicline or bupropion as compared to NRT and no increased risk of depression.^{234,235} Another prospective study showed no adverse events when treating participants with current or past major depression and also showed higher abstinence rates for the varenicline group as compared to placebo at weeks 9 to 52 (20.3% versus 10.4%, $p < 0.001$).²³⁶ Varenicline should be considered a viable cessation pharmacotherapy for cancer patients.

The clinical practice guideline also identifies two non-nicotine-based medications—clonidine and nortriptyline—as second-line pharmacotherapies for tobacco dependence. A second-line agent is used when a smoker cannot use first-line medications due to either contraindications or lack of effectiveness. Both clonidine, an antihypertensive, and nortriptyline, a tricyclic antidepressant, have been shown to effectively assist smokers achieve abstinence.^{227,237} Unfortunately, many patients who quit will eventually relapse, and rates of long-term abstinence remain low. Because smoking poses enormous health risks to individuals and their families, even a modest reduction in smoking may translate into a significant impact on public health. Clinicians should continue to encourage recalcitrant smokers to stop tobacco use and use pharmacotherapy where appropriate with repeated quit attempts.

Empirically Tested Cessation Interventions with Cancer Patients

The overwhelming majority of cessation research has been performed in the general population, but there are several studies that have been performed in cancer patients. Gritz et al.²³⁸ conducted the first physician- or dentist-delivered randomized cessation

intervention comparison in 186 newly diagnosed head and neck cancer patients. Patients were treated with either minimal advice or an enhanced intervention with trained clinicians consisting of strong personalized advice to stop smoking, a contracted quit date, tailored written materials, and booster advice sessions. No significant differences were found between treatments, but a 70.2% continuous abstinence rate was found at 12-month follow-up regardless of treatment condition, suggesting that many cancer patients can benefit from brief physician-delivered advice. A later study by Schnoll et al.,²³⁹ comparing cognitive behavioral treatment with standardized health education advice, also failed to find significant differences in quit rates. All patients received NRT, and quit rates in both groups approached 50% at 1-month follow-up and 40% at 3-month follow-up.

Additional studies, ranging from 15 to 80 patients, examined nurse-delivered cessation interventions for a variety of cancer patients. The lowest cessation rates were found with a single session intervention: a 21% cessation rate in the intervention group versus 14% in the usual care group 6 weeks' postintervention.²⁴⁰ Higher cessation rates were associated with a more intensive intervention consisting of three inpatient visits, supplementary materials, and five postdischarge follow-up contacts. Additional studies demonstrate higher cessation rates with more intensive intervention (40% to 75%) as compared with usual care (43% to 50%), suggesting more intensive interventions may yield higher cessation rates.^{241–243} In general, more intense interventions appear to be more efficacious, but even brief advice is important to achieve tobacco cessation.

In a randomized trial of 432 cancer patients coordinated by the Eastern Cooperative Oncology Group (ECOG) with a physician-delivered intervention (comprised of cessation advice, optional NRT, and written materials) or usual care (unstructured advice from physicians), there were no significant intervention effects and generally low abstinence rates (12% to 15%

at 6 to 12 months).²⁴⁴ However, patients with head and neck or lung cancer were significantly more likely to have quit smoking compared to patients with tumors that were not smoking related. Analyses of outcomes from the Mayo Clinic Nicotine Dependence Center found that although lung cancer patients were more likely to achieve 6-month tobacco abstinence than controls (22% versus 14%), no significant differences were observed after adjusting for covariates.²⁴⁵ Garces et al.²⁴⁶ also found no significant differences in abstinence rates between head and neck cancer patients and controls (33% versus 26%). However, higher abstinence rates were found for both head and neck and lung cancer patients treated within 3 months of diagnosis compared to those treated for more than 3 months after the diagnosis, emphasizing the potential importance of the *teachable moment* at the time of the cancer diagnosis.

The potential importance of addressing smoking combined with considering comorbid disease has been noted in a few studies. In a randomized head and neck cancer patients of usual care versus 9 to 11 sessions of a nurse-administered intervention consisting of cognitive-behavioral therapy and medications, targeting comorbid smoking, drinking, and depression significantly increased quit rates at 6-month follow-up for the intervention group compared to the usual control group (47% versus 31%, $p < 0.05$).²⁴⁷ In a randomized trial of 246 cancer patients treated with 9 weeks of NRT with or without bupropion, there was no significant difference with the addition of bupropion to NRT, but in patients with depressive symptoms, bupropion increased abstinence rates, lowered withdrawal, and improved quality of life.²⁴⁸ Patients without depression symptoms did equally well when treated with bupropion versus transdermal nicotine and counseling alone.

Patient recruitment has been a problem noted by some studies, including 5.5 years to accrue 246 patients with telephone screening of over 7,500 potential patients.²⁴⁹ A pilot trial of varenicline in thoracic oncology patients required screening 1,130 patients to accrue 49 participants randomized to a 12-week course of either varenicline or placebo paired with a behavioral counseling platform of seven sessions.²⁵⁰ A randomized trial of 185 smoking cancer patients comparing the efficacy of a hospital-based standard care smoking cessation model versus standard care augmented by a behavioral tapering regimen via a handheld device before inpatient hospitalization for cancer surgery demonstrated no difference in quit rates (both 32%).²⁵¹ However, over 29,000 patients were screened to conduct a randomized clinical trial with a smoking cancer patient population. These studies highlight the potential difficulty recruiting participants who smoke, including considerations for the importance of medical comorbidity in guiding smoking cessation treatment, patient mix (multiple tumor sites), treatment status (awaiting treatment to completed treatment), variation in stage of disease, and considering how psychiatric conditions such as depression reflect the difficulty of conducting research in the oncology setting and the importance of these variables in future studies.

Although accruing patients to intervention trials may seem discouraging, several studies demonstrate the benefit of counseling over self-help. Emmons et al.²⁵² conducted a randomized controlled trial in 796 young adult survivors of pediatric cancer that included six calls, tailored and targeted written materials, and optional NRT as compared with self-help. Significantly higher quit rates were found in the counseling group compared to the self-help group at all reported follow-up time points, including 12 months (15% versus 9%; $p < 0.01$). A randomized trial of a motivational interviewing-based smoking cessation intervention in a south Australian hospital was delivered over a 3-month period, consisted of multiple contacts with a trained counselor, and provided supplementary material tailored to cancer patients with NRT.²⁵³ The control group received brief advice to quit and generic supplementary material. Quit rates did not differ by treatment group (5% to 6% at 3-month follow-up), but the intervention group was significantly more likely to report attempts to quit smoking.

Current Tobacco Assessment and Cessation Support by Oncologists

Access to cessation support is critical to address tobacco use by cancer patients. A recent survey of 58 NCI-designated cancer centers indicated that about 80% reported a tobacco use program available to their patients and about 60% routinely offered educational materials, but less than 50% had a designated individual who provided services.²⁵⁴ A recent survey of over 1,500 members of the International Association for the Study of Lung Cancer (IASLC)²⁵⁵ and a parallel study of 1,197 ASCO members²⁵⁶ observed that approximately 90% of physicians believe that tobacco affects outcomes, tobacco cessation should be a standard part of cancer care, and approximately 80% regularly advise patients to stop using tobacco, but only approximately 40% discuss medications or assist with quitting. Dominant perceived barriers to cessation support were patient resistance to treatment, an inability to get patients to quit, a lack of cessation resources, and a lack of clinician education. These data showed that even motivated clinicians are not regularly providing tobacco cessation support. A recent survey of 155 actively accruing cooperative group clinical trials further demonstrated that only 29% of active trials collected any tobacco use information, 4.5% collected any tobacco use information at follow-up, and none addressed tobacco cessation.⁵⁵ Few oncology meetings offer educational workshops or talks, and they are often poorly attended when they are offered.²⁵⁷ Collectively, these data demonstrate that oncologists are not regularly providing cessation support and that we are not capturing tobacco use information that may be critical to understanding the effects of tobacco on cancer treatment outcomes.

More in-person talks as well as written and Web-based training should be made available, as well as new approaches that move from the traditional 5 A's model delivered by a single professional to referral systems that efficiently connect tobacco users to multiple resources for tobacco cessation.²⁵⁸⁻²⁶⁰ The ASCO *Prevention Curriculum* has a chapter devoted to educating oncology health-care professionals on the evaluation and treatment of tobacco use.²¹³ Innovative curricula, such as the Texas Tobacco Outreach Education Program (TOEP), are available and can facilitate program development in other states.²⁶¹ However, specialty programs in tobacco cessation treatment that are based in cancer centers and other medical centers are valuable resources that need to be further developed.

Addressing tobacco use in cancer patients may be approached in a systematic and efficient manner. A recent report highlighted the potential utility of automated tobacco assessment and smoking cessation using structured assessments in the EMR where all patients were automatically referred to a dedicated cessation program consisting of phone-based cessation support.⁴⁵ In 2,700 patients referred for cessation support, half received only a mailing and only 1% contacted the cessation program. However, in the arm with at least five phone call attempts made by the cessation service, 81% of patients were successfully contacted and only 3% refused cessation support. Furthermore, assessments implemented every 4 weeks, rather than more frequent assessments every 2 weeks, resulted in delayed cessation referrals in less than 1% of smokers. This is the first report to try and identify clinically efficient mechanisms of addressing tobacco use that may be useful in clinical practice or research that may be an effective method of increasing patient participation in cessation support, but substantial work is needed to assess who may benefit from low versus high intensity support in such a program.

Examples of Model Tobacco Treatment Programs

Several dedicated tobacco treatment programs at cancer centers have been developed. Table 31.4 contrasts the core elements of

TABLE 31.4

Attributes of Prototypical Tobacco Treatment Programs

four active model programs at the end of 2013 (University of Texas M.D. Anderson Cancer Center, Roswell Park Cancer Institute, Yale Cancer Center, and Memorial Sloan Kettering Cancer Center), each of which employ different methods to help cancer patients quit smoking. All programs follow the evidence-based 5 A's model described previously from PHS Guidelines.¹⁹⁹ All programs were made available to patients at their respective medical centers and are now designed to evaluate and treat all patients who self-report current tobacco use. Importantly, not all cancer centers can treat smoking cessation in the same manner. Financing of a cessation program is critical and may include institutional funds, state funds, research funds, and third-party billing. Notably, given the broad spectrum of adverse health effects associated with smoking, cancer centers should carefully consider the potential health benefits and cost savings associated with tobacco cessation due to reductions in treatment complications and recurrence associated with smoking by cancer patients. There is no one "correct" way to create and sustain a tobacco treatment program at a cancer center, but at the very least and consistent with evidence, rigorous behavioral counseling should be provided and, if possible, medication management as well.

FUTURE CONSIDERATIONS

Research Considerations

The past several years have shown a surge in activities identifying the effects of tobacco in cancer patients and increasing awareness is being developed for cessation support at cancer centers as well as through several national organizations. There are three fundamental areas of research that need to be expanded:

1. *Evaluating the effects of tobacco use and cessation on clinical cancer outcomes.* The 2014 SGR concluded that smoking caused adverse outcomes in cancer patients,⁷ but several limitations remain. Tobacco-use definitions should be standardized and implemented at diagnosis, during treatment, and follow-up. Biochemical confirmation with cotinine or exhaled carbon monoxide may improve the accuracy of tobacco assessment in at-risk groups such as current smokers who are trying to quit or patients who reported quitting in the past year.^{171,185,186,262} Although smoking is the predominant form of tobacco consumption, all tobacco products should be considered. A further understanding of the effects of tobacco on the efficacy and toxicity of cancer treatment, tumor response, quality of life, survival, recurrence,

compliance, second primary, and noncancer-related comorbidity is needed. All cancer disease sites and stages are important to consider.

2. *Understanding the effects of tobacco and cessation on cancer biology.* Although not a primary focus of this chapter, tobacco and tobacco-related products increase tumor growth, angiogenesis, migration, invasion and metastasis and decrease response to conventional cancer treatments such as CT and RT. These and other areas are important to consider, including the potential effects on immune-related therapy and vaccine development. *In vivo* models of exposure and cancer response are not well developed, yet are critical to this research area. Work is also needed to assess the effect of emerging tobacco-related products such as e-cigarettes.
3. *Advance understanding of models to increase access to cessation support and increase efficacy of tobacco cessation methods for cancer patients.* This diverse area includes assessing the timing of intervention, intensity, duration, follow-up, and the potential effects of harm-reduction strategies. Cessation pharmacology requires additional consideration in combination with unique approaches to motivational and behavioral counseling in cancer patients. Significant work is needed to disseminate evidence-based cessation support and to assess the cost-effectiveness of different cessation strategies, particularly with regard to improving the cost of cancer care as a whole. Preventing relapse and evaluating the safety of transition to alternative products such as e-cigarettes is equally important and increasingly complex with the addition of new tobacco-related products. Identifying and addressing barriers to effective cessation support is also needed. As related to the cancer patient, clinicians and cessation specialists should consider how their research relates to cancer care. Taking advantage of new integrated medical management systems presents a significant opportunity to improve cessation support access as well as to develop a more effective tracking of patient outcomes.

Policy Implications and Systematic Issues

Several national and international organizations have emphasized the importance of tobacco assessments and cessation for the general population and for cancer patients that include tools to evaluate tobacco use at diagnosis, during treatment, and follow-up appointments, as well as routine support for smoking cessation.^{5,6,188-191} In 2012, ASCO, with the contribution of the American Legacy Foundation, published a Tobacco Cessation Toolkit for the oncology setting.²⁶³ This evidence-based guideline intends to help

oncology providers integrate tobacco cessation strategies into their patient care. Utilization of the EMR and standardized, automated systems for more efficacious and efficient access to tobacco cessation support has also been suggested,⁴⁵ but requires participation by clinicians, institutions, insurers, and health departments. Not only should providers be aware of the need for tobacco cessation and available interventions, but health-care institutions must also build such treatment into their overall system of care. Thus, the identification of patients who smoke or use any alternative tobacco product, referral or direct treatment by providers, billing and reimbursement for treatment provided, and consistent efforts from professional oncology organizations are critically important.²⁵⁷ The

tremendous public health burden from tobacco-related disability and death has not been countered by a proportional level of funding in tobacco control, cancer treatment research, or public advocacy. Researchers, clinicians, and advocates must come together to persuade policy makers to increase funding in tobacco-related research, treatment, and policy initiatives on behalf of healthy individuals and patients. A united front is critically needed in support of a common agenda that includes both increased tobacco-control efforts and additional funding for disease-related research and treatment. With clinical rationale, guidelines, and advocacy in place, the final steps in effective tobacco control and improving health outcomes are to implement these recommendations into practice.

32 Role of Surgery in Cancer Prevention

José G. Guillem, Andrew Berchuck, Jeffrey F. Moley, Jeffrey A. Norton, Sheryl G. A. Gabram-Mendola, and Vanessa W. Hui

INTRODUCTION

Since the heritable component of some cancer predispositions has been linked to mutations in specific genes, clinical interventions have been formulated for mutation carriers within affected families. The primary interventions for mutation carriers for highly penetrant syndromes, such as multiple endocrine neoplasia (MEN), familial adenomatous polyposis (FAP), hereditary nonpolyposis colorectal cancer (CRC), and hereditary breast and ovarian cancer syndromes, are primarily surgical. This chapter is divided into five sections addressing breast (S.G.A.G.), gastric (J.N.), ovarian and endometrial (A.B.), and MENs (J.F.M.) and colorectal (J.G.G., V.W.H.). For each, the clinical and genetic indications and timing of prophylactic surgery and its efficacy, when known, are provided.

Prophylactic surgery in hereditary cancer is a complex process, requiring a clear understanding of the natural history of the disease and variance of penetrance, a realistic appreciation of the potential benefit and consequence of a risk-reducing procedure in an otherwise potentially healthy individual, and the long-term sequelae of such surgical intervention, as well as the individual patient's and family's perception of surgical risk and anticipated benefit.

PATIENTS AT HIGH RISK FOR BREAST CANCER

Identification of Patients at Risk

A detailed family history is the most important tool for identifying individuals at increased risk for hereditary cancers. The US Preventive Services Task Force updated their recommendation for risk assessment, genetic counseling, and genetic testing for asymptomatic women who have not been diagnosed with a *BRCA*-related cancer. In this update, the use of a risk screening tool is highly recommended to identify appropriate patients for referral for genetic counseling.¹ The American Society of Clinical Oncology has also updated the policy on genetic and genomic testing for cancer susceptibility, and this update includes information on genetic tests of uncertain clinical utility and direct-to-consumer marketing, both of which impact the practice of oncology and preventive medicine.² Historically, genetic counseling and testing were offered by health-care providers. However, with the advent of direct-to-consumer marketing, individuals may obtain tests and receive results directly from a company. The American Society of Clinical Oncology still endorses pre- and posttest counseling for thorough disclosure of the impact of testing. Before any woman considers risk-reduction surgery such as bilateral mastectomy or salpingo-oophorectomy, referral to a high-risk or genetic screening program is desirable, as women often overestimate their actual breast cancer risk.³

The most common cancer syndromes that place women at risk for breast cancer are *BRCA1*⁴ and *BRCA2*⁵ gene mutations. Other less common syndromes are listed in Table 32.1.^{6,7}

Following referral for genetic assessment, three groups of patients emerge.⁸ The first consists of those women who have undergone genetic testing and have been found to harbor a mutated gene associated with high penetrance for breast cancer. Given that the possibility of developing breast cancer in this group may be as high as 90%, there is a role for enhanced surveillance or risk-reduction surgery. The American Cancer Society has published guidelines for magnetic resonance imaging (MRI) screening as a method for enhanced surveillance.⁹ Women in this first group qualify for such screening, which can be offered annually but scheduled at 6-month intervals with screening mammography to increase the rate of identifying interval cancers. Alternatively, simultaneous screening with MRI and mammography to compare one modality with the other on an annual basis may also be offered. Another choice for this group of women is to pursue bilateral risk-reduction mastectomy with an option for immediate reconstruction. Bilateral salpingo-oophorectomy for *BRCA1* and *BRCA2* mutation carriers may also be considered, as this procedure has been shown to reduce breast cancer risk by almost 50%.^{8,10} This is especially true for *BRCA2* mutation carriers, who tend to develop hormone receptor-positive breast cancers.

The second group consists of women with strong family histories suggestive of hereditary breast cancer who test negative for both the *BRCA1* and *BRCA2* mutations as well as the other described syndromes. In this group, there may not have been a family member with cancer who was tested for the mutation. Therefore, a negative test does not necessarily indicate that a woman's risk is equivalent to that of the general population.⁷ There may also be an undetected mutation in such a family, indicating the possibility of higher-than-average risk for that particular woman. These women may or may not qualify for enhanced surveillance with MRI screening,⁹ and accurate assessment of their risk may require the use of other risk prediction tools,³ in addition to evaluating for the presence of lobular carcinoma in situ, atypical lobular hyperplasia, or atypical ductal hyperplasia, and determining if a more intensive surveillance regimen is necessary based on heterogeneously or extremely dense breast tissue on mammography.

The third group consists of women with a strong family history of breast cancer, who for various reasons, have chosen not to pursue genetic testing. These individuals may have other health-related problems, psychological concerns, cost issues, or they may fear perceived medical insurance discrimination. Women in all groups can be educated that with passage of the Genetic Information Nondiscrimination Act in 2008, significant advances have occurred that protect patients from discrimination by employers and health insurers.¹¹

Women in the second and third groups may still qualify for bilateral risk-reduction mastectomy and immediate reconstruction. Often, women who elect this path are influenced by their family history or by witnessing breast and/or ovarian cancer deaths in close family members, giving them a significant fear of a breast or ovarian cancer diagnosis. For women in all three groups, the decision of whether to pursue risk-reducing surgery is difficult. Often, the expertise of a cancer clinical psychologist or psychiatrist

TABLE 32.1

Hereditary Carcinoma Syndromes Including Breast Cancer

Syndrome	Chromosome/Gene	Primary Carcinoma	Secondary Carcinoma	Breast Cancer Penetrance
Familial breast cancer/ ovarian cancer syndrome	17q21; <i>BRCA1</i> Autosomal dominant	Breast cancer, ovarian cancer	Colon, prostate	60%–80%
Familial breast cancer/ ovarian cancer syndrome	13q12; <i>BRCA2</i> Autosomal dominant	Breast cancer, ovarian cancer	Male breast cancer, endometrial, prostate, oropharyngeal, pancreatic	60%–80%
Li-Fraumeni syndrome	17p13.1 and 22q12.1; <i>TP53</i> and <i>CHEK2</i> Autosomal dominant	Soft tissue cancers (including breast)	Soft tissue sarcoma, leukemia, osteosarcoma, melanoma, colon, pancreas, adrenal syndrome, cortex, and brain tumors	50%–85% (for all types of cancers in this syndrome)
PTEN hamartoma syndrome (Cowden's)	10q23.31; <i>PTEN</i> mutation Autosomal dominant	Breast cancer	Thyroid (follicular) and endometrial carcinoma	25%–50%
Peutz-Jeghers syndrome	19p13.3; <i>STK11</i> Autosomal dominant	Gastrointestinal cancers	Esophagus, stomach, small intestine, large bowel, pancreas, lung, ovary, endometrial	29%
Diffuse gastric cancer	16q22.1; <i>CDH1</i> Autosomal dominant	Diffuse gastric cancer	Colorectal, lobular breast cancer	39% (lobular breast cancer)
Louis-Bar syndrome	11q22.3; <i>ATM</i> Autosomal recessive	Leukemia and lymphoma	Ovarian, breast, gastric, melanoma, leiomyomas, sarcomas	38% (for all types of cancers in the syndrome)

PTEN, phosphatase and tensin homolog.

Data from Lux MP, Fasching PA, Beckmann MW. Hereditary breast and ovarian cancer: review and future perspectives. *J Mol Med* 2006;84:16–28; and Shannon KM, Chittenden A. Genetic testing by cancer site: breast. *Cancer J* 2012;18:310–319.

is enlisted, as risk-reduction mastectomy involves an irreversible procedure with body image and sexual implications.⁸

Updated in 2007, the Society of Surgical Oncology published a position statement on the role of prophylactic mastectomy for patients at high risk for breast cancer, as well as those patients recently diagnosed with breast cancer who are considering contralateral prophylactic breast surgery.¹² For women at high risk, indications fall into three broad categories: presence of a mutation in *BRCA* or other susceptible genes, strong family history with no demonstrable mutation, and histologic risk factors (biopsy-proven atypical ductal hyperplasia, atypical lobular hyperplasia, or lobular carcinoma in situ especially in patients with a strong family history of breast cancer). Recommendations for patients with recently diagnosed breast cancer are similar in that they include the indications for high-risk individuals previously noted, as well as future surveillance challenges for the opposite breast (clinically and mammographically dense breast tissue or diffuse, indeterminate microcalcifications in the contralateral breast). Another important consideration is the need for symmetry in patients with large, ptotic, or disproportionately sized contralateral breasts.

Surgical Issues and Technique

In a single institution's 33-year experience,¹³ the risk for breast cancer in both moderate- and high-risk groups of women based on family history was reduced by at least 89% for women who underwent bilateral prophylactic mastectomy. From a technical perspective, in this study, women either had a subcutaneous mastectomy (removal of the majority of breast tissue with sparing of the nipple-areola complex) or total mastectomy (removal of the entire breast through the nipple-areola complex). Most of the recurrences occurred in women undergoing a subcutaneous mastectomy. However, this was the most frequent procedure performed at that

time and thus may have contributed to the number of increased recurrences.

Another surgical option for high-risk women is bilateral salpingo-oophorectomy. Among a cohort of women with *BRCA1* and *BRCA2* mutations, this procedure has been associated with a lower risk of mortality from both breast and ovarian cancer.¹⁰ As an additional benefit, this procedure also decreases the risk of breast cancer in this patient population, likely through the mechanism of decreasing hormonal exposure at a younger age.

Contemporary surgical procedures for risk-reducing bilateral mastectomy include total mastectomy, skin-sparing mastectomy (preservation of the skin envelope by removal of the entire breast through a circumareolar incision around the nipple-areola complex), subcutaneous mastectomy, areola-sparing mastectomy (removal of the nipple while sparing the areola), and nipple-sparing mastectomy (removal of entire breast and nipple core tissue but preservation of nipple-areolar skin).¹⁴ Given advances in reconstructive nipple-areolar techniques, it appears that total mastectomy with or without skin-sparing methods reduces the risk of breast cancer to the greatest extent with reasonable cosmesis. More limited and long-term follow-up data are available on areola- and nipple-sparing techniques. The potential limitations of these procedures are distortion of the nipple-areola complex and lack of sensitivity after breast tissue has been completely removed.⁸

Immediate reconstruction is offered to patients and performed in the vast majority undergoing bilateral risk-reduction mastectomy. Choices of reconstruction include a bilateral pedicled or free tissue transverse rectus abdominis muscle flap, a free bilateral deep inferior epigastric perforator flap or superficial inferior epigastric artery flap, bilateral latissimus flaps with or without implant or expanders, or bilateral implant or expander placement alone.¹⁴ Although tissue flap transfer gives a more natural appearance and texture to the reconstructed site, individual body contour drives the ultimate plan for reconstruction. The decision about the type

of reconstruction should be made by the plastic surgeon with input from the surgical oncologist, especially for the group of women with breast cancer desiring bilateral mastectomies who may require adjuvant radiation for treatment.

Although the risk reduction is dramatic for bilateral mastectomy, residual breast tissue may be left behind, especially with skin-sparing procedures. Patients should be educated that careful chest wall surveillance is recommended after such a procedure. Local recurrences after bilateral implant reconstruction are reliably detected by clinical examination. Recurrences after reconstruction with autologous tissue present most commonly on the skin 50% to 72% of the time and are detectable by physician examination.¹⁵ Nonpalpable deeper recurrences in this setting are less common, and use of mammography image surveillance may be indicated, especially if significant breast tissue was left behind unintentionally during the bilateral mastectomy procedure. At times, an initial “screening” mammogram may be performed, if significant residual breast tissue is suspected; this should occur well after all healing has taken place to delineate the amount of visible breast tissue on imaging. This drives future decisions of whether to follow a patient with imaging. Finally, all patients should be instructed to return for clinical breast examination with the health provider if any change is noted on the reconstructed breasts, regardless of imaging plan.

Although risk-reduction bilateral mastectomy may be exceedingly beneficial for high-risk women, especially for those testing positive for *BRCA1*, *BRCA2*, or other deleterious mutations, or belonging to a family afflicted with a cancer syndrome, they are never emergent procedures. Along with risk-reduction bilateral salpingo-oophorectomy, risk-reduction bilateral mastectomy resides at the far end of the spectrum of an individual's choices.¹⁶ These procedures should be offered only after appropriate genetic counseling and accurate assessment of a woman's actual risk for breast and ovarian cancer. An in-depth consultation with the patient and her family members is necessary prior to proceeding with an operative plan.

HEREDITARY DIFFUSE GASTRIC CANCER

Gastric cancer is the fourth most common cause of cancer worldwide and is the second leading cause of cancer mortality.¹⁷ Although environmental agents, including *Helicobacter pylori* and diet, are the primary risk factors for this disease, approximately 10% of gastric cancers are a result of familial clustering.^{18,19} Histologically, gastric cancers may be classified as either intestinal or diffuse types. The intestinal type histopathology is linked to environmental factors and advanced age. The diffuse type occurs in younger patients and is associated with a familial predisposition. Because of

a decrease in intestinal-type gastric cancers, the overall incidence of gastric cancer has declined significantly in the past 50 years. However, the incidence of diffuse gastric cancer (DGC), which is also called signet ring cell or linitis plastica, has remained stable and, by some reports, may be increasing.

Hereditary DGC (HDGC) is a genetic cancer susceptibility syndrome defined by one of the following: (1) two or more documented cases of DGC in first- or second-degree relatives, with at least one diagnosed before the age of 50; or (2) three or more cases of documented DGC in first- or second-degree relatives, independent of age of onset. The average age of onset of HDGC is 38, and the pattern of inheritance is autosomal dominant.²⁰ Figure 32.1 shows a pedigree with HDGC.

In 1998, inactivating germline mutations in the E-cadherin gene *CDH1* were identified in three Maori families, each with multiple cases of poorly differentiated DGC.²¹ The *CDH1* mutations in these families were inherited in an autosomal dominant pattern, with incomplete but high penetrance. Onset of clinically apparent cancer was early, with the youngest affected individual dying of DGC at the age of 14.²¹ Since then, germline mutations of *CDH1* have been identified in 30% to 50% of all patients with HDGC.^{19,22} More than 50 mutations have been recognized across diverse ethnic backgrounds, including European, African American, Pakistani, Japanese, Korean, and others.¹⁹ In addition to gastric cancers, germline *CDH1* mutations are associated with increased risk of lobular carcinoma of the breast, and this was the first manifestation of a *CDH1* mutation in one series.²³ *CDH1* is, to date, the only gene implicated in HDGC. Penetrance of DGC in patients carrying a *CDH1* mutation is estimated at 70% to 80%, but may be higher. The need for a systematic study of specimens is supported by recent work by Gaya et al.²⁴ in which initial total gastrectomy specimens were reported as negative, but detailed sectioning and analysis showed invasive carcinoma.

CDH1 is localized on chromosome 16q22.1 and encodes the calcium-dependent cell adhesion glycoprotein E-cadherin. Functionally, E-cadherin impacts maintenance of normal tissue morphology and cellular differentiation. It is hypothesized that *CDH1* acts as a tumor suppressor gene in HDGC, with loss of function leading to loss of cell adhesion and subsequently to proliferation, invasion, and metastases. Figure 32.2 shows the *CDH1* mutation for the pedigree depicted in Figure 32.1.

The germline *CDH1* mutation is most frequently a truncating mutation. Germline missense mutations are causative in a few HDGC kindreds, but are more often clinically insignificant. In vitro assays for cellular invasion and aggregation may predict the functional impact of missense mutations to aid in this distinction.²² Within the gastric mucosa, the “second hit” leading to complete loss of E-cadherin function results from *CDH1* promoter methylation, as has been described in sporadic gastric cancer.²⁵

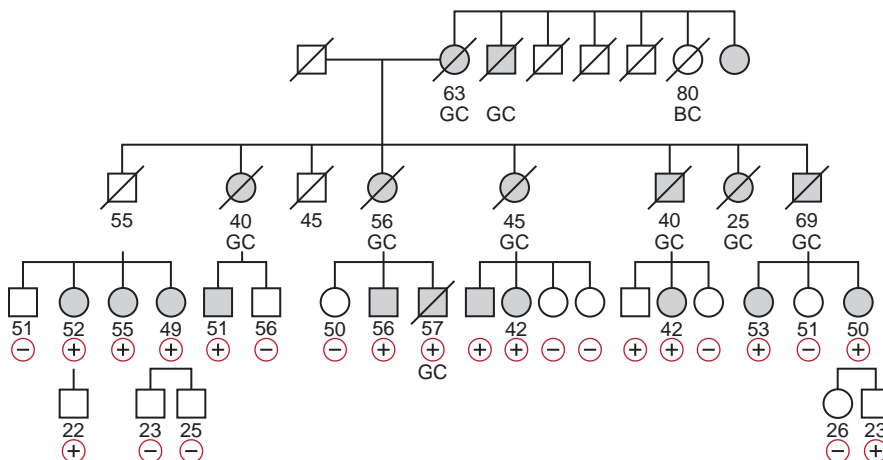

Figure 32.1 A family pedigree showing autosomal dominant inheritance of gastric cancer. Individual mutation testing results for the codon 1003 *CDH1* mutation are indicated by + or -. Individuals affected with gastric cancer are shaded. (From Norton JA, Ham CM, Van Dam J, et al. *CDH1* truncating mutations in the E-cadherin gene: an indication for total gastrectomy to treat hereditary diffuse gastric cancer. *Ann Surg* 2007;245:873.)

Figure 32.2 The mutation in this kindred is located in the central region of the E-cadherin gene that codes for the extracellular cadherin domains of the protein containing calcium-binding motifs important in the adhesion process. The C → T transition in exon 7 of nucleotide 1003 results in a premature stop codon (R335X), producing truncated peptides that lack the transmembrane and cytoplasmic β -catenin-binding domains essential for tight cell-cell adhesion. *Black* area indicates truncated portion of peptide. N, N-terminus; C, C-terminus; S, signal peptide; PRE, precursor sequence; TM, transmembrane domain; CP, cytoplasmic domain. (From Norton JA, Ham CM, Van Dam J, et al. *CDH1* truncating mutations in the E-cadherin gene: an indication for total gastrectomy to treat hereditary diffuse gastric cancer. *Ann Surg* 2007;245:873.)

It remains unclear whether specific *CDH1* mutations are associated with distinctive phenotypic characteristics or rates of penetrance, although this may become apparent as more recurrent mutations are recognized. To date, most mutations identified have been novel and distributed throughout *CDH1*. Recognition of recurrent mutations has usually resulted from independent events; however, there is evidence for the role of founder effects in certain kindreds.²² At present, it is also unclear whether patients with HDGC without detectable *CDH1* mutations have mutation of a different gene or merely a *CDH1* mutation that has gone unrecognized.

New recommended screening criteria for *CDH1* mutations are as follows:

1. Families with one or more cases of DGC
2. Individuals with DGC before the age of 40 years without a family history
3. Families or individuals with cases of DGC (one case below the age of 50 years) and lobular breast cancer
4. Cases where pathologists detect in situ signet ring cells or pagetoid spread of signet ring cells adjacent to diffuse type gastric cancer.^{18,26}

As in other familial cancer syndromes, genetic counseling should take place prior to genetic testing so that the family understands the potential impact of the results. After obtaining informed consent, a team comprising a geneticist, gastroenterologist, surgeon, and oncologist should discuss the possible outcomes of testing and the management options associated with each. Genetic testing should first be performed on a family member with HDGC or on a tissue sample if no affected relative is living. In addition to direct sequencing, multiplex ligation-dependent probe amplification is recommended to test for large genomic rearrangements. If a *CDH1* mutation is identified, asymptomatic family members may proceed with genetic testing, preferably by the age of 20.¹⁹ If no mutation is identified in the family member with DGC, the value of testing asymptomatic relatives is low.

Among individuals found to carry a germline *CDH1* mutation, clinical screening is problematic. Histologically, DGC is characterized by multiple infiltrates of malignant signet ring cells, which may underlie normal mucosa.²⁷ Because these malignant foci are small in size and widely distributed, they are difficult to identify via random endoscopic biopsy. Chromoendoscopy and positron emission tomography have reportedly been used, but the clinical utility of these tools in early detection remains unproven. Lack of a sensitive screening test for HDGC makes early diagnosis extremely challenging. By the time patients are symptomatic and present for treatment, many have diffuse involvement of the stomach or linitis plastica, and rates of mortality are high. Published case reports describe patients who have presented with extensive DGC despite recent normal endoscopy and negative biopsies.²⁸ The 5-year survival rate for individuals who develop

clinically apparent DGC is only 10%, with the majority dying before age 40.

Because of high cancer penetrance, poor outcome, and inadequacy of clinical screening tools for HDGC, prophylactic total gastrectomy is recommended as a management option for asymptomatic carriers of *CDH1* mutations.¹⁸ Although total gastrectomy is performed with prophylactic intent in these cases, most specimens have been found to contain foci of diffuse signet ring cell cancer.^{19,28,29} Foci of DGC have been identified even in patients who have undergone extensive negative screening, including high-resolution computed tomography, positron emission tomography scan, chromoendoscopy-guided biopsies, and endoscopic ultrasonography.¹⁹ However, HGDC in asymptomatic *CDH1* carriers is usually completely resected by prophylactic gastrectomy, as pathologic analyses of resected specimens have shown only T1N0 disease.

Because these signet ring cell cancers are multifocal and distributed throughout the entire stomach, especially in the cardia,³⁰ prophylactic gastrectomy should include the entire stomach, and the surgeon must transect the esophagus and not the proximal stomach. Furthermore, it should be performed by a surgeon experienced in the technical aspects of the procedure and familiar with HDGC. In asymptomatic patients, lymph node metastases have not been observed; therefore, D2 lymph node resection is not necessary. The optimal timing of prophylactic gastrectomy in individuals with *CDH1* mutations is unknown, but recent consensus recommendations indicate that age 20 is reasonable.¹⁸

Although it is a potentially lifesaving procedure, prophylactic gastrectomy for *CDH1* mutation carries significant risks that must be considered. Overall mortality for total gastrectomy is estimated to be as high as 2% to 4%, although it is estimated to be 1% when performed prophylactically. Patients must also be aware that there is a nearly 100% risk of long-term morbidity associated with this procedure, including diarrhea, dumping, weight loss, and difficulty eating.¹⁹ A recent study of the effects of prophylactic gastrectomy for *CDH1* mutation demonstrated that physical and mental function were normal at 12 months, but specific digestive issues were recognized. Overall, 70% had diarrhea, 63% fatigue, 81% eating discomfort, 63% reflux, 45% eating restrictions, and 44% had altered body image, suggesting that this operation impacted negatively on quality of life.³¹ Because of these complications and the fact that lymph node spread has not been observed, some recommend vagus-preserving gastrectomy done either open or laparoscopically. In addition, because the penetrance of *CDH1* mutations is incomplete, some patients who undergo prophylactic gastrectomy would never have gone on to develop clinically significant gastric cancer. Prophylactic gastrectomy has, in fact, been performed on several patients reported to show no evidence of gastric cancer on pathology.²⁹

Some individuals with *CDH1* mutations choose not to pursue prophylactic gastrectomy. These individuals should undergo careful surveillance, including biannual chromoendoscopy with biopsies, beginning when they are at least 10 years younger than

the youngest family member with DGC was at time of diagnosis. It is recommended that any endoscopically visible lesion is targeted and that six random biopsies are taken from the following regions: antrum, transitional zone, body, fundus, and cardia. Careful white-light examination with targeted and random biopsies combined with detailed histopathology can identify early lesions and help to inform decision making with regard to gastrectomy.³² Additionally, because women with *CDH1* mutations have a nearly 40% lifetime risk of developing lobular breast carcinoma, they should be carefully screened with annual mammography and breast MRI starting at age 35.²³ They should also do monthly self-examinations and have a breast examination by a physician every 6 months. The same surveillance recommendations are probably appropriate for HDGC families without identifiable *CDH1* mutations, although no current guidelines for this exist.

The emergence of gene-directed gastrectomy as a treatment strategy for patients with HDGC represents the culmination of a successful collaboration between molecular biologists, geneticists, oncologists, gastroenterologists, and surgeons. It is anticipated that the recognition of similar molecular markers in other familial cancer syndromes will transform the approach to the early diagnosis and treatment of a variety of tumors.

SURGICAL PROPHYLAXIS OF HEREDITARY OVARIAN AND ENDOMETRIAL CANCER

Hereditary Ovarian Cancer (*BRCA1*, *BRCA2*)

Inherited mutations in *BRCA1* and *BRCA2* strongly predispose women to breast cancer and to high-grade serous cancers of the ovary, fallopian tube, and peritoneum.^{33,34} About two-thirds are due to *BRCA1* mutations and one-third *BRCA2* mutations, and these account for about 15% to 20% of high-grade serous cases. The lifetime risk of these gynecologic cancers increases from a baseline of 1.5% to about 15% to 25% in *BRCA2* carriers and 30% to 60% in *BRCA1* carriers.^{33,34} *BRCA1/2* mutations are rare in most populations (<1 in 500 individuals); one notable exception is the Ashkenazi Jewish population, in which the carrier frequency is 1 in 40.³⁵ *BRCA1*-associated cases peak in the 50s and *BRCA2*-associated cancers in the 60s.³⁶ In addition to *BRCA1/2* mutations, germline mutations in a number of other genes in the homologous recombination DNA repair pathway confer high penetrance susceptibility to ovarian cancer (e.g., *RAD51C*, *RAD51D*, *BRIP1*, *PALB2*).³⁷ This has led to the development of more comprehensive cancer genetic testing panels that are increasingly being used to identify women who are candidates for risk-reducing salpingo-oophorectomy (RRSO).

Genetic testing for inherited high-penetrance mutations in *BRCA1/2* and other genes should be discussed with women who have a significant family history of early onset breast cancer and/or cancers of the ovary, fallopian tube, or peritoneum. Involvement of a genetic counselor prior to testing is helpful, as they have expertise in managing the inherent clinical and social issues. Most *BRCA1/2* mutations involve base deletions or insertions in the coding sequence or splice sites that encode truncated protein products that are clearly dysfunctional. Less frequently, disease-causing mutations may occur that alter a single amino acid, though most of these missense variants represent innocent polymorphisms. The clinical significance of missense mutations can sometimes be elucidated by determining whether they segregate with cancer in other family members. In addition, genomic rearrangements may occur that inactivate *BRCA1* or *BRCA2*, and identification of such alterations requires molecular testing beyond sequencing.

Penetrance of ovarian cancer is not 100% in those with clearly deleterious *BRCA1/2* mutations, but presently it is not possible to provide more precise personalized risk estimates to guide the use of RRSO. However, common variants have been discovered

in other genes that appear to affect the risk of ovarian cancer in *BRCA1/2* carriers.³⁸ Based on the known ovarian cancer risk-modifying loci, it has been reported that the 5% of *BRCA1* carriers at lowest risk have a lifetime risk of $\leq 28\%$ of developing ovarian cancer, whereas the 5% at highest risk have a $\geq 63\%$ lifetime risk. In the future, when modifier loci are more completely catalogued, more precise estimates of cancer risk may be provided to individual patients who are considering RRSO.

As about 20% of women with high-grade serous ovarian cancers have *BRCA1/2* mutations, it has been suggested that all of these women undergo genetic testing regardless of family history.³⁹ Mutational analysis in women with these cancers may increasingly become standard practice as the cost of genetic testing declines. Testing may also be driven by the availability of poly(ADP-ribose) polymerase inhibitor therapy for women whose cancers have germline or sporadic mutations in genes such as *BRCA1/2* and others that are involved in homologous recombination DNA repair.

RRSO is strongly recommended in women who carry *BRCA1/2* mutations because of the high mortality rate of ovarian cancer and the lack of effective screening and prevention approaches. Although screening with pelvic ultrasound and serum CA125 is generally recommended for *BRCA1/2* carriers during their 20s and 30s, it is not proven to reduce ovarian cancer mortality because even early stage high-grade cancers have a very high mortality. Oral contraceptives reduce the risk of ovarian cancer in the general population and appear to have a similar effect in *BRCA1/2* carriers, but this must be balanced against concerns regarding increased breast cancer risks.

The past practice of performing RRSO based solely on family history has been replaced by reliance on genetic testing. Clinical management of women with a strong family history in whom a deleterious germline mutation is not found, or those with variants of uncertain significance, should be resolved on a case-by-case basis. RRSO may be deemed appropriate in some cases, despite the absence of a clearly deleterious mutation. Fortunately, the risk of hereditary ovarian cancer does not rise dramatically until the mid-30s in women with *BRCA1* mutations and the 40s for women with *BRCA2* mutations.³⁶ As a result, most women are able to complete childbearing prior to undergoing RRSO. It is advisable for *BRCA1* carriers to undergo RRSO around age 35, as there is a 4% risk of ovarian cancer being discovered clinically or at the time of RRSO by age 40.¹⁰ *BRCA2* carriers may choose to delay surgery into their 40s due to their lower risk of ovarian cancer, but this could diminish the protection against breast cancer that is afforded by RRSO. If a mutation carrier, particularly a *BRCA1* carrier, chooses to pursue fertility into her 40s, then she should be counseled that she is at considerable risk of developing a life-threatening cancer that is largely preventable.

Several studies have provided evidence of the efficacy of RRSO. In one early study of *BRCA1/2* carriers, RRSO reduced the rate of breast and ovarian cancer by 75% over several years of follow-up.⁴⁰ A separate study in 2002 examined outcome in 551 *BRCA1/2* carriers from various registries.⁴¹ Among 259 women who had undergone RRSO, 6 (2.3%) were found to have stage I ovarian cancer at the time of the procedure and 2 (0.8%) subsequently developed serous peritoneal carcinoma. Among the controls, 58 (20%) women developed ovarian cancer after a mean follow-up of 8.8 years. With the exclusion of the six women whose cancers were diagnosed at surgery, RRSO reduced ovarian cancer risk by 96%. More recently, in 2014, an international registry study of over 5,783 subjects with median follow-up of 5.6 years found that RRSO reduced ovarian, tubal, and peritoneal cancer risk by 80%.³⁶ There was an estimated lifetime risk of primary peritoneal cancer after RRSO of about 4% for *BRCA1* carriers and 2% for *BRCA2* carriers.³⁶ The risk of death from all causes was reduced by 77%. A prospective cohort study noted that RRSO was associated with reduction in breast cancer-specific (hazard ratio [HR] = 0.44; 95% confidence interval [CI] = 0.26 to 0.76), ovarian cancer-specific (HR = 0.21; 95% CI = 0.06 to 0.80), and all-cause mortality (HR = 0.40; 95% CI = 0.26 to 0.61).¹⁰

Figure 32.3 Hematoxylin and eosin (A) and immunohistochemical staining (B) demonstrating overexpression of mutant *TP53* in serous carcinoma in situ of the fallopian tube from a *BRCA1* mutation carrier who underwent risk-reducing bilateral salpingo-oophorectomy.

Removal of the ovaries, as internal organs, usually has little effect on body image and self-esteem, and most *BRCA1/2* mutation carriers elect to undergo RRSO. Insurance payers will almost always pay for RRSO in proven mutation carriers.

RRSO can be performed laparoscopically in most women, with discharge to home the same day. If a laparoscopic approach is problematic due to obesity or adhesions, the surgery can be performed through a small lower abdominal incision. Morbidity including bleeding, infection, and damage to the urinary or gastrointestinal tracts can occur, but the incidence of serious complications is very low. As the fallopian tubes and ovaries are small discrete organs, they are relatively easy to remove completely. Attention should be paid to transecting the ovarian artery and vein proximal to the ovary and tube so that remnants are not left behind. This involves opening the pelvic sidewall peritoneum, visualizing the ureter, and then isolating the ovarian blood supply. If there are adhesions between the adnexa and adjacent structures, careful dissection should be performed to ensure complete removal of the ovaries and fallopian tubes. If the uterus is not removed, care should be taken to remove the entire fallopian tube. A small portion of the tube inevitably will be left in the cornu of the uterus, but the risk of fallopian tube cancer developing in such remnants appears to be negligible.

Though there is not strong evidence that *BRCA1/2* mutations increase uterine cancer risk, many women elect to have the uterus removed as part of the surgical procedure because they have completed their family or have other gynecologic indications. Although the addition of a hysterectomy may increase operative time, blood loss, surgical complications, and hospital stay, it usually can be performed laparoscopically and serious adverse outcomes are infrequent. Furthermore, the likelihood of future exposure to tamoxifen in the context of breast cancer prevention or treatment, which increases endometrial cancer risk two- to three-fold, also argues for concomitant hysterectomy. Women who receive hormone replacement therapy after surgery will require a progestin along with estrogen to protect against the development of endometrial cancer if the uterus is not removed.

In younger women, surgical menopause after RRSO is associated with vasomotor symptoms, vaginal atrophy, decreased libido, and an accelerated onset and incidence of osteoporosis and cardiovascular disease. In premenopausal women who do not have a personal history of breast cancer, estrogen replacement can be administered to ameliorate many of the deleterious effects of premature menopause. Systemic estrogen levels are lower in oophorectomized premenopausal women taking hormone replacement than if the ovaries had been left in place. The therapeutic benefit of oophorectomy in women with breast cancer has long been

appreciated, and more recent studies support the contention that RRSO reduces the risk of breast cancer by about half in *BRCA1/2* carriers.⁴² However, a meta-analysis showed that while RRSO was strongly protective against estrogen receptor–positive breast cancer (HR = 0.22), there was no protection against estrogen receptor–negative breast cancer.⁴² Many carriers are identified after developing early onset breast cancer, and this group represents the most difficult in which to balance the potential risks and benefits of estrogen replacement therapy.

Early stage high-grade serous cancers and in situ lesions with *TP53* mutations have been identified in the fallopian tubes of some RRSO specimens (Fig. 32.3). This has led to a paradigm shift in which it is now thought that most high-grade serous cancers found in the ovary, fallopian tube, and peritoneum are derived from cells that originate in the tubal fimbria.⁴³ The frequency of occult malignancies has varied between reports, but appears to be about 3%.⁴³ In view of this, the pelvis and peritoneal cavity should be examined carefully. Malignant cells also have been found in peritoneal cytologic specimens, and washings of the pelvis should be obtained when performing RRSO. The pathologist should be informed of the indication for surgery and serial sections of the fallopian tubes should be performed to look for the presence of early lesions. Patients found to have occult invasive high-grade serous cancers should be treated with chemotherapy after surgery. Those with in situ lesions appear to have a good outcome without chemotherapy.⁴⁴

Cases of peritoneal serous carcinoma indistinguishable from ovarian cancer have been observed years after RRSO, but the origin of these cancers is unclear. Some may represent recurrences of occult ovarian or tubal cancers. In this regard, retrospective examination of the ovaries and fallopian tubes sometimes has revealed primary cancers that were not originally recognized. In contrast, some of these cancers likely arise directly from fallopian tube cells that have implanted in the peritoneum and subsequently become malignant. Patients who undergo RRSO should be made aware of their residual risk of peritoneal cancer, but there is no evidence that continued surveillance using CA125 and/or ultrasound is beneficial.

HEREDITARY ENDOMETRIAL CANCER (LYNCH SYNDROME)

Although Lynch syndrome (LS, also known as hereditary non-polyposis CRC syndrome) typically manifests as familial clustering of early onset CRC, there is also an increased incidence of several other types of cancers—most notably endometrial cancer in women.⁴⁵ About 3% of endometrial cancers are attributable to

inherited mutations in the DNA mismatch repair (MMR) genes that cause LS. Most often, *MSH2* and *MLH1* are implicated, but mutations in *MSH6* and *PMS2* also occur.⁴⁵ The risk of ovarian cancer is also significantly increased in LS, but to a lesser degree than in *BRCA1/2* mutation carriers, and accounts for only about 1% of all ovarian cancers.

Cells in which one of the LS genes have been inactivated exhibit a phenomenon called microsatellite instability (MSI).⁴⁶ This occurs as DNA mismatches cause shortening or lengthening of repetitive DNA sequences and these mismatches go unrepaired. This results in generation of alleles in the cancer that contain a greater or lesser number of repeats than are present in normal cells from that individual. MSI occurs in most LS-associated colorectal and endometrial cancers.⁴⁶ However, MSI is found in about 20% of sporadic cancers that arise in these organs, and in most cases is caused by silencing of the *MLH1* gene due to promoter hypermethylation. Screening strategies for identification of MMR gene alterations in families with LS-associated cancers include analysis of tumor tissue for MSI and/or loss of DNA MMR gene expression using immunohistochemistry (IHC).⁴⁶ In cancers with MSI or loss of expression of one of the MMR genes, or in families with pedigrees suggestive of LS, these genes can be sequenced to identify disease-causing mutations, most of which cause truncated protein products.⁴⁷ Although it has been suggested that it may be cost-effective to do these tests on all endometrial cancers, this approach has not been widely adopted.⁴⁷

The risk of a woman who carries a LS mutation developing endometrial cancer ranges from 20% to 60% in various reports.^{45,48} The risk of ovarian cancer is increased to about 5% to 12%. Whereas the mean age of women with sporadic endometrial cancers is in the early 60s, cancers that arise in association with LS are often diagnosed before menopause, with the average age in the 40s. The clinical features of these endometrial cancers are similar to those of most sporadic cases (well-differentiated, endometrioid histology, early stage), and survival is about 90%. The mean age of onset of ovarian cancer in LS is in the early 40s, and the clinical features of these cancers are generally more favorable than in sporadic cases. They usually are identified at an early stage, are well- or moderately differentiated, have favorable survival, and some occur in the setting of a synchronous endometrial cancer.

Recommendations for screening and risk-reducing surgery in LS are better established for CRC than for extracolonic malignancies.⁴⁹ Transvaginal ultrasound has been proposed as a screening test for endometrial cancer (and ovarian cancer), but its efficacy is unproven.⁵⁰ Endometrial biopsy is the most sensitive means of diagnosing endometrial cancer, and it has been suggested that this should be employed periodically beginning around age 30 to 35. However, there are no published studies demonstrating that this approach prevents endometrial cancer deaths compared to simply performing a biopsy if abnormal uterine bleeding occurs.

Most experts believe that risk-reducing hysterectomy has a role in the management of some women with LS because of the high incidence of endometrial cancer. The risk of endometrial cancer is low during the prime reproductive years, and the uterus does not serve a vital function once childbearing has been completed. In view of the increased risk of ovarian cancer in LS, concomitant bilateral salpingo-oophorectomy should also be considered. One study demonstrated that there were no cases of endometrial or ovarian cancer in 61 LS carriers who underwent risk-reducing hysterectomy and bilateral salpingo-oophorectomy, while endometrial cancer occurred in 33% and ovarian cancer in 5% who retained their uterus and ovaries.⁵¹ Despite the low risk of death from gynecologic cancers in LS, cost-effectiveness analyses of various approaches suggest that risk-reducing hysterectomy and salpingo-oophorectomy leads to both the lowest cost and the greatest increase in quality-adjusted life-years.⁵² Estrogen replacement after removal of the ovaries in premenopausal women with LS is not contraindicated, as there is no evidence that this adversely affects the incidence of other cancers.

Many women with LS elect to undergo risk-reducing colectomy, which provides an opportunity to perform concomitant hysterectomy. Hysterectomy in concert with colectomy, either via laparoscopy or laparotomy, does not greatly increase operative time or surgical complications. If an endometrial biopsy has not been performed preoperatively, an intraoperative inspection of the uterine cavity and possibly frozen section should be performed to exclude the presence of cancer. If cancer is found in the uterus, surgical staging—including sampling of the regional lymph nodes—should be considered in addition to hysterectomy.⁵³ It is also appropriate to discuss risk-reducing hysterectomy with LS carriers who do not elect to undergo prophylactic colectomy. The operative approach (vaginal versus laparotomy versus laparoscopy) can be determined based on the presence or absence of uterine pathology (e.g., myomas), whether the patient has had prior abdominal surgery, and whether the ovaries are also to be removed.

GYNECOLOGIC CANCER RISK IN VERY RARE HEREDITARY CANCER SYNDROMES

Several very rare hereditary cancer syndromes also increase the risk of gynecologic cancers, and some of these women could potentially benefit from risk-reducing surgery to remove the ovaries and/or uterus. Peutz-Jeghers syndrome is characterized by intestinal polyps and an increased risk of colorectal and breast cancers. This rare syndrome is due to inherited mutations in the *STK11* gene. Affected women also have an increased risk of ovarian sex cord-stromal tumors with annular tubules and adenoma malignum of the cervix. Li-Fraumeni syndrome is caused by inherited mutations in the *TP53* gene, and carriers are predisposed to a number of types of cancers including sarcomas and breast cancer. The risk of ovarian cancer is increased as well, but is not a major cause of cancer in these families. Cowden syndrome is due to germline *PTEN* mutations and increases the risk of several malignancies including breast, thyroid, mucocutaneous, and endometrial cancers. Finally, small cell carcinoma of the ovary, hypercalcemic type, is due to mutations in the *SMARCA4* gene. These highly lethal ovarian cancers occur at a very young age (median 24 years) and present difficult challenges related to timing of RRSO. There are no well-accepted evidence-based guidelines for early detection and prevention of gynecologic cancers in these very rare hereditary cancer syndromes. An awareness of the risk and natural history of gynecologic cancers in these families provides a basis for counseling individual patients.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

Gene Carriers

The MEN type 2 syndromes include MEN 2A, MEN 2B, and familial (non-MEN) medullary thyroid carcinoma (FMTC).^{54–56} These are autosomal dominant inherited syndromes caused by germline mutations in the *RET* proto-oncogene. Their hallmark is the development of multifocal bilateral medullary thyroid carcinoma (MTC) associated with C-cell hyperplasia. MTCs arise from the thyroid C-cells, also called parafollicular cells. C-cells secrete the hormone calcitonin, a specific tumor marker for MTC. A slow-growing tumor in most cases, MTC causes significant morbidity and death in patients with uncontrolled local or metastatic spread. Large tumor burden is associated with diarrhea and flushing. In the MEN 2 syndromes, there is almost complete penetrance of MTC. Other features are variably expressed, with incomplete penetrance (summarized in Table 32.2).

In MEN 2A, all patients develop MTC. Approximately 42% of affected patients also develop pheochromocytomas, associated with adrenal medullary hyperplasia. Hyperparathyroidism develops in

TABLE 32.2

Clinical Features of Sporadic Medullary Thyroid Carcinoma, Multiple Endocrine Neoplasia 2A, Multiple Endocrine Neoplasia 2B, and Familial Medullary Thyroid Carcinoma

Clinical Setting	Features of MTC	Inheritance Pattern	Associated Abnormalities	Genetic Defect
Sporadic MTC	Unifocal	None	None	Somatic <i>RET</i> mutations in >20% of tumors
MEN 2A	Multifocal, bilateral	Autosomal dominant	Pheochromocytomas, hyperparathyroidism, cutaneous lichen amyloidosis, Hirshprung's disease	Germline missense mutations in extracellular cysteine codons of <i>RET</i>
MEN 2B	Multifocal, bilateral	Autosomal dominant	Pheochromocytomas, mucosal neuromas, megacolon, skeletal abnormalities	Germline missense mutation in tyrosine kinase domain of <i>RET</i>
FMTC	Multifocal, bilateral	Autosomal dominant	None	Germline missense mutations in extracellular or intracellular cysteine codons of <i>RET</i>

MTC, medullary thyroid carcinoma; MEN, multiple endocrine neoplasia; FMTC, familial medullary thyroid carcinoma.

10% to 35%. Cutaneous lichen amyloidosis and Hirschsprung's disease are infrequently associated with MEN 2A.⁵⁷⁻⁶⁰

MEN 2B appears to be the most aggressive form of hereditary MTC. In MEN 2B, MTC develops in all patients at a very young age (infancy). All affected individuals develop neural gangliomas, particularly in the mucosa of the digestive tract, conjunctiva, lips, and tongue; 40% to 50% develop pheochromocytomas. Patients with MEN 2B may also have megacolon, skeletal abnormalities, and markedly enlarged peripheral nerves. They do not develop hyperparathyroidism.

FMTC is characterized by development of MTC in the absence of any other endocrinopathies. MTC in these patients has a more indolent clinical course. Some individuals with FMTC may never manifest clinical evidence (i.e., symptoms or a lump in the neck), although biochemical testing and histologic evaluation of the thyroid demonstrates MTC.^{55,56}

RET Genotype-Phenotype Correlations

Mutations in the *RET* proto-oncogene are responsible for MEN 2A, MEN 2B, and FMTC.⁶¹⁻⁶⁴ This gene encodes a transmembrane tyrosine kinase protein.^{57,65} The mutations that cause the MEN 2 syndromes are activating gain-of-function mutations affecting constitutive activation of the protein. This is unusual among hereditary cancer syndromes, which are usually caused by loss-of-function mutations in the predisposition gene (e.g., familial polyposis, *BRCA1* and 2, von Hippel-Lindau, and MEN 1). More than 30 missense mutations have been described in patients affected by the MEN 2 syndromes (Fig. 32.4).

There is a relationship between the type of inherited *RET* mutation and presentation of MTC. The most virulent form is seen in patients with MEN 2B. These patients most commonly have a germline mutation in codon 918 of *RET* (ATG->ACG), although other mutations have been described (codon 883 and 922). As noted previously, MTC in MEN 2B has an extremely early age of onset (infancy). Despite its distinctive clinical appearance and associated gastrointestinal difficulties, the disease is often not detected until the patient develops a neck mass. Metastatic spread is usually present at the time of initial treatment, and calcitonin levels often remain elevated postoperatively.

MTC has a variable course in patients with MEN 2A, similar to that of sporadic MTC. Codon 634 and 618 mutations are the most common *RET* mutations associated with MEN 2A, although

mutations at other codons are also observed (see Fig. 32.4). Some patients do extremely well for many years, even with distant metastases, while others develop inanition, symptomatic liver, lung or skeletal metastases, as well as disabling diarrhea. Recurrence in the central neck, with invasion of the airway or great vessels, may cause death.

In patients with FMTC, MTC is usually indolent. These individuals most commonly have mutations of codons 609, 611, 618, 620, 768, 804, or 891, although mutations of other codons have been identified (see Fig. 32.4). Many patients with FMTC are cured by thyroidectomy alone, and even those with persistent elevation of calcitonin levels do well for many years. Occasionally, patients with FMTC survive into the seventh or eighth decade without clinical signs of disease, although pathologic examination of the thyroid will reveal MTC or C-cell hyperplasia.⁶⁶

Risk-Reducing Thyroidectomy in RET Mutation Carriers

Genetic counseling and informed consent should be obtained prior to genetic testing. Specific issues that should be covered in genetic counseling sessions include explaining the patterns of heritability, likelihood of expression of different tumors, their prevention and treatment, insurability, nonpaternity, survivor guilt, and others.

It has been shown that *RET* mutation carriers may harbor foci of MTC in the thyroid gland, even when calcitonin levels are normal.⁶⁷ While the age of onset and rate of disease progression may differ, the lifetime penetrance of MTC is near 100% in carriers of *RET* mutations associated with MEN 2 syndromes. At-risk individuals who are found to have inherited a *RET* gene mutation are therefore candidates for thyroidectomy, regardless of their plasma calcitonin levels.

The best option for prevention of MTC in *RET* mutation carriers is complete surgical resection prior to malignant transformation. Prophylactic thyroidectomy prior to the development of MTC is the goal in these patients. A number of studies have demonstrated improved biochemical cure rates and/or decreased recurrence rates from early thyroidectomy, performed after positive screening by calcitonin testing or *RET* mutation testing.⁶⁸⁻⁷⁰

MEN 2B mutations are the highest risk level, designated level III (see Fig. 32.4).^{55,71} Patients with MEN 2B have the most aggressive form of MTC, with invasive disease reported in patients <1 year of age. These patients should have preventative surgery

Figure 32.4 *RET* mutation sites associated with multiple endocrine neoplasia (MEN) 2 syndromes. Codons previously reported in association with MEN-2 syndromes are listed by structural domain within the *RET* protein. Risk level is based on consensus guidelines or more recent clinical reports. Previously reported phenotypes for each codon are shown. MTC, medullary thyroid carcinoma; Pheo, pheochromocytoma; HPT, hyperparathyroidism; FMTC, familial medullary thyroid carcinoma; HSCR, Hirschsprung's disease. Asterisk indicates risk level based on recent clinical reports not available at publication of the consensus guidelines. (From Traugott AL, Moley JF. The *RET* protooncogene. *Cancer Treat Res* 2010;153:303–319.)

early in the first year of life, if possible. Identification and preservation of parathyroid glands can be extremely difficult in these infants, due to their small size, translucent appearance, and the presence of exuberant thymic and perithyroidal nodal tissue. These procedures should be performed by surgeons experienced in parathyroid and/or pediatric thyroid operations.

Patients with MEN 2A with mutations in codons 634, 620, 618, and 611 are also considered high risk (level II).^{55,71} Patients with level II mutations should undergo a total thyroidectomy at 5 to 6 years of age. There is evidence that the risk of lymph node metastasis is very low in patients with MEN 2A under the age of 8, with normal calcitonin levels. Central lymph node dissection is associated with higher risk of hypoparathyroidism, and recurrent laryngeal nerve injury and should be reserved for patients with elevated calcitonin levels.

A larger subset of *RET* mutations, associated with MEN 2A and/or FMTC, is considered the lowest risk (level I).^{55,71} These include mutations at codons 768, 790, 791, 804, and 891. For patients with low-risk level I mutations, total thyroidectomy is recommended before age 5 to 10 years. This decision, however, regarding ideal age at preventative thyroidectomy in low-risk mutation carriers, is currently being reviewed, and may be driven by additional clinical data such as the basal or stimulated serum calcitonin level.^{72,73} There are no guidelines at present that address the issue of timing of surgery based on calcitonin level, and at present, pentagastrin (the primary calcitonin secretagogue used in testing) is not available in the United States. It is anticipated that within a decade, there will

be enough published data to direct timing of interventions based upon this information. As with the level II mutations, the need for central lymph node dissection should be guided by calcitonin levels and clinical features of the patient and kindred.

Until recently, some groups recommended total thyroidectomy with central neck lymph node dissection and total parathyroidectomy with autotransplantation for all *RET* mutation carriers. Recent studies and personal experience, however, have demonstrated an extremely low likelihood of nodal metastases in patients with MEN 2A or FMTC younger than 8 years of age, and in patients with a normal calcitonin level.⁷⁰ Our current strategy is to leave the parathyroid in situ in these patients, if possible.⁷⁴ Often, however, the desired complete removal of thyroid tissue results in compromise of parathyroid blood supply. In these situations, autotransplantation of devascularized parathyroid is required. We routinely remove and autotransplant the parathyroid if a central node dissection is done. In parathyroid autotransplantation, parathyroid glands are sliced into 1 mm × 3 mm fragments and autotransplanted into individual muscle pockets in the muscle of the nondominant forearm in patients with MEN 2A, or in the sternocleidomastoid muscle in patients with FMTC or MEN 2B. Patients are maintained on calcium and vitamin D supplementation for 4 to 8 weeks postoperatively.

In a recent series of thyroidectomies performed in 50 individuals with MEN 2A (identified by genetic screening), total thyroidectomy and central node dissection with parathyroidectomy and parathyroid autografting were performed in all patients (Fig. 32.5).⁷⁰

Figure 32.5 Total thyroidectomy specimen with attached central nodes from a patient with germline *RET* mutation and elevated calcitonin levels. Note small visible foci of medullary thyroid carcinoma (arrows).

All autografts functioned, but three patients required supplemental calcium. The percentage of individuals requiring calcium supplementation following parathyroidectomy with parathyroid autografting reportedly ranges from 0% to 18%. Parathyroidectomy should be performed in all patients showing gross parathyroid enlargement or biochemical evidence of parathyroid disease at time of surgery. The operating surgeon should have expertise in preservation of parathyroid function. It is important that the surgeon performing an operative procedure for MTC be familiar with the techniques described here. If not, the patient should be referred to a center where these procedures are routinely performed.

Some patients with MEN 2 will be found to have elevated calcitonin levels prior to thyroidectomy. This is usually associated with medullary thyroid carcinoma or C-cell hyperplasia in the gland, and may be associated with lymph node metastases. Much has been written about the correlation between preoperative calcitonin levels and extent of nodal involvement. It has been suggested that preoperative calcitonin level may guide the extent of node dissection. In a study of 300 European patients with MTC, node metastases were not identified when the preoperative basal calcitonin level was <20 pg/ml.⁷⁵ Involvement of nodal groups was correlated with basal calcitonin level as follows: ipsilateral central and lateral neck nodes (basal calcitonin >20 pg/ml), contralateral central nodes (basal calcitonin >50 pg/ml), contralateral lateral neck nodes (basal calcitonin >200 pg/ml), and mediastinal nodes (basal calcitonin >500 pg/ml). Based upon these findings, this group (who also wrote the European guidelines) recommends thyroidectomy only if basal calcitonin is <20 pg/ml, ipsilateral central and lateral neck dissection if the calcitonin is 20 to 50 pg/ml, and contralateral central neck dissection if the basal calcitonin is 50 to 200 pg/ml, with the addition of contralateral lateral neck dissection if the calcitonin is 200 to 500 pg/ml. Most experts agree that sternotomy with mediastinal neck dissection should be reserved for patients with image evidence of mediastinal disease. In contrast, most North American surgeons rely heavily upon preoperative ultrasound imaging to map the extent of nodal involvement and determine extent of surgery based upon calcitonin and imaging results.^{55,74,76}

Follow-up

Following thyroidectomy, thyroid hormone replacement is required for life. Patients may need several weeks of oral calcium and vitamin D until parathyroid function recovers. Intermittent calcitonin testing may be done to monitor for persistent or recurrent

MTC. The importance of regular monitoring of patients' compliance with thyroid medication following thyroidectomy should not be underestimated. Children and teenagers are frequently non-compliant, and this can be determined by routine measurement of thyroid-stimulating hormone levels. Continued noncompliance can result in growth problems. Occasionally, local human services agencies may need to be involved in particularly difficult cases.

The term "biochemical cure" is used to refer to patients with normal calcitonin levels after surgery for MTC. Complete postoperative normalization of calcitonin has been associated with decreased long-term risk of MTC recurrence, though the evidence is less clear for a survival benefit. A persistent or recurrent elevation in calcitonin indicates residual or recurrent MTC and warrants additional investigation by imaging. However, as most MTC has a fairly indolent course, patients with biochemical evidence of recurrent disease may not have corollary imaging findings for some time.

Conclusions

Identification of *RET* gene mutations in individuals at risk for developing hereditary forms of MTC has simplified management, expanding the scope of indications for surgical intervention. Patients who carry this mutation can be offered operative treatment at a very young age, hopefully before the cancer has developed or spread, and those identified as not having the mutation are spared further genetic and biochemical screening. This achievement marks a new paradigm in surgery: the indication that an operation be performed based on the results of a genetic test. As in the decision to perform any surgical procedure, meticulous preparation and detailed discussion with patient and family must precede the final recommendation. It is also important that the patient and family be involved in preoperative discussions with genetic counselors. Postoperative follow-up for compliance with thyroid medication is important, especially in children and teenagers who are still growing and developing into adults.

FAMILIAL ADENOMATOUS POLYPOSIS, MYH-ASSOCIATED POLYPOSIS, AND LYNCH SYNDROME

Inherited CRC syndromes with multiple adenomatous polyps include FAP, *MYH*-associated polyposis (MAP), and LS. In some cases, the diagnosis is suspected because of a striking family history

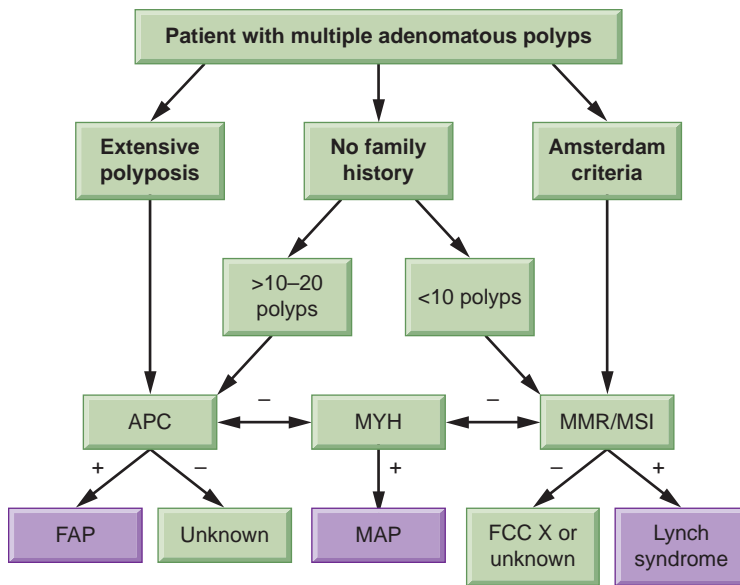

Figure 32.6 Schematic demonstrating the potential genetic workup for a patient with multiple adenomatous colorectal polyps and suspected of having an inherited colorectal cancer syndrome. APC, adenomatous polyposis coli; MMR, mismatch repair; MSI, microsatellite instability; FAP, familial adenomatous polyposis; MAP, *MUTYH*-associated polyposis; FCC X, familial colorectal cancer syndrome X.

of CRC, while in others, suspicion arises from a very young onset of CRC or florid polyposis.

Although adenomatous polyp burden and family history may suggest one syndrome over another, an initial negative genetic test result should be followed by further evaluation for other syndromes. For example, in clinical practice, a negative adenomatous polyposis coli (*APC*) gene test in a patient with a suspected CRC syndrome is followed by reflex testing for MAP and LS, as shown in Figure 32.6.

FAP is an autosomal dominant syndrome that accounts for <1% of the annual CRC burden, is caused by mutations in the tumor-suppressor *APC* gene. It is characterized by the presence of ≥ 100 adenomatous polyps in the colorectum, nearly 100% penetrance, and an inevitable risk of CRC if prophylactic colectomy is not performed.^{8,77} Patients with a less severe form known as attenuated FAP (AFAP) usually present with <100 colorectal adenomas that tend to be proximally located. MAP is an autosomal recessive syndrome that often presents phenotypically as attenuated polyposis. While an estimated 2% of the general population are monoallelic carriers of a mutated base-excision-repair *MUTYH* (*MYH*) gene, biallelic germline mutations may account for 9% to 18% of patients with FAP or AFAP phenotypes who have no demonstrable *APC* mutation.^{78–80}

LS accounts for 1% to 4% of all newly diagnosed CRC and is attributable to a germline mutation in one of the DNA MMR genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*).^{81–83} Epigenetic silencing of the *MSH2* gene via a 3'-end deletion in *EPCAM* (*TACSTD1*), a neighbor of *MSH2* that plays a role in cell adhesion, also accounts for 20% to 25% of all suspected *MSH2* cases and 1% to 6% of LS cases overall.^{84–86} LS is characterized by early age-of-onset CRC, predominance of lesions proximal to the splenic flexure, an increased rate of metachronous CRC, and a unique spectrum of benign and malignant extracolonic tumors. Lifetime risk of CRC in patients with LS may be as high as 80%.^{83,87} MSI reflects a deficiency in DNA repair secondary to MMR gene mutation and is a hallmark feature of LS-associated tumors.

Variability in penetrance, phenotypic expression, and certainty of disease development mandate distinctly different surgical approaches in these three syndromes, including the type and timing of risk-reducing colon and rectal surgery.⁸⁸

Familial Adenomatous Polyposis

Surveillance of at-risk family members should begin around age 10 to 15 years with an annual colonoscopy or flexible sigmoidoscopy.⁸⁹

At-risk individuals who belong to families with an AFAP phenotype should undergo colonoscopic screening every 2 to 3 years starting in their late teens. Informative genetic testing is possible in families with a demonstrated *APC* mutation, and mutations are detected in most pedigrees. However, approximately 25% of patients with FAP will have a de novo *APC* mutation.⁸⁷ Severity of polyposis should be established during colonoscopy, as the timing of surgery and the risk of developing colorectal is dependent on the extent of polyp burden. Patients with mild polyposis and a correspondingly lower CRC risk can undergo surgery in their late teens. Patients with severe polyposis, a high degree of dysplasia, multiple adenomas >5 mm in size, and symptoms (bleeding, persistent diarrhea, anemia, failure to thrive, psychosocial stress, etc.) should undergo risk-reducing colorectal surgery as soon as is practical after diagnosis.^{90,91} However, in carefully selected, fully asymptomatic patients who have small adenomas but a strong family history of aggressive abdominal desmoid disease, consideration can be given to delaying prophylactic colectomy, as the risk of desmoid-related complication may be greater than the risk of CRC development.

The three current surgical options for patients with FAP are total proctocolectomy (TPC) with permanent ileostomy, total colectomy with ileorectal anastomosis (IRA), and proctocolectomy with ileal pouch-anal anastomosis (IPAA). IPAA can be a double-stapled, end-of-pouch-to-anus anastomosis, which may leave behind approximately 1 cm of anal transition zone. An alternative approach, which is preferred when there is carpeting of the anal transition zone with adenomas, is to perform a mucosal stripping of the anal transition zone down to the dentate line followed by a hand-sewn per anal anastomosis of pouch to the dentate line. Selection of the optimal procedure for an individual patient is based on several factors, including characteristics of the FAP syndrome within the patient and family, differences in likely postoperative functional outcome, preoperative anal sphincter status, and patient preference.⁸

TPC with permanent ileostomy, although rarely chosen as a primary procedure, is used in patients with invasive cancer involving the sphincters or levator complex, or patients for whom an IPAA is not technically feasible (secondary to desmoid disease and foreshortening of the small bowel mesentery, making it surgically impossible to bring the ileal pouch to the anus) nor likely to lead to good function such as massive obesity or weak anal sphincters. However, TPC is occasionally chosen as a primary procedure by patients who perceive that their lifestyle would be compromised by the frequent bowel movements (five to six per day) sometimes associated with the IPAA procedure.

In addition to these issues, the key in deciding between an IPAA and an IRA is based primarily on the risk of rectal cancer development if the rectum is left in situ. The risk of rectal cancer following IRA may range from 3% to 10% at 10 years, while the risk for a secondary proctectomy for uncontrolled rectal polyposis ranges from 10% to 61% at 20 years following initial colectomy with IRA.⁹²⁻⁹⁴ The magnitude of risk in an individual patient is, however, related to the overall extent of colorectal polyposis. IRA may be considered for patients with <1,000 colorectal polyps (including those with attenuated FAP) and <20 rectal adenomas, as these individuals have a relatively low risk of developing rectal cancer.^{88,93} Patients with severe rectal (>20 adenomas) or colonic (>1,000 adenomas) polyposis, an adenoma >3 cm, or an adenoma with severe dysplasia should ideally undergo a risk-reducing procedure that will include a proctectomy.^{90,91,95}

The risk of secondary rectal excision, due to uncontrollable rectal polyposis or rectal cancer, may be estimated by identifying the specific location of the causative APC mutation. Patients with mutations located between codons 1250 and 1464 have been shown to have a six-fold increased risk of developing rectal cancer, compared to those with mutations prior to codon 1250 or after codon 1464 (mean number of rectal polyps 42 versus 22, respectively).^{8,92} Although the use of the genotype-phenotype relationship to guide patient management may be appealing,⁹² it is important to recognize the variability of phenotypic expression that exists even among members of the same family. This suggests that at the current time, the choice between an IRA and an IPAA should be based primarily on clinical (rather than genetic) grounds.⁹⁰

The risk of polyp and cancer development following primary surgery is not limited to patients undergoing IRA. In patients undergoing IPAA, neoplasia may occur at the site of ileal pouch anastomosis; the frequency appears to be greater after stapled anastomosis (28% to 31%) than after mucosectomy and hand-sewn anastomosis (10% to 14%).⁹⁵ In the case of neoplasia developing at the anal transition zone after a stapled anastomosis, transanal mucosectomy may be performed, followed by advancement of the pouch to the dentate line. Of additional concern is the development of adenomatous polyps in the ileal pouch, which occurs in approximately 45% of patients by 10-year follow-up.⁹⁶ Consequently, depending on polyp burden, lifetime endoscopic surveillance of the rectal remnant (after IRA) every 6 to 12 months or the ileal pouch (after IPAA) every 1 to 3 years is required following either procedure.⁸⁹

Another important consideration in choosing between IPAA and IRA is postoperative bowel function and quality of life. Some studies have associated IPAA with higher frequency of both daytime and nocturnal bowel movements, higher incidence of passive incontinence and incidental soiling, and greater postoperative morbidity.⁹⁷ However, long-term follow-up demonstrates a comparable quality of life following IPAA for FAP relative to the patient's preoperative baseline.⁹⁸ Therefore, although the choice of procedure must be carefully individualized, because of the risk of rectal cancer associated with IRA, the authors favor IPAA for most patients with FAP whenever feasible. However, an IRA should be considered in specific circumstances, such as when there is mild rectal polyposis (as in AFAP), or a young patient with rectal sparing who is not interested in undergoing the multiple procedures that accompany an IPAA and diverting loop ileostomy, or a young woman interested in having children and trying to avoid the decreased fecundity associated with an IPAA procedure.⁹⁹ The use of minimally invasive techniques such as laparoscopy may reduce the risk of infertility associated with IPAA.^{100,101} Though a diverting loop ileostomy should be performed in all IPAA procedures, it is not always feasible due to a number of anatomic factors such as body habitus.

Endoscopic surveillance of the rectal segment at 6- to 12-month intervals after the index surgery is recommended, with subsequent surveillance frequencies dependent on the number and size of adenomas observed.⁸⁹ Although small (<5 mm) scattered adenomas can be safely observed or removed with biopsy forceps, polyps >5 mm should be removed by snare. However, repeated

fulguration and polypectomy over many years can lead to difficulty with subsequent polypectomy, reduced rectal compliance, and difficulty identifying flat cancers in the background of scar tissue. The development of severe dysplasia and/or villous adenomas not amenable to endoscopic removal is indication for proctectomy.

Long-Term Considerations from Extracolonic Manifestations

Despite the reduced risk of CRC-related death following prophylactic colectomy, patients with FAP are still at increased risk of mortality from both rectal cancer and other causes relative to the general population. The three main causes of death following IRA are progression of desmoid disease, stomach and duodenal cancer, and perioperative mortality. Additional FAP-related extraintestinal manifestations include epidermoid cysts, supernumerary teeth, osteomas of the jaw and/or skull, congenital hypertrophy of the retinal pigment epithelium, cancers of the hepatopancreatobiliary tract and genitourinary tract, and thyroid cancer.¹⁰²⁻¹⁰⁴

Desmoids

Desmoids may occur in 10% to 25% of patients with FAP.^{105,106} Unlike those found in the general population, FAP-associated desmoids tend to be intra-abdominal and arise following abdominal surgery.^{106,107} Although conflicting reports exist, it appears that female patients, those with extracolonic manifestations of FAP, a positive family history of desmoids, and APC mutations located at 3' of codon 1440 are at increased risk of developing desmoids.^{106,108,109} These tumors often involve the small bowel mesentery as well as the retroperitoneum and are often life-threatening due to invasion or compression of adjacent viscera. Further, recurrence and morbidity rates are high following attempted resection, with recurrent disease often more aggressive than the initial desmoid. Estimated 5-year overall survival for patients with intra-abdominal desmoids causing severe symptoms such as significant pain and septic fistula/abscess, diameter >20 cm or rapidly growing, and/or need for parenteral nutrition is only 53%.¹⁰⁷ Therefore, desmoid resection is evaluated on an individualized case-by-case basis with surgery reserved for highly select cases.

Desmoids that involve the small bowel mesentery may preclude the formation of an IPAA secondary to foreshortening of the small bowel mesentery, especially in patients undergoing proctectomy after an initial IRA.¹¹⁰ Surgery for intra-abdominal and abdominal wall desmoids should be reserved for limited disease where the likelihood of clear margins is high.

In symptomatic cases where resection of an intra-abdominal desmoid may not be feasible, intestinal bypass or ureteral stenting may be necessary to alleviate bowel or urinary obstruction secondary to mass effect. In addition to surgical intervention, several medical options with variable efficacy are available for the management of desmoid disease and include nonsteroidal anti-inflammatory drugs (e.g., sulindac), selective estrogen receptor modulators (e.g., tamoxifen), immunomodulators (e.g., imatinib, sorafenib, interferon), doxorubicin-based cytotoxic chemotherapy, and radiation.

MYH-Associated Polyposis

MAP should be suspected in patients with >10 colorectal adenomas, a weak history of CRC, and no family history of FAP. The diagnosis is confirmed by *MUTYH* (*MYH*) gene testing.^{80,88}

Depending on the polyp burden, the management of the colon and rectum of a patient with a biallelic *MYH* mutation can be endoscopic or surgical. If the polyp burden is limited and an endoscopic approach is pursued, colonoscopy should be performed every 1 to 3 years.^{87,89} If the polyp burden is not amenable to an endoscopic approach at the time of diagnosis, then a resection is indicated. In most cases in which surgery is deemed necessary, an IRA is sufficient. However, if rectal polyposis is severe, an IPAA

may be indicated. Indications for surgery following an endoscopic surveillance program include increasing polyp size or number, or worsening histology.

Extracolonic manifestations of MAP are similar to FAP and include osteomas, desmoids, congenital hypertrophy of the retinal pigment epithelium, as well as cancers of the thyroid, ovary, bladder, sebaceous gland, and breast. In addition, patients with MAP are also at a 4% lifetime risk of developing duodenal cancer and require upper endoscopies every 1 to 3 years beginning as early as ages 18 to 20 years and starting no later than ages 30 to 35 years.^{87,89,171}

Lynch Syndrome

Due to the discordance associated with the term hereditary non-polyposis colorectal cancer, the use of this term has largely been abandoned with reversion back to the eponym LS, which refers to individuals with a predisposition to CRC and other malignancies as a result of a germline MMR mutation.¹¹² Overall, CRC occurs in up to 80% of patients with LS by their mid-40s.^{8,82} Endometrial cancer occurs in 40% to 60%, gastric cancer in 11% to 19%, urinary tract cancer in 5% to 18%, and ovarian cancer in 9% to 15% of affected individuals.^{8,82,87}

The Amsterdam criteria and revised Bethesda guidelines¹¹³ (Table 32.3) are used in clinical practice to identify patients at risk for LS who require further genetic evaluation. The Amsterdam criteria, which led to the identification of the LS-causing MMR gene mutations require that there be:

- Three relatives (one a first-degree relative of the other two) with colorectal, endometrial, stomach, ovary, small bowel, ureteral/renal pelvis, brain, hepatobiliary, and/or sebaceous cancer;
- In two or more successive generations;
- With at least one case of cancer diagnosed before the age of 50;
- And that FAP as a diagnosis is excluded.¹¹⁴

Though the Amsterdam criteria can be used clinically to identify potential patients with LS, using it alone will result in identification

of only 42% of LS mutation carriers.¹¹⁵ Families meeting Amsterdam criteria but lacking an MMR mutation are referred to as having “familial colorectal cancer type X” and appear to have a lower incidence of colorectal and extracolonic cancers than those with a LS germline MMR mutation (see Fig. 32.6). Of note, they have an increased incidence of left-sided and nonmucinous microsatellite stable tumors.^{77,88}

Patients with CRC who belong to pedigrees suspicious for LS should be offered screening by IHC for loss of MMR protein expression or by MSI analysis. As the sensitivity of IHC testing for loss of MMR protein expression is comparable to MSI testing, either approach can be pursued.¹¹² However, IHC testing is less expensive and can also identify a specific MMR protein loss, which can help target subsequent germline testing. Routine IHC testing for loss of MMR protein in individuals younger than 50 years at the time of CRC diagnosis is feasible and has led to the identification of patients with LS who might otherwise have been missed.^{116,117} Patients with MSI-high tumors should undergo testing for germline MMR mutations in *MSH2*, *MLH1*, *MSH6*, and *PMS2*. Reflex IHC and/or MSI testing on all newly diagnosed CRC has been advocated by some expert groups and has been successfully implemented at some institutions.^{83,112,118} However, a majority of cancer programs nationwide currently do not have a protocol for reflex testing for LS, citing lack of institutional protocols as well as fear of nonreimbursement.¹¹⁹ As such, a unified move toward universal testing remains some time away. In families for which tumor tissue is not available, initial germline testing may be considered though the financial burden is not insignificant, with the cost of finding a single LS carrier measuring approximately \$58,000 (compared to the \$5,000 spent in finding a single LS carrier using IHC screening).¹²⁰ As in FAP, a mutation in an affected individual must be established for testing in at-risk individuals to be conclusive.

In lieu of universal testing, several predictive models such as the MMRpredict, MMRpro, and PREMM_{1,2,6} have been devised in order to assess an individual’s likelihood of harboring LS.^{115,121,122} These models quantify an individual’s risk for carrying an *MLH1*, *MSH2*, or *MSH6* germline mutation by using clinical characteristics such as age at onset of CRC and/or other LS-associated cancers, location of CRC, family history, history of synchronous or metachronous CRC, among others. A study of these predictive models demonstrated that they all performed better than the revised Bethesda guidelines in terms of identifying patients with germline mutations for LS.¹²³ The MMRpredict model appeared to have to be the best predictor, with a sensitivity and specificity for LS of 94% and 91%, respectively. Other validation studies, however, have not demonstrated the superiority of MMRpredict compared to the other aforementioned models.^{124,125} It appears that the use of clinical characteristics in combination with MSI or MMR protein expression status in predictive models may potentially improve our ability to establish LS diagnoses in patients with CRC. However, the practicality and applicability of these tools in a clinical setting requires further assessment.

Although development of CRC in LS is not a certainty, the 80% lifetime risk, the 16% to 30% risk of metachronous CRC, and the possibly accelerated adenoma-to-carcinoma sequence mandate consideration of prophylactic surgical options.^{82,87,126–129} Patients with LS who have a CRC or more than one advanced adenoma should be offered the options of prophylactic total colectomy with IRA or segmental colectomy with annual postoperative surveillance colonoscopy. Careful surveillance is also necessary after total colectomy and IRA, as the risk of high-risk adenomas and cancer in the retained rectum at a median of 104 months are 11% and 8%, respectively.¹²⁶ Although there has been no study demonstrating an improved survival for patients with LS undergoing total colectomy and IRA versus segmental colectomy, mathematical models suggest a slight survival benefit for total colectomy and IRA, especially for individuals under the age of 30.^{130,131} In addition, because of increased rates of metachronous CRC development and the risk of multiple abdominal surgeries

TABLE 32.3

The Revised Bethesda Guidelines for Testing Colorectal Tumors for Microsatellite Instability

Tumors from individuals should be tested for MSI in the following situations:

1. Colorectal cancer diagnosed in a patient who is <50 y of age.
2. Presence of synchronous, metachronous colorectal, or other HNPCC-associated tumors,^a regardless of age.
3. Colorectal cancer with the MSI-H^b histology^c diagnosed in a patient who is <60 y of age.^d
4. Colorectal cancer diagnosed in one or more first-degree relatives with an HNPCC-related tumor, with one of the cancers being diagnosed under age 50 years.
5. Colorectal cancer diagnosed in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age.

MSI, microsatellite instability; HNPCC, hereditary nonpolyposis colorectal cancer; MSI-H, microsatellite instability–high.

^a HNPCC-related tumors include colorectal, endometrial, stomach, ovarian, pancreas, ureter and renal pelvis, biliary tract, and brain (usually glioblastoma as seen in Turcot syndrome) tumors, sebaceous gland adenomas and keratoacanthomas in Muir-Torre syndrome, and carcinoma of the small bowel.

^b MSI-H in tumors refers to changes in two or more of the five National Cancer Institute–recommended panels of microsatellite markers.

^c Presence of tumor-infiltrating lymphocytes, Crohn’s-like lymphocytic reaction, mucinous/signet ring differentiation, or medullary growth pattern.

^d There was no consensus among the workshop participants on whether to include the age criteria in guideline 3; participants voted to keep <60 years of age in the guidelines.

From Umar A, Boland CR, Terdiman JP, et al. Revised Bethesda Guidelines for hereditary nonpolyposis colorectal cancer (Lynch syndrome) and microsatellite instability. *J Natl Cancer Inst* 2004;96:261–268.

in those undergoing a segmental resection, a total colectomy and IRA has emerged as the procedure of choice for the index cancer, with consideration for TPC in cases where a high risk of metachronous rectal cancer can be predicted.¹²⁶⁻¹²⁸ Targeted genetic testing approaches—such as the single amplicon MSH2 A636P mutation test in Ashkenazi Jewish patients with CRC—have demonstrated how a rapid and inexpensive preoperative genetic test can help direct the extent of colon resection.¹³²

LS mutation carriers with a normal colon and without a history of CRC may also be offered prophylactic colectomy in highly select situations. One rationale for this approach is the similarity of lifetime cancer risk between patients with APC and MMR gene mutations, and the fact that total abdominal colectomy with IRA produces less functional disturbance than the prophylactic procedure recommended for FAP (TPC with IPAA). However, an alternate strategy for these individuals is surveillance by colonoscopy, which is cost-effective and greatly reduces the rate of CRC development and overall mortality.¹³³ There is a risk of CRC development in the interval between colonoscopies, though most interval cancers tend to be early stage.^{134,135} As such, given that metachronous CRC may develop in as short a duration as a median of 11.3 months,¹³⁶ the recommended interval for surveillance colonoscopies is now every 1 to 2 years.⁸⁹ While prophylactic colectomy is not routinely recommended, it may be indicated in highly select patients for whom colonoscopic surveillance is not technically possible or in those who refuse to undergo regular surveillance. A decision analysis model suggests that prophylactic subtotal colectomy at age 25 may offer a survival benefit of 1.8 years, compared with surveillance colonoscopy. The benefit of prophylactic colectomy decreases when surgery is delayed until later in life and is negligible when performed at the time of cancer development.¹³⁷ Thus, the decision between prophylactic surgery and surveillance for a gene-positive unaffected individual is based on many factors including penetrance of disease in the

TABLE 32.4

Prophylactic Total Abdominal Colectomy and Ileorectal Anastomosis for Lynch Syndrome Patients without Cancer

Pros

- Elimination of colon cancer risk
- Elimination of need for surveillance colonoscopy
- Alleviating patient anxiety over the prospect of colon cancer development

Cons

- Persistence of risk of rectal cancer development
- Rectum still requires flexible endoscopic surveillance
- Patient anxiety of prospect of rectal cancer persists
- Possible altered bowel function
- Risk of surgery and possible associated complications

family, early age-of-onset in affected family members, functional and quality-of-life considerations, and likelihood of compliance with surveillance. Table 32.4 lists some of the pros and cons of a prophylactic colectomy for germline mutation carriers for LS without a history of CRC. Patients with LS and an index rectal cancer should be offered the options of TPC with IPAA or anterior proctosigmoidectomy with primary reconstruction.^{128,138} The rationale for TPC is the 10% to 15% associated risk of metachronous colon cancer in the remaining colon following the index rectal cancer. Choosing between the two procedures depends, in part, on the patient's willingness to undergo intensive surveillance of the retained proximal colon, as well as issues regarding quality of life and bowel function.

Dean E. Brenner, Scott M. Lippman, and Susan T. Mayne

WHY CANCER PREVENTION AS A CLINICAL ONCOLOGY DISCIPLINE

Until recently, clinical oncology has been defined as a medical specialty that attempts to intervene in order to slow or reverse the final stage of the cancer process—the clonally derived, genomically damaged, invasive cell mass. Cancer is a long process, a stepwise carcinogenic progression that encompasses critical molecular events that culminate in the loss of key cellular control homeostatic functions (e.g., control of proliferation, apoptosis, invasion, angiogenesis).¹ These events occur prior to and during the morphologic changes that have historically defined neoplasia. Morphologic changes, such as subtle increases in cellular proliferation that progress to early and late precancerous lesions containing dysplastic cells, characterize the carcinogenesis process (Fig. 33.1).¹⁻³ Opportunities for intervention in this process can include diverse, nonpharmacologic approaches (e.g., obesity management via diet/lifestyle interventions) or pharmacologic interventions (e.g., drugs or nutrients/nonnutrient substances used as drugs) aimed at delaying or reversing the carcinogenesis process prior to or following the appearance of early morphologic changes. Cancer screening and early detection strategies (e.g., surveillance endoscopy, fecal occult blood testing, mammography) identify not only those individuals with early stage, curable malignant transformations, but also those individuals with noninvasive neoplasias who are at risk for progression to transformed invasive malignancies.

Recognizing that cancer is a continuum, oncologists are increasingly expected to be knowledgeable about a diverse array of cancer-related topics including lifestyle behaviors such as diet and exercise, risk assessment, screening, other preventive interventions, in addition to current treatments for advanced malignancy. The understanding, use, and management of interventions designed to delay or reverse the carcinogenesis process have become integral components of the this role.⁴

DEFINING CANCER RISK-REDUCING AGENTS (CHEMOPREVENTION)

Cancer risk reduction, commonly referred to as chemoprevention, is the use of a range of interventions from drugs to isolated dietary components to whole-diet modulation to block, reverse, or prevent the development of invasive cancer.^{5,6} Human cancer risk reduction asserts that one can intervene at many steps in the carcinogenic process, which occurs over many years. This prolonged latency provides opportunities to intervene at many time points and at multiple events in the carcinogenic process. Successful deployment of cancer risk-reducing agent interventions requires evidence of reduced cancer-associated incidence and/or mortality.

The concept of field carcinogenesis was first described in the early 1950s as *field cancerization* in squamous cell carcinomas of the head and neck, and subsequently ascribed to many epithelial sites. The field carcinogenesis concept is that patients have a wide surface area of precancerous or cancerous tissue change that can

be detected at the gross (oral premalignant lesions, polyps), microscopic (metaplasia, dysplasia), and/or molecular (gene loss or amplification) levels. Recent molecular studies detecting profound genetic alterations in histologically normal tissue from high-risk individuals have provided strong support for the field carcinogenesis concept. The implication of the field effect is that multifocal, genetically distinct, and clonally related premalignant lesions can progress over a broad tissue region.¹ The essence of cancer risk reduction, then, is intervention within the multistep carcinogenic process and throughout a wide field.

IDENTIFYING POTENTIAL CANCER RISK-REDUCING AGENTS

Cancer risk-reducing agent identification results from the synthesis of data from population, basic, translational, and clinical sciences. Findings from all of these disciplines are combined to contribute to the identification of agents with the potential to delay or reverse the carcinogenesis process (see Fig. 33.1).

The Hanahan and Weinberg hallmarks of malignant transformation—self-sufficiency in growth signals, insensitivity to growth-inhibitory signals, evasion of apoptosis, limitless replication potential, sustained angiogenesis, and tissue invasion and metastasis⁷—reflect the loss of cellular signaling control. The molecular damage that results in transformation is triggered by a large array of genetic and environmental stressors such as chronic inflammation, oxidation, inherited genetic mutations, and exogenous environmental exposures. Many such signaling intermediates have common functions in multiple organ sites (see Fig. 33.1). The complexity and overlap of signal transduction pathways suggests that single molecular therapeutic/preventive targets may have limited effectiveness. Interventions aimed at preventing the occurrence of or overcoming the effects of molecular defects in multiple pathways or targets may be required to arrest or reverse carcinogenesis. Using the Hanahan and Weinberg hallmarks, examples of possible targets are shown in Table 33.1.

PRECLINICAL DEVELOPMENT OF CANCER RISK-REDUCING AGENTS

Similar to the development of therapeutic interventions, the assessment of efficacy and toxicity of single chemically synthesized entities, agents designed *in silico*, botanicals, nutrients/nonnutrient substances used as drugs for cancer risk-reducing agent efficacy proceeds through a translational paradigm that identifies efficacy in cell culture models, in live animal models, and in humans. Preclinical models that simulate the carcinogenesis process in target epithelia identify molecular biomarkers for modulation by interventions. These models can be used to identify potential toxicity of interventions and to assess the effect of interventions on the development and progression of preneoplasia/neoplasia.⁸

The U.S. National Cancer Institute's (NCI) PREVENT Cancer Preclinical Drug Development Program is a prime example of a

Molecular Biomarkers of Carcinogenesis

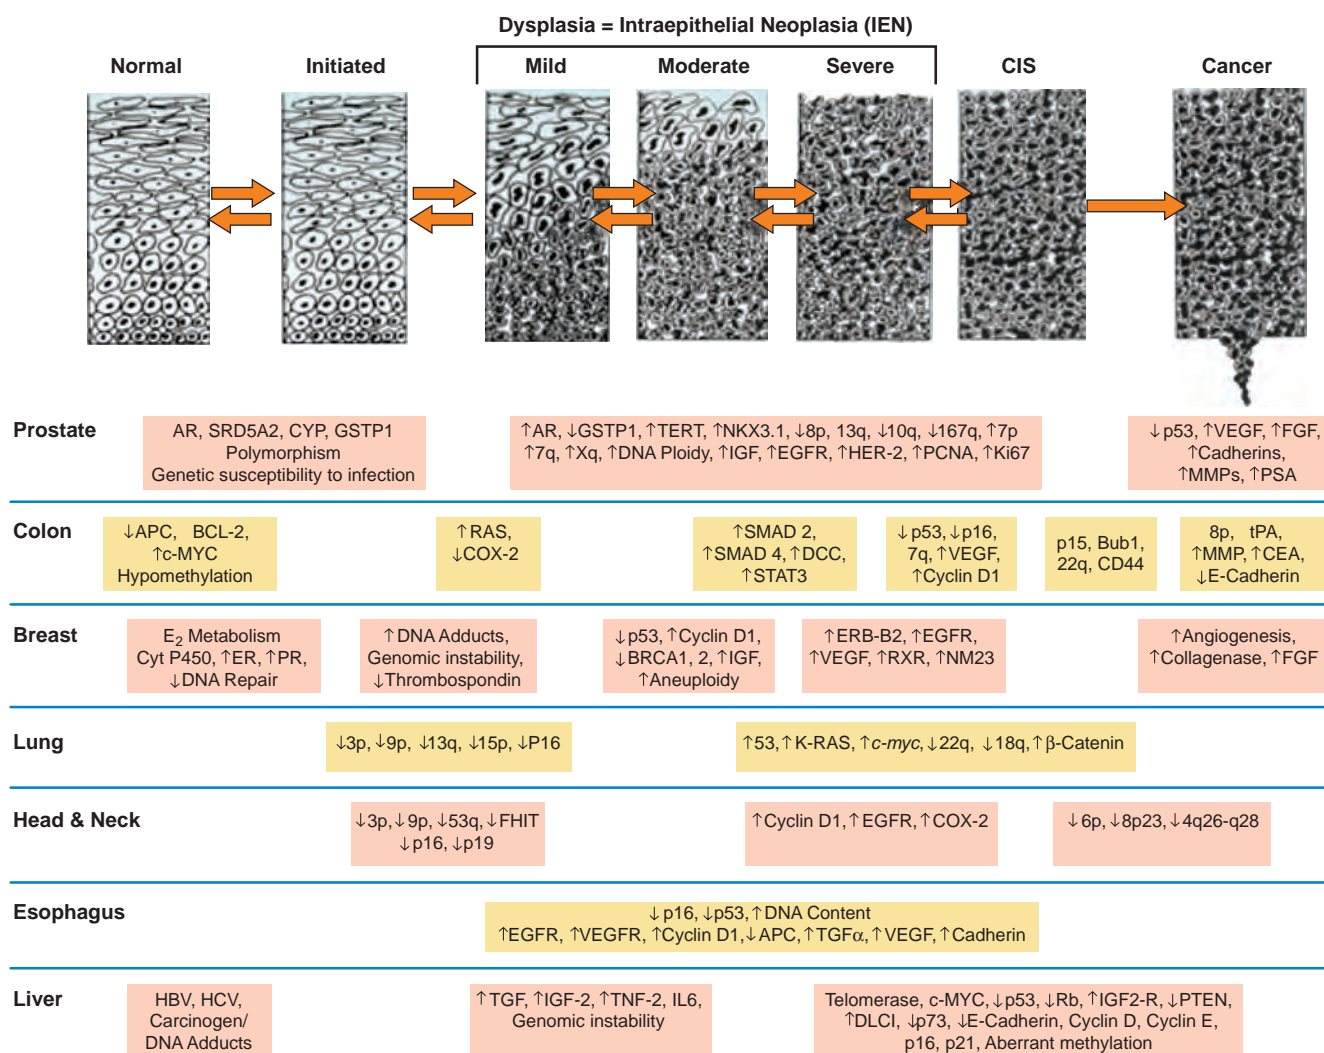

Figure 33.1 Genetic progression in major cancers. Carcinogenesis is driven by genetic progression. This progression is marked by the appearance of molecular biomarkers in distinctive patterns representing accumulating changes in gene expression and correlating with changes in histologic phenotype as cells move from normal through the early stages of clonal expansion to dysplasia and finally to early invasive, locally advanced, and metastatic cancer. The figure²⁵⁷ shows candidate molecular biomarkers of genetic progression in seven target organs: the prostate,^{300–302} the colon,² the breast,^{303,304} the lung,^{305–307} the head and neck,^{308–311} the esophagus,^{312,313} and the liver.³¹⁴ CIS, carcinoma in situ; AR, androgen receptor; CYP, cytochrome P-450; GSTP1, glutathione S transferase P1; TERT, telomerase reverse transcriptase; NKX3.1, NK 3 transcription factor related, locus 1 (prostate specific, androgen regulated); IGF, insulin-like growth factor; EGFR, epidermal growth factor receptor; HER-2, human epidermal growth factor receptor-2; PCNA, proliferating cell nuclear antigen; VEGF, vascular endothelial growth factor; FGF, fibroblast growth factor; MMP, matrix metalloproteinase; PSA, prostate-specific antigen; APC, adenomatous polyposis coli; BCL-2, B-cell lymphoma 2 gene, apoptosis control; c-MYC, v-myc avian myelocytomatosis viral oncogene homolog; COX-2, cyclooxygenase-2; SMAD, homolog of mothers against decapentaplegic + *C. Elegans* SMA protein; DCC, deleted in colon cancer gene; CEA, carcinoembryonic antigen; ER, estrogen receptor; PR, progesterone receptor; ERB-B2, Receptor tyrosine-protein kinase erbB-2, same as HER-2; RXR, retinoid X receptor; NM23, Nucleoside diphosphate kinase A; K-RAS, Kirsten rat sarcoma viral oncogene homolog; FHIT, fragile histidine triad protein; TGFα, tumor growth factor alpha; HBV, hepatitis B virus; HCV, hepatitis C virus; TNF-2, tumor necrosis factor 2; IL6, interleukin 6; PTEN, phosphatase and tensin homolog. (Figure and revised caption from Kelloff GJ, Lippman SM, Dannenberg AJ, et al. Progress in chemoprevention drug development: the promise of molecular biomarkers for prevention of intraepithelial neoplasia and cancer—a plan to move forward. *Clin Cancer Res* 2006;12:3661–3697, published with permission from the American Association for Cancer Research.)

rational strategy to select promising agents for clinical trials through a stepwise approach of preclinical *in vitro* testing followed by *in vivo* screening.^{8–10} This system involves several phases: biochemical prescreening assays, *in vitro* efficacy models, *in vivo* short-term screening, animal efficacy testing, and preclinical toxicology testing.

Biochemical Prescreening Assays

Prescreening assays are a series of short-term, mechanistic assays developed to evaluate the ability of a test compound to modulate biochemical events presumed to be mechanistically linked to carcinogenesis.⁸

These *in vitro* assays are rapidly completed for potential cancer risk-reducing agents. Examples of such assays include carcinogen-DNA binding, prostaglandin synthesis inhibition, glutathione-S-transferase inhibition, and ornithine decarboxylase inhibition.

In Vitro Efficacy Models

In vitro assays test the cancer risk-reducing activity of a screened compound in four epithelial cell systems (primary rat tracheal epithelial cells, human lung tumor [A427] cells, mouse mammary organ cultures [MMOC], and human foreskin epithelial cells).

TABLE 33.1

Molecular Mechanisms Common to Transforming Cells and Potential Preventive Interventions

Characteristics of Neoplasia	Possible Molecular Targets
■ Self-sufficiency in cell growth	EGFR, platelet-derived growth factor, MAPK, PI3K
■ Insensitivity to antigrowth signals	SMADs, pRb, cyclin-dependent kinases, MYC
■ Limitless replicative potential	hTERT, pRb, p53
■ Evading apoptosis	Bcl-2, BAX, caspases, Fas, tumor necrosis factor receptor, insulin growth factor/PI3K/Akt, mTOR, p53, NF-κB, PTEN, RAS
■ Sustained angiogenesis	VEGF, basic fibroblast growth factor, integrins (α _v β ₃), thrombospondin-1, HIF-1α
■ Tissue invasion and metastases	MMPs, MAPK, E-cadherin

EGFR, epidermal growth factor receptor; MAPK, mitogen-activated protein kinase; PI3K, phosphoinositide 3-kinase; SMAD, drosophila protein, mothers against decapentaplegic gene and the *Elegans* protein SMA; pRb, phosphorylated Rb protein; hTERT, human telomerase reverse transcriptase; mTOR, mammalian target of rapamycin; NF-κB, nuclear factor kappa B; PTEN, phosphatase and tensin homolog; VEGF, vascular endothelial growth factor; HIF-1α, hypoxia-inducible factor-1α; MMP, Matrix metalloproteinases. Progress in chemoprevention drug development: the promise of molecular biomarkers for prevention of intraepithelial neoplasia and cancer—a plan to move forward. *Clin Cancer Res* 2006;12:3661–3697 and derived from Hanahan D, Weinberg RA. The hallmarks of cancer. *Cell* 2000;100:57–70.

The assays measure the ability of potential cancer risk-reducing agents to reverse transformation in normal epithelial cells exposed to carcinogens. For example, after treatment with a carcinogen such as 7,12-dimethylbenz(a)anthracene, MMOCs develop lesions similar to alveolar nodules that are considered precancerous in mouse mammary glands in vivo.¹¹ Pretreatment of organ cultures before carcinogen exposure measures the effect of cancer risk-reducing agents in the initiation stage of carcinogenesis, whereas treatment

after carcinogen exposure measures activity during tumor promotion. Three of these assays (using rat tracheal epithelial, A427, and MMOC cells) have shown predictive values of 76% to 83% for cancer risk-reducing agent efficacy in in vivo models.⁸

Preclinical In Vivo Models for Cancer Risk-Reducing Agent Efficacy Testing

Animal models remain a crucial link in the efficacy assessment of cancer risk-reducing agents for epithelial cancer. Chemical carcinogenesis models provide the reproducible development of tumors in animals following the administration of a known chemical initiator or combination initiator/promoter and have been the primary in vivo screening tool for cancer risk-reducing agents (Table 33.2A).^{12,13} Carcinogenesis models employing genetically engineered mice permit the interrogation of targeted pathways and the corresponding efficacy of cancer risk-reducing agents. Although useful for mechanistic studies, knockout or genetic mutational models create accelerated neoplastic progression that does not accurately recapitulate the more complex, stepwise, human carcinogenesis process. Recombinant alleles can be driven by the addition of drug-sensitive regulatory elements, such as tetracycline or tamoxifen analogs. The drug-sensitive regulatory elements achieve temporal control over a gene promoter through the administration of the drug that binds to the regulatory element. Such a system permits the inhibition or overexpression of the organ-specific gene using Cre recombinase, a site-specific DNA recombinase that targets DNA regions flanked by loxP sequences. Tables 33.2A and 2B list representative organ-specific chemical and transgenic mouse models that may be used for cancer risk-reducing agent testing.

CLINICAL DEVELOPMENT OF CANCER RISK-REDUCING AGENTS

Special Features of Cancer Risk-Reducing Agent Development

The clinical efficacy assessment of cancer risk-reducing agents employs phased testing (phase I to III) models used for development of drugs¹⁴ but with crucial differences in study design and end points. Special features for the clinical development of

cancer risk–reducing agents create the following challenges to be overcome: (1) the need for large therapeutic index (doses associated with potential toxicity of an intervention need to substantially exceed doses aimed at delaying or reversing transformation) for use in individuals who are asymptomatic yet may benefit from an extended (years) treatment course; (2) the long latency to malignant transformation (an assessment of effectiveness based on the reduction in cancer incidence requires studies lasting for years and involving thousands of participants); (3) adherence (once-daily dosing regimens using interventions that have sufficiently long half-lives may minimize the impact of a missed dose yet maintain the biologic impact on the physiologic target; minimal toxicity and strong psychological commitment to preventive goals also enhance adherence¹⁵); and (4) complex risk assessment for cancer (individuals with highly penetrant but infrequent, germ-line genetic susceptibility to breast and colon cancers^{16,17} are excellent candidates for cancer risk–reducing agents and are likely to accept some toxicity for reduced cancer risk). For individuals at more modestly increased risk (e.g., long-term, current smokers; persons with a family history of cancer; women with mammographically dense breasts), quantitative risk assessment algorithms may be useful in the future to identify optimal cancer risk–reducing agents. The refinement of cancer risk calculators for breast,¹⁸ colon,¹⁹ and prostate cancer²⁰ promises to appropriately select high-risk individuals for cancer risk–reducing agents such that anticipated benefits exceed potential risks.

Biomarkers as Cancer Risk–Reducing Agent Targets and Efficacy End Points

A biomarker is a characteristic that is measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to therapeutic interventions.²¹ A surrogate end point for cancer prevention assumes that a measured biologic feature will predict the presence or future development of a cancer outcome.²² Biomarkers enable a reduction in the size and duration of an intervention trial by replacing a rare or distal end point with a more frequent, proximate end point.²³ Intraepithelial

neoplasia has served and continues to serve as a biomarker for invasive malignancy (Table 33.3). Although many advocate the use of intraepithelial neoplasia-based biomarkers as regulatory surrogate end points, others caution that intraepithelial neoplasias may not serve as sufficiently robust surrogate biomarkers for cancer incidence or mortality.²⁴

In order to be useful as end points for cancer risk–reducing agent efficacy testing as regulatory end points, any biomarker must have statistical accuracy, precision, and effectiveness of results²⁴ that demonstrate prediction of a *hard* disease end point—cancer incidence or mortality. An independent validation data set must address defined standards of validation that minimize bias in the study design and the populations studied.²⁵ The biomarker must be generalizable to the specific clinical or screening population (Table 33.4).

Phases of Cancer Risk–Reducing Agent Development

Phase I cancer risk–reducing agent trials define an optimal cancer risk–reducing agent dose. An optimal cancer risk–reducing agent dose is one that is usually nontoxic, scheduled once daily, and modulates a tissue, cellular, or serum biomarker of drug activity (e.g., the dose of aspirin that inhibits prostaglandin production in a target tissue site). The definition of a maximum tolerated dose is not an essential end point of a phase I cancer risk–reducing agent trial. Higher, yet nontoxic doses may lower cancer risk–reducing agent efficacy. For example, β-carotene at high doses has pro-oxidant activity and may enhance the carcinogenesis process, whereas at low doses, it is a potent antioxidant and differentiating agent.²⁶

Phase II cancer risk–reducing agent trials begin to define cancer risk–reduction efficacy. These short-term (6 months to 1 year) treatment periods gather evidence of risk reduction by assessing drug effects on tissue, cellular, or blood surrogate markers of carcinogenesis. Phase IIa trials are nonrandomized, biomarker modulation trials. Phase IIb trials are randomized, placebo-controlled trials of several hundred subjects testing, for example, whether a risk-reducing agent reduces recurrence of a previously resected intraepithelial neoplastic lesion as the primary end point. Cellular dynamic

TABLE 33.3

Common Intraepithelial Neoplasias		
Epithelium	Intraepithelial Neoplasia	References
Colon and rectum	Adenoma	(264)
Lower esophagus	Barrett esophagus	(265)
Upper esophagus	Squamous dysplasia	(266, 267)
Skin: Squamous/ basal cell	Actinic keratosis	(268)
Skin: Pigmented	Dysplastic nevus	(269)

Lung	Bronchial dysplasia	(273)
Pancreas	Pancreatic intraepithelial neoplasia	(274)

(e.g., proliferation, apoptotic index), biochemical, or molecular (e.g., p53, cyclin D) end points may be used as secondary end points. Preoperative or *window of opportunity trials* enroll subjects for brief study periods prior to obtaining tissue by a planned resection of an invasive neoplasm. Such designs permit the exploration of biomarker modulation in the invasive neoplasm and in contiguous epithelial fields proximal and distal to the invasive neoplasm.²⁷

Phase III cancer risk-reducing agent trials define reduction in a hard cancer end point such as cancer incidence or mortality. Such trials, using large, higher risk populations in a randomized, double-blinded intervention, are designed to identify a standard of preventive care for a given risk population. For example, trials of tamoxifen for the reduction of breast cancer incidence,^{28,29} finasteride for the reduction of prostate cancer incidence,³⁰ and β -carotene for the reduction of lung cancer incidence³¹ serve as examples of well-conducted, definitive phase III cancer risk-reducing agent clinical trials.

Some investigators consider randomized, controlled clinical trials with an end point sufficient for regulatory review as phase III.

TABLE 33.4

Characteristics of Biomarkers for Use as End Points in Cancer Risk-Reducing Agent Efficacy Assessment
■ Variability of expression between phases of the carcinogenesis process
■ Detected early in the carcinogenesis process
■ Genetic progression or protein pathway based
■ Target of modulation by preventive interventions
■ Changes in biomarker linked to reduction in incident cancer of epithelial target
■ Changes in biomarker linked to clinical benefit
■ Can be quantified directly or via closely related activity such as a downstream target or upstream kinase
■ Measurable in an accessible biosample (preferably urine, serum, saliva, stool, or breath)
■ High throughput, technically feasible, analytical procedure with strong quality assurance/quality control procedures
■ Cost-effective

Using such a definition, a clinical trial with an end point of reduction in adenoma recurrence is considered a phase III trial. Other investigators define phase III cancer risk-reducing agent trials as randomized, controlled clinical trials with a cancer incidence or mortality end point. This controversy causes confusion in the literature. For the purpose of clarity in this textbook, the latter definition of phase III trial is used—a prospective, randomized, controlled clinical trial with a cancer incidence or mortality end point. Randomized, controlled clinical trials with a surrogate biomarker end point such as an intraepithelial neoplasia (e.g., adenoma) are defined as phase IIb cancer risk-reducing agent trials.

MICRONUTRIENTS

Definition

Micronutrients comprise a large, diverse group of molecules typically ingested as part of the diet that play roles in normal human biology. This group of compounds has been investigated extensively as cancer risk-reducing agents in purified forms (i.e., supplements), as components of multiagent cocktails, and occasionally, as components of food extracts/other mixtures. Although retinoids are not micronutrients per se, they are related to retinol (vitamin A) and share certain properties with carotenoids, which are diet derived and, therefore, included along with micronutrients.

Retinoids, Carotenoids, and Antioxidant Nutrients

Overview and Mechanisms

Retinoids are the natural derivatives and synthetic analogs of vitamin A.³² Cancer risk-reduction intervention studies have evaluated the parent compound (retinol, typically given as retinyl acetate or palmitate), naturally occurring retinoids such as all-trans-retinoic acid (ATRA) and 13-cis-retinoic acid (13cRA), and also synthetic retinoids such as etretinate and fenretinide (4-hydroxy[phenyl]retinamide [4HPR]). These agents have been of interest for cancer risk reduction for decades. Mechanistically, retinoids have been shown to modulate cellular growth and differentiation, as well as apoptosis.³² A large body of research indicates that retinoids have activity in the promotion and progression phases of carcinogenesis, including extensive evidence of efficacy in the setting of premalignant lesions, leading to their evaluation in human Phase III trials. Nuclear retinoic acid receptors mediate many of the retinoid-signaling effects; however, retinoids interact with other signaling pathways, such as estrogen signaling in breast cancer.³³

Carotenoids are a group of naturally occurring plant pigments, only some of which are found in appreciable levels in the human diet and human tissues, including beta-carotene, alpha-carotene, lycopene, lutein, and β -cryptoxanthin.³⁴ Of these, the most widely studied carotenoids for cancer risk reduction are beta-carotene and lycopene. Beta-carotene has the highest pro-vitamin A activity of the carotenoids, but alpha-carotene and β -cryptoxanthin also possess pro-vitamin A activity. Other carotenoids, such as lycopene, do not possess vitamin A activity but are known to have potent antioxidant activity, particularly with regard to singlet oxygen quenching.³⁵ Furthermore, eccentric cleavage products of beta-carotene,³⁶ as well as other non-pro-vitamin A carotenoids such as lycopene (e.g., apocarotenals, apocarotenoic acids) appear to be biologically active and may also act via retinoid-signaling pathways.³⁷

Because of the known antioxidant function of carotenoids, they are often studied for risk-reducing efficacy in combination with other antioxidant nutrients, especially vitamins E and C and selenium (sometimes as a cocktail, versus placebo). Thus, we will consider this group of nutrients first, followed by other micronutrients that are thought to act via different mechanisms and/or pathways.

Epidemiology

A large body of literature indicates that people who consume greater amounts of carotenoids from foods (primarily fruits and vegetables) and people with higher serum or plasma levels of various carotenoids have a lower risk for various cancers.³⁸ In particular, according to the systematic review of the literature conducted by the World Cancer Research Fund/American Institute for Cancer Research,³⁸ foods containing carotenoids are “probably” associated with lower risks of cancers of the mouth/pharynx/larynx and lung; foods containing beta-carotene are “probably” associated with lower risks of cancers of the esophagus; and foods containing lycopene are “probably” associated with lower risks of prostate cancer. Preformed retinol intake is inconsistently associated with risks of various cancers but that, in part, likely reflects confounding, because dietary sources of preformed retinol primarily include foods of animal origin (e.g., liver, eggs, milk). Vitamin C in the diet comes primarily from the consumption of fruits and vegetables; therefore, vitamin C and carotenoids often trend together in epidemiologic findings. Vitamin E, in contrast, is found in different foods, especially nuts, seeds, and vegetable oils; intake and blood concentrations are somewhat inconsistently associated with cancer risk.³⁹ Selenium, being a trace mineral, is difficult to measure in the diet, but higher selenium status has been associated with a lower risk of certain cancers, although the results are not entirely consistent.³⁹

Preclinical In Vivo Models

In preclinical models, retinoids induce differentiation as well as arrest proliferation³³ of various cancers, making them attractive agents for cancer risk reduction.⁴⁰ The International Agency for Research on Cancer reviewed the preclinical research involving beta-carotene, concluding that there was “sufficient” evidence of cancer preventive activity, particularly involving mouse skin tumor models and the hamster buccal pouch model.⁴¹ Notably, there was inconsistent evidence of efficacy in respiratory tract models. Lycopene has been evaluated in numerous cell culture systems and in a variety of models of prostate carcinogenesis, including chemically induced, orthotopic implantation, transgenic, and xenotransplantation, with mixed evidence of efficacy.⁴² Evidence, primarily from cell culture studies, suggests that lycopene metabolites may be at least partially responsible for anticarcinogenic activity.³⁷

Clinical Trials: Retinoids, Carotenoids, and Antioxidant Nutrients

Retinoids, carotenoids, and antioxidant nutrients have been evaluated in the setting of preneoplasia/neoplasia in many different organ sites, as will be discussed. Of the many clinical trials of retinoids and carotenoids/other antioxidant nutrients, key trials with cancer incidence/recurrence as primary outcomes are tabulated (see Tables 33.5 and 33.6) and reviewed.

Clinical Efficacy in the Upper Airway

Many trials of cancer risk-reducing agents have been done in the setting of squamous cell carcinomas of the head and neck, in large part because of the substantial clinical problem of relatively high rates of recurrences and second primary tumors in curatively treated cancer patients. Early work demonstrated that high-dose 13cRA (50 to 100 mg/m² per day) produced no significant differences in disease recurrence (local, regional, or distant) but significantly lowered the rate of second primary invasive neoplasms,⁴³ with the benefits persisting for at least 5 years.⁴⁴ Substantial retinoid toxicity, however, including skin dryness and peeling, cheilitis, conjunctivitis, and hypertriglyceridemia, was evident in a large proportion of patients. Subsequent trials thus used lower doses of retinoids (13cRA or a synthetic retinoid, etretinate), but failed to show efficacy in reducing second primary tumor formation (Table 33.5).^{45,46}

Supplemental beta-carotene has also been studied as a single agent and in combination with other agents for the prevention of second primary cancers of the mouth and throat (Table 33.6). One trial of beta-carotene alone observed no harm or benefit⁴⁷; another observed nonsignificantly fewer second head and neck cancers but more lung cancers⁴⁸; and a third gave beta-carotene with α -tocopherol (400 IU per day).⁴⁹ In the third trial, beta-carotene was discontinued early due to adverse findings from lung cancer prevention trials (see the following); however, after a median follow-up of 6.5 years, all-cause mortality was increased, which the authors attributed to the supplemental α -tocopherol. As will be discussed later, adverse effects of antioxidant nutrients are not limited to head and neck cancer patients; potential mechanisms for adverse effects are discussed further.

Clinical Efficacy in the Lung (Lower Airway)

Reversal of Metaplasia or Dysplasia. Active smokers and recent quitters have multiple preinvasive metaplastic and dysplastic lesions in the pulmonary tree. Most of these lesions resolve upon smoking cessation, but some remain and progress to invasive neoplasms. Unfortunately, micronutrient or retinoid interventions have not demonstrated preventive efficacy in most rigorous trials in patients with early lesions. For example, a US trial randomized 755 asbestos workers to receive beta-carotene (50 mg per day) and retinol (25,000 IU every other day) versus placebo; sputum atypia was not reduced after 5 years.⁵⁰ As another example, eligible smokers with lung metaplasia or dysplasia were randomized to 6 months of 13cRA or placebo. The extent of metaplasia decreased similarly (in approximately 50% of subjects) in both study arms.⁵¹ Only smoking cessation was associated with a significant reduction in the metaplasia index during the 6-month intervention.

Prevention of Invasive Neoplasms. Large, phase III efficacy trials of beta-carotene plus other micronutrients for primary prevention of lung cancer have been completed, as summarized in Table 33.6. The Alpha-Tocopherol, Beta-carotene (ATBC) Trial involved 29,133 men from Finland who were heavy cigarette smokers at entry.⁵² In a two-by-two factorial design, participants were randomized to receive either supplemental α -tocopherol, beta-carotene, the combination, or placebo. Unexpectedly, participants receiving beta-carotene (alone or in combination with α -tocopherol) had a statistically significant 18% increase in lung cancer incidence and an 8% increase in total mortality relative to participants receiving placebo. α -Tocopherol had no effect.

The finding of an increased incidence of lung cancer in the beta-carotene-supplemented smokers was replicated in the Carotene and Retinol Efficacy Trial (CARET), a large randomized trial of supplemental beta-carotene plus retinol versus placebo in asbestos workers and smokers.⁵³ This trial was terminated early, but, at the time of termination, overall lung cancer incidence was increased by 28% in the supplemented subjects and total mortality was also increased by 17%. In contrast, the Physicians' Health Study (PHS) of supplemental beta-carotene versus placebo in 22,071 male US physicians reported no significant effect—positive or negative—of 12 years of supplementation of beta-carotene on total cancer, lung cancer, or cardiovascular disease (see Table 33.6).⁵⁴ Two other trials involving supplemental beta-carotene alone (the Women's Health Study⁵⁵) or with other antioxidant nutrients (the Medical Research Council/British Heart Foundation Heart Protection Study⁵⁶) on overall cancer incidence also failed to observe efficacy.

Prevention of Second Primary Invasive Neoplasms. EUROSCAN was a multicenter trial employing a two-by-two factorial design to test retinyl palmitate and *N*-acetylcysteine (also a compound with known antioxidant activity) in preventing second primary invasive neoplasms in patients with early stage cancers

TABLE 33.5

Larger, Randomized Trials of Retinoids in Human Cancer Risk Reduction with Cancer Outcomes^{a,b}

Population	Drug (Dose)	End Point	Outcomes	References
United States, prior HNSCC	13cRA (50–100 mg/m ² /d)	Second primary tumor	Significant reduction in second primary tumors at 32 and 55 mos; however, substantial toxicity	(43, 44)
France, prior HNSCC	Etretinate (50/25 mg/d)	Second primary tumor	No difference	(46)
United States, prior HNSCC	13cRA (30 mg/d)	Second primary tumor	No difference	(45)
Europe, prior HNSCC, NSCLC	Vitamin A (300,000/150,000 IU/d) +/- N-acetylcysteine	Second primary tumor	No difference	(57)
United States, Prior NSCLC	13cRA (30 mg/d)	Second primary tumor	No difference, but second primary tumors were lower in nonsmokers on drug but higher in smokers on drug	(58)
Italy, prior breast cancer	4HPR (200 mg/d) No treatment	Contralateral breast cancer	Nonsignificant reduction; premenopausal women did better but opposite in postmenopausal women	(60)
United States, prior BCC	13cRA (10 mg/d)	Second basal cell carcinoma	No difference	(65)
United States, prior actinic keratosis	Retinol (25,000 IU/d)	Skin cancer incidence	Reduction in squamous cell carcinomas but not basal cell carcinomas	(67)
United States, prior BCC/SCC of the skin	13cRA (5–10 mg/d) Retinol (25,000 IU/d)	Second skin cancer	No significant difference for either agent	(66)
Netherlands, renal transplant patients	Acitretin (30 mg/d)	Skin cancer	Significant reduction	(64)
United States, aggressive SCC of the skin	13cRA (1 mg/kg/d) + interferon alpha	Second primary tumors and tumor recurrences	No effect	(275)
United States, prior bladder TCC	Megadose vitamins (40,000 IU retinol/d) versus RDA vitamins	Recurrence	Significant reduction in recurrence	(73)
United States, prior bladder TCC	4HPR (200 mg/d)	Recurrence	No difference	(72)

^aTrials of retinoids that also included beta-carotene are listed under Table 33.2 only.

^bVersus placebo unless otherwise indicated.

HNSCC, head and neck squamous cell carcinoma; NSCLC, non-small-cell lung cancer; BCC, basal cell carcinoma; TCC, transitional cell carcinoma; RDA, recommended dietary allowance.

of the head and neck or lung. None of the interventions reduced second airway primary invasive neoplasms.⁵⁷ The Lung Intergroup Trial randomized patients with surgically resected lung cancer to 13cRA versus placebo and found no significant differences between the two arms in second primary tumors.⁵⁸ Notably, smoking status modified the effect of the 13cRA intervention, which was harmful in current smokers yet beneficial in former smokers.

Thus, phase III trials of both carotenoids/antioxidants and retinoids indicate that these agents overall do not reduce the risk of developing invasive lung cancers, nor do they prevent the development of second primary invasive neoplasms. However, the finding that former smokers seemed to benefit from both 13cRA⁵⁸ and beta-carotene⁵³ is intriguing. Mechanistic work suggests this interaction is real rather than chance (see the following), suggesting that (1) risk-reduction in smokers is especially challenging,⁵⁹ and (2) trials in former smokers may merit consideration.

Clinical Efficacy in the Breast

Moon et al.⁴⁰ first showed that fenretinide was a promising cancer risk-reducing agent for the breast, having a high therapeutic index and synergistic interaction with tamoxifen in mammary carcinogenesis model studies. This laboratory work led to a large-scale

randomized trial of fenretinide (versus no treatment) for 5 years to prevent contralateral breast cancer in women aged 30 to 70 years with a history of resected early breast cancer and no prior adjuvant therapy.⁶⁰ The intervention produced no significant overall effect, although fenretinide reduced contralateral and ipsilateral breast cancer rates in premenopausal women, with an opposite (adverse) trend observed in postmenopausal women. The reduced incidence of second breast cancer in premenopausal patients persisted with longer follow-up.⁶¹

Retinoid X receptor (RXR)-selective retinoids are also being evaluated in preclinical and clinical studies. Ongoing work suggests that combination treatment may represent a promising new strategy to suppress both estrogen receptor-negative and estrogen receptor-positive breast tumors, and the combination of retinoids with antiestrogens may be particularly effective.⁶²

Clinical Efficacy in the Skin

Retinoids have been widely studied for cancer risk-reducing efficacy in skin. Early work was done in patients who have substantial skin cancer risk either due to xeroderma pigmentosum or medication-induced immunosuppression for transplants. For example, 13cRA reduced skin cancer by 63% in patients with

TABLE 33.6

Randomized Trials of Antioxidant Nutrients in Human Cancer Risk Reduction with Cancer Outcomes^a

Population	Drug (Dose)	End Point	Outcomes	References
United States, prior head/neck cancer	Beta-carotene (50 mg/d)	Second primary head and neck cancers	Nonsignificant reduction in second head and neck cancer, increase in lung cancer	(48)
Italy, prior head/neck cancer	Beta-carotene (75 mg/d) for 3 mos with 1 mo off	Second primary head and neck cancers	No effect on second primary tumors, nonsignificant decrease in death	(47)
Canada, prior head/neck cancer	30 mg beta-carotene/d + 400 IU vitamin E/d	Deaths	Beta-carotene discontinued, mortality increased at end of trial	(49)
Finland, male smokers	20 mg beta-carotene/d +/- 50 mg vitamin E/d	Lung cancer	Lung cancer increased with beta-carotene, no effect vitamin E	(52)
United States, smokers and asbestos workers	Beta-carotene (30 mg/d) + retinol (25,000 IU/d)	Lung cancer	Lung cancer increased with beta-carotene + vitamin A	(53)
United States, resected stage I non-small-cell lung cancer	Selenized yeast, 200 µg/d versus placebo	Second primary cancer	No effect	(276)
United States, male physicians	Beta-carotene (50 mg every other day)	Total cancer	No effect	(54)
United States, female health professionals	Beta-carotene (50 mg/ every other day)	All cancers	No effect	(55)
United Kingdom, adults at risk for coronary heart disease	20 mg beta-carotene/d + 600 mg vitamin E/d + 250 mg vitamin C/d	Total cancers	No effect	(56)
United States, prior skin cancer	50 mg beta-carotene/d	Second skin cancer	No effect	(68)
Australia	Beta-carotene (30 mg/d)	Incident squamous cell skin cancer incident basal cell skin cancer	No effect	(69)
United States, prior skin cancer	200 µg selenium/d	Second skin cancer	No effect, with longer follow-up became adverse	(70)
Linxian County, China, general population	15 mg beta-carotene/d + 30 mg vitamin E/d + 50 µg selenium/d	Stomach cancer death Esophageal cancer death	Significant decrease in stomach cancer death; no effect on esophageal cancer death	(75)
Linxian County, China, esophageal dysplasia	Multivitamin/multimineral + 15 mg beta-carotene/d	Stomach cancer death Esophageal cancer death	No effect	(78)
United States, males	200 µg selenium/d +/- 400 IU vitamin E/d	Prostate cancer incidence	No effect; with longer follow-up vitamin E became adverse	(84)
United States, male physicians II	500 mg vitamin C/d + 400 IU vitamin E every other day	Prostate cancer incidence, total cancer incidence	No effect	(86)

^a All versus placebo.

xeroderma pigmentosum; however, severe, acute mucocutaneous toxicity with the 13cRA occurred.⁶³ Also, the preventive effect of the retinoid was lost after stopping retinoid therapy. In renal transplant patients, acitretin (30 mg per day) reduced the numbers of premalignant lesions, the number of patients with skin cancer, and the cumulative number of skin cancers.⁶⁴

In lower risk populations, low-dose 13cRA (10 mg per day)⁶⁵ and retinol or 13cRA alone did not reduce the recurrence of basal or squamous cell skin cancers,⁶⁶ although retinol alone reduced squamous but not basal cell carcinomas in patients with prior actinic keratoses.⁶⁷

Beta-carotene (50 mg per day), in a randomized trial did not reduce the recurrence of nonmelanoma skin cancers.⁶⁸ Consistent with findings in the lung, the risk was increased by 44% in current smokers randomized to beta-carotene but not in never smokers randomized to beta-carotene as compared with placebo.

Supplemental beta-carotene (30 mg per day) also did not prevent basal cell carcinoma or squamous cell carcinoma of the skin in an Australian trial.⁶⁹

Clark et al.⁷⁰ randomized patients with a history of nonmelanoma skin cancer to 200 µg per day selenium or placebo.⁷⁰ Selenium did not reduce the incidence of second skin cancers; a further report of this trial with longer follow-up⁷¹ indicated that there was instead a significant increase in total nonmelanoma skin cancer (hazard ratio [HR] = 1.17; 95% confidence interval [CI], 1.02 to 1.34) and squamous cell skin cancer (HR = 1.25; 95% CI, 1.03 to 1.51).

Clinical Efficacy in the Bladder

A trial of fenretinide (200 mg per day orally for 12 months) versus placebo was conducted for preventing tumor recurrence in

patients with nonmuscle-invasive bladder transitional cell carcinoma after transurethral resection with or without adjuvant intravesical bacillus Calmette-Guérin; recurrence rates were similar in both groups.⁷² Another trial randomized 65 patients with biopsy-confirmed transitional cell carcinoma of the bladder to a multivitamin (recommended dietary allowance [RDA] levels) alone or supplemented with 40,000 IU retinol, 100 mg pyridoxine, 2,000 mg ascorbic acid, 400 U of α -tocopherol, and 90 mg zinc.⁷³ The 5-year estimate of tumor recurrence was 91% in the RDA arm versus 41% in the higher-dose nutrient arm ($p = 0.0014$).

Clinical Efficacy in the Cervix

Randomized trials include four with beta-carotene (alone or with other antioxidant nutrients), and five with retinoids. Only one of these trials, involving ATRA,⁷⁴ found a significant treatment effect. This trial administered a 0.372% ATRA solution by collagen sponge in a cervical cap delivery system. There was a higher complete response rate in the ATRA group (43%) than the placebo group (27%; $p = 0.041$) among the 141 patients with moderate dysplasia; no significant differences in dysplasia regression rates between the two study arms were detected in patients with severe dysplasia. The investigators experienced substantial losses to follow-up in this patient population.

Clinical Efficacy in the Esophagus and Stomach

Certain regions of China (Huixian and Linxian) have strikingly high incidence rates of esophageal and gastric cancers. Two trials were done in Linxian County; one was a general population trial that tested the efficacy of four different nutrient combinations at inhibiting the development of esophageal and gastric cancers.⁷⁵ Those who were given the combination of beta-carotene, vitamin E, and selenium had a 13% reduction in total cancer deaths, a 4% reduction in esophageal cancer deaths, and a 21% reduction in gastric cancer deaths (see Table 33.6). None of the other nutrient combinations reduced gastric or esophageal cancer deaths significantly in this trial. The treatment benefit has been shown to persist for 10 years postintervention, with greater efficacy seen in participants under age 55 years.⁷⁶ This finding stands in contrast to most other antioxidant nutrient supplement intervention trials, suggesting that the applicability of these results for populations with adequate nutritional status and for other tumor sites may be limited.⁷⁷

The other Linxian trial evaluated a multivitamin/multimineral preparation plus beta-carotene (15 mg per day) in residents with esophageal dysplasia.⁷⁸ There was no clear evidence of efficacy, although confidence intervals were wide.

Clinical Efficacy in the Colon/Rectum

Of the randomized trials aimed at the prevention of recurrent colorectal adenomas with micronutrients that have been completed, some used beta-carotene alone⁷⁹ or with other nonmicronutrient interventions.⁸⁰ Others evaluated beta-carotene with and without supplemental vitamins C and E.⁸¹ None of the trials observed benefit with supplementation. A subsequent report from one trial noted that alcohol intake and cigarette smoking modified the efficacy of beta-carotene.⁸² Among nonsmokers and nondrinkers, beta-carotene was associated with a significant decrease in the risk of one or more recurrent adenomas (relative risk [RR] = 0.56). Among persons who smoked and also drank more than one alcoholic drink per day, beta-carotene significantly increased the risk of recurrent adenoma (RR = 2.07).

Clinical Efficacy in the Prostate

Because oxidative stress may play a role in the etiology of prostate cancer, several antioxidant nutrients, including vitamin E, selenium, and lycopene, have been of interest for preventing

prostate cancer. The largest trial to date of these nutrients is the Selenium and Vitamin E Cancer Prevention Trial (SELECT), which tested selenium and vitamin E in a two-by-two factorial design for the primary prevention of prostate cancer. Despite preliminary indications of prostate cancer risk-reducing efficacy for selenium (from a trial of selenium for skin cancer⁷⁰) and vitamin E (from a trial of vitamin E to prevent lung cancer⁸³), there was no evidence of efficacy.⁸⁴ With extended follow-up, the nonsignificant adverse effect of vitamin E became significantly adverse.⁸⁵ Negative/neutral findings also were reported for vitamins E and C and prostate and total cancer in the PHS II randomized controlled trial.⁸⁶

The carotenoid lycopene has generated much interest with regard to prostate cancer risk, and several intervention trials have been conducted based on lycopene supplements. These studies have been small, short term, based on intermediate end points, and often lack adequate control groups. The use of a tomato sauce-based intervention is arguably a better approach to evaluate, based on animal data indicating that tomato powder (which includes lycopene along with other phytochemicals), but not lycopene alone, was effective at inhibiting prostate carcinogenesis.⁸⁷

Mechanisms for Ineffective Retinoid and Carotenoid Cancer Risk-Reducing Activity

There are now a number of trials demonstrating that supplemental beta-carotene/retinoids given to current smokers can produce increases rather than reductions in cancer incidence. In tobacco users, beta-carotene and other carotenoids may produce oxidative carotenoid breakdown products that alter retinoid metabolism and signaling pathways, along with pro-oxidation.⁸⁸ For retinoids such as 13cRA, smoking may induce genetic and epigenetic changes in the lung that affect retinoid activity; for example, tobacco smoking can affect RAR- β expression.⁸⁸ The adverse effects of supplemental nutrients are not limited to smokers; α -tocopherol increased rather than reduced prostate cancer in SELECT (which had relatively few smokers) and selenium increased prostate cancer among men without a baseline selenium deficiency.⁸⁹ This may be a consequence of the relatively high doses used in SELECT,⁷⁷ but certainly calls into question the notion that reducing oxidative stress is a pivotal cancer risk-reduction strategy, even in nonsmokers.

It has become clear that reactive oxygen species (ROS), such as hydrogen peroxide, can act as important physiologic regulators of intracellular signaling pathways.^{90,91} Data in mouse models have shown that vitamin E accelerates lung tumor growth by disrupting the ROS-p53 axis, potentially by removing oxidative damage to DNA, which can serve as a potent stimulus for p53 activation.⁹² Although some of the large cancer risk-reducing trials may have failed in their primary objective, they may indirectly contribute to a clearer understanding of cancer biology, leading to the recognition that the role of oxidative stress and ROS in human disease is much more nuanced than originally hypothesized.⁹³

As for the retinoids, these agents are generally too toxic to be used as single agents for risk-reducing efficacy; however, a major area of ongoing research is examining retinoids (low doses) given in combination with other agents, especially those that regulate the epigenome, such histone deacetylase (HDAC) inhibitors.³³

Folic Acid and Other B Vitamins

Overview and Mechanisms. Folate is a water-soluble B vitamin found in foods, whereas folic acid is the synthetic form found in supplements and fortified foods. Adequate folate is critical for DNA methylation, repair, and synthesis.^{94,95} The methylation status of genes can play a key role in gene silencing and gene expression, lending plausibility to the idea that folate could be a key nutrient in regulating cell growth and proliferation.

Epidemiology. Epidemiologic studies have linked low folate intake with higher risk of several cancers, most notably colorectal

cancer.⁹⁶ Long-term use of multivitamin supplements, which are a major source of folate and other B vitamins, has been associated with a reduction in the risk of colon cancer in some studies, including recent (postfortification) findings.⁹⁷⁻⁹⁹ Supporting an anticancer role of folate is that genotypes for methylene tetrahydrofolate reductase, an enzyme known to be involved in folate metabolism, predict the risk of colon cancer dependent on folate intake or status.¹⁰⁰ Vitamin B₆ has been less studied in relation to cancer than folate, but some epidemiologic studies suggest that vitamin B₆ may be important for colorectal cancer.^{101,102} A higher risk of cancer related to deficiencies of these vitamins has been suggested for alcohol drinkers.¹⁰³

Clinical Trials: Folic Acid and B Vitamins. Risk-reducing efficacy for supplemental folic acid has been primarily evaluated in the setting of prevention of recurrent colorectal adenomas (i.e., in patients with prior adenomas). Of six randomized trials of folic acid, two small trials reported suggestions of benefit of folic acid supplementation.^{104,105} However, benefits were not observed in two much larger trials, the Aspirin/Folate Polyp Prevention Study (AFPPS) (dose: 1 mg of folic acid daily)¹⁰⁶ and the United Kingdom Colorectal Adenoma Prevention (ukCAP) trial (dose: 500 µg of folic acid daily).¹⁰⁷ AFPPS found indications of an increased risk for advanced lesions and multiple adenomas with prolonged treatment and follow-up. A third large trial, the Nurses Health Study/Health Professionals Follow-up Study (NHS/HPFS) folic acid polyp prevention trial, showed no overall risk reduction.¹⁰⁸ The most recent trial, done in a Chinese population >50 years of age,¹⁰⁹ reported that 1 mg folic acid per day reduced sporadic colorectal adenomas when compared to no intervention (not a placebo-controlled study). One possible explanation for the discrepancy of the Chinese trial versus North American and European trials is the baseline plasma folate status. In the Chinese trial, the mean baseline folate concentration of 5 ng/mL¹⁰⁹ was half of the reported 10 ng/mL in a United States trial,¹⁰⁶ where folate fortification of the food supply occurs.

Calcium and Vitamin D

Overview and Mechanisms. There are two major forms of vitamin D: ergocalciferol (D₂) and cholecalciferol (D₃). Vitamin D₂ is absorbed through dietary sources such as fortified milk products, and D₃ is synthesized via ultraviolet (UV) B light isomerization of 7-dehydrocholesterol in the epidermis.¹¹⁰ Vitamin D₃ is converted to calcitriol (1, 25-[OH]₂ D₃) in a two-step process requiring both hepatic and renal hydroxylation. Calcitriol binds to the vitamin D receptor, which translocates to the nucleus and binds to multiple gene promoter sites. Through this mechanism, vitamin D regulates cytoplasmic signaling pathways that impact cellular differentiation and growth through proteins such as Ras and mitogen-activated protein kinase (MAPK), protein lipase A, prostaglandins, cyclic adenosine monophosphate (AMP), protein kinase A, and phosphatidylinositol 3 kinase.¹¹⁰ 1,25(OH)₂D₃ regulates cellular proliferation and apoptosis. For example, 1,25(OH)₂D₃ can induce cleavage of caspase 3, poly (ADP-ribose) polymerase (PARP), and MAPK, leading to apoptosis. 1,25(OH)₂D₃ inhibits the expression and phosphorylation of Akt, a key regulator of cellular proliferation. The differentiation properties of 1,25(OH)₂D₃ are mediated through transcriptional activation of the CDK inhibitor p21. The effects of vitamin D on multiple signal transduction pathways operational in cancer cells are reviewed by Deeb et al.¹¹¹

Epidemiology. Observational epidemiologic studies have shown a relatively consistent inverse association between low calcium intake, including that from supplements, and increased colorectal and colon cancer risk.^{112,113} Vitamin D exposure is typically assessed by measuring 25(OH)vitamin D in plasma because exposure is derived not only from diet and supplements, but also from cutaneous synthesis following dermal exposure to UV radiation. A large number of observational studies have evaluated the

association between vitamin D status and cancer risk, as systematically reviewed by the Agency for Healthcare Research and Quality (AHRQ).¹¹⁴ The evidence is inconsistent for most cancer sites, with the exception of studies showing that individuals with lower blood vitamin D levels have a higher risk of colorectal cancer or adenoma. Although some observational studies have reported that higher serum vitamin D is associated with lower breast cancer risk, the association is inconsistent.^{114,115} Also, there are some studies suggesting high serum vitamin D is associated with increases in certain cancers, particularly pancreatic cancer.¹¹⁶

Clinical Trials: Calcium and Vitamin D

Clinical Efficacy in the Colon. Baron et al.¹¹⁷ randomized subjects with a recent history of colorectal adenomas to either calcium carbonate (1,200 mg per day of elemental calcium) or placebo. Results showed significant benefit for the calcium arm (adjusted RR = 0.81; 95% CI, 0.67 to 0.99; *p* = 0.04). In a smaller, similar study of calcium gluconolactate and carbonate (2 g elemental calcium daily), the adjusted odds ratio (OR) for adenoma recurrence was 0.66 (95% CI, 0.38 to 1.17; *p* = 0.16) for calcium treatment,¹¹⁸ and while not statistically significant, it was similar to the data of Baron et al.¹¹⁷

In the largest trial of calcium and vitamin D with primary cancer end points (e.g., colon, breast), the US Women's Health Initiative (WHI) evaluated the combination of 400 IU of vitamin D per day plus 1,000 mg of calcium per day in 36,282 postmenopausal women. For colon cancer, there was no benefit observed,¹¹⁹ although the mean baseline intake of calcium was already very high (more than 1,151 mg per day). With regard to vitamin D as a single agent, there was also no suggestion of benefit for colon cancer incidence in a 5-year British trial of vitamin D (100,000 IU every 4 months) that reported colon cancer incidence,¹²⁰ although this was not a primary end point.

Clinical Efficacy in the Breast. Vitamin D has received considerable attention for a possible role in the prevention of breast cancer,¹²¹ although no trials have yet investigated vitamin D as a single agent for breast cancer risk reduction. The large WHI trial gave a combination of calcium and vitamin D, as noted previously, and there was no significant effect of this combination on breast cancer risk (HR, 0.96; 95% CI, 0.85 to 1.09).¹²² Lappe et al.¹²³ conducted a trial that examined the relation between calcium plus vitamin D (1,100 IU per day) supplementation (versus calcium alone or placebo) in 1,179 healthy postmenopausal women in Nebraska.¹²³ Although fracture was the primary outcome of the trial, total cancer incidence was reportedly lower in the calcium plus vitamin D group, although the number of end points was very small (*n* = 50 total cancers observed during the follow-up). An ongoing randomized trial of vitamin D and omega-3 fatty acids (the VITamin D and Omega-3 Trial [VITAL]) among 20,000 participants is expected to provide more definitive data on a possible role of vitamin D in the prevention of breast and other cancers.¹²⁴

Summary and Conclusion: Micronutrients

Certain agents, including the retinoids, beta-carotene, folic acid, calcium plus vitamin D, vitamin E, and selenium, have received substantial attention for a possible role in reducing the risk of cancer in humans. As reviewed herein, some of the trials have observed statistically significant reductions in the risk of the primary end point (e.g., retinoids in skin carcinogenesis models, calcium in colorectal adenomas, antioxidant nutrients in Linxian, China, for gastric cancer prevention), whereas others have observed statistically significant increases in the risk of the primary end points (beta-carotene and retinoid lung cancer prevention trials in smokers, vitamin E and prostate cancer, selenium and nonmelanoma skin cancer). Considering the completed trials, there is clear evidence against the general use of nutrient supplements for cancer prevention, which is

the conclusion also reached by the World Cancer Research Fund/American Institute for Cancer Research.³⁸ Note that there is no evidence that food sources of these nutrients increase risk.

Having noted that, there are other key themes emerging from this growing body of research. One such theme is that nutrient supplementation may be of benefit to some but not all. One such population that may benefit includes persons who are low in the nutrient of interest at baseline.⁷⁷ This was initially suggested in the Linxian Country trial (done in a micronutrient-deficient population), with growing support from subgroup analyses of several completed trials.⁷⁷ However, the hypothesis that nutrient supplementation can reduce cancer risk in subgroups selected based on inadequate nutritional status has, to date, not been formally evaluated in intervention trials.

Another consistent theme is that lifestyle factors (e.g., smoking) and genetics (polymorphisms) may determine who is most likely to benefit from supplementation. Trial data will likely be increasingly mined to identify genetic profiles associated with both better outcomes (risk prediction) and response to intervention.^{125,126} Ultimately, a more personalized approach to cancer risk reduction may emerge, consistent with the movement toward a more personalized approach for cancer treatment.

Finally, nearly all of these trials initiate intervention with older adults (who are more likely to develop cancer end points during the follow-up); but, animal models suggest that the timing of exposure may likely be quite relevant. For example, folic acid may protect against initiation, but may also promote the proliferation of existing neoplasms.¹²⁷ Thus, the dose, form (food versus supplement), timing, and nutritional and lifestyle characteristics may all be relevant in affecting the efficacy of risk-reducing interventions involving nutrients and related substances. Further research, drawing upon newer tools now available through the field of nutritional genomics, will be needed to gain greater clarity on the heterogeneous biologic effects observed in nutrient-based risk reduction.

ANTI-INFLAMMATORY DRUGS

Mechanism

Nonsteroidal anti-inflammatory drugs (NSAIDs) represent a class of drugs that reduce cellular inflammation through multiple mechanisms, the most prominent of them being the modulation of eicosanoid metabolism.¹²⁸ Eicosanoids are metabolites of dietary fatty acids, primarily linoleic acid. Linoleic acid is metabolized to arachidonic acid, which is stored in the lipid membrane and, once mobilized from the membrane, further metabolized by prostaglandin-H synthases (PGHS) 1 and 2 to PGD₂, PGE₂, PGF_{2α}, PGI₂, or thromboxane A₂ (TxA₂) by specific synthases. Leukotriene pathways involve the conversion of arachidonic acid to leukotriene A₄ by 5-lipoxygenase and subsequent hydrolysis of leukotriene A₄ to other downstream leukotrienes. Newly formed prostaglandins function primarily through binding to prostaglandin receptors (EP receptors), releasing coupled G-proteins to elicit responses in the same or neighboring cells.¹²⁹

Prostaglandins (PG) play crucial roles in controlling cellular proliferation, apoptosis, cellular invasiveness, and angiogenesis and in modulating immunosuppression.¹²⁹ Because PGE₂ is the most abundant PG in tumors, reducing local concentrations of PGE₂ may be a pivotal cancer preventive strategy.¹²⁹

PGHS-independent mechanisms of NSAID action may, at least in part, explain NSAID preventive efficacy.¹³⁰ A diverse group of NSAIDs inhibit apoptosis via multiple mechanisms. Among the more prominent of these mechanisms is the inhibition of cyclic guanosine monophosphate (cGMP) phosphodiesterase activity, attenuation of beta-catenin mRNA through suppressing transcription of the *CTNNB1* gene, and activation of c-Jun N-terminal kinase 1.¹³⁰ NSAIDs activate peroxisome proliferator-activated receptor (PPAR)γ, leading to increased E-cadherin

expression and reduced colony formation in vitro, while reducing PPARδ, leading to reduced resistance to apoptosis.¹³⁰ Selective cyclooxygenase 2 (COX-2) inhibitors inhibit Akt signaling and induce apoptosis of human colorectal and prostate cancer cells in vitro in a COX-2-independent manner via the inhibition of phosphoinositide-dependent kinase-1 (PDK-1). NSAIDs inhibit nuclear factor kappa B (NF-κB) at pharmacologic concentrations and key cellular proliferation signaling intermediates such as activator protein 1 (AP-1) and other intermediates of the MAPK pathway.¹³⁰ The impact of NSAIDs on carcinogenic events driven by these upstream pathways in humans as opposed to preliminary in vitro or in vivo models remains unclear.

Epidemiology

Pooled analyses of 34 controlled trials of aspirin 75 mg to 100 mg daily (69,224 participants), conducted primarily for cardiovascular disease reduction, observed reduced cancer deaths (OR, 0.63; 95% CI, 0.49 to 0.82). Most of the benefit occurred after 5 years follow-up.¹³¹ In a pooled analysis of 150 case control and 45 cohort studies, in addition to a reduced risk of death from colorectal cancer (OR, 0.58; 95% CI, 0.44 to 0.78), chronic and frequent (once daily or more) use of aspirin also reduced the risk of death from esophageal (OR, 0.58; 95% CI, 0.44 to 0.76), gastric (OR, 0.61; 95% CI, 0.40 to 0.93), and breast (OR, 0.81; 95% CI, 0.72 to 0.93) cancers.¹³² An analysis of 662,624 men and women enrolled in the American Cancer Society's Cancer Prevention Study II found that aspirin taken at least 16 times per month over a 6-year period conferred a 40% reduced risk of colorectal cancer mortality.¹³³ Both the 46,363 male patients of the Health Professional Study¹³⁴ and the 82,911 patients of the Nurse's Health Study¹³⁵ suggest that prolonged use (>10 years) of 325 mg of aspirin twice weekly or more reduces colorectal cancer risk (RR, 0.77; 95% CI, 0.67 to 0.88, from the Nurse's Health Study). Daily NSAID intake is associated with a 40% reduction (OR, 0.56; 95% CI, 0.43 to 0.73) in the risk of esophageal adenocarcinoma.¹³⁶

Evidence in Preclinical In Vivo Carcinogenesis Models

NSAIDs, including aspirin, indomethacin, piroxicam, sulindac, ibuprofen, and ketoprofen, suppress colonic tumorigenesis induced chemically (1,2-dimethylhydrazine or its metabolites) or transgenically (Min⁺).^{137,138} The selective COX-2 inhibitors were the most efficacious colon tumorigenesis inhibitors in both chemical and transgenic rodent models.^{139,140} In preclinical models, NSAIDs affect the onset and progression of cancers in the stomach, skin, breast, lung, prostate, and urinary bladder, although the evidence is more limited than for colon cancers.¹⁴¹

Clinical Trials

Key clinical trials of NSAIDs for the prevention of colorectal cancer are summarized in Table 33.7. Sulindac reduced the size and number of preexisting adenomas in patients with familial adenomatous polyposis but did not suppress the development of new adenomas,¹⁴² whereas the selective COX-2 inhibitor, celecoxib, suppressed the development of new adenomatous polyps in patients with familial adenomatous polyposis.¹⁴³ Although these results are promising, reports of invasive neoplasms developing in familial adenomatous polyposis patients being treated with sulindac¹⁴⁴ raise the question of whether NSAIDs preferentially alter the formation or regression of those adenomas less likely to progress to invasive adenocarcinomas, as compared to those more likely to progress.

Randomized, double-blinded placebo controlled trials of NSAIDs as cancer risk-reducing agents for colorectal adenocarcinoma (see Table 33.7) have confirmed that aspirin suppresses

TABLE 33.7

Summary of Clinical Trials of Nonsteroidal Anti-Inflammatory Drugs as Colorectal Cancer Risk-Reducing Agents

Population	Drug (Dose), Duration	Phase	Endpoint	Outcome	References
<i>Gene Associated</i>					
Familial adenomatous polyposis (FAP)	Sulindac (300–400 mg/d, divided doses)	IIb	Polyp regression	Colorectal and duodenal polyps regressed in ~50%	(277, 278) (279)
Hereditary nonpolyposis colon cancer (Lynch syndrome)	Aspirin 600 mg/d, resistant starch	III	Cancer	≥2 yr, hazard ratio (HR) colon cancer 0.41; 95% CI, 0.19–0.86; all cancers Incidence rate ratio 0.37; 95% CI, 0.18–0.78; no effect of starch	(280, 281)
<i>Sporadic Risk</i>					
Previous adenomatous polyps, healthy subjects	Aspirin (40, 81, 325, 650 mg once per day)	I, IIa	Dose-biomarker	Aspirin dose of 81 mg daily sufficient to suppress colorectal mucosal prostaglandin E ₂	(282–284)
Previous adenomatous polyps	Sulindac (300 mg), 4 mos	IIb	Polyp regression	Sulindac did not significantly decrease the number or size of polyps	(146)
Previous adenomatous polyps	Piroxicam (7.5 mg), 2 yr	IIb	Polyp recurrence	Colorectal mucosal PGE ₂ reduced in piroxicam treated arm, unacceptable toxicity	(145)
Prior colorectal cancer	Aspirin (325 mg once per day), 3 yr	IIb	Polyp recurrence	Aspirin use associated with delayed development of adenomatous polyps	(285)
Previous adenomatous polyps	Aspirin (81 mg once per day or 325 mg once per day) and/or folate, 3 yr	IIb	Polyp recurrence	Low-dose aspirin reduced the recurrence of adenomatous polyps	(286)
Previous adenomatous polyps	Celecoxib and rofecoxib	IIb	Polyp recurrence	Celecoxib and rofecoxib reduced the recurrence of adenomatous polyps, unacceptable toxicity	(148–150)

adenoma recurrence in patients previously treated for adenomas or for cancer. Neither sulindac nor piroxicam alone suppressed adenoma formation in high-risk, sporadic populations at tolerable doses.^{145,146} Sulindac, in combination with difluoromethylornithine, has potent colorectal anticarcinogenesis effects.¹⁴⁷ Selective COX-2 inhibitors (celecoxib, rofecoxib) reduce the recurrence of adenomas by one-third in all patients previously treated for adenomas and by one-half in patients with previously resected large (≥1 cm) adenomas,^{148–150} but they are too toxic as cancer risk-reducing agents due to their cardiovascular toxicity.^{151,152} Although most NSAIDs (piroxicam, indomethacin) have sufficient gastrointestinal (GI) toxicity to reduce their acceptability as cancer risk-reducing agents,^{153,154} the long-term administration of low-dose aspirin in vascular prevention trials demonstrates acceptable GI toxicity.¹⁵⁵

Up to 40% of individuals screened for colorectal neoplasms will have an adenomatous polyp detected and removed, yet only 10% of these lesions will progress to invasive neoplasms. To date, prospective NSAID trials of only 2 to 3 years cannot substitute for cancer incidence or mortality end points. Given the 10-year latency between adenoma formation and a cancer event, prospective trials sufficiently powered to detect colorectal cancer incidence end points are unlikely in the future.¹⁵⁶ Alternatively, a follow-up of patients randomized on trials of aspirin in the prevention of vascular events in the 1980s and 1990s offers secondary analysis opportunities. In a pooled analysis of three prospective vascular end point cohort studies, 20-year low-dose aspirin treatments reduced cancer deaths from all solid tumors (OR, 0.69; CI, 0.54 to 0.88) and from lung and esophageal adenocarcinomas (OR, 0.66; CI, 0.56 to 0.77).¹⁵⁵ Despite this, the U.S. Preventive Services Task Force (USPSTF) does not recommend the use of aspirin or NSAIDs as cancer risk-reducing agents for normal risk populations, preferring adherence to colorectal cancer screening recommendations (fecal occult blood testing and endoscopy).^{153,154,157}

Minimal prospective cancer risk reduction data are available at other epithelial organ sites. Ketorolac, given as a 1% rinse solution, did not reduce the size or histology of leukoplakia lesions.¹⁵⁸ Celecoxib reduces the Ki67 labeling index and increases the expression of nuclear survivin without significantly changing the cytoplasmic survivin in bronchial biopsies of smokers.¹⁵⁹ Cancer prevention trials of aspirin as interventions for delaying progression from intraepithelial neoplasias in other epithelial sites remain ongoing for the lower esophagus.¹³⁶ No prospective, randomized trials or data are available for breast, prostate, or gynecologic cancer prevention.

EPIGENETIC TARGETING AGENTS (SELECTIVE ESTROGEN RECEPTOR MODULATORS, 5 α -STEROID REDUCTASE INHIBITORS, POLYAMINE INHIBITORS)

Posttranslational pathway targets remain a fertile source of chemopreventive strategies. Phase III data support cancer risk-reduction agent efficacy of selective estrogen receptor modulators (SERM) and 5 α -steroid reductase inhibitors for breast and prostate cancer prevention, respectively. Inhibitors of the polyamine pathway may be useful preventives for colorectal cancer.

Selective Estrogen Receptor Modulators

Mechanism

SERMs function as estrogen receptor (ER) agonists and antagonists depending on the SERM structure and target tissue. Predominant ER α receptors occur in the human uterus, cortical bone, and the liver; whereas predominant ER β receptors occur in blood vessels,

cancellous bone, the whole brain, and immune cells.^{160,161} During carcinogenesis, the amount of ER α increases while the amount of ER β decreases in breast tissues.¹⁶² Ideally, a desirable SERM for cancer prevention will function as an antiestrogen in the breast and uterus, but a partial estrogen agonist in skeletal, cardiovascular, central nervous system (CNS), GI tract, and vaginal tissues. In addition, an ideal SERM will not have procoagulant effects and will not cause perimenopausal symptoms such as hot flashes.¹⁶²

Tamoxifen. Tamoxifen is a triphenylethylene compound developed for the treatment of ER-positive breast cancer in the 1960s and 1970s.^{163,164} Tamoxifen inhibits the initiation and promotion phases of breast carcinogenesis in the dimethylbenzanthracene chemical carcinogenesis model.^{164,165} When tamoxifen binds to ER β , which then binds to an AP-1 type gene promoter, it functions as an estrogen agonist. When bound to ER α , which binds to an estrogen response element (ERE) target gene promoter, tamoxifen functions as an estrogen antagonist.^{162,166} Tamoxifen has estrogen antagonist effects in the human breast; partial estrogen agonist effects in bone, the cardiovascular system, and CNS; and predominant estrogen agonist effects in the uterus, liver, and vagina. The estrogen agonist effects in the liver and uterus result in tamoxifen's toxicities of thromboembolism and endometrial cancer, respectively. The clinical finding that tamoxifen reduces the incidence of contralateral second primary breast cancers during adjuvant treatment regimens catalyzed the push for its development as a cancer risk-reduction agent.^{167,168}

Raloxifene. The benzothiophene structure of raloxifene confers a different tissue-specific ER-binding profile than the triphenylethylene tamoxifen. Raloxifene has greater estrogen agonist activity

in bone but reduced estrogen agonist activity in the uterus. Raloxifene was studied for the treatment and prevention of osteoporosis in a large, pivotal trial (the Multiple Outcomes of Raloxifene Evaluation [MORE]) and was found to reduce the rate of vertebral fracture as compared to placebo in postmenopausal women.¹⁶⁹

Lasofoxifene and Arzoxifene. Lasofoxifene and arzoxifene are third-generation SERMs developed as more potent blockers of bone resorption with the goal of reducing the risk of fractures, breast cancer, and heart disease while minimizing the SERM-induced risk of endometrial hyperplasia in postmenopausal women. Both agents proved potent *in vitro* and in preliminary clinical trials for bone fracture prevention.¹⁷⁰⁻¹⁷³

Selective Estrogen Receptor Modulators as Risk-Reducing Agents for Breast Cancer Prevention

Efficacy. Table 33.8 summarizes the phase III data for SERM-based breast cancer–risk reduction. In a systematic review of MEDLINE and Cochrane databases through December, 2012, the USPSTF identified seven trials of tamoxifen or raloxifene that showed a reduced incidence of invasive breast cancer by 7 to 9 cases in 1,000 women over 5 years compared to placebo.¹⁷⁴ Tamoxifen is more effective than raloxifene; it reduces breast cancer incidence more than raloxifene by 5 cases in 1,000 women. Both drugs reduce the incidence of ER-positive breast cancer, but neither reduces the risk of ER-negative breast cancer. Neither drug reduced breast cancer–specific or all cause mortality rates. Based on benefit–risk models, women with estimated 5-year risks of breast cancer of 3% or greater are likely to benefit from treatment.¹⁷⁵ Using similar

Table and data adapted from Cuzick J, Sestak I, Bonanni B, et al. Selective oestrogen receptor modulators in prevention of breast cancer: an updated meta-analysis of individual participant data. *Lancet* 2013;381:1827–1834.

analysis methods as the USPSTF, the American Society of Clinical Oncology recommends the use of tamoxifen (20 mg per day orally for 5 years) or raloxifene (60 mg per day orally for 5 years) “in premenopausal women who are age ≥ 35 years with a 5-year projected absolute breast cancer risk $\geq 1.66\%$ according to the NCI Breast Cancer Risk Assessment Tool (or equivalent measures), or with lobular carcinoma in situ.”¹⁷⁶ Tamoxifen reduces the risk of in situ (preinvasive) breast neoplasms (lobular carcinoma in situ, ductal carcinoma in situ) by 50%.^{177,178} The reduction during treatment persists for at least 5 years after treatment.^{177,178} Raloxifene does not reduce the risk of in situ breast neoplasms.

Data from two trials designed to evaluate the safety and efficacy of lasofoxifene (PEARL)^{170,171} and arzoxifene (GENERATIONS)^{172,173} as bone fracture preventives have been analyzed for breast cancer–risk reduction. Their effect at reducing breast cancer incidence was captured in secondary analyses (see Table 33.8). Neither lasofoxifene nor arzoxifene have been evaluated in phase III randomized controlled breast cancer prevention trials. Arzoxifene development has been discontinued in the United States.

Toxicity Profiles. Tamoxifen causes a twofold increase in the risk of endometrial adenocarcinoma (RR, 2.13; 95% CI, 1.36 to 3.32) and is related to more benign gynecologic conditions, uterine bleeding, and surgical procedures than the placebo controls, whereas raloxifene did not increase the risk for endometrial cancer or uterine bleeding.¹⁷⁴ Tamoxifen causes a twofold increase in thromboembolic events (RR, 1.93; 95% CI, 1.41 to 2.64), whereas raloxifene causes a 60% increase in risk of venous thromboembolism (RR, 1.60; 95% CI, 1.15 to 2.23).¹⁷⁴ Raloxifene does not differ from tamoxifen in risk of fractures, other cancers, or cardiovascular events.¹⁷⁷ Raloxifene’s lower risk of endometrial adenocarcinomas compared to tamoxifen needs to be weighed against the increased risk of stroke seen in the MORE/CORE trials (see Table 33.8).¹⁷⁹ Raloxifene’s effectiveness in the community may also be compromised by its poor bioavailability (2%) due to rapid phase II enzyme metabolism in the gut and liver,¹⁸⁰ whereas tamoxifen is more bioavailable and has active metabolites that permit a prolonged drug effect. Missed raloxifene doses may potentially compromise efficacy and prevention outcomes in widespread, community use.

Aromatase Inhibitors. In adjuvant clinical trials for breast cancer, aromatase inhibitors (anastrozole, exemestane, letrozole) given after 5 years of tamoxifen enhance the reduction of breast cancer recurrence in the contralateral breast compared to tamoxifen alone.¹⁸¹ In a phase I cancer risk–reducing agent trial, letrozole reduced the Ki-67 proliferation index of breast epithelial cells aspirated from high-risk women.¹⁸² Exemestane reduced the overall risk of ER-positive invasive breast cancer (Table 33.9). It did not reduce the risk of noninvasive breast neoplasms or ER-negative breast cancer.¹⁸³ Exemestane has no increased risk of venous thromboembolism, endometrial cancer, fracture, or cataract,¹⁸³ but losses in bone mineral density and cortical thickness of the distal tibia and radius occurred after 2 years of treatment despite calcium and vitamin D supplementation.¹⁸⁴ The results of the

International Breast Cancer Intervention Study II (IBIS-II), comparing anastrozole with placebo, are similar to those reported for exemestane.¹⁸⁵ Compared to exemestane, anastrozole decreases the incidence of ductal carcinoma in situ (DCIS), whereas exemestane does not. Neither aromatase inhibitor increased survival compared to placebo controls. The American Society of Clinical Oncology recommends exemestane for breast cancer prevention in addition to tamoxifen and raloxifene.

Use Counseling. Despite the widespread evidence of breast cancer preventive efficacy for tamoxifen and raloxifene, only 3% to 20% of eligible high-risk women agree to take tamoxifen for primary prevention.¹⁸⁶ The low willingness of eligible women to take tamoxifen for 5 years demonstrates the issue of risk benefit for cancer risk–reducing agents. Women with high short-term risk (5 year Gail risk of $>3\%$)—for example, those with ER-positive atypical hyperplasia, lobular carcinoma in situ, and the majority of non–high-grade ductal carcinoma in situ lesions—have an acceptable risk to benefit ratio and are the most likely to benefit from a 5-year cancer risk–reducing agent intervention with a SERM.^{175,176} The toxicity profile of aromatase inhibitors differs from SERMs. Although aromatase inhibitors may have a more favorable risk to benefit profile than SERMs, long-term outcomes and toxicity experience for aromatase inhibitor risk–reducing agent intervention are not available to date. In the National Surgical Adjuvant Breast and Bowel Project, tamoxifen-treated women with a *BRCA2* mutation but not a *BRCA1* mutation had reduced cancer incidence,¹⁸⁷ but subsequent data from another group have found reduced cancer risk in women with both *BRCA* mutations.¹⁸⁸ Data remain insufficient to recommend the use of SERMs for risk reduction in women with *BRCA* mutations.

5 α -Steroid Reductase Inhibitors

Mechanism

Prostate cancers require androgens to proliferate and evade apoptosis. The primary nuclear androgen responsible for the maintenance of epithelial function is dihydrotestosterone. The testes and adrenal gland synthesize dihydrotestosterone by the conversion of testosterone by 5 α -steroid reductase types 1 and 2 isozymes. Dihydrotestosterone binds to intracellular androgen receptors to form a complex that binds to DNA hormone response elements controlling cellular proliferation and apoptosis. Finasteride, a selective, competitive inhibitor of type 2 5 α -steroid reductase,¹⁸⁹ inhibits proliferation in the transformed prostate cell. In the 3,2'-dimethyl-4-aminobiphenyl (DMAB), methylnitrosourea (MNU), and testosterone chemical carcinogenesis models in rats, finasteride reduces prostate tumor incidence by close to six-fold. Finasteride appears to be more effective in the promotion phase of prostate carcinogenesis.¹⁹⁰ Dutasteride inhibits both 5 α -steroid reductase inhibitor types 1 and 2 isoforms and has similar anticarcinogenesis activity in preclinical models to finasteride.

PSA, prostate specific antigen.

Cancer Risk-Reducing Agent Activity

Randomized, placebo-controlled cancer incidence end point risk-reducing agent clinical trials demonstrated that finasteride and dutasteride reduced the incidence of prostate cancer by approximately 22% (Table 33.10).^{30,191,192} Patients who are treated with either drug yet progress to transformed neoplasms develop more tumors of a high Gleason grade (7 to 10) compared to the placebo arm (22%). After 18 years of follow-up, no significant differences in overall survival or survival after prostate cancer diagnosis were found in the finasteride-treated group compared to the placebo-treated group.¹⁹³ Sexual function side effects (e.g., erectile dysfunction, loss of libido, gynecomastia) were more common in the finasteride- or dutasteride-treated groups.^{30,192}

The 5 α -steroid reductase inhibitors, finasteride and dutasteride, prevent or delay carcinogenesis progression in the prostate, yet progression of high-grade lesions is unaffected. Use of finasteride for a period of 7 years reduced the incidence of prostate cancer but did not significantly affect mortality.¹⁹³ Increasing the diagnosis of low-grade prostate cancer through prostate-specific antigen (PSA) testing or intervention with a drug with a minimal toxicity profile without reducing mortality is of no benefit and “all forms of therapy cause considerable burden to the patient and to society.”¹⁹³

SIGNAL TRANSDUCTION MODIFIERS

Both cancer therapy and cancer prevention have investigated drugs that modify specific targets in signal transduction pathways. Although the emphasis in drug development has focused on cancer treatment, interventions aimed at modulating signal transduction pathways promise new approaches to interventions in the carcinogenic process. Because of the complexity of signaling systems, the inhibition of single targets may not be effective or may cause unacceptable toxicity.

Difluoromethylornithine

Mechanism

Polyamines (spermidine, spermine, and the diamine, putrescine) are required to maintain cellular growth and function.¹⁹⁴ In mammalian cells, polyamine inhibition by genetic mutation or pharmaceutical agents is associated with virtual cessation in cellular growth. Difluoromethylornithine (DFMO) is an enzyme-activated irreversible inhibitor of ornithine decarboxylase (which is trans-activated by the *c-MYC* oncogene and cooperates with the RAS oncogene in malignant transformation).¹⁹⁵

Evidence in Preclinical In Vivo Carcinogenesis Models

Extensive preclinical data has found that DFMO prevents tumor promotion in a variety of systems, including skin, mammary, colon, cervical, and bladder carcinogenesis models.¹⁹⁴ Synergistic

or additive activity with retinoids, butylated hydroxyanisole, tamoxifen, piroxicam, and fish oil has been demonstrated with low concentrations of DFMO.¹⁹⁴

Clinical Trials

In phase I prevention trials, DFMO at a dose of 0.5 mg/m² per day reduced tissue polyamines in the colon and skin^{196,197} and causes regression of cervical intraepithelial neoplasia when used topically,¹⁹⁸ but does not reduce tissue polyamines or other biomarkers of cellular proliferation in the human breast.¹⁹⁹ As a single agent, DFMO has anticarcinogenic activity for nonmelanoma skin cancers, primarily basal cell carcinoma. In combination with an NSAID (sulindac), DFMO reduced adenoma recurrences, suggesting a synergistic reduction of colorectal cancer risk (Table 33.11). Preliminary data suggest some cancer risk-reducing agent activity for the lower esophagus and the prostate (see Table 33.11).²⁰⁰

Statins

Mechanism

Statins are hydroxyl-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors that inhibit the conversion of HMG-CoA to mevalonate, a cholesterol precursor. The statins are a class of medications with similar structures but with variable moieties that can result in hydrophilic forms (e.g., pravastatin, rosuvastatin) and lipophilic forms (e.g., lovastatin, simvastatin, fluvastatin, atorvastatin).²⁰¹ Statins decrease the risk of cancer in preclinical studies by inhibiting RAS- and RHO-mediated cell proliferation, upregulating cell cycle inhibitors (e.g., p21 and p27), and inducing apoptosis of transformed cells and the inhibition of angiogenesis.²⁰²

Evidence in Preclinical In Vivo Carcinogenesis Models

Lipophilic statins delay progression of pancreatic intraepithelial neoplasias and the growth of pancreatic carcinoma xenografts. Atorvastatin alone and in combination with NSAIDs reduced colonic adenoma and adenocarcinoma incidence and multiplicity by half in rodent transgenic and chemical carcinogenesis models. Lovastatin reduced lung adenoma multiplicity but not incidence.²⁰¹

Clinical Trials

Although several large trials of pravastatin or simvastatin on cardiovascular disease risk with cancer as secondary end points have shown no benefit for reducing cancer risk with follow-ups between 18 months to 4 years, these trials were not adequately powered to examine cancer end points.²⁰¹ Several case control studies evaluating statin effects have shown a significant association with lower risk of colorectal adenocarcinoma with odds ratios ranging from 0.53 to 0.91 for arzoxifene. A secondary analysis of a celecoxib prevention trial demonstrated no statin protection against colorectal

TABLE 33.11

Summary of Clinical Trials of Difluoromethylornithine as a Cancer Risk-Reducing Agent

Population	Dose per Day, Duration	Phase	Endpoint	Outcome	References
Low risk bladder cancer (Ta, T1, Grades 1 or 2)	1 gm versus placebo × 1 year	III	Bladder cancer recurrence	Did not prevent or delay recurrence	(293)
Prostate risk: men with family history prostate cancer, age 35–70 yr	500 mg versus placebo × 1 yr	IIb	Prostate volume, polyamines, PSA	10-fold reduction of prostate size increase over 1 yr compared to placebo, PSA reduction not significant	(294)
Nonmelanoma skin cancer	500 mg/m ² versus placebo × 4–5 y	III	New nonmelanoma skin cancers	Lower rate of basal cell carcinomas per year (0.28 versus 0.40); persistent reduction in nonmelanoma skin cancers, not statistically significant	(295, 296)
Colon adenomas	DFMO: 500 mg Sulindac: 150 mg versus placebo × 3 y	IIb	Adenoma recurrence	RR for adenoma recurrence for DFMO/sulindac treatment 5 0.30 (0.18–0.49)	(147)

PSA, prostate specific antigen.

neoplasms.²⁰³ The Women's Health Initiative (prospective longitudinal cohort of 159,319 women) found that lovastatin was associated with a lower risk of developing colorectal cancer (HR = 0.62; 95% CI, 0.39 to 0.99).²⁰⁴ Prospective longitudinal studies have shown mixed results. The PHS reported statin use was inversely associated with prostate cancer (adjusted RR, 0.51),²⁰⁵ whereas the Nurse's Health Study showed no association with risk of breast cancer.²⁰⁶ Interventional trials to determine statin preventive efficacy for colon and breast cancer are ongoing.²⁰¹ Statins may be effective risk-reducing agents in individuals with the A/A variant of the predominant T/T genotype of rs12654264 of the HMG-CoA reductase gene.²⁰⁷

Bisphosphonates

Mechanism

Bisphosphonates are pyrophosphate analogs with a central phosphorus-carbon-phosphorus bond that resists bone degradation preventing bone loss and fractures. Second- and third-generation amino bisphosphonates (pamidronic, alendronic, risedronic, ibandronic, and zoledronic acids) inhibit farnesyl diphosphate synthase downstream of HMG-CoA reductase, leading to decreased post-translational prenylation of GTP-binding proteins such as RAS and Rho. Amino bisphosphonates inhibit cell proliferation, angiogenesis, and cell cycle arrest while inducing apoptosis.²⁰¹

Evidence in In Vivo Preclinical and Clinical Models

HER2-transgenic mice treated with zoledronic acid had increased tumor-free survival and overall survival. Zoledronic acid suppressed bone, lung, and liver metastases when treated prior to an injection of breast cancer cells.²⁰¹ The short-term use of bisphosphonates is associated with reduced breast cancer incidence in case control studies^{208,209} and prospective cohort studies (HR = 0.68; 95% CI, 0.52 to 0.88 in a prospective cohort study).²¹⁰ Randomized trials of amino-bisphosphonates in postmenopausal women with breast cancer treated for 1 year have found a reduction of breast cancer risk in the contralateral breast (HR = 0.39; 95% CI, 0.18 to 0.88).²¹¹ Case control data suggesting a bisphosphonate-associated reduction in colorectal cancer risk have not been confirmed by prospective cohort studies (i.e., Women's Health Initiative, Nurse's Health Study).²⁰¹

Metformin

Mechanism

Metformin, an oral antidiabetic drug in the biguanide class, is the first-line drug of choice for the treatment of type 2 diabetes.²¹² Cancers are more common in diabetics and obese individuals than their normal weight and normoglycemic counterparts, leading to the hypothesis that elevated serum insulin concentrations promote cancer risk.^{213,214} Insulin and insulin-like growth factors (IGF1 and 2) stimulate cellular DNA synthesis, proliferation, and tumor growth through phosphoinositide-3 kinase (PI3K), mammalian target of rapamycin (mTOR), and the RAS-MAPK signaling pathways.²¹³ Metformin activates the adenosine monophosphate-activated protein kinase (AMPK) via LKB1, a protein-threonine kinase that has tumor-suppressor activity.²⁰¹ Metformin anticarcinogenesis activity appears to be broad and includes downregulation of erbB-2 and epidermal growth factor receptor (EGFR) expression, inhibiting the phosphorylation of erbB family members, IGF1R, Akt, mTOR, and STAT3 in vivo. Low doses of metformin inhibit the self-renewal/proliferation of cancer stem cells in breast, colon, and pancreatic models.^{215,216}

Evidence in Preclinical In Vivo Carcinogenesis Models

Metformin reduces tobacco carcinogen-induced tumors in mice, and pancreatic premalignant and malignant tumors in hamsters.²⁰¹ However, metformin's anticarcinogenic activity appears dependent on the dose and the induced carcinogenesis process. Metformin promoted carcinogenesis in MNU-induced rat breast cancers, MMTV-Neu ER-negative breast cancers, OH-BBN induced bladder cancer, and Min⁺ mouse intestinal tumors using nonobese rodents.²¹⁷ Metformin cancer risk-reducing agent effects may be limited to obesity- and diabetes-associated carcinogenesis mechanisms.

Clinical Trials

Two large retrospective cohort studies have shown that metformin therapy is associated with a reduced risk of solid tumors by 25% to 30%.²⁰¹ The Women's Health Initiative observed a lower incidence of invasive breast cancer in metformin-treated women with type 2

diabetes mellitus.²¹⁸ Phase II window of opportunity randomized trials have shown reduced proliferation and increased apoptosis in resected tissue of breast cancer patients.²⁰¹

Diet-Derived Natural Products

Mechanism

Polyphenolic phytochemicals, such as curcumin, resveratrol, epigallocatechin gallate (EGCG), genistein, and ginger, are attractive as cancer risk-reducing agents for their low toxicity and multimechanism anticarcinogenic properties. They have anti-inflammatory activity, in part through scavenging of ROS, modulation of protein kinase signal transduction pathways (e.g., STAT-3, HER2/neu, MAPK, and Akt), and downstream inhibition of eicosanoid synthesis potentially due to upstream inhibition of NF- κ B and PPAR or direct blockade or inhibition of eicosanoid-metabolizing enzymes.²¹⁹⁻²²¹ Curcumin, and presumably other polyphenolics, downregulate stem cell driver signaling systems Wnt, Hedgehog, and Notch with subsequent reductions of breast, pancreatic, and colonic stem cell self-renewal.^{222,223}

Omega-3 fatty acids (derived from marine products) compete with omega-6 fatty acid substrates for eicosanoid-metabolizing enzymes with subsequent tissue reduction of these inflammatory mediators.^{224,225} These fatty acids have other diverse anticarcinogenic mechanisms (e.g., G-protein inhibition, changes in membrane physical characteristics that alter transmembrane signaling protein dynamics) that make them attractive as cancer risk-reducing agents.^{226,227}

Whole berries, black raspberries, and strawberries contain mixtures of multiple anticarcinogenic compounds such as ellagic acid, anthocyanins, and tocopherols.²²⁸ Research-grade berries are grown in a standardized cultivation environment and assayed for key components to ensure year-to-year reproducibility despite yearly climatologic variation. Berries have potent stabilization of methylation properties in addition to the expected anti-inflammatory and antioxidative properties associated with the prominent components.^{229,230}

Preclinical and Clinical Anticarcinogenesis Efficacy. Diverse diet-derived natural products have moderate-to-strong anticarcinogenic effects in both chemical and transgenic rodent carcinogenesis models (Table 33.12). Phase I clinical trials of curcumin detected little parent compound in plasma or tissues, raising the possibility of biologically active conjugates or deconjugation at the target site.²³¹⁻²³³ Resveratrol's plasma bioavailability exceeds that of curcumin and ginger, and partitions into human colon tissue at 10-fold concentrations compared to plasma.^{219,234,235} No natural products have been studied in large prospective, cancer incidence risk-reduction trials. Using intraepithelial biomarker end points in human phase II trials, berry formulations reduce esophageal dysplasia and oral leukoplakia.^{236,237} Curcumin reduces the number of colon aberrant crypt foci in human smokers.²³⁸

ANTI-INFECTIVES

Many infectious agents are known causes of human cancers, including the human hepatitis viruses, hepatitis B virus (HBV) and hepatitis C virus (HCV) for hepatocellular carcinoma²³⁹; *Helicobacter pylori* for gastric adenocarcinoma²⁴⁰; human papilloma viruses (HPV) for cervical, anal, vulva, penis, and oral cavity and pharynx carcinomas²⁴¹; herpes virus-8 for Kaposi sarcoma²⁴²; Epstein-Barr virus for Burkitt and other lymphomas²⁴³; liver flukes for cholangiocarcinoma²⁴⁴; and schistosomes for bladder carcinoma.²⁴⁵ The success of the HPV vaccine at reducing the incidence of intraepithelial neoplasia of the cervix (reviewed in Chapter 72) is one example that demonstrates the potential of

immunochemoprevention for epithelial targets for which an etiologic agent can be identified.

Helicobacter pylori

Intestinal-type gastric adenocarcinoma arises through a multistep process that begins with chronic gastritis initiated by *H. pylori*, progressing through gastric mucosal atrophy, intestinal metaplasia to dysplasia, and ultimately, to adenocarcinoma.²⁴⁶ *H. pylori* infects 50% of the world's population.²⁴⁰ Infection occurs early in life, remains quiescent, and may be associated with chronic gastritis of variable intensity but with minimal symptoms. Although the majority of *H. pylori* organisms remain in the gastric mucous layer, 10% adhere to the gastric mucosa through adhesion *Baba*, an outer membrane protein that binds to the Lewis-B histo-blood group antigen.²⁴⁰ Progression to atrophic gastritis and peptic ulcer disease (occurs in 10% to 15% of infected individuals) requires other bacterial and host cofactors.^{245,246} Infection with *H. pylori* is associated with an OR of 2.7 to 6.0 for gastric cancer; *CagA* increases this risk by 20- to 40-fold. The risk of developing gastric adenocarcinoma with an *H. pylori* infection is estimated to be 1% to 3%.^{245,246}

The eradication of *H. pylori* with antibiotics and anti-inflammatory agents—for example, amoxicillin, metronidazole, and bismuth subsalicylate—increases the rate of regression of non-metaplastic gastric atrophy and intestinal metaplasia in geographically diverse regions.^{247,248} A combination of a 2-week course of a proton pump inhibitor (omeprazole) and an antibiotic (amoxicillin) reduced the risk of gastric cancer in a high-risk population in China (OR = 0.61; 95% CI, 0.36 to 0.96) for 14.7 years after the treatment.²⁴⁹ The sequence of giving proton pump inhibitors and antibiotic therapy does not alter the treatment outcome. In addition to contributing to gastric cancer risk, *H. pylori* infections may also contribute to pancreatic cancer risk.²⁵⁰ Because *H. pylori* infections are so widespread, mass eradication campaigns in high-risk regions are being considered.²⁵¹ However, complicating this is that *H. pylori* infections have also been associated with a reduced risk of both esophageal adenocarcinoma and gastric cardia carcinoma.²⁵²

MULTIAGENT APPROACHES TO CANCER RISK REDUCTION

In the transition to molecularly targeted interventions, combinations of targets that logically address critical carcinogenic pathways may have greater efficacy than single agents. For example, previously demonstrated interactive signaling of EGFRs and COX-2 experiments in Min⁺ mice²⁵³ demonstrates cancer preventive synergism. Combining atorvastatin with selective or nonselective COX inhibitors enhanced the inhibition of azoxymethane-induced colon carcinogenesis in F344 rats and reduced the dose of the combined drugs required to achieve a reduction of colon carcinogenesis.²⁵⁴

DFMO plus sulindac inhibited adenoma formation in a phase IIb trial of 375 patients with a prior history of adenomas followed for 36 months (see Table 33.11).¹⁴⁷ Cardiovascular-adverse outcomes were higher in DFMO/sulindac-treated patients who had preexisting high baseline cardiovascular risk; however, the cardiovascular-adverse events were similar to placebo in moderate or low cardiovascular risk patients.²⁵⁵ Using IGF-1 as a biomarker, Guerrieri-Gonzaga et al.²⁵⁶ showed that the combination of low-dose tamoxifen with low-dose fenretinide is safe but not synergistic. As more data accumulate from in vivo models, combined drugs aimed at specific targets in coordinated signaling pathways will enter clinical biomarker-based trials. Optimal doses, toxicity, and biomarker modulation data will select those combinations useful for risk reduction trials and, ultimately, generalized use in at-risk populations.

TABLE 33.12

Selected Diet-Derived Natural Products with Cancer Risk-Reducing Activity

Nutritional Extract	Source	Mechanisms	In Vivo Anticarcinogenesis Efficacy	Human Trials	References
Curcumin ([1E,6E]-1,7-bis-[4-hydroxy-3-methoxyphenyl]-1,6-heptadiene-3,5-dione/diferuloylmethane)	Turmeric, rhizome of <i>Curcuma longa</i>	Inhibits: PGE ₂ synthesis via direct binding to COX-2 and through inhibition of NF-κB; angiogenesis. ErbB2 transduction; PI3K-Akt transduction; Inhibits stem cell self renewal Agonist: vitamin D receptor	Colon, breast, skin	Phase I: Poor bioavailability due to biotransformation in gut, enterohepatic cycling of metabolites; Phase IIa: reduced aberrant crypt foci	(219, 238)
Resveratrol (3,5,4'-trihydroxy-trans-stilbene)	Grapes, mulberries, peanuts, and <i>Cassia quinquangulata</i> plants	Inhibits: Carcinogen activation via inhibition of phase I isozyme, eicosanoids via direct binding; NF-κB; Nrf2. Acts as a caloric restriction mimetic, activates the histone deacetylase SIRT1 and AMPK	Colorectal, breast, pancreas, skin, and prostate	Phase I: 1 g dose generated peak concentration ~2 μM, conjugates 10-fold higher; resveratrol tissue concentrations 10-fold higher than plasma; Phase IIa: Small reduction in IGF-1 and IGFBP-1	(220, 234)
Ginger (gingerols, paradols, shagaols)	Rhizome of <i>Zingiber officinale</i>	Induces apoptosis via caspase-3 mechanisms; Inhibits NF-κB activation and downstream COX-2 expression; reduces iNOS expression and ornithine decarboxylase activity	Colon, breast, skin, oral cavity, liver	Phase I: 2 g dose nontoxic; Phase IIa: Small reductions in PGE ₂ , increased Bax in upper colon crypt	(235, 297, 298)
Green tea (epigallocatechin gallate, other catechins)	Green tea extract	Inhibits: PI3K-Akt transduction, IGF-1, IGFBP-3; NK-κB; catenin reduces methylation via inhibition of DNA methyltransferase 1	Lung, prostate, skin, colorectal	Phase IIa: 500–1,000 mg/m ² × 12 wk reduced oral premalignant lesions in 50%; Phase IIb: 2.5 g × 1 yr reduced colorectal adenoma recurrence by 50%	(221)
Omega-3 fatty acids (eicosapentaenoic acid; docosahexaenoic acid)	Fish oil	Reduction of inflammation via eicosanoid reduction; direct binding to G receptor proteins; PPAR activation; induction of anti-inflammatory lipid mediators (resolvins, protectins, maresins)	Colon, breast, prostate	Phase II: 4–7 mg/d reduced colon adenomas in familial adenomatous polyposis; ongoing trials for sporadic; extensive case control studies	(226, 299)
Berries	Black raspberries, strawberries	Reduction of methylation via inhibition of methyltransferases, re-regulated Wnt; inhibits NF-κB; inhibits cyclooxygenases; inhibits proliferation	Esophageal squamous cell, colon, skin	Phase IIb: Freeze dried strawberries reduced esophageal dysplasia; Phase IIa: Blackberry gel reduced leukoplakia	(228, 229, 236, 237)

IGFBP-1, insulin growth factor binding protein-1; iNOS, inducible isoform of nitric oxide synthase.

34 Cancer Screening

Otis W. Brawley and Howard L. Parnes

INTRODUCTION

Cancer screening refers to a test or examination performed on an asymptomatic individual. The goal is not simply to find cancer at an early stage, nor is it to diagnose as many patients with cancer as possible. The goal of cancer screening is to prevent death and suffering from the disease in question through early therapeutic intervention.

The assumption that early detection improves outcomes can be traced back to the concept that cancer inexorably progresses from a small, localized, primary tumor to local-regional spread, to distant metastases and death. This linear model of disease progression predicts that early intervention would reduce cancer mortality.

Cancer screening was an element of the “periodic physical examination,” as espoused by the American Medical Association in the 1920s.¹ It consisted of palpation to find a mass or enlarged lymph nodes and auscultation to find a rub or abnormal sound. Today, screening has grown to include radiologic testing, the measurement of serum markers of disease, and even molecular testing. A positive screening test leads to further diagnostic testing, which might lead to a cancer diagnosis.

The intuitive appeal of early detection accounts for the emphasis that has long been placed on screening. However, it is not widely understood that screening tests are always associated with some harm (e.g., anxiety, financial costs) and may actually cause substantial harm (e.g., invasive follow-up diagnostic or therapeutic procedures). Because screening is, by definition, done in healthy people, all early detection tests should be carefully studied and their risk-benefit ratio determined before they are adopted for widespread usage.

Screening is a public health intervention. However, some draw a distinction between screening an individual within the doctor-patient relationship and mass screening, a program aimed at screening a large population. The latter may involve advertising campaigns to encourage people to be screened for a particular cancer at a shopping mall or at a community event, such as state fair.

Screening may be either *opportunistic* (i.e., a patient sees a health-care provider who chooses to screen or not to screen) or *programmatically*. Programmatic refers to a standardized approach with algorithms for screening and follow-up as well as recall of patients for regular routine screening with quality control measures. Programmatic screening is usually more effective.

PERFORMANCE CHARACTERISTICS

The degree to which a screening test can discriminate between individuals with and without a particular disease is described by its performance characteristics. These include the a test’s sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) (Table 34.1). It should be noted that these measures relate to the accuracy of a screening test;

they do not provide any information regarding a test’s efficacy or effectiveness.

- Sensitivity is the proportion of persons designated positive by the screening test among all individuals who have the disease: true positive (TP)/(TP + false negative [FN]).
- Specificity is the proportion of persons designated negative by the screening test among all individuals who do not have the disease: true negative TN/(TN + false positive [FP]).
- Positive predictive value is the proportion of individuals with a positive screening test who have the disease: (TP)/(TP + FP).
- Negative predictive value is the proportion of individuals with a negative screening test who do not have the disease: (TN)/(TN + false negative [FN]).²

For a given screening test, sensitivity and specificity are inversely related. For example, as one lowers the threshold for considering a serum prostate-specific antigen (PSA) level to represent a *positive* screen, the sensitivity of the test increases and more cancers will be detected. This increased sensitivity comes at the cost of decreased specificity (i.e., more men without cancer will have *positive* screenings tests and, therefore, will be subjected to unnecessary diagnostic procedures).

Some screening tests, such as mammograms, are more subjective and operator dependent than others. For this reason, the sensitivity and specificity of screening mammography varies among radiologists. For a given radiologist, the lower his or her threshold for considering a mammogram to be suspicious, the higher the sensitivity and lower the specificity will be for them. However, mammography can have both a higher sensitivity and higher specificity in the hands of a more experienced versus a less experienced radiologist.

As opposed to sensitivity and specificity, the PPV and NPV of a screening test are dependent on disease prevalence. PPV is also highly responsive to small increases in specificity. As shown in Table 34.2, given a disease prevalence of 5 cases per 1,000 (0.005), the PPV of a hypothetical screening test increases dramatically as specificity goes from 95% to 99.9%, but only marginally as sensitivity goes from 80% to 95%. Given a disease prevalence of only 1 per 10,000 (0.0001), the PPV of the same test is poor even at high sensitivity and specificity. The positive association between breast cancer prevalence and age is the major reason why screening mammography is a better test (higher PPV) for women aged 50 to 59 than for women 40 to 49 years of age.

ASSESSING SCREENING TESTS AND OUTCOMES

Screening Test Results

Lead time bias occurs whenever screening results in an earlier diagnosis than would have occurred in the absence of screening.

TABLE 34.1

Performance Characteristics of a Screening Test

Sensitivity is the proportion designated positive by the screening test among all individuals who have the disease.

$$\frac{TP}{TP + FN}$$

Specificity is the proportion designated negative by the screening test among all those who do not have the disease.

$$\frac{TN}{TN + FP}$$

Positive predictive value is the proportion of individuals with a positive test who have the disease.

$$\frac{TP}{TP + FP}$$

Negative predictive value is the proportion of individuals with a negative test negative who do not have the disease.

$$\frac{TN}{TN + FN}$$

TP, true positive, the condition present and the test is positive; FN, false negative, the condition is present and the test is negative; FP, false positive, the condition is absent and the test is positive; TN, true negative, the condition is absent and test is negative.

Because survival is measured *from the time of diagnosis*, an earlier diagnosis, by definition, increases survival. Unless an effective intervention is available, lead time bias has no impact on the natural history of a disease and death will occur at the same time it would have in the absence of early detection (Fig. 34.1).

Length bias is a function of the biologic behavior of a cancer. Slower growing, less aggressive cancers are more likely to be detected by a screening test than faster growing cancers, which are more likely to be diagnosed due to the onset of symptoms between scheduled screenings (interval cancers). Length bias has an even greater effect on survival statistics than lead time bias (Fig. 34.2).

Overdiagnosis is an extreme form of length bias and represents pure harm. It refers to the detection of tumors, often through highly sensitive modern imaging modalities and other diagnostic tests, that fulfill the histologic criteria for malignancy

TABLE 34.2

Positive Predictive Value Given Varying Sensitivity and Specificity and Prevalence

Prevalence 0.005		Sensitivity %		
		80	90	95
Specificity %	95	7	8	9
	99	29	31	32
	99.9	80	82	83
Prevalence 0.0001		Sensitivity %		
		80	90	95
Specificity %	95	0.2	0.2	2.0
	99	0.8	0.9	0.9
	99.9	0.7	8.0	9.0

PPV improves dramatically in response to small changes in specificity. Changes in specificity influence PPV much more than changes in sensitivity. Note the influence of prevalence on PPV. Screening tests do not perform as well in populations with a low prevalence of disease.

Lead Time Bias

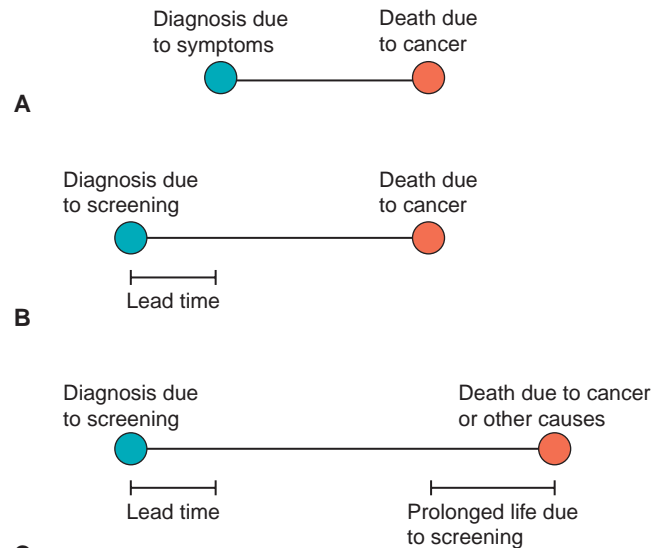

Figure 34.1 Survival is the time from cancer diagnosis to death. **(A)** Lead time bias occurs when screening results in an earlier diagnosis. Without screening, a patient is diagnosed with cancer due to symptoms. **(B)** With screening, the patient is often diagnosed earlier. When screening and treatment do not prolong life, the screened patient can have a longer survival solely due to the earlier diagnosis. The survival increase is pure lead time bias. **(C)** When screening and treatment are beneficial, the patient is diagnosed before the onset of symptoms and the patient lives beyond the point in which death would have occurred without screening.

but are not biologically destined to harm the patient (see Fig. 34.2).

There are two categories of overdiagnosis: the detection of histologically defined *cancers* not destined to metastasize or harm the patient, and the detection of cancers not destined to metastasize or cause harm *in the life span of the specific patient*. The importance of this second category is illustrated by the widespread practice in the United States of screening elderly patients with limited life expectancies, who are thus unlikely to benefit from early cancer diagnosis.

Overdiagnosis occurs with many malignancies, including lung, breast, prostate, renal cell, melanoma, and thyroid cancers.³ Neuroblastoma provides one of the most striking examples of overdiagnosis.⁴ Urine vanillylmandelic acid (VMA) testing is a highly sensitive screening test for the detection of this pediatric disease. After screening programs in Germany, Japan, and Canada showed marked increases in the incidence of this disease without a concomitant decline in mortality, it was noticed that nearby areas that did not screen had similar death rates with lower incidence.^{4,5} It is now appreciated that screen-detected neuroblastomas have a very good prognosis with minimal or no treatment. Many actually regress spontaneously.

Stage shift—i.e., a cancer diagnosis at an earlier stage than would have occurred in the absence of screening—is necessary, but not sufficient, for a screening test to be effective in terms of reducing mortality. Both lead time bias and length bias contribute to this phenomenon. Although it is tempting to speculate that diagnosis at an earlier stage must confer benefit, this is not necessarily the case. For example, a substantial proportion of men treated with radical prostatectomy for what appears to be a localized prostate cancer relapse after undergoing surgery. Conversely, some men who are treated with definitive therapy would never have gone on to develop metastatic disease in the absence of treatment.

Figure 34.2 Length bias and cancer screening. The *red line* is indicative of a fast-growing tumor that is not amenable to regular screening. The *blue line* is indicative of a fast-growing tumor that can be diagnosed by screening or later by symptoms; death may possibly be prevented by treatment. The *green line* is a slower growing but potentially deadly cancer that can be detected by symptoms or several screenings and treated, possibly preventing death. The *orange line* is indicative of a very slow growing tumor that would never cause death and would never need treatment despite being screen detected. This is classic overdiagnosis.

Selection bias occurs when enrollees in a clinical study differ from the general population. In fact, people who voluntarily participate in clinical trials tend to be healthier than the general population, perhaps due to a greater interest in health and health-care research. Screening studies tend to enroll individuals healthier than the general population. This so-called *healthy volunteer effect*^{6,7} can introduce a powerful bias if not adequately controlled for by randomization procedures.

Assessing Screening Outcomes

The usual primary goal of cancer screening is to reduce mortality from the disease in question (a reduction in disease-specific mortality). Screening studies generally do not have sufficient statistical power to assess the impact of screening for a specific malignancy on overall mortality. (Lung cancer screening provides an exception to this rule; see the following.) As discussed previously, the fact that a screening test increases the percentage of people diagnosed with early stage cancer and decreases that of late stage cancer (stage shift) is not equivalent to proof of mortality reduction. Further, due to the healthy volunteer effect, case control and cohort studies cannot provide definitive evidence of mortality benefit. Prospective, randomized clinical trials are required to address this issue. In such trials, volunteers are randomized to be screened or not and are then followed longitudinally to determine if there is a difference in disease-specific or overall mortality.

A reduction in mortality rates or in the risk of death is often stated in terms of relative risk. However, this method of reporting may be misleading. It is preferable to report both the relative and absolute reduction in mortality. For example, the European Randomized Study of Screening for Prostate Cancer (ERSPC) showed that screening reduced the risk of prostate cancer death by 20%. However, this translates into only 1 prostate cancer death averted per 1,000 men screened (5 prostate cancer deaths per 1,000 men not screened versus 4 prostate cancer deaths per 1,000 men screened) and a relatively modest lifetime reduction in the absolute risk of prostate cancer death of only 0.6%, from 3.0% to 2.4%.⁸

PROBLEMS WITH RANDOMIZED TRIALS

It is important to acknowledge that even prospective, randomized trials can have serious methodologic shortcomings. For example, imbalances caused by flaws in the randomization scheme can prejudice the outcome of a trial. Other flaws include so-called *drop-in* or *contamination*, in which some participants on the control arm get the intervention. Patients on the intervention arm may also

drop out of the study. Both drop-ins and drop-outs reduce the statistical power of a clinical trial.

In the United States, it is now considered standard to obtain informed consent before randomization takes place. However, there have been several published studies that randomized participants from rosters of eligible subjects such as census lists. In these trials, informed consent was obtained after randomization and only among those randomized to the screening arm of the study. Those randomized to the control arm were not contacted, and indeed, did not know they were in a clinical trial. They were followed through national death registries. Although the study was analyzed on an intent-to-screen basis, this method can still introduce biases. For example, only patients on the intervention arm had access to the screening facility and staff for counseling and treatment if diagnosed; those in the control group were more likely to be treated in the community as opposed to high-volume centers of excellence and were less likely to be treated with surgery and more likely to be treated with hormones alone than those on the screened arm. The study arms would also tend to differ in their knowledge of the disease, which may contribute to an overestimate of the benefits of a screening test.⁹

Virtually every screening test is a balance between known harms and potential benefits. The most important risk of screening is the detection and subsequent treatment of a cancer that would never have come to clinical detection or harmed the patient in the absence of screening (i.e., overdiagnosis and overtreatment). Treatment can cause emotional and physical morbidity and even death.¹⁰ Even when screening has a net mortality benefit, there can be considerable harm. For example, in the recent randomized trial of spiral lung computed tomography (CT) scan, approximately 27,000 current smokers and former smokers were given three annual low-dose CT scans. More than 20% had a *positive* screening CT scan, necessitating further testing. About 1,000 subsequently underwent invasive diagnostic procedures and 16 deaths were reported within 60 days of the procedure.¹¹ It is not known how many of these deaths were directly related to the screening.

It can be dangerous to extrapolate estimates of benefit from one population to another. In particular, studies showing that a radiographic test is beneficial to average risk individuals may not mean that it is beneficial to a population at high risk, and vice versa. For example, women at high risk for breast cancer due to an inherited mutation of a DNA repair gene may be at higher risk for radiation-induced cancer from mammographies compared to the general population; a screening test (e.g., spiral lung CT scan), shown to be efficacious in a high-risk population of heavy smokers may result in net harm if applied to a low or average risk population.

SCREENING GUIDELINES AND RECOMMENDATIONS

A number of organizations develop cancer screening recommendations or guidelines. These organizations use varying methods. The Institute of Medicine (IOM) has released two reports to establish standards for developing trustworthy clinical practice guidelines and conducting systematic evidence reviews that serve as their basis.^{12,13} The U.S. Preventive Services Task Force (USPSTF) and the American Cancer Society (ACS) are two organizations that issue respected and widely used cancer guidelines (Table 34.3). Both have changed their methods to comply with the IOM standards.

The USPSTF is a panel of experts in prevention and evidence-based medicine.¹⁴ They are primary care providers specializing in internal medicine, pediatrics, family practice, gynecology and obstetrics, nursing, and health behavior. The task force process begins by conducting an extensive structured scientific evidence review. The task force then develops recommendations for primary care clinicians and health-care systems. They adhere to some of the highest standards for recommending a screening test. They are very much concerned with the question, “Does the evidence supporting a screening test demonstrate that the benefits outweigh its harms?”

The ACS guidelines date back to the 1970s. The current process for making guidelines involves commissioning academics to do an independent systematic evidence review. A single generalist group digests the evidence review, listens to public input, and writes the guidelines. The ACS panel tries to clearly articulate the benefits, limitations, and harms associated with a screening test.¹⁵

BREAST CANCER

Mammographies, clinical breast examinations (CBE) by a health-care provider, and breast self-examinations (BSE) have long been advocated¹⁶ for the early detection of breast cancer. In recent years, ultrasound, magnetic resonance imaging (MRI), and other technologies have been added to the list of proposed screening modalities.

Mammographic screening was first advocated in the 1950s. The Health Insurance Plan (HIP) Study was the first prospective, randomized clinical trial to formally assess its value in reducing death from breast cancer. In this study, started in 1963, about 61,000 women were randomized to three annual mammograms with clinical breast examination versus no screening, which was the standard practice at that time. HIP first reported that mammography reduced breast cancer mortality by 30% at about 10 years after study entry. With 18 years of follow-up, those in the screening arm had a 25% lower breast cancer mortality rate.¹⁶

Nine additional prospective randomized studies have been published. These studies provide the basis for the current consensus that screening women 40 to 75 years of age does reduce the relative risk of breast cancer death by 10% to 25%. The 10 studies demonstrate that the risk–benefit ratio is more favorable for women over 50 years of age. Mammography has also been shown to be operator dependent, with better performance characteristics (higher sensitivity and specificity and lower FP rates) reported by high-volume centers (Table 34.4).

It is important to note that every one of these studies has some flaws and limitations. They vary in the questions asked and their findings. The Canadian screening trial suggests mammographies and clinical breast examinations do not decrease risk of death for woman aged 40 to 49 and that mammographies add nothing to CBEs for women age 50 to 59 years.¹⁷ On the other extreme, the Kopparberg Sweden study suggests that mammographies are associated with a 32% reduction in the risk of death for women aged 40 to 74 years.¹⁸

To date, no study has shown that BSEs decrease mortality. BSEs have been studied in two large randomized trials. In one, approximately 266,000 Chinese women were randomized to receive intensive BSE instruction with reinforcements and reminders compared to a control group receiving no instruction on BSE. At 10 years of follow-up, there was no difference in mortality, but the intervention arm had a significantly higher incidence of benign breast lesions diagnosed and breast biopsies performed. In the second study, 124,000 Russian women were randomized to monthly BSEs versus no BSEs. There was no difference in mortality rates, despite the BSE group having a higher proportion of early stage tumors and a significant increase in the proportion of cancer patients surviving 15 years after diagnosis.

Ultrasonography is primarily used in the diagnostic evaluation of a breast mass identified by palpation or mammography. There is little evidence to support the use of ultrasound as an initial screening test. This modality is highly operator dependent and time consuming, with a high rate of FP findings.¹⁹ An MRI is used for screening women at elevated breast cancer risk due to BRCA1 and BRCA2 mutations, Li-Fraumeni syndrome, Cowden disease, or a very strong family history. MRI is more sensitive but less specific than mammography, leading to a high FP rate and more unnecessary biopsies, especially among young women.²⁰ The impact of MRI breast screening on breast cancer mortality has not yet been determined.

Thermography, an infrared imaging technology, has some advocates as a breast cancer screening modality despite a lack of evidence from several small cohort studies.²¹ Nipple aspirate cytology and ductal lavage have also been suggested as possible screening methods. Both should be considered experimental at this time.²²

Effectiveness of Breast Cancer Screening

Breast cancer screening has been associated with a dramatic rise in breast cancer incidence. At the same time, there has been a dramatic decrease in breast cancer mortality rates. However, in the United States and Europe, incidence-by-stage data show a dramatic increase in the proportion of early stage cancers without a concomitant decrease in the incidence of regional and metastatic cancers.²³ These findings are at odds with the clinical trials data and raise questions regarding the extent to which early diagnosis is responsible for declining breast cancer mortality rates.

From 1976 to 2008, the incidence of early-stage breast cancer for American women aged 40 and older increased from 112 to 234 per 100,000. This is a rise of 122 cases per 100,000, whereas the absolute decrease in late-stage cancers was only 8 cases per 100,000 (from 102 to 94 cases per 100,000). These data raise questions regarding the magnitude of benefit, as well as the potential risks, of breast cancer screening. The discrepancy between the magnitude of the increase of early disease and the decrease of late-stage cancer and cancer mortality suggests that a proportion of invasive breast cancers diagnosed by screening represents overdiagnosis. These data suggest that overdiagnosis accounts for up to 31% of all breast cancers diagnosed by screening.²⁴ Others have estimated that up to 50% of breast cancers detected by screening mammography are overdiagnosed cancers. In an exhaustive review of the screening literature, a panel of experts concluded that overdiagnosis does exist and estimated it to be 11% to 19% of breast cancers diagnosed by screening.²⁵

A confounding factor with regard to the mortality benefits of breast cancer screening is the improvement that has occurred in breast cancer treatment over this period of time. The effects of the advances in therapy are supported by cancer modeling studies. Indeed, the Cancer Intervention and Surveillance Modeling Network (CISNET), supported by the U.S. National Cancer Institute (NCI), has estimated that two-thirds of the observed breast cancer mortality reduction is attributable to modern therapy, rather than to screening.²⁶

TABLE 34.3

Screening Recommendations for Normal-Risk Asymptomatic Subjects

Cancer Type	Test or Procedure	American Cancer Society	U.S. Preventive Services Task Force
Breast	Self-examination	Women ≥20 years: Breast self-exam is an option	"D"
	Clinical examination	Women 20–39 years: Perform every 3 years Women ≥40 years: Perform annually	Women ≥40 years: "I" (as a stand alone without mammography)
	Mammography	Women ≥40 years: Screen annually for as long as the woman is in good health	Women 40–49 years: The decision should be an individual one, and take patient context/values into account ("C") Women 50–74 years: Every 2 years ("B") Women ≥75 years: "I"
	MRI	Women >20% lifetime risk of breast cancer: Screen with MRI plus mammography annually Women 15%–20% lifetime risk of breast cancer: Discuss option of MRI plus mammography annually Women <15% lifetime risk of breast cancer: Do not screen annually with MRI	"I"
Cervical	Pap test (cytology)	Women ages 21–29 years: Screen every 3 years Women 30–65 years: Acceptable approach to screen with cytology every 3 years (see HPV test) Women <21 years: No screening Women >65 years: No screening following adequate negative prior screening Women after total hysterectomy for noncancerous causes: Do not screen	Women ages 21–65 years: Screen every 3 years ("A") Women <21 years: "D" Women >65 years, with adequate, normal prior Pap screenings: "D"
	HPV test	Women <30 years: Do not use HPV testing Women ages 30–65 years: Preferred approach to screen with HPV and cytology cotesting every 5 years (see Pap test) Women >65 years: No screening following adequate negative prior screening Women after total hysterectomy for noncancerous causes: Do not screen	Women after total hysterectomy for noncancerous causes: "D" Women ages 30–65 years: Screen in combination with cytology every 5 years if woman desires to lengthen the screening interval (see Pap test) ("A") Women <30 years: "D" Women >65 years, with adequate, normal prior Pap screenings: "D" Women after total hysterectomy for noncancerous causes: "D"
Colorectal	Sigmoidoscopy	Adults ≥50 years: Screen every 5 years Note: For all CRC screening tests, stop screening when benefits are unlikely due to life-limiting comorbidity.	Adults 50–75 years: Every 5 years in combination with high-sensitivity fecal occult blood testing (FOBT) every 3 years ("A") ^a Adults 76–85 years: "C" Adults ≥85 years: "D"
	Fecal occult blood testing (FOBT)	Adults ≥50 years: Screen every year with high sensitivity guaiac based FOBT or fecal immunochemical test (FIT) only	Adults 50–75 years: Annually, for high-sensitivity FOBT ("A") Adults 76–85 years: "C" Adults ≥85 years: "D"
	Colonoscopy	Adults ≥50 years: Screen every 10 years	Adults 50–75 years: every 10 years ("A") Adults 76–85 years: "C" Adults ≥85 years: "D"
	Fecal DNA testing	Adults ≥50 years: Screen, but interval uncertain	"I"
	Fecal immunochemical testing (FIT)	Adults ≥50 years: Screen every year	"I"
	CT colonography	Adults ≥50 years: Screen every 5 years	"I"
Lung	Complete skin examination by clinician or patient	Men and women, 55–74 years, with ≥30 pack-year smoking history, still smoking or have quit within past 15 years: Discuss benefits, limitations, and potential harms of screening. Only perform screening in facilities with the right type of CT scanner and with high expertise/specialists.	"I" ("B" draft recommendation issued for public comment in July 2013)

(continued)

TABLE 34.3

Screening Recommendations for Normal-Risk Asymptomatic Subjects (continued)

Cancer Type	Test or Procedure	American Cancer Society	U.S. Preventive Services Task Force
Ovary	CA-125 Transvaginal ultrasound	There is no sufficiently accurate test proven effective in the early detection of ovarian cancer. For women at high risk of ovarian cancer and/or who have unexplained, persistent symptoms, the combination of CA-125 and transvaginal ultrasound with pelvic exam may be offered.	"D" "D"
Prostate	Prostate-specific antigen (PSA)	Starting at age 50, men should talk to a doctor about the pros and cons of testing so they can decide if testing is the right choice for them. If African American or have a father or brother who had prostate cancer before age 65, men should have this talk starting at age 45. How often they are tested will depend on their PSA level.	Men, all ages: "D"
	Digital rectal examination (DRE)	As for PSA; if men decide to be tested, they should have the PSA blood test with or without a rectal exam.	No individual recommendation
Skin	Complete skin examination by clinician or patient	Self-examination monthly; clinical exam as part of routine cancer-related checkup	"I"

Note: Summary of the screening procedures recommended for the general population by the American Cancer Society and the U.S. Preventive Services Task Force. These recommendations refer to asymptomatic persons who have no risk factors for the cancer, other than age or gender.

^a USPSTF lettered recommendations are defined as follows:

"A": The USPSTF recommends the service, because there is high certainty that the net benefit is substantial.

"B": The USPSTF recommends the service, because there is high certainty that the net benefit is moderate or moderate certainty that the net benefit is moderate to substantial.

"C": The USPSTF recommends selectively offering or providing this service to individual patients based on professional judgment and patient preferences. There is at least moderate certainty that the net benefit is small.

"D": The USPSTF recommends against the service, because there is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits.

"I": The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service.

Questions have also been raised regarding the quality of the randomized screening trials that demonstrated the mortality benefits of mammography and clinical breast examination because these trials suffered from a variety of design flaws. In some, randomization methods were suboptimal, others reported varying numbers of participants over the years, and still others had substantial contamination (drop-ins). Perhaps more importantly, most trials were started and concluded before the widespread use of more advanced mammographic technology, before the modern era of adjuvant therapy, and before the advent of targeted therapy.

Although randomized control trials (RCT) remain the gold standard for assessing the benefits of a clinical intervention, they cannot take into account improvements in both treatment and patient awareness that occurred over time. For this reason, observational and modeling studies can provide important, complementary information.

One systematic review of 17 published population-based and cohort studies compared breast cancer mortality in groups of women aged 50 to 69 years who started breast cancer screening at different times. Although these studies are subject to methodologic limitations, only four suggested that breast cancer screening reduced the relative risk of breast cancer mortality by 33% or more and five suggested no benefit from screening. The review concluded that breast cancer screening likely reduces the risk of breast cancer death by no more than 10%.²⁷

Even with these limitations, a systematic review of the data sponsored by the USPSTF concluded that regular mammography reduces breast cancer mortality in women aged 40 to 74 years.²⁸ The task force also concluded that the benefits of mammography are most significant in women aged 50 to 74 years.

Screening Women Age 40 to 49

Experts disagree about the utility of screening women in their forties. In the HIP Randomized Control Trial, women who entered at

age 40 to 49 years had a mortality benefit at 18 years of follow-up. However, to a large extent, the mortality benefit among those aged 45 to 49 years at entry was driven by breast cancers diagnosed after they reached age 50 years.¹⁶

Mammography, like all screening tests, is more efficient (higher PPV) for the detection of disease in populations with higher disease prevalence (see Table 34.2). Mammography is, therefore, a better test in women age 50 to 59 years than it is among women age 40 to 49 years because the risk of breast cancer increases with age. Mammography is also less optimal in women age 40 to 49 years compared to women 50 to 59 years of age for the following reasons:

- A larger proportion have increased breast density, which can obscure lesions (lower sensitivity).
- Younger women are more likely to develop aggressive, fast-growing breast cancers that are diagnosed between regular screening visits. By definition, these *interval cancers* are not screen detected.²⁹

The USPSTF meta-analysis of eight large randomized trials suggested a 15% relative reduction in mortality (relative risk [RR], 0.85; 95% confidence interval [CI], 0.75 to 0.96) from mammography screening for women aged 40 to 49 years after 11 to 20 years of follow-up. This is equivalent to a needing to invite 1,904 women to screenings over 10 years to prevent one breast cancer death. Studies, however, show that more than half of women aged 40 to 49 years screened annually over a 10-year period will have an FP mammogram necessitating further evaluation, often including biopsy. In addition, estimates of overdiagnosis in this group range from 10% to 40% of diagnosed invasive cancers.³⁰

In an effort to decrease FP rates, some have suggested screening every 2 years rather than yearly. Comparing biennial with annual screening, the CISNET Model consistently shows that biennial screening of women ages 40 to 70 only marginally decreases the number of lives saved while halving the false positive rate.²⁹ Notably, the Swedish two-county trial, which had a planned 24-month screening interval (the actual interval was 33 months) reported one

TABLE 34.4

Randomized Controlled Trials

Study	Randomization	Sample Size	Intervention and Age at Entry	Follow-up	Finding
Health Insurance Plan, United States 1963 ^{a,b}	Individual	60,565–60,857	MMG and CBE for 3 years Age 40–64 years	18 years	RR 0.77 (95% CI: 0.61–0.97)
Malmö, Sweden 1976 ^{c,d}	Individual	42,283	Two-view MMG every 18–24 months × 5 Age 45–69 years	12 years	RR 0.81 (95% CI: 0.62–1.07)
Ostergötland (County E of Two-County Trial) Sweden 1977 ^{e-g}	Geographic cluster	38,405–39,034 study 37,145–37,936 control	Three single-view MMG every 2 years women, Age 40–50 years Every 33 months women, Age 50–74	12 years	RR 0.82 (95% CI: 0.64–1.05)
Kopparberg (County W of Two-County Trial) Sweden 1977 ^{e-g}	Geographic cluster	38,562–39,051 intervention 18,478–18,846 control	Three single-view MMG every 2 years women, Age 40–50 years Every 33 months women, Age 50–74 years	12 years	RR 0.68 (95% CI: 0.52–0.89)

of the greatest reductions in breast cancer mortality among the RCTs conducted to date.

Screening Women at High Risk

There is interest in creating risk profiles as a way of reducing the inconveniences and harms of screening. It might be possible to identify women who are at greater risk of breast cancer and refocus screening efforts on those most likely to benefit.

Risk factors for breast cancer include the following:

- Extremely dense breasts on mammography or a first-degree relative with breast cancer are each associated with at least a twofold increase in breast cancer risk
- Prior benign breast biopsy, second-degree relatives with breast cancer, or heterogeneously dense breasts each increase risk 1.5- to twofold
- Current oral contraceptive use, nulliparity, and age at first birth 30 years and older increase risk 1- to 1.5-fold.³¹

Importantly, these are risk factors for breast cancer diagnosis, not breast cancer mortality. Few studies have assessed the association between these factors and death from breast cancer; however, reproductive factors and breast density have been shown to have limited influence on breast cancer mortality.^{32,33}

Genetic testing for *BRCA1* and *BRCA2* mutations and other markers of breast cancer risk has identified a group of women at high risk for breast cancer. Unfortunately, when to begin and the optimal frequency of screening have not been defined. Mammography is less sensitive at detecting breast cancers in women carrying *BRCA1* and *BRCA2* mutations, possibly because such cancers occur in younger women in whom mammography is known to be less sensitive.

MRI screening may be more sensitive than mammography in women at high risk, but specificity is lower. MRIs are associated with both an increase in FP and an increase in the detection of smaller cancers, which are more likely to be biologically indolent. The impact of MRIs on breast cancer mortality with or without concomitant use of mammographies has not been evaluated in a randomized controlled trial.

Breast Density

It is well established that mammogram sensitivity is lower in women with heterogeneously dense or very dense breasts.^{29,32} However, at this time, there are no clear guidelines regarding whether or how screening algorithms should take breast density into account.

In the American College of Radiology's Imaging Network (ACRIN)/NCI 666 Trial, breast ultrasound was offered to women with increased mammographic breast density and, if either test was positive, they were referred for a breast biopsy.³⁴ The radiologists performing the ultrasounds were not aware of the mammographic findings. Mammography detected 7.6 cancers per 1,000 women screened; ultrasound increased the cancer detection rate to 11.8 per 1,000. However, the PPV for mammography alone was 22.6%, whereas the PPV for mammography with ultrasound was only 11.2%.

It has yet to be determined whether supplemental imaging reduces breast cancer mortality in women with increased breast density. Although it continues to be strongly advocated by some, systematic reviews have concluded that the evidence is currently insufficient to recommend for or against this approach.³⁵ There are also a number of barriers to supplemental imaging, including inconsistent insurance coverage, lack of availability in many communities, concerns about cost-effectiveness (particularly with regard to MRI), and the increased FP rate associated with supplemental imaging leading to unnecessary biopsies.³⁶

Newer technologies may improve screening accuracy for women with dense breasts. Compared to conventional mammography, full field digital mammography (FFDM) appears to have less FPs. This could reduce the number of women needing

supplemental imaging and biopsies.³⁷ Digital breast tomosynthesis (DBT) uses x-rays and a digital detector to generate cross-sectional images of the breasts. Data are limited, but compared to mammograms, DBT appears to offer increased sensitivity and a reduction in the recall rates.³⁸ Another potential supplementary imaging modality currently under investigation is three-dimensional (3-D) automated breast ultrasound, and having screening ultrasounds performed by technologists rather than radiologists.

Ductal Carcinoma In Situ

The incidence of noninvasive ductal carcinoma in situ (DCIS) has increased more than fivefold since 1970 as a direct consequence of widespread screening mammographies.³⁹ DCIS is a heterogeneous condition with low- and intermediate-grade lesions taking a decade or more to progress. Nevertheless, women with this diagnosis are uniformly subjected to treatment. A better understanding of this entity and an increased ability to predict its biologic behavior may enable more judicious, personalized treatment of DCIS.

There is little evidence that the early detection and aggressive treatment of low- and intermediate-grade DCIS reduces breast cancer mortality. The standard of care for all grades of DCIS is lumpectomy with radiation or mastectomy, followed by tamoxifen for 5 years. Interestingly, patterns of care studies indicate that mastectomy rates are increasing,⁴⁰ and that women are more often choosing double mastectomies for the treatment of DCIS.⁴¹ Genomic characterization will hopefully lead to the identification of a subset of noninvasive cancers that can be treated less aggressively or even observed.

Harms

The harms and disadvantages of mammography screening include overdiagnosis, FP tests, FN tests, and the possibility of radiation-induced breast cancer.

The fact that mammography screening has increased the incidence of localized disease without a significant change in metastatic disease at the time of diagnosis suggests that there is some degree of overdiagnosis. The risk of overdiagnosis is greatest at the first screening³ and varies with patient age, tumor type, and grade of disease.

FP screening tests lead to substantial inconvenience and anxiety in addition to unnecessary invasive biopsies with their attendant complications. In the United States, about 10% of all women screened for breast cancer are called back for additional testing, and less than half of them will be diagnosed with breast cancer.³⁹ The risk of a FP mammogram is greater for women under the age of 50.³⁷

FN tests delay diagnosis and provide false reassurance. They are more common in younger women and in women with dense breasts.^{42,43} Certain histologic subtypes are also more difficult to see on mammogram. Mucinous and lobular tumors and rapidly growing tumors tend to blend in with normal breast architecture.⁴⁴

A typical screening mammogram provides approximately 4 mSv of radiation. It has been estimated that annual mammographies will cause up to 1 case of breast cancer per 1,000 women screened from age 40 to age 80 years. Radiation exposure at younger ages causes a greater risk of breast cancer.⁴⁵ There is also concern that ionizing radiation from mammographies might disproportionately increase the breast cancer risk for women with certain *BRCA1* or *BRCA2* mutations, because these genes are related to DNA repair.⁴⁶

Recommendations

Women at Average Risk

The ACS and most other medical groups recommend that average risk women undergo a CBE every 3 years starting at age 20 and that women 40 years of age and over should undergo CBEs and screening mammograms annually. Women should be informed

of the benefits, limitations, and harms associated with breast cancer screening. A mammography will not detect all breast cancers, and some breast cancers detected with mammographies may still have a poor prognosis. The harms associated with breast cancer screening also include the potential for FP results, causing substantial anxiety. When abnormal findings cannot be resolved with additional imaging, a biopsy is required to rule out the possibility of breast cancer. A majority of biopsies are benign. Finally, some breast cancers detected by a mammography may be biologically indolent, meaning they would not have caused a problem or have been detected in a woman's lifetime had she not undergone a mammography.

The USPSTF, the American College of Physicians, and the Canadian Task Force on the Periodic Health Examination recommend routine screening beginning at age 50 years.^{30,47,48} For women aged 40 to 49 years of age, these groups advise physicians to enter into a discussion with the patient. The physician and patient should take into account individual risks and concerns before deciding to screen.⁴⁷

An Advisory Committee on Cancer Prevention in the European Union recommends that women between the ages of 50 and 69 years be offered mammogram screening in an organized screening program with quality assurance.⁴⁹ This committee says women aged 40 to 49 years should be advised of the potential harms of screening and, if mammographic screening is offered, it should be performed with strict quality standards and double reading.

Women at High Risk

The ACS has issued guidelines for women who were known or likely carriers of a *BRCA* mutation and other rarer high-risk genetic syndromes, or at high risk for other reasons.⁵⁰ Annual screening mammographies and MRIs starting at age 30 is recommended for women:

- With a known *BRCA* mutation
- Who are untested but have a first-degree relative with a *BRCA* mutation
- Who had been treated with radiation to the chest for Hodgkin disease
- Who have an approximately 20% to 25% or greater lifetime risk of breast cancer based on specialized breast cancer risk estimation models.

COLON CANCER SCREENING

Colorectal cancer screening with the rigid sigmoidoscope dates back to the late 1960s. The desire to examine the entire colon led to the use of a barium enema and the development of fecal occult blood tests. With the development of fiber optics, flexible sigmoidoscopies and, later, colonoscopies were employed. Today, fecal occult blood testing (FOBT), stool DNA testing, flexible sigmoidoscopies, colonoscopies, and CT colonographies and, occasionally, barium enemas are all used in colorectal cancer screening. MRI colonoscopy is in development.

Screening examinations of the colon and rectum can find cancer early, but also find precancerous polyps. Randomized trials have demonstrated that endoscopic polypectomies reduce the incidence of colorectal cancer by about 20%.^{51–53}

FOBT was the first colorectal screening test studied in a prospective randomized clinical trial. The Minnesota Colon Cancer Control Study randomized 46,551 adults to one of three arms: annual FOBTs, biennial screening, or usual care. A rehydrated guaiac test was used. With 13 years of follow-up, the annual screened arm had a 33% relative reduction in colorectal cancer mortality compared to the usual care group.⁵⁴ At 18 years of follow-up, the biennially screened group had a 21% reduction in colorectal cancer

mortality.⁵⁵ This study would subsequently show that stool blood testing was associated with a 20% reduction in colon cancer incidence.⁵¹ These results were confirmed by two other randomized trials.^{56,57} A reduction in colon cancer–specific mortality persisted in the Minnesota trial through 30 years of follow-up. Overall mortality was not affected.

Rehydration increases the sensitivity of FOBT at the expense of lowering specificity.⁵⁸ Indeed, rehydrated specimens have a very high FP rate. Overall, 1% to 5% of FOBTs are positive, but only 2% to 10% of those with a positive FOBT have cancer.

Fecal immunochemical tests (FIT) are stool tests that do not react to hemoglobin in dietary products. They appear to have higher sensitivity and specificity for colorectal cancer when compared to nonrehydrated FOBT tests.⁵⁹

Fecal DNA testing is an emerging modality. These tests look for DNA sequences specific to colorectal polyps and colorectal cancer. They may have increased sensitivity and specificity compared to FOBT. Although fecal DNA tests appear to find cancer, the body of evidence on their ability to reduce colorectal cancer mortality is limited due to a lack of study. This test has been intermittently available.

Flexible sigmoidoscopies are, of course, limited to an examination of the rectum and sigmoid colon. A prospective randomized trial of once-only flexible sigmoidoscopies demonstrated a 23% reduction in colorectal cancer incidence and a 31% reduction in colorectal cancer mortality after a median 11.2 years of follow-up.⁶⁰ In the NCI's Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO), there was a 21% reduction in colorectal cancer incidence and a 26% reduction in colorectal cancer mortality with two sigmoidoscopies done 3 to 5 years apart compared with the usual care group after a median follow-up of 11.9 years.⁵³ In both studies, there was no effect on proximal lesions (i.e., right and transverse colon) due to the limited reach of the scope. It is estimated that flexible sigmoidoscopies can find 60% to 80% of cancers and polyps found by colonoscopies.⁶¹

In two meta-analyses of five randomized controlled trials of sigmoidoscopies, there was an 18% relative reduction in colorectal cancer incidence and a 28% relative reduction in colorectal cancer mortality.^{62,63} Participants ranged in age from 50 to 74 years. Follow-up ranged from 6 to 13 years.

The *colonoscopy* has become the preferred screening method of many, although there have been no prospective, randomized trials of colonoscopy screening. A positive FOBT, FIT, fecal DNA test, or sigmoidoscopy warrants a follow-up diagnostic colonoscopy. Perhaps the best support for colonoscopy screening is indirect evidence from the Minnesota Colon Cancer Control Study, which required that all participants with a positive stool blood test have diagnostic imaging of the entire colon. In the Minnesota study, more than 40% of those screened annually eventually received a colonoscopy. One can also make the argument that the sigmoidoscopy studies indirectly support the efficacy of colonoscopy screening, although it can be argued that embryologic and epidemiologic evidence indicate that the right and left colon are biologically distinct and, therefore, the mortality benefits from sigmoidoscopies do not constitute proof that a colonoscopy would similarly reduce mortality from proximal colon lesions.

In studies involving repeat colonoscopies by a second physician, 21% of all adenomas were missed, including 26% of 1 to 5 mm adenomas and 2% of adenomas 10 mm or more in length.⁶⁴ Other limitations of colonoscopies include the inconvenience of the bowel preparation and the risk of bowel perforation (about 3 out of 1,000 procedures, overall, with nearly all of the risk among patients who undergo colonoscopic polypectomies). The cost of the procedure and the limited number of physicians who can do the procedure are also of concern.

A *CT colonography* or *virtual colonoscopy* allows a physician to visually reproduce the endoscopic examination on a computer screen. A CT colonography involves the same prep as a colonoscopy, but is less invasive. It might have a higher compliance rate.

In experienced hands, the sensitivity of a CT colonography for the detection of polyps ≥ 6 mm appears to be comparable to that of a colonoscopy. In a meta-analysis of 30 studies, 2-D and 3-D CT colonographies performed equally well.⁶⁵

The disadvantages of a CT colonography include the fact that it requires a colonic prep and a finding on CT requires a follow-up diagnostic colonoscopy. The rate of extracolonic findings of uncertain significance is high (~15% to 30%), and each one must be evaluated, thereby contributing to additional expense and potential morbidity. The long-term, cumulative radiation risk of repeated colonography screenings is also a concern.

Current Recommendations

The ACS, the American College of Gastroenterology, the American Gastroenterological Association, the American Society for Gastrointestinal Endoscopy, and the American College of Radiology have issued joint colorectal cancer guidelines. These groups consider FOBT, FIT, rigid and flexible sigmoidoscopies, colonoscopies, and CT colonographies to all be reasonable screening methodologies.

They recommend the following: (1) Screening modalities be chosen based on personal preference and access, and (2) average risk adults should begin colorectal cancer screening at age 50 years with *one* of the following options:

1. Annual high sensitivity FOBT or FIT
2. A flexible sigmoidoscopy every 5 years
3. A colonoscopy every 10 years
4. A double contrast barium enema every 5 years
5. A CT colonography every 5 years

No test is of unequivocal superiority. Patient preferences should be incorporated into screening in order to increase compliance. The guidelines also stress that a single screening examination is far from optimal and that patients should be in a program of regular screening.

Although some colorectal cancers are diagnosed in persons under the age of 50 years, screening persons age 40 to 49 years has low yield.⁶⁶ The guidelines also state that patients with less than a 10-year life expectancy should not be screened.

The USPSTF issued colorectal cancer screening guidelines in 2008.⁶⁷ The guidelines were based on a systematic literature review and decision models. The task force concluded that three screening strategies appear to be equivalent for adults age 50 to 75 years:

1. An annual FOBT with a sensitive test
2. A flexible sigmoidoscopy every 5 years, with a sensitive FOBT every 3 years
3. A colonoscopy every 10 years

The task force recommends that patients age 76 to 85 years be evaluated individually for screening. They found “insufficient evidence” to recommend CT colonographies or fecal DNA testing.

Patients at Increased Risk of Colorectal Cancer

Patients can have higher than average risk of colorectal cancer due to familial or hereditary factors and clinical conditions such as inflammatory bowel disease. These patients technically undergo surveillance and not screening. Nevertheless, there are few clinical studies to guide recommendations. Guidelines have been created based on professional opinion and an understanding of the biology of colorectal cancer (Table 34.5).⁶⁸

OTHER CANCERS OF THE GASTROINTESTINAL TRACT

There are no widely accepted screening guidelines for cancers of the esophagus, stomach, pancreas, and liver. However, surveillance is advocated for some patients at high risk.

Esophageal Cancer Screening

Esophageal cancer screening has centered on endoscopic examinations for those at high risk due to chronic, severe gastroesophageal reflux disease.⁶⁹ Some physicians advocate routine endoscopic surveillance of patients with Barrett esophagus. At this time, there is no evidence that such surveillance is effective at reducing cancer mortality.

TABLE 34.5

Colorectal Cancer Screening Recommendations for People with Familial or Inherited Risk

Familial Risk Category	Screening Recommendation
First-degree relative ^a affected with <i>colorectal cancer</i> or an <i>adenomatous polyp</i> at age ≥ 60 years, or two second-degree relatives ^b affected with <i>colorectal cancer</i>	Same as average risk but starting at age 40 years
Two or more first-degree relatives with <i>colon cancer</i> , or a single first-degree relative with <i>colon cancer</i> or <i>adenomatous polyps</i> diagnosed at an age < 60 years	Colonoscopy every 5 years, beginning at age 40 years or 10 years younger than the earliest diagnosis in the family, whichever comes first
One second-degree or any third-degree relative ^{b,c} with <i>colorectal cancer</i>	Same as average risk
Gene carrier or at risk for familial adenomatous polyposis ^d	Sigmoidoscopy annually, beginning at age 10–12 years ^e
Gene carrier or at risk for HNPCC	Colonoscopy, every 1–2 years, beginning at age 20–25 years or 10 years younger than the earliest case in the family, whichever comes first

^a First-degree relatives include patients, siblings, and children.

^b Second-degree relatives include grandparents, aunts, and uncles.

^c Third-degree relatives include great-grandparents and cousins.

^d Includes the subcategories of familial adenomatous polyposis, Gardner syndrome, some Turcot syndrome families, and attenuated adenomatous polyposis coli (AAPC).

^e In AAPC, colonoscopy should be used instead of sigmoidoscopy because of the preponderance of proximal colonic adenomas. Colonoscopy screening in AAPC should probably begin in the late teens or early 20s.

HNPCC, hereditary nonpolyposis colon cancer.

From Winawer S, Fletcher R, Rex D, et al. Colorectal cancer screening and surveillance: clinical guidelines and rationale: update based on new evidence. *Gastroenterology* 2003;124:544–560, with permission.

Gastric Cancer Screening

Barium-meal photofluorography, serum pepsinogen, and gastric endoscopy have been proposed as screening methods for the early detection of gastric cancer. There are no randomized trials evaluating the impact of these modalities on gastric cancer mortality. Indeed, screening with barium-meal photofluorography has been studied in high-risk populations for more than 40 years without clear evidence of benefit.

Time-trend analysis and case control studies of gastric endoscopy have suggested a decrease in gastric cancer mortality among those at high risk in screened versus unscreened individuals; however, a large observational study in a high-risk population failed to demonstrate a benefit.^{70,71}

Although widespread gastric screenings cannot be advocated, there may be justification for endoscopic screenings of high-risk populations. Candidates for screening might include elderly individuals with atrophic gastritis or pernicious anemia, patients who have had partial gastrectomy,⁷² those with a history of sporadic adenomas, and patients with familial adenomatous polyposis or hereditary nonpolyposis colon cancer.

Pancreatic Cancer Screening

At this time, there are no data from prospective clinical trials to support a role for pancreatic cancer screening. Some patients with an extensive family history have undergone periodic CT scanning of the abdomen, but this approach has not been shown to reduce pancreatic cancer mortality. There is an ongoing search for screening biomarkers. There is a need to follow large cohorts prospectively after collecting and storing biologic samples to identify biomarkers of risk.⁷³

Liver Cancer Screening

Screening for liver cancer or hepatocellular carcinoma (HCC) has focused on very high-risk individuals, such as those with cirrhosis.⁵⁴ To date, trial results are unreliable due to small study sizes and a lack of randomization.

Serum alpha-fetoprotein (AFP), a fetal-specific glycoprotein antigen, is an HCC tumor marker used in screening. It is not specific to HCC because it may be elevated in hepatitis, pregnancy, and some germ cell tumors. AFP has variable sensitivity and has not been tested in any randomized clinical trial with a mortality end point.

In one prospective, 16-year, population-based observational study, screening was done on 1,487 Alaska natives with chronic hepatitis B virus (HBV) infection. The survival of those with screen-detected HCC was compared with a historical group of clinically diagnosed HCC patients.⁷⁴ With a target of AFP determination every 6 months, there was a 97% sensitivity and 95% specificity for HCC. Such high sensitivity and specificity have not been found in other studies. It is not known if AFP screening decreases HCC mortality.⁷⁵

Hepatic ultrasound has been used as an additional method for detection of HCC. This procedure is operator dependent with variable sensitivity and specificity. Ultrasound screening is commonly used in patients with hepatitis and cirrhosis.^{76,77}

Interest in CT scanning has grown due to the limitations of AFP and ultrasound. CT scans may be a more sensitive test for HCC than ultrasound or AFP.⁷⁵

GYNECOLOGIC CANCER

Cervical Cancer Screening

Dr. George Papanicolaou first introduced the Pap smear or Pap test in the early 1940s. The test was widely adopted based on its

ability to identify squamous premalignancies and malignancies (from the ectodermal cervix) and glandular dysplasia and adenocarcinomas (from the endocervix). It is, however, more sensitive at detecting squamous lesions.

The Pap test was introduced before the advent of the prospective, randomized clinical trial and, therefore, has never been so tested. However, a number of observational studies over the past 60 years support the effectiveness of this screening test.^{78,79} Multiple ecologic studies have shown an inverse correlation between the introduction of Pap testing in a given country and reductions in both cervical cancer incidence and mortality.⁸⁰ Importantly, mortality reductions in these studies have been proportional to the intensity of screening. In one series, more than half of women diagnosed with cervical cancer either had never had a Pap test or had not been screened within 5 years of diagnosis.⁸⁰

Cervical cytology has evolved over the years. The original Pap smear used an ectocervical spatula to apply a specimen ("smear") to glass slides. It later included an endocervical brush. The smear was fixed, stained, and manually examined under a microscope. That method is still used today, but a liquid-based/thin-layer system capable of being analyzed by computer is gaining in popularity.⁸¹

Human papillomavirus (HPV) 16 and 18 are the cause of more than 70% of cervical cancers. Thirteen other HPV subtypes are known to be associated with cervical cancer. With increasing understanding of the role of HPV in cervical disease, interest in developing tests to determine the presence of HPV DNA and RNA has grown. HPV screening can be used along with cytology (*cotesting*), in response to an abnormal cytologic test (*reflexive testing*), or as a stand-alone test. One advantage of the liquid-based/thin-layer tests over the older smears is that it makes reflexive testing easier to perform. An abnormal cytology screen can be objectively verified by testing for the presence of the HPV virus without calling the patient back.

HPV testing is especially useful because of its negative predictive value. Although a positive test for HPV infection is not diagnostic of cervical disease, a negative HPV test strongly suggests that the abnormal Pap does not represent a premalignant condition.

The utility of the HPV test is limited in younger women because one-third or more of women in their 20s have active cervical infections at any given time. The overwhelming majority of these infections and resultant dysplasia will regress and resolve within 8 to 24 months. For women over the age of 30, screening for the presence of HPV DNA or RNA appears to be superior to cytology in identifying women at risk for cervical dysplasia and cancer.⁸² An HPV infection in women over the age of 30 is more likely to be persistent and clinically significant.⁸⁵ The risk of cervical cancer also increases with age, and most cervical cancer deaths occur in women over 50 years of age.

Cytologic Terminology

The terminology of the Pap smear has changed over time. The traditional cytologic categories were mild, moderate, and severe dysplasia and carcinoma in situ. *Mild* correlated with cervical intraepithelial neoplasia (CIN)1 histology on biopsy; *moderate* usually indicated CIN2; and *severe* dysplasia indicated CIN3 or carcinoma in situ.

There was some subjectivity and some overlap, especially in the area of mild and moderate dysplasia. The NCI sponsored the development of the Bethesda system in 1988. This system provides an assessment of the adequacy of the cervical specimen and a way of categorizing and describing the Pap smear findings. It more effectively and uniformly communicates cytology results from the laboratory to the patient caregiver. The Bethesda system was modified in 1991 and again in 2001.⁸⁴ Today, more than 40 international professional societies have endorsed the Bethesda system.

The Bethesda system recognizes both squamous and glandular cytologic abnormalities.

Squamous cell abnormalities include:

- Atypical squamous cells (ASC), which are categorized as either:
 - Of undetermined significance (ASC-US)
 - Cannot exclude high-grade squamous intraepithelial lesions (ASC-H)
- Low-grade squamous intraepithelial lesion (LSIL), which correlates with histologic CIN1
- High-grade squamous intraepithelial lesion (HSIL), which correlates with histologic CIN2, CIN3, and carcinoma in situ

Glandular cell abnormalities (features suggestive of adenocarcinoma) include:

- Atypical glandular cells (AGC): endocervical, endometrial, or not otherwise specified
- AGCs, favor neoplastic
- Endocervical or not otherwise specified
- Endocervical adenocarcinoma in situ (AIS)
- Adenocarcinoma

ASCs differ from normal cells but do not meet criteria for LSIL or HSIL. A small proportion of ASC-US smears are from CIN1 lesions; a smaller proportion are from CIN2 or 3. LSILs are usually due to a transient HPV infection. HSILs are more likely to be due to a persistent HPV infection and are more likely to progress to cervical cancer than LSILs.

The Lower Anogenital Squamous Terminology (LAST) project of the College of American Pathology and the American Society for Colposcopy and Cervical Pathology has proposed that histologic cervical findings be described using the same terminology as cytologic findings.⁸⁵

Women under the age of 30 who have not received the HPV vaccine have a high incidence of HPV infection⁸⁶ and the highest prevalence of CIN. However, the overwhelming majority of these HPV infections and associated CIN will spontaneously regress.^{87,88} Due to the high regression rates, cervical screening and treatment in women aged 20 to 24 years appear to have little or no impact on the incidence of invasive cervical cancer. It is estimated that about 6% of CIN1 lesions progress to CIN3, and 10% to 20% of CIN3 lesions progress to invasive cancer.⁸⁹

The Atypical Squamous Cells of Undetermined Significance (ASCUS)-LSIL Triage Study (ALTS) evaluated women with abnormal Pap smears.⁹⁰ The investigators concluded that women with ASC-US should be tested for HPV. Those who are HPV positive should receive a colposcopy. In addition, because most women with LSIL or HSIL had an HPV infection, an immediate colposcopy and a biopsy of lesions was recommended.⁹¹ HPV DNA testing is very sensitive for identifying CIN2 or worse pathology. Among women 30 to 69 years of age, the sensitivity of the Pap test with HPV testing was 95% compared with 55% for the Pap test alone.⁹²

Performance Characteristics of Cervical Cytology

The sensitivity of cytology varies and is a function of the adequacy of the cervical specimen. It is also affected by the age of the woman and the experience of the cytologist. The addition of HPV testing increases the number of women referred for a colposcopy. Not surprisingly, sensitivity is improved by serial examinations over time versus a single screen.

Screening Recommendations

Cervical screening, like other screening tests, is associated with some degree of overdiagnosis as evidenced by the phenomenon of spontaneous regression (see previous) and, therefore, potential harm from overtreatment, such as cervical incompetence, which may reduce fertility and the ability to carry a pregnancy to term. Because dysplasia takes years to progress to cervical cancer,

increasing the screening interval can reduce overdiagnosis and excessive treatment without decreasing screening efficacy.

In 2012, the ACS, the American Society for Colposcopy and Cervical Pathology (ASCCP), and the American Society for Clinical Pathology (ASCP) issued joint screening guidelines.⁹³ These guidelines recommend different surveillance strategies and options based on a woman's age, screening history, risk factors, and choice of screening tests. The following are the recommendations for a woman at average risk.

- Screening for cervical cancer should begin at 21 years of age. Women aged 21 to 29 years should receive cytology screening (with either conventional cervical cytology smears or liquid-based cytology) every 3 years. HPV testing should not be performed in this age group (although it can be used to follow-up a diagnosis of ASC-US). Women under 21 years of age should not be screened regardless of their age of sexual initiation.
- For women aged 30 to 65 years, the preferred approach is to be screened every 5 years with both HPV testing and cytology (*cotesting*). It is also acceptable to continue screening every 3 years with cytology alone.
- Women should discontinue screening after age 65 years if they have had three consecutive negative cytology tests or two consecutive negative HPV test results within the 10-year period before ceasing screening, with the most recent test occurring within the last 5 years.
- Women who have undergone a hysterectomy for noncancerous conditions do not need to undergo cervical cancer screening.
- Women, regardless of age, should NOT be screened annually by any screening method.
- Women who have received HPV vaccinations should still be screened according to the previously listed schedule.

Screening in Low Resource Countries

Cytology and HPV testing is not widely available in much of the world. Cervical cancer remains a leading cause of death in many of these areas. Visual inspection of the cervix is a low-tech method of screening that is now recognized as having the potential to save thousands of lives per year. A clustered, randomized trial in India compared one-time cervical visual inspection and immediate colposcopy, biopsy, and/or cryotherapy (where indicated) versus counseling on cervical cancer deaths in women aged 30 to 59 years. After 7 years of follow-up, the age-standardized rate of death due to cervical cancer was 39.6 per 100,000 person-years in the intervention group versus 56.7 per 100,000 person-years in unscreened controls.^{94,95} This was the first prospective randomized clinical trial to evaluate cervical cancer screening.

Ovarian Cancer Screening

Modalities proposed for ovarian cancer screening include the bimanual pelvic examination, serum CA-125 antigen measurement, and transvaginal ultrasound (TVU). The bimanual pelvic examination is subjective and not very reproducible, but serum CA-125 can be objectively measured. Unfortunately, CA-125 is neither sensitive nor specific. It is elevated in only about half of women with ovarian cancer and may be elevated in a number of nonmalignant diseases (e.g., diverticulosis, endometriosis, cirrhosis, normal menstruation, pregnancy, uterine fibroids).⁹⁶⁻⁹⁸ TVU has shown poor performance in the detection of ovarian cancer in average and high-risk women.⁹⁹ There is interest in the analysis of serum proteomic patterns, but this should be considered experimental.^{100,101}

The combination of CA-125 and TVU has been assessed in two large, prospective randomized trials. The U.S. trial, the Prostate Lung Colorectal and Ovarian trial (PLCO), enrolled

78,216 women of average risk age 55 to 74 years.^{102,103} Participants were randomized to receive annual examinations with CA-125 (at entry and then annually for 5 years) and TVU (at entry and then annually for 3 years) ($n = 39,105$), or usual care ($n = 39,111$). Participants were followed for a maximum of 13 years, with mortality from ovarian cancer as the main study outcome. At the conclusion of the study, the number of deaths from ovarian cancer was similar in each group. There were 3.1 ovarian cancer deaths per 10,000 women years in the screened group versus 2.6 deaths per 10,000 women years in the control group (RR = 1.18; 95% CI, 0.82 to 1.71).¹⁰³

The U.K. Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) is a randomized trial assessing the efficacy of CA-125 and TVU in more than 200,000 postmenopausal women. In this trial, CA-125 is being used as a first-line test and TVU as a follow-up test using a risk of ovarian cancer algorithm (ROCA).¹⁰⁴ The ROCA measures changes in CA-125 over time rather than using a predefined cut point.¹⁰⁵ ROCA is believed to improve sensitivity for smaller tumors without measurably increasing the FP rate. A mortality assessment is expected in 2015.¹⁰⁶

No organization currently recommends screening average risk women for ovarian cancer. In 2012, the USPSTF recommended against screening for ovarian cancer, concluding that there was “adequate evidence” that (1) annual screening with TVU and CA-125 does not reduce ovarian cancer mortality and (2) screening for ovarian cancer can lead to important harms, mainly surgical interventions in women without ovarian cancer.¹⁰⁷

Women at High Risk for Ovarian Cancer

Although no study has shown a mortality benefit for ovarian cancer screening of high-risk individuals, a National Institutes of Health (NIH) consensus panel concluded that it was prudent for women with a known hereditary ovarian cancer syndrome, such as *BRCA1/2* mutations or HNPCC, to have annual rectovaginal pelvic examinations, CA-125 determinations, and TVU until child-bearing is completed or at least until age 35 years, at which time a prophylactic bilateral oophorectomy is recommended.¹⁰⁸

Endometrial Cancer Screening

There is insufficient evidence to recommend endometrial cancer screening either for women at average risk or for those at increased risk due to a history of unopposed estrogen therapy, tamoxifen therapy, late menopause, nulliparity, infertility or failure to ovulate, obesity, diabetes, or hypertension.¹⁰⁹ The ACS recommends that women be informed about the symptoms of endometrial cancer—in particular, vaginal bleeding and spotting—after the onset of menopause. Women should be encouraged to immediately report these symptoms to their physician.

Women at High Risk for Endometrial Cancer

Women with a suspected autosomal-dominant predisposition to colon cancer (e.g. Lynch syndrome), should consider undergoing an annual endometrial biopsy to evaluate endometrial histology, beginning at age 35 years.^{110,111} This is based only on *expert opinion*, given the paucity of clinical trial data. Women should be informed about the potential benefits, harms, and limitations of testing for early endometrial cancer.

LUNG CANCER SCREENING

Lung cancer screening programs using chest radiographs (CXR) and sputum cytology began in the late 1940s.¹¹² An evaluation of these programs showed that screening led to the diagnosis of

an increased number of cancers, an increased proportion of early stage cancers, and a larger proportion of screen-diagnosed patients surviving more than 5 years.

These findings led many to advocate for mass lung cancer screening, whereas others called for a prospective, randomized trial with a lung cancer mortality endpoint.¹¹³ The Mayo Lung Project (MLP), which began in 1971, was such a trial. More than 9,200 male smokers were enrolled and randomized to either have sputum cytology collected and CXRs done every 4 months for 6 years or to have these same tests performed annually.

At 13 years of follow-up, there were more early stage cancers in the intensively screened arm ($n = 99$) than in the control arm ($n = 51$), but the number of advanced tumors was nearly identical (107 versus 109, respectively).¹¹⁴ Despite an increase in 5-year survival (35% versus 15%) intensive screening was not associated with a reduction in lung cancer mortality (3.2 versus 3.0 deaths per 1,000 person-years, respectively).¹¹⁵

The impact of screening on cancer incidence persisted through nearly 20 years of follow-up. There were 585 lung cancers diagnosed on the intensive screening arm versus 500 on the control arm ($p = 0.009$) and intensive screening continued to be associated with a significant increase in disease-specific survival. However, a concomitant decrease in lung-cancer mortality did not emerge with long-term follow-up (4.4 lung cancer deaths per 1,000 person-years in the intensively screened arm versus 3.9 per 1,000 person-years in the control arm).¹¹⁶ This suggests that some lung cancers diagnosed by screening would not have resulted in death had they not been detected (i.e., overdiagnosis).¹¹⁶

Two other large, randomized studies of CXR and sputum cytology were conducted in the United States during the same time period. All three studies evaluated different screening schedules rather than screening versus no screening. Paradoxically, a meta-analysis of the three studies found that more frequent screening was associated with an increase (albeit not statistically significant), rather than a decrease, in lung cancer mortality when compared with less frequent screening.¹¹⁷ A study conducted in Czechoslovakia in the 1980s also failed to show a reduction in lung cancer mortality with CXR screening.¹¹⁸

More recently, the NCI conducted the PLCO trial at 10 sites across the United States. This was a prospective, randomized trial of nearly 155,000 men and women, aged 55 to 74 years. Participants were randomized to receive annual, single-view, posteroanterior CXRs for 4 years versus routine care. With 13 years of follow-up, no significant difference in lung cancer mortality was observed. A total of 1,213 lung cancer deaths occurred on the intervention arm versus 1,230 in the control group (RR, 0.99; 95% CI, 0.87 to 1.22).¹¹⁹

Low-dose computerized tomography (LDCT) is an appealing technology for lung cancer screening. It uses an average of 1.5 mSv of radiation to perform a lung scan in 15 seconds. A conventional CT scan uses 8 mSv of radiation and takes several minutes. The LDCT image is not as sharp as the conventional image, but sensitivity and specificity for the detection of lung lesions are similar.

As in the early chest radiograph trials, a number of single-arm LDCT studies reported a substantial increase in the number of early stage lung cancers diagnosed. These studies also demonstrated that 5-year survival rates were increased in screened compared to unscreened populations.

These findings led to the conduct of several randomized trials of LDCT for the early detection of lung cancer. The largest, longest, and first to report a mortality end point is the National Lung Screening Trial (NLST). In this trial, approximately 53,000 persons were randomized to receive three annual LDCT scans or single-view posteroanterior CXRs. Eligible participants were current and former smokers between 55 and 74 years of age at the time of randomization with at least a 30 pack-year smoking history; former smokers were eligible if they had quit smoking within the previous 15 years.

With a median follow-up of 6.5 years, 13% more lung cancers were diagnosed and a 20% (95% CI, 6.8 to 26.7; $p = 0.004$)

relative reduction in lung cancer mortality was observed in the LDCT arm compared to the CXR arm.¹¹ This corresponds to rates of death from lung cancer of 247 and 309 per 100,000 person-years, respectively.¹¹ Another important finding from the NLST was a 6.7% (95% CI, 1.2 to 13.6; $p = 0.02$) decrease in death from any cause in the LDCT group.

NLST participants were at high risk for developing lung cancer based on their smoking history. Indeed, 25% of all participant deaths were due to lung cancer. A further analysis of the NLST shows that screening prevented the greatest number of lung cancer deaths among participants who were at the highest risk but prevented very few deaths among those at the lowest risk. These findings provide empirical support for risk-based screening.¹²⁰

LDCT screening is clearly promising, but there are some notable caveats. The risk of a FP finding in the first screen was 21%. Overall, after three CT scans, 39.1% of participants had at least one positive screening result. Of those who screened positive, the FP rate was 96.4% in the LDCT group.¹¹ Positive results require additional workup, which can include conventional CT scans, a needle biopsy, bronchoscopy, mediastinoscopy, or thoracotomy. These diagnostic procedures are associated with anxiety, expense, and complications (e.g., pneumo- or hemothorax after a lung biopsy). In the LDCT study arm, there were 16 deaths within 60 days of an invasive diagnostic procedure. Of the 16 deaths, 6 ultimately did not have cancer. Although it is not known whether these deaths were directly caused by the invasive procedure, such findings do give pause. Although the radiation dose from LDCT is low, the possibility that this screening test could cause radiation-induced cancers is at least a theoretical concern. The possibility of this long-term phenomenon will have to be assessed in future analyses.

The CXR lung screening studies suggested that there is a reservoir of biologically indolent lung cancer and that a percentage of screen-detected lung cancers represent overdiagnosis. The estimated rate of overdiagnosis in the long-term follow-up of the Mayo Lung Study and the other CXR studies was 17 to 18.5%.¹²¹ Similarly, it is estimated that 18.5% of the cancers diagnosed on the LDCT arm of the NLST represented overdiagnosis.¹²²

There are estimates that widespread, high-quality screening has the potential to prevent 12,000 lung cancer deaths per year in the United States.¹²³ However, the NLST was performed at 33 centers specifically chosen for their expertise in the screening, diagnosis, and treatment of lung cancer. It is not known whether the widespread adoption of LDCT lung cancer screening will result in higher complication rates and a less favorable risk–benefit ratio.

Although LDCT lung cancer screening should clearly be considered for those at high risk of the disease, those at lower risk are equally likely to suffer the harms associated with screening but less likely to reap the benefits.

Following the announcement of the NLST results, the ACS, the American College of Chest Physicians (ACCP), the American Society of Clinical Oncology (ASCO), and the National Comprehensive Cancer Network (NCCN) recommended that clinicians should initiate a discussion about lung cancer screening with patients who would have qualified for the trial. That is:

- Age 55 to 74 years
- At least a 30 pack-year smoking history
- Currently smoke or have quit within the past 15 years
- Relatively good health

Core elements of this discussion should include the benefits, uncertainties, and harms associated with screening for lung cancer with LDCT. Adults who choose to be screened should enter an organized screening program at an institution with expertise in LDCT screening, with access to a multidisciplinary team skilled in the evaluation, diagnosis, and treatment of abnormal lung lesions. If such a program is not available, the risks of harm due to screening may be greater than the benefits.^{124,125} The guidelines recommend an annual LDCT screening with the caveat that participants in NLST had only three annual screens.

The USPSTF guidelines give LDCT a grade B recommendation, concluding that there is moderate certainty that annual screening for lung cancer with LDCT is of moderate net benefit in asymptomatic persons at high risk for lung cancer based on age, total cumulative exposure to tobacco smoke, and years since quitting.

PROSTATE CANCER SCREENING

Hugh Hampton Young first advocated the early detection of prostate cancer with a careful digital rectal examination (DRE) in 1903. Screening for prostate cancer with the DRE and serum PSA was first advocated in the mid 1980s and became commonplace by 1992. PSA screening is directly responsible for prostate cancer becoming the most common nonskin cancer in American men.

PSA is a glycoprotein produced almost exclusively by the epithelial component of the prostate gland. This protein was discovered in the late 1970s, and a serum test to measure circulating levels was developed in the early 1980s. Although PSA is prostate specific, it is not prostate cancer specific and may be elevated in a variety of conditions (e.g., benign prostatic hyperplasia, inflammation and following trauma to the gland, the presence of prostate cancer).

The PSA test has been widely advocated for prostate cancer screening because it is objective, easily measured, reproducible, noninvasive, and inexpensive. Although PSA screening increases the detection of potentially curable disease, there is substantial debate about the overall utility of the test. This is because PSA screening introduces substantial lead time and length bias as well as being associated with a high FN and FP rates and having a low positive predictive value. The prostate cancer conundrum was best summarized by the distinguished urologist, Willet Whitmore when he said, “Is cure necessary for those in whom it is possible? Is cure possible for those in whom it is necessary?”¹²⁶

Observational studies suggest that the problem of prostate cancer overdiagnosis precedes the PSA era. In a landmark analysis with 20-year follow-up, only a small proportion of 767 men, diagnosed with localized prostate cancer in the 1970s and early 1980s and followed expectantly, died from prostate cancer: 4% to 7% of those with Gleason 2 to 4 tumors, 6% to 11% of those with Gleason 5 disease, and 18% to 30% of men with Gleason 6 cancer.¹²⁷

Although obviously present in the pre-PSA era, overdiagnosis increased substantially after the introduction of PSA screening. This is illustrated by an examination of the prostate cancer incidence and mortality rates in Washington state and Connecticut. Due to the earlier uptake of PSA screening, the incidence of prostate cancer in Washington increased to twice that of Connecticut during the 1990s. However, mortality rates remained similar throughout the decade and, in fact, have remained similar to this day. The Surveillance, Epidemiology, and End Results (SEER) cancer registries show that, over the last 2 decades, a larger proportion of men living in western Washington have been diagnosed with prostate cancer and definitively treated, without a concomitant reduction in prostate cancer mortality compared to that of men living in Connecticut.¹²⁸

Additional evidence of the potential for overdiagnosis comes from the unexpectedly large number of men diagnosed with prostate cancer in the Prostate Cancer Prevention Trial (PCPT). The PCPT was a prospective, randomized, placebo-controlled trial of finasteride for prostate cancer prevention. Men were screened annually during this trial, and those who had not been diagnosed with prostate cancer after 7 years on-study were asked to undergo an end-of-study prostate biopsy. Of 4,692 men on the placebo arm whose prostate cancer status had been determined by biopsy or transurethral resection (TURP), 24.4% were diagnosed with prostate cancer. Given that the lifetime risk of prostate cancer mortality in the United States is less than 3%, it is clear that many men harbor indolent prostate cancer and, therefore, are at risk of being overdiagnosed.

The unexpectedly high rate of positive end-of-study biopsies in men with PSA levels less than or equal to 4.0 ng/mL provided a more accurate assessment of disease prevalence and thus a more accurate assessment of PSA sensitivity than was previously possible. Of the 2,950 men on the placebo arm of the PCPT with PSA levels consistently less than or equal to 4 ng/mL who underwent end-of-study biopsies, 449 (15.2%) were diagnosed with prostate cancer. Accordingly, a PSA level <4.0 ng/mL is more likely to be a *false* negative. Because Sensitivity = True Positives / (True Positives + False Negatives), a higher FN rate means a lower sensitivity at any given PSA threshold. This has prompted some to advocate using a lower PSA threshold for recommending biopsies. However, although lowering the PSA threshold from 4.0 to 2.5 ng/mL increases the sensitivity from 24% to 42.8%, it reduces specificity from 92.7% to an unacceptably low 80%.¹²⁹

In the PCPT, cancer was found on end-of-study biopsies at all PSA levels (e.g., including 10% of biopsies in men with PSA levels between 0.6 and 1.0 ng/mL and 6% of biopsies in men with PSA levels between 0 and 0.6 were positive), suggesting a continuum of prostate cancer risk and no cut point with simultaneously high sensitivity and high specificity. High-grade disease was also documented at all PSA levels, albeit at an overall frequency of only 2.3% of men with PSAs <4 ng/mL.^{130,131}

Does Prostate Cancer Treatment Prevent Deaths?

In order for screening to work, treatment has to work. The first prospective, randomized studies showing that any prostate cancer treatment saves lives were published in the late 1990s. These studies demonstrated an overall survival benefit for the addition of long-term androgen deprivation to radiation therapy in men with locally advanced, high-risk prostate cancer.¹³²

The value of surgery for localized disease was assessed by the Scandinavian Prostate Cancer Group 4 study (SPCG-4). In this trial, 695 men with clinically localized prostate cancer were prospectively randomized to receive radical prostatectomy (RP) or watchful waiting (WW). In the expectant management group, hormonal therapy was given at the time of symptomatic metastases. About 60% of those enrolled had low-grade, 23% had moderate-grade, 5% had high-grade tumors, and 12% had tumors of unknown grade. At a median follow-up of 12.8 years, the RP group had significantly lower overall (RR 0.75; $p = 0.007$) and prostate cancer-specific mortality (RR 0.62; $p = 0.01$), with 14.6% of the PR group and 20.7% of the WW group having died of prostate cancer. The number needed to treat or prevent one prostate cancer death was 15. The survival benefit associated with RP was similar before and after 9 years of follow-up and for men with low and high-risk disease. However, a subset analysis suggested that the mortality benefit of surgery was limited to men less than 65 years of age. An important limitation of this trial is that 75% of the study participants had palpable disease, only 12% had nonpalpable disease, and only 5% of the cancers had been screen detected. It is, therefore, difficult to apply these data to the US prostate cancer population, which is dominated by nonpalpable, screen-detected disease.¹³³

In contrast to the SPCG-4, the Prostate Intervention versus Observation Trial (PIVOT) was conducted in the United States during the early PSA era. In this study, 731 men with screen-detected prostate cancer were randomized to receive RP or WW. Of the participants, 50% had nonpalpable disease and, using established criteria for PSA levels, grade, and tumor stage, 43% of men had low-risk, 36% had intermediate-risk, and 21% had high-risk prostate cancer. With a median follow-up of 12 years, during which time 48.4% (354 of 731) of the study participants had died, RP was associated with statistically insignificant 2.9% and 2.6% absolute reductions in overall and prostate cancer-specific mortality,

respectively. Subgroup analyses suggested mortality benefits for men with PSA values greater than 10 ng/mL and for those with intermediate- and high-risk disease.¹³⁴

The Prospective Randomized Screening Trials

The PLCO Cancer Screening Trial was a multicenter, phase III trial conducted in the United States by the NCI. In this trial, nearly 77,000 men age 55 to 74 years were randomized to receive annual PSA testing for 6 years or usual care. At 13 years of follow-up, a nonsignificant increase in cumulative prostate cancer mortality was observed among men randomized to annual screening (RR, 1.09; 95% CI, 0.87 to 1.36).¹³⁵ The most important limitation of this trial was the high rate of PSA testing among men randomized to the control arm. This *drop-in* or *contamination* served to reduce the statistical power of the study to detect differences in outcome between the two arms. It has also been argued that, due to the high rate of PSA screening on the control arm, PLCO effectively compared regular prostate cancer screening to opportunistic screening rather than comparing screening to no screening.

The ERSPC is a multicenter trial initiated in 1991 in the Netherlands and Belgium; five additional European countries joined between 1994 and 1998.^{136,137} The frequency of PSA testing was every 4 years in all countries except Sweden, in which it was every 2 years. The study results were initially reported in 2009 and updated in 2012.^{136,137} Although the overall analysis of 182,160 men, aged 50 to 74, did not show a reduction in prostate cancer-specific mortality, screening was associated with a significant decrease in prostate cancer mortality in the prespecified core age group, 55 to 69 years, which included 162,243 men. After a median follow-up of 11 years, a 21% relative reduction of prostate cancer death (RR, 0.79; 95% CI, 0.68 to 0.91) was observed in this group. In absolute terms, prostate cancer mortality was reduced from 5 to 4 men per 1,000 screened and 37 men had to be diagnosed to avert one prostate cancer death. It remains to be seen whether the benefits of screening will increase with continued follow-up.

The recruitment and randomization procedures of the ERSPC differed among countries. Notably, potential participants in Finland, Sweden, and Italy were identified from population registries and underwent randomization *before* written informed consent was obtained. In some trials, men on the control arm were not aware they were in the study. Therefore, men on the intervention arm in these countries were more likely to be cared for at high-volume referral centers. This may have contributed to the higher proportion of men on the screening arm, with clinically localized cancer being treated with RPs.¹³⁸

In a separate report on 20,000 men randomized to screening or a control group in Göteborg, Sweden, there was a 40% (95% CI, 1.50 to 1.80) risk reduction at 14 years of follow-up.¹³⁹ They reported 293 (95% CI, 177 to 799) needed to be screened and 12 needed to be diagnosed in order to prevent one prostate cancer death. Three-fourths of the men in this report and 89% of the prostate cancer deaths were included in the published ERSPC analysis. Given this, these data do not constitute independent evidence of the efficacy of prostate cancer screening.

The other site to report separately was in Finland. A total of 80,144 men were randomized to a screening or usual care arm. At 12 years after randomization, there was no statistical difference in risk of prostate cancer death (hazard ratio [HR] = 0.85; 95% CI, 0.69 to 1.04).¹⁴⁰ Possible explanations as to why Sweden and Finland would have such different outcomes include differences in the frequency of screening (every 2 years versus every 4 years, respectively) and the higher background rate of death from prostate cancer in the control group in the Göteborg cohort. Given that the mortality data from these two cohorts have been largely included in the ERSPC analyses, they do not provide independent evidence of the efficacy of prostate cancer screening.

The decline in prostate cancer mortality in the United States since the introduction of PSA screening 2 decades ago is often offered as evidence supporting a mortality benefit for prostate cancer screening. However, prostate cancer mortality rates have also declined in many countries that have not widely adopted screening.¹⁴¹ Thus, it is likely that improvements in treatment have contributed, at least in part, to the observed decline in prostate cancer mortality. Another possible contributing factor may be the World Health Organization (WHO) algorithm for adjudicating cause of death. A change occurred just as mortality rates began to go up in the late 1970s, and WHO changed back to the older algorithm in 1991 when prostate cancer mortality began declining in many countries.¹⁴² All of these factors, including a beneficial effect from screening, may be contributing to the declining prostate cancer mortality rates in the United States.

Screening Recommendations

The topic of prostate cancer screening tends to evoke strong emotional reactions. Although the intuitive appeal of early detection is undeniable and screening may save some lives, the magnitude of the mortality reduction is relatively small, whereas the harms associated with screening can be substantial. Whether the potential benefits outweigh the known harms is a question that each man must answer for himself based on his individual preferences.

Several professional organizations in the United States, Europe, and Canada have recently reviewed the screening data and issued screening guidelines. All acknowledge that legitimate concerns remain regarding the risk–benefit ratio of prostate cancer screening. There is also general agreement that prostate cancer screening should only be done in the context of fully informed consent and that men should know that experts do not agree as to whether the benefits of screening for this disease outweigh the harms. Most recommend against mass screening in public meeting places, malls, churches, etc.

In 2009, the American Urological Association (AUA) PSA Best Practice Statement was published, which stated, “Given the uncertainty that PSA testing results in more benefit than harm, a thoughtful and broad approach to PSA is critical. Patients need to be informed of the risks and the benefits of testing before it is undertaken. The risks of over-detection and over-treatment should be included in this discussion.”¹⁴³

In 2010, the ACS updated their guidelines, stating that the balance of benefits and harms related to prostate cancer early detection are uncertain and the existing evidence is insufficient to support a recommendation for or against the routine use of PSA screening.¹⁴⁴ The ACS called for discussion and shared decision making within the physician–patient relationship.

The most recent 2012 USPSTF guidelines recommend against the use of PSA screening on the basis that there is moderate certainty that the harms of PSA testing outweigh the benefits and, on that basis, recommended against PSA-based screening for all men.¹⁴ The task force did acknowledge that some men will continue to request screening and some physicians will continue to offer it. Like the ACS and AUA, they state that screening under such circumstances should respect patient preferences.

In 2013, the AUA conducted a systematic review of over 300 studies. They recommended against screening men younger than 40 years of age, and against screening average-risk men age 40 to 54 years, most men over 70 years of age, and men with a life expectancy of less than 10 to 15 years. They recommend that screening decisions be individualized for higher risk men ages 40 to 54 years and men over 70 years of age who are in excellent health. They placed primacy on shared decision making versus physician judgments about the balance of benefits and harms at the population level.¹⁴⁵ Even for men aged 55 to 69 years, the AUA concluded that the quality of evidence for benefits associated

with screening was moderate, whereas the quality of the evidence for harm was high. They recommended shared decision making for this group, in whom they have concluded the benefits may outweigh the harm.

SKIN CANCER SCREENING

Assessments of skin cancer screening have focused on melanoma end points with very little attention to screening for nonmelanoma skin cancer. A systematic review of skin cancer screening studies examining the available evidence through mid 2005 concluded that direct evidence of improved health outcomes associated with skin cancer screening is lacking.¹⁴⁶

No randomized, clinical trial of skin cancer screening has been attempted. However, several observational studies have suggested that melanoma screening might reduce mortality. For example, a decrease in melanoma mortality did occur after a Scottish campaign to promote awareness of the signs of suspicious skin lesions and encourage early self-referral. However, uncontrolled, ecologic studies such as this provide a relatively low level of evidence, because it is not possible to determine whether the observed mortality reduction was due to screening or other factors.

More recently, the Skin Cancer Research to Provide Evidence for Effectiveness of Screening project, or SCREEN project, compared a region of Germany in which intensive skin cancer screening was performed to areas of Germany without intensive screening. Approximately 360,000 residents of the Schleswig-Holstein region aged 20 years and older participated. They chose either to be screened by a nondermatologist physician trained in skin examinations or by a dermatologist. Almost 16,000 biopsies were performed and 585 melanomas were diagnosed. Overall, 1 in 23 participants had an excisional skin biopsy and 620 persons needed to be screened to detect one melanoma. This screening effort led to a 16% and 38% increase in melanoma incidence among men and women, respectively, compared to 2 years earlier. The melanoma incidence rate returned to preprogram levels after the program ended. Of the screen-detected melanomas, 90% were less than 1 mm thick. Screening was performed in 2003 to 2004, and melanoma mortality in this region subsequently declined. In 2008, it was nearly 50% lower in both men and women compared to the rest of Germany.^{147,148}

Recommendations of Experts

Skin cancer screening recommendations are based on *expert opinion*, given the absence of a randomized clinical trial data and limited observational studies. The ACS recommends monthly skin self-examinations and a yearly clinical skin examination as part of a routine cancer-related checkup.¹⁴⁹ The USPSTF finds insufficient evidence to recommend for or against either routine skin cancer screening of the general population by primary care providers or counseling patients to perform periodic skin self-examinations. The task force does recommend that clinicians “remain alert” for skin lesions with malignant features when performing a physical examination for other purposes, particularly in high-risk individuals. The American Academy of Dermatology recommends that persons at highest risk (i.e., those with a strong family history of melanoma and multiple atypical nevi), perform frequent self-examination and seek a professional evaluation of the skin at least once per year.¹⁵⁰

High-risk individuals are persons with multiple nevi or atypical moles. There is consensus they should be educated about the need for frequent surveillance by a trained health-care provider beginning at an early age. In the United States, Australia, and Western Europe, Caucasian men age 50 years and over account for nearly half of all melanoma cases. There is some discussion that melanoma early detection efforts should be focused on this population.

35 Genetic Counseling

Ellen T. Matloff and Danielle C. Bonadies

INTRODUCTION

Clinically based genetic testing has evolved from an uncommon analysis ordered for the rare hereditary cancer family to a widely available tool ordered on a routine basis to assist in surgical and radiation decision making, chemoprevention, and surveillance of the patient with cancer, as well as management of the entire family. The evolution of this field has created a need for accurate cancer genetic counseling and risk assessment. Extensive coverage of this topic by the media, including Angelina Jolie's public disclosure of her *BRCA1*+ status in May 2013, and widespread advertising by commercial testing laboratories have further fueled the demand for counseling and testing.

Cancer genetic counseling is a communication process between a health-care professional and an individual concerning cancer occurrence and risk in his or her family.¹ The process, which may include the entire family through a blend of genetic, medical, and psychosocial assessments and interventions, has been described as a bridge between the fields of traditional oncology and genetic counseling.¹

The goals of this process include providing the client with an assessment of individual cancer risk, while offering the emotional support needed to understand and cope with this information. It also involves deciphering whether the cancers in a family are likely to be caused by a mutation in a cancer gene and, if so, *which one*. There are >30 hereditary cancer syndromes, many of which can be caused by mutations in different genes. Therefore, testing for these syndromes can be complicated. Advertisements by genetic testing companies bill genetic testing as a simple process that can be carried out by health-care professionals with no training in this area; however, there are many genes involved in cancer, the interpretation of the test results is often complicated, the risk of result misinterpretation is great and associated with potential liability, and the emotional and psychological ramifications for the patient and family can be powerful.^{2,3} A few hours of training by a company generating a profit from the sale of these tests does not adequately prepare providers to offer their own genetic counseling and testing services.⁴ Furthermore, the delegation of genetic testing responsibilities to office staff and, recently, mammography technicians, is alarming and likely presents a huge liability for these ordering physicians, their practices, and their institutions.^{5,6} *Providers should proceed with caution before taking on the role of primary genetic counselor for their patients.*

Counseling about hereditary cancers differs from *traditional* genetic counseling in several ways. Clients seeking cancer genetic counseling are rarely concerned with reproductive decisions, which are often the primary focus in traditional genetic counseling, but are instead seeking information about their own and other relatives' chances of developing cancer.¹ Additionally, the risks given are not absolute but change over time as the family and personal history changes and the patient ages. The risk reduction options available are often radical (e.g., chemoprevention or prophylactic surgery), and are not appropriate for every patient at every age. The surveillance and management plan must be tailored to the

patient's age, childbearing status, menopausal status, risk category, ease of screening, and personal preferences and will likely change over time with the patient. The ultimate goal of cancer genetic counseling is to help the patient reach the decision best suited to her personal situation, needs, and circumstances.

There are now a significant number of referral centers across the country specializing in cancer genetic counseling, and the numbers are growing. However, some experts insist that the only way to keep up with the overwhelming demand for counseling will be to educate more physicians and nurses in cancer genetics. The feasibility of adding another specialized and time-consuming task to the clinical burden of these professionals is questionable, particularly with average patient encounters of 19.5 and 21.6 minutes for general practitioners and gynecologists, respectively.^{7,8} A more practical goal is to better educate clinicians in the area of risk assessment so that they can screen their patient populations for individuals at high risk for hereditary cancer and refer them on to comprehensive counseling and testing programs. Access to genetic counseling is no longer an issue because there are now internet, phone, and satellite-based telemedicine services available (Table 35.1), with most major health insurance companies now covering these services⁹⁻¹¹ and several requiring them.¹²

WHO IS A CANDIDATE FOR CANCER GENETIC COUNSELING?

Only 5% to 10% of most cancer is thought to be caused by single mutations within autosomal-dominant inherited cancer susceptibility genes.¹³ The key for clinicians is to determine which patients are at greatest risk to carry a hereditary mutation. There are seven critical risk factors in hereditary cancer (Table 35.2). The first is early age of cancer onset. This risk factor, *even in the absence of a family history*, has been shown to be associated with an increased frequency of germline mutations in many types of cancers.¹⁴ The second risk factor is the presence of the same cancer in multiple affected relatives on the same side of the pedigree. These cancers do not need to be of similar histologic type in order to be caused by a single mutation. The third risk factor is the clustering of cancers known to be caused by a single gene mutation in one family (e.g., breast/ovarian/pancreatic cancer or colon/uterine/ovarian cancers). The fourth risk factor is the occurrence of multiple primary cancers in one individual. This includes multiple primary breast or colon cancers as well as a single individual with separate cancers known to be caused by a single gene mutation (e.g., breast and ovarian cancer in a single individual). Ethnicity also plays a role in determining who is at greatest risk to carry a hereditary cancer mutation. Individuals of Jewish ancestry are at increased risk to carry three specific *BRCA1/2* mutations.¹⁵ The presence of a cancer that presents unusually—in this case, breast cancer in a male—represents a sixth risk factor and is important even when it is the only risk factor present. Finally, the last risk factor is pathology. Certain types of cancer are overrepresented in hereditary cancer families. For example, medullary and triple negative breast

cancers (where the estrogen, progesterone and Her2 receptors are all negative, often abbreviated ER-PR/Her2) are overrepresented in *BRCA1* families,^{16,17} and the National Comprehensive Cancer Network (NCCN) *BRCA* testing guidelines now include individuals diagnosed with a triple negative breast cancer <age 60 years.¹⁸ However, breast cancer patients without these pathologic findings are *not* necessarily at lower risk to carry a mutation. In contrast, patients with a borderline or mucinous ovarian carcinoma are at lower risk to carry a *BRCA1* or *BRCA2* mutation¹⁹ and may instead

TABLE 35.2**Risk Factors that Warrant Genetic Counseling for Hereditary Cancer Syndromes**

1. Early age of onset (e.g., <50 years for breast, colon, and uterine cancer)
2. Multiple family members on the same side of the pedigree with the same cancer
3. Clustering of cancers in the family known to be caused by a single gene mutation (e.g., breast/ovarian/pancreatic; colon/uterine/ovarian; colon cancer/polyps/desmoid tumors/osteomas)
4. Multiple primary cancers in one individual (e.g., breast/ovarian cancer; colon/uterine; synchronous/metachronous colon cancers; <15 gastrointestinal polyps; <5 hamartomatous or juvenile polyps)
5. Ethnicity (e.g., Jewish ancestry for breast/ovarian cancer syndrome)
6. Unusual presentation of cancer/tumor (e.g., breast cancer in a male; medullary thyroid cancer; retinoblastoma; even one sebaceous carcinoma or adenoma)
7. Pathology (e.g., triple negative [ER/PR/Her-2] breast cancer <60; medullary breast cancers are overrepresented in women with hereditary breast and ovarian cancer; a colon tumor with an abnormal microsatellite instability (MSI) or immunohistochemistry (IHC) result increases the risk for a hereditary colon cancer syndrome)

carry a mutation in a different gene. It is already well-established that medullary thyroid carcinoma, sebaceous adenoma or carcinoma, adrenocortical carcinoma before the age of 25 years, and multiple adenomatous, hamartomatous, or juvenile colon polyps are indicative of other rare hereditary cancer syndromes.^{11,20} These risk factors should be viewed in the context of the entire family history, and must be weighed in proportion to the number of individuals who have not developed cancer. The risk assessment is often limited in families that are small or have few female relatives; in such families, a single risk factor may carry more weight.

A less common, but extremely important, finding is the presence of unusual physical findings or birth defects that are known to be associated with rare hereditary cancer syndromes. Examples include benign skin findings, autism, large head circumference^{20,21} and thyroid disorders in Cowden syndrome, odontogenic keratocysts in Gorlin syndrome,²² and desmoid tumors or dental abnormalities in familial adenomatous polyposis (FAP).²³ These and other findings should prompt further investigation of the patient's family history and consideration of a referral to genetic counseling.

In this chapter, the breast/ovarian cancer counseling session with a female patient will serve as a paradigm by which all other sessions may follow broadly.

COMPONENTS OF THE CANCER GENETIC COUNSELING SESSION**Precounseling Information**

Before coming in for genetic counseling, the counselee should be informed about what to expect at each visit, and what information he/she should collect ahead of time. The counselee can then begin to collect medical and family history information and pathology reports that will be essential for the genetic counseling session.

Family History

An accurate family history is undoubtedly one of the most essential components of the cancer genetic counseling session. Optimally, a family history should include at least three generations; however, patients do not always have this information. For each individual affected with cancer, it is important to document the exact diagnosis, age at diagnosis, treatment strategies, and environmental exposures (i.e., occupational exposures, cigarettes, other agents).²⁴ The current age of the individual, laterality, and occurrence of any other cancers must also be documented. Cancer diagnoses should be confirmed with pathology reports whenever possible. A study by Love et al.²⁵ revealed that individuals accurately reported the primary site of cancer only 83% of the time in their first degree relatives with cancer, and 67% and 60% of the time in second and third degree relatives, respectively. It is common for patients to report a uterine cancer as an ovarian cancer, or a colon polyp as an invasive colorectal cancer. These differences, although seemingly subtle to the patient, can make a tremendous difference in risk assessment. Individuals should be asked if there are any consanguineous (inbred) relationships in the family, if any relatives were born with birth defects or mental retardation, and whether other genetic diseases run in the family (e.g., Fanconi anemia, Cowden syndrome), because these pieces of information could prove to be important in reaching a diagnosis.

The most common misconception in family history taking is that somehow a maternal family history of breast, ovarian, or uterine cancer is more significant than a paternal history. Conversely, many still believe that a paternal history of prostate cancer is more significant than a maternal history. Few cancer genes discovered thus far are located on the sex chromosomes and, therefore, both maternal and paternal history are significant and must be explored thoroughly. It has also become necessary to elicit the spouse's personal and family history of cancer. This has bearing on

the cancer status of common children, but may also determine if children are at increased risk for a serious recessive genetic disease such as Fanconi anemia.²⁶ Children who inherit two copies of a *BRCA2* mutation (one from each parent) are now known to have this serious disorder characterized by defective DNA repair and high rates of birth defects, aplastic anemia, leukemia, and solid tumors.²⁶ Patients should be encouraged to report changes in their family history over time (e.g., new cancer diagnoses, genetic testing results in relatives), because this may change their risk assessment and counseling.

A detailed family history should also include genetic diseases, birth defects, mental retardation, multiple miscarriages, and infant deaths. A history of certain recessive genetic diseases (e.g., ataxia telangiectasia, Fanconi anemia) can indicate that healthy family members who carry just one copy of the genetic mutation may be at increased risk to develop cancer.^{26,27} Other genetic disorders, such as hereditary hemorrhagic telangiectasia, can be associated with a hereditary cancer syndrome caused by a mutation in the same gene—in this case, juvenile polyposis.²⁸

Dysmorphology Screening

Congenital anomalies, benign tumors, and unusual dermatologic features occur in a large number of hereditary cancer predisposition syndromes. Examples include osteomas of the jaw in FAP, palmar pits in Gorlin syndrome, and papillomas of the lips and mucous membranes in Cowden syndrome. Obtaining an accurate past medical history of benign lesions and birth defects, and screening for such dysmorphology can greatly impact diagnosis, counseling, and testing. For example, *BRCA1/2* testing is inappropriate in a patient with breast cancer who has a family history of thyroid cancer and the orocutaneous manifestations of Cowden syndrome.

Risk Assessment

Risk assessment is one of the most complicated components of the genetic counseling session. It is crucial to remember that risk assessment changes over time as the person ages and as the health statuses of their family members change. Risk assessment can be broken down into three separate components.

- What is the chance that the counselee will develop the cancer observed in his/her family (or a genetically related cancer such as ovarian cancer due to a family history of breast cancer)?
- What is the chance that the cancers in this family are caused by a single gene mutation?
- What is the chance that we can identify the gene mutation in this family with our current knowledge and laboratory techniques?

Cancer clustering in a family may be due to genetic and/or environmental factors, or may be coincidental because some cancers are very common in the general population.²⁹ Although inherited factors may be the primary cause of cancers in some families, in others, cancer may develop because an inherited factor increases the individual's susceptibility to environmental carcinogens. It is also possible that members of the same family may be exposed to similar environmental exposures due to shared geography or patterns in behavior and diet that may increase the risk of cancer.³⁰ Therefore, it is important to distinguish the difference between a familial pattern of cancer (due to environmental factors or chance) and a hereditary pattern of cancer (due to a shared genetic mutation). Emerging research is also evaluating the role and clinical utility of more common low-penetrance susceptibility genes and single nucleotide polymorphisms (SNP) that may account for a proportion of familial cancers.³¹

Several models are available to calculate the chance that a woman will develop breast cancer, including the Gail and Claus

models.^{32,33} Computer-based models are also available to help determine the chance that a *BRCA* mutation will be found in a family.³⁴ At first glance, many of these models appear simple and easy to use, and it may be tempting to exclusively rely on these models to assess cancer risk. However, each model has its strengths and weaknesses, and the counselor needs to understand the limitations well and know which are validated, which are considered problematic, when a model will not work on a particular patient, or when another genetic syndrome should be considered. For example, none of the existing models are able to factor in other risks that may be essential in hereditary risk calculation (e.g., a sister who was diagnosed with breast cancer after radiation treatment for Hodgkin disease).

The risk of a detectable mutation will also vary based on cancer history and the degree of relationship to an affected family member. For example, family members with early-onset breast cancer have a higher likelihood of testing positive than unaffected family members. Therefore, the risk assessment process should include a discussion of which family member is the best candidate for testing.

DNA Testing

DNA testing is now available for a variety of hereditary cancer syndromes. However, despite misrepresentation by the media, testing is feasible for only a small percentage of individuals with cancer. DNA testing offers the important advantage of presenting clients with *actual risks* instead of the empiric risks derived from risk calculation models. DNA testing can be very expensive; full sequencing and rearrangement testing of the *BRCA1/2* genes currently averages \$2,500, and full panel testing costs up to \$7,000 per patient. Importantly, testing should begin in an affected family member whenever possible to maximize scientific accuracy. Most insurance companies now cover cancer genetic testing in families where the test is medically indicated.

One of the most crucial aspects of DNA testing is accurate result ordering and interpretation. Unfortunately, errors in ordering and interpretation are the greatest risk of genetic testing and are very common.³⁵ Emerging data reveal that between 30% to 50% of genetic tests are ordered inappropriately, which is problematic for patients, clinicians, and insurers.^{36–38} Recent data demonstrate that many medical providers have difficulty interpreting even basic pedigrees and genetic test results.^{33–35} Additional studies have demonstrated that an inaccurate interpretation of genetic testing has been shown to result in inappropriate medical management recommendations, unnecessary prophylactic surgeries, a massive waste of health-care dollars, psychosocial distress, and false reassurance for patients.^{2,3}

Interpretations are becoming increasingly complicated as more tests and gene panels become available. For example, one study demonstrated that approximately 25% of high-risk families that were *BRCA1* and *BRCA2* negative by commercially available sequencing were found to carry a deletion or duplication in one of these genes, or a mutation in another gene.³⁹

This is particularly concerning in an era in which testing companies are canvassing physicians, and now mammography technicians, and encouraging them to perform their own counseling and testing. The potential impact of test results on the patient and his/her family is great and, therefore, accurate interpretation of the results is paramount. Professional groups have recognized this and have adopted standards encouraging clinicians to refer patients to genetics experts to ensure proper ordering and interpretation of genetic tests. The U.S. Preventive Services Task Force recommends that women whose family history is suggestive of a *BRCA* mutation be referred for genetic counseling before being offered genetic testing.⁴⁰ The American College of Surgeons' Commission on Cancer standards include "cancer risk assessment, genetic counseling and testing services provided to patients either on site

or by referral, by a qualified genetics professional.”⁴ In an effort to reduce errors, some insurance companies are requiring genetic counseling by a certified genetic counselor before testing for hereditary breast or colon cancer syndromes.¹²

Results can fall into a few broad categories. It is important to note that a negative test result can actually be interpreted in three different ways, detailed in #2, #3, and #4, which follows.

1. **Deleterious mutation “positive.”** When a deleterious mutation in a well-known cancer gene is discovered, the cancer risks for the patient and her family are relatively straightforward. However, with the development of multigene panels and the inclusion of many lesser known genes, the risks of detecting a mutation within a gene whose cancer risks are ill defined and medical management options unknown is much greater. Even for well-known genes, the risks are not precise and should be presented to patients as a risk range.^{41,42} When a true mutation is found, it is critical to test both parents (whenever possible) to determine from which side of the family the mutation is originating, even when the answer appears obvious.
2. **True negative.** An individual does not carry the deleterious mutation found in her family, which ideally, has been proven to segregate with the cancer family history. In this case, the patient’s cancer risks are usually reduced to the population risks.
3. **Negative.** A mutation was not detected, and the cancers in the family are not likely to be hereditary based on the personal and family history assessment. For example, a patient is diagnosed with breast cancer at age 38 years and comes from a large family with no other cancer diagnoses and relatives who died at old ages of other causes.
4. **Uninformative.** A mutation cannot be found in affected family members of a family in which the cancer pattern appears to be hereditary; there is likely an undetectable mutation within the gene, or the family carries a mutation in a different gene. If, for example, the patient developed breast cancer at age 38 years, has a father with breast cancer, and has a paternal aunt who developed breast and ovarian cancers before age 50 years, a negative test result would be almost meaningless. It would simply mean that the family has a mutation that could not be identified with our current testing methods or a mutation in another cancer gene. The entire family would be followed as high risk.
5. **Variant of uncertain significance.** A genetic change is identified, the significance of which is unknown. It is possible that this change is deleterious or completely benign. It may be helpful to test other *affected* family members to see if the mutation segregates with disease in the family. If it does not segregate, the variant is less likely to be significant. If it does, the variant is more likely to be significant. Other tools, including a splice site predictor, in conjunction with data on species conservation and amino acid difference scores, can also be helpful in determining the likelihood that a variant is significant. It is rarely helpful (and can be detrimental) to test *unaffected* family members for such variants. The rates of variants of uncertain significance vary greatly depending on the reporting protocols of the lab and the genes analyzed. Creation of open databases through a nationwide movement called Free the Data will likely improve variant reporting for all laboratories.

In order to pinpoint the mutation in a family, an affected individual most likely to carry the mutation should be tested first whenever possible. This is most often a person affected with the cancer in question at the earliest age. Test subjects should be selected with care, because it is possible for a person to develop sporadic cancer in a hereditary cancer family. For example, in an early-onset breast cancer family, it would not be ideal to first test a woman diagnosed with breast cancer at age 65 years because she may represent a sporadic case.

If a mutation is detected in an affected relative, other family members can be tested for the same mutation with a great degree

of accuracy. Family members who do not carry the mutation found in their family are deemed true negative. Those who are found to carry the mutation in their family will have more definitive information about their risks to develop cancer. This information can be crucial in assisting patients in decision making regarding surveillance and risk reduction.

If a mutation is not identified in the affected relative, it usually means that either the cancers in the family are (1) not hereditary, or (2) caused by an undetectable mutation or a mutation in a different gene. A careful review of the family history and the risk factors will help to decipher whether interpretation 1 or 2 is more likely. Additional genetic testing may need to be ordered at this point. In cases in which the cancers appear hereditary and no mutation is found, DNA banking should be offered to the proband for a time in the future when improved testing may become available. A letter indicating exactly who in the family has access to the DNA should accompany the banked sample.

The genetic counseling result disclosure session should also include a detailed discussion of which other family members would benefit from genetic counseling and testing and referral information. This can apply not only to families who have been found to carry a deleterious mutation, but may also prove useful in other families (e.g., test a higher risk relative or determine segregation of a variant within a family).

The penetrance of mutations in cancer susceptibility genes is also difficult to interpret. Initial estimates derived from high-risk families provided very high cancer risks for *BRCA1* and *BRCA2* mutation carriers.⁴³ More recent studies done on populations that were not selected for family history have revealed lower penetrances.⁴⁴ Because exact penetrance rates cannot be determined for individual families at this time, and because precise genotype/phenotype correlations remain unclear, it is prudent to provide patients with a range of cancer risk and to explain that their risk probably falls somewhere within this spectrum. This can prove challenging for genes that lack published long-term data on cancer associations and risks.

Female carriers of *BRCA1* and *BRCA2* mutations have a 50% to 85% lifetime risk to develop breast cancer and between a 15% to 60% lifetime risk to develop ovarian cancer.^{15,42,43} It is important to note that the classification “ovarian cancer” also includes cancer of the fallopian tubes and primary peritoneal carcinoma.^{44,45} *BRCA2* carriers also have an increased lifetime risk of male breast cancer, pancreatic cancer, and possibly, melanoma.^{46,47}

Options for Surveillance, Risk Reduction, and Tailored Treatment

The cancer risk counseling session is a forum to provide counselees with information, support, options, and hope. Mutation carriers can be offered: earlier and more aggressive surveillance, chemoprevention, and/or prophylactic surgery. Detailed management options for *BRCA* carriers are discussed in this chapter.

Surveillance recommendations are evolving with newer techniques and additional data. At this time, it is recommended that individuals at increased risk for breast cancer, particularly those who carry a *BRCA* mutation, have annual mammograms beginning at age 25 years, with a clinical breast exam by a breast specialist, a yearly breast magnetic resonance imaging (MRI) with a clinical breast exam by a breast specialist, and a yearly clinical breast exam by a gynecologist.^{48,49} It is suggested that the mammogram and MRI be spaced out around the calendar year so that some intervention is planned every 6 months. Recent data suggest that MRI may be safer and more effective in *BRCA* carriers <40 years of age and may someday replace mammograms in this population.⁵⁰

BRCA carriers may take a selective estrogen-receptor modulator (SERM) or aromatase inhibitor in hopes of reducing their risks of developing breast cancer. These medications have been proven effective in women at increased risk due to a positive family history

of breast cancer.⁵¹⁻⁵³ There are limited data on the effectiveness of such medications in unaffected *BRCA* carriers⁵⁴⁻⁵⁶; however, there are some data to suggest that *BRCA* carriers taking tamoxifen as treatment for a breast cancer reduce their risk of a contralateral breast cancer.⁵⁷ Additionally, the majority of *BRCA2* carriers who develop breast cancer develop an estrogen-positive form of the disease,⁵⁸ and it is hoped that this population will respond especially well to chemoprevention. Further studies in this area are necessary before drawing conclusions about the efficacy of chemoprevention in this population. Prophylactic bilateral mastectomy reduces the risk of breast cancer by >90% in women at high-risk for the disease.⁵⁹ Before genetic testing was available, it was not uncommon for entire generations of cancer families to have at-risk tissues removed without knowing if they were *personally* at increased risk for their familial cancer. Fifty percent of unaffected individuals in hereditary cancer families will *not* carry the inherited predisposition gene and can be spared prophylactic surgery or invasive high-risk surveillance regimens. Therefore, it is clearly not appropriate to offer prophylactic surgery until a patient is referred for genetic counseling and, if possible, testing.⁶⁰

Women who carry *BRCA1/2* mutations are also at increased risk to develop second contralateral and ipsilateral primaries of the breast.⁶¹ These data bring into question the option of breast conserving surgery in women at high risk to develop a second primary within the same breast. For this reason, the *BRCA1/2* carrier status can have a profound impact on surgical decision making,⁶² and many patients have genetic counseling and testing immediately after diagnosis and before surgery or radiation therapy. Those patients who test positive and opt for prophylactic mastectomy can often be spared radiation and the resulting side effects that can complicate reconstruction. Approximately 30% to 60% of previously irradiated patients who later opt for mastectomy with reconstruction report significant complications or unfavorable cosmetic results.^{62,63}

Women who carry *BRCA1/2* mutations are also at increased risk to develop ovarian, fallopian tube, and primary peritoneal cancer, even if no one in their family has developed these cancers. Surveillance for ovarian cancer includes transvaginal ultrasounds and CA-125 testing; however, the effectiveness of such surveillance in detecting ovarian cancers at early, more treatable stages has not been proven in any population. Oral contraceptives reduce the risk of ovarian cancer in all women, including *BRCA* carriers.⁶⁴ Recent data indicate that the impact of this intervention on increasing breast cancer risk, if any, is low.^{56,65} Given the difficulties in screening and in the treatment of ovarian cancer, the risk/benefit analysis likely favors the use of oral contraceptives in young carriers of *BRCA1/2* mutations³⁰ who are not yet ready to have their ovaries removed. Prophylactic bilateral salpingo-oophorectomy (BSO) is currently the most effective means to reduce the risk of ovarian cancer and is recommended to *BRCA1/2* carriers by the age of 35 to 40 or when childbearing is complete.⁶⁶ Specific operative and pathologic protocols have been developed for this prophylactic surgery.⁶⁷ In *BRCA1/2* carriers whose pathologies come back normal, this surgery is highly effective at reducing the subsequent risk of ovarian cancer.⁶⁸ A decision analysis, comparing various surveillance and risk-reducing options available to *BRCA* carriers, has shown an increase in life expectancy if BSO is pursued by age 40.⁶⁹ Emerging data indicate that most ovarian cancers begin in the fallopian tube, and that salpingectomy may someday be sufficient in reducing ovarian cancer risk in young women; however, more data are needed before this option is offered to patients outside of clinical trials.⁷⁰ A relatively small percentage of women who pursue BSO may develop primary peritoneal carcinoma.^{44,71} There has been some debate about whether *BRCA1/2* carriers should also opt for total abdominal hysterectomy (TAH) due to the fact that small stumps of the fallopian tubes remain after BSO alone. The question of whether *BRCA* carriers are at increased risk for uterine serous papillary carcinoma (USPC) has also been raised.⁷²⁻⁷⁴ If a relationship does exist between *BRCA* mutations and uterine

cancer, the risk appears to be low and not elevated over that of the general population.⁷⁵ Removing the uterus may make it possible for a *BRCA* carrier to take unopposed estrogen or tamoxifen in the future without the risk of uterine cancer, but this surgery is associated with a longer recovery time and has more side effects than does BSO alone. Each patient should be counseled about the pros and cons of each procedure and the risks associated with premature menopause before having surgery.⁷⁶

A secondary, but important, reason for female *BRCA* carriers to consider prophylactic oophorectomy is that it also significantly reduces the risk of a subsequent breast cancer, particularly if they have this surgery before menopause.^{77,78} The reduction in breast cancer risk remains even if a healthy premenopausal carrier elects to take low-dose hormone-replacement therapy (HRT) after this surgery.⁷⁹ Early data suggest that tamoxifen, in addition to premenopausal oophorectomy, in *BRCA* carriers may have little additional benefit in terms of breast cancer risk reduction.⁸⁰ Research is needed in balancing quality of life issues secondary to estrogen deprivation with cancer risk reduction in these young female *BRCA1/2* carriers.

New developments are also emerging in the treatment and, possibly, the prevention of *BRCA*-related cancers. Early data revealed that breast and ovarian cancers in *BRCA* carriers were particularly sensitive to treatment with poly adenosine diphosphate (ADP)-ribose polymerases (PARP) inhibitors in combination with chemotherapy.^{81,82} New trials are focusing on which chemotherapeutic regimens are most effective in mutation carriers. More data are needed on larger cohorts of patients and are currently being studied in multiple clinical trials.

Genetic counseling and testing is also available for dozens of cancer syndromes, including Lynch syndrome, von Hippel-Lindau syndrome, multiple endocrine neoplasias, and familial adenomatous polyposis. Surveillance and risk reduction for patients who are known mutation carriers for such conditions may decrease the associated morbidity and mortality of these syndromes.

Follow-up

A follow-up letter to the patient is a concrete means of documenting the information conveyed in the sessions so that the patient and his/her family members can review it over time. This letter should be sent to the patient and health-care professionals to whom the patient has granted access to this information. A follow-up phone call and/or counseling session may also be helpful, particularly in the case of a positive test result. Some programs provide patients with an annual or biannual newsletter updating them on new information in the field of cancer genetics or patient support groups. It is now recommended that patients return for follow-up counseling sessions months, or even years, after their initial consult to discuss advances in genetic testing and changes in surveillance and risk reduction options. This can be beneficial for individuals who have been found to carry a hereditary predisposition, for those in whom a syndrome/mutation is suspected but yet unidentified, and for those who are ready to move forward with genetic testing. Follow-up counseling is also recommended for patients whose life circumstances have changed (e.g., preconception, after childbearing is complete), who are preparing for prophylactic surgery, or who are ready to discuss the family genetics with their children.

ISSUES IN CANCER GENETIC COUNSELING

Psychosocial Issues

The psychosocial impact of cancer genetic counseling cannot be underestimated. Just the process of scheduling a cancer risk counseling session may be quite difficult for some individuals

with a family history who are not only frightened about their own cancer risk, but also are reliving painful experiences associated with the cancer of their loved ones.¹³ Counselees may be faced with an onslaught of emotions, including anger, fear of developing cancer, fear of disfigurement and dying, grief, lack of control, negative body image, and a sense of isolation.²⁴ Some counselees wrestle with the fear that insurance companies, employers, family members, and even future partners will react negatively to their cancer risks. For many, it is a double-edged sword as they balance their fears and apprehensions about dredging up these issues with the possibility of obtaining reassuring news and much needed information.

A person's perceived cancer risk is often dependent on many "nonmedical" variables. They may estimate that their risk is higher if they look like an affected individual, or share some of their personality traits.²⁴ Their perceived risks will vary depending on if their relatives were cancer survivors or died painful deaths from the disease. Many people wonder not *if* they are going to get cancer, but *when*.

The counseling session is an opportunity for individuals to express why they believe they have developed cancer, or why their family members have cancer. Some explanations may revolve around family folklore, and it is important to listen to and address these explanations rather than dismiss them.²⁴ In doing this, the counselor will allow the clients to alleviate their greatest fears and to give more credibility to the medical theory. Understanding a patient's perceived cancer risk is important, because that fear may *decrease* surveillance and preventive health-care behaviors.⁸³ For patients and families who are moving forward with DNA testing, a referral to a mental health-care professional is often very helpful. Genetic testing has an impact not only on the patient, but also on his/her children, siblings, parents, and extended relatives. This can be overwhelming for an individual and the family, and should be discussed in detail prior to testing.

To date, studies conducted in the setting of pre- and post-genetic counseling have revealed that, at least in the short term, most patients do not experience adverse psychological outcomes after receiving their test results.^{84,85} In fact, preliminary data have revealed that individuals in families with known mutations who seek testing seem to fare better psychologically at 6 months than those who avoid testing.⁸⁴ Among individuals who learn they are *BRCA* mutation carriers, anxiety and distress levels appear to increase slightly after receiving their test results but returned to pre-test levels in several weeks.⁸⁶ Although these data are reassuring, it is important to recognize that genetic testing is an individual decision and will not be right for every patient or every family.

Presymptomatic Testing in Children

Presymptomatic testing in children has been widely discussed, and most concur that it is appropriate only when the onset of the condition regularly occurs in childhood or if there are useful interventions that can be applied.⁸⁷ For example, genetic testing for mutations in the *BRCA* genes and other adult-onset diseases is generally limited to individuals who are >18 years of age. The American College of Medical Genetics states that if the "medical or psychosocial benefits of a genetic test will not accrue until adulthood . . . genetic testing generally should be deferred."⁸⁸ In contrast, the DNA-based diagnosis of children and young adults at risk for hereditary medullary thyroid carcinoma (MTC) is appropriate and has improved the management of these patients.⁸⁹ DNA-based testing for MTC is virtually 100% accurate and allows at-risk family members to make informed decisions about prophylactic thyroidectomy. FAP is a disorder that occurs in childhood and in which mortality can be reduced if detection is presymptomatic.⁹⁰ Testing is clearly indicated in these instances.

Questions have been raised about the parents' right to demand testing for adult-onset diseases, and this is now happening regularly

with direct-to-consumer tests and whole exome testing of children.⁹¹ The risks of such testing to the child, and the child's right *not* to be tested must be considered. Whenever childhood testing is not medically indicated, it is preferable that testing decisions are postponed until the children are adults and can decide for themselves whether to be tested.

Confidentiality

The level of confidentiality surrounding cancer genetic testing is paramount due to concerns of genetic discrimination. Careful consideration should be given to the confidentiality of family history information, pedigrees, genetic test results, pathology reports, and the carrier status of other family members as most hospitals and clinicians transition to electronic medical records systems. The goal of electronic records is to share information about the patient with his/her entire health-care team. However, genetics is a unique specialty that involves the whole family. Patient's charts often contain Health Insurance Portability and Accountability Act (HIPAA)-protected health information and genetic test results for many other family members. This information may not be appropriate to enter into an electronic record. The unique issues of genetics services need to be considered when designing electronic medical record standards.

Confidentiality of test results *within* a family can also be of issue, because genetic counseling and testing often reveals the risk statuses of family members other than the patient. Under confidentiality codes, the patient needs to grant permission before at-risk family members can be contacted. For this reason, many programs have built in a "share information with family members" clause to their informed consent documents. It has been questioned whether or not a family member could sue a health-care professional for negligence if they were identified at high risk yet not informed.⁹² Most recommendations have stated that the burden of confidentiality lies between the provider and the patient. However, more recent recommendations state that confidentiality *should* be violated if the potential harm of not notifying other family members outweighs the harm of breaking a confidence to the patient.⁹³ There is no patent solution for this difficult dilemma, and situations must be considered on a case-by-case basis with the assistance of the in-house legal department and ethics committee.

Insurance and Discrimination Issues

When genetic testing for cancer predisposition first became widely available, the fear of health insurance discrimination by both patients and providers was one of the most common concerns.^{94,95} It appears that the risks of health insurance discrimination were overstated and that almost no discrimination by health insurers has been reported.⁹⁶ HIPAA banned the use of genetic information as a preexisting condition.^{97,98} In May of 2008, Congress passed the Genetic Information Nondiscrimination Act (GINA, HR 493), which provides broad protection of an individual's genetic information against health insurance and employment discrimination.⁹⁹ In addition, the Health Care and Education Reconciliation Act of 2010 (HR 4872) prohibits group health plans from denying insurance based on preexisting conditions and from increasing premiums based on health status.¹⁰⁰ Health-care providers can now more confidently reassure their patients that genetic counseling and testing will not put them at risk of losing group or individual health insurance.

More and more patients are choosing to submit their genetic counseling and/or testing charges to their health insurance companies. In the past few years, more insurance companies have agreed to pay for counseling and/or testing,¹⁰¹ perhaps in light of data that show these services reduce errors related to ordering and interpreting genetic testing and that decision analyses have revealed

subsequent prophylactic surgeries to be cost effective.¹⁰² The risk of life or disability insurance discrimination, however, is more realistic. Patients should be counseled about such risks before they pursue genetic testing.

Reproductive Issues

Reproductive technology in the form of preimplantation genetic diagnosis, prenatal testing, or sperm sorting are options¹⁰³ for men and women with a hereditary cancer syndrome, but are requested by few patients for adult-onset conditions in which there are viable options for surveillance and risk reduction. Importantly, if a *BRCA2* carrier is considering having a child, it is important to assess the spouse's risk of also carrying a *BRCA2* mutation. If the spouse is of Jewish ancestry or has a personal or family history of breast, ovarian, or pancreatic cancer, *BRCA* testing should be considered and a discussion of the risk of Fanconi anemia in a child with two *BRCA2* mutations should take place.¹⁰⁴

RECENT ADVANCES AND FUTURE DIRECTIONS

Cancer genetic counseling and testing were thrust into the national spotlight in the spring of 2013 when Hollywood icon Angelina Jolie publically disclosed that she was a *BRCA1* carrier. One month later the Supreme Court unanimously ruled against gene patents. Referrals for genetic testing spiked across the country and have not returned to baseline levels at most centers. Within hours of the ruling, other labs began offering less expensive and more comprehensive *BRCA* testing, dramatically changing the marketplace of genetic testing for hereditary breast cancer.

All laboratories that have entered the *BRCA* marketplace have done so by including *BRCA1* and *BRCA2* in gene panels. These panels simultaneously analyze groups of genes that contribute to increased risk for breast, colon, ovarian, uterine, and other cancers. The cost of this technology continues to decrease with some multi-gene panels costing just a few hundred dollars less than traditional *BRCA* testing (~\$4,000). Some panels include only well-known genes (e.g., *p53*, *APC*, *MLH1*), although many include lesser known genes (e.g., *BRIP1*, *NBN*, *MRE11A*) for which cancer risks are ill defined and medical management options are unknown. Because testing for these genes is new to the clinical setting, it is expected to take several years to compile accurate cancer risk estimates and appropriate recommendations for surveillance and risk reduction. Furthermore, the rate of variants of uncertain significance will likely be more common in the lesser known genes. These changes have increased the complexity of genetic testing exponentially. In response, several state and one national insurance company have mandated genetic counseling by certified providers before they will cover cancer genetic testing. In a surprising response, the American Society of Clinical Oncology (ASCO) opposed this insurer's decision, despite more than a decade's worth of data demonstrating that the majority of physicians do not have the time or expertise to offer genetic counseling and testing^(38,105-108). The AMA will decide whether to back the ASCO resolution in June 2014.

Some companies are now offering direct-to-consumer (DTC) genetic testing via websites. The accuracy of some of these DTC genetic tests are in question, and the leading company, 23andMe, has recently come under fire by the U.S. Food and Drug Administration.¹⁰⁵

Maintaining high standards for thorough genetic counseling, informed consent, and accurate result interpretation will be paramount in reducing potential risks and maximizing the benefits of genetic technology in the next century.

Practice of Oncology

36 Design and Analysis of Clinical Trials

Richard M. Simon

INTRODUCTION

Clinical trials are experiments to determine the value of a treatment. There are two key components to the experimental approach. First, results rather than plausible reasoning are required to support conclusions. Second, in an experiment the treatments are assigned so that one can conclude that differences in outcome are due to differences in treatment effect. In observational studies, treatments are not assigned as part of the study, so differences in outcome between treatment groups may merely result from the fact that sicker patients received less intensive treatments. Experiments should be prospectively planned and conducted under controlled conditions to provide definitive answers to well-defined questions. Using tumor registry data to compare the survival rates of patients with prostate cancer treated with surgery to those of patients receiving radiotherapy is an example of an *observational study*, not a clinical trial. In an observational study, the investigators are passive observers. Treatment assignments, staging workup, and follow-up procedures are out of the control of the investigators, and are conducted with no considerations about the validity of the subsequent attempt at comparison. The statistical associations resulting from such studies are, consequently, a weak basis for causal inferences about relationships between the treatments administered and the outcomes observed. Surprisingly, this does not seem to be realized by the politicians and health-care administrators allocating enormous sums of money to outcomes research based on electronic medical records from general practice. In such observational studies, treatments are usually selected on the basis of subjective assessment of the prognosis of the patient, specialties of the physician, and diagnostic evaluations. Unknown patient selection factors generally are more important determinants of patient outcome than are differences between treatments. For example, Subramanian and Simon¹ found that in observational studies that developed gene expression prognostic signatures for patients with early stage nonsmall-cell lung cancer, those who received chemotherapy had poorer survivals than those who did not even after adjusting for all recorded prognostic factors.

Clinical trials require careful planning. The first result of the planning process is a written protocol. Typical subject headings for the protocol are shown in Table 36.1, and the protocol development process is discussed in more detail by Green et al.² The protocol should define treatment and evaluation policies for a well-defined set of patients. It also should define the specific questions to be answered by the study and should directly justify that the number of patients and the nature of the controls are adequate to answer these questions. Some clinical trials are really only guidelines for clinical management supplemented by lofty objectives with no scientific meaning and no realistic chance of providing a reliable answer to a well-defined medical question. Such studies are a disservice to the patients who are undergoing some inconvenience to contribute to the welfare of future patients.

PHASE 1 CLINICAL TRIALS

The main objectives of phase 1 trials have traditionally been to determine a dose that is appropriate for use in phase 2 and 3 trials and to determine information about the pharmacokinetics of distribution of the drug. Patients with advanced disease that is resistant to standard therapy but who have normal organ function are usually included in such trials.

Phase 1 trials are usually initiated at a low dose that is not expected to produce serious toxicity. A starting dose of one-tenth the lethal dose (expressed as milligrams per square meter of body surface area) in the most sensitive species usually is used.³ The dose is increased for subsequent patients according to a series of preplanned steps. Dose escalation for subsequent patients occurs only after sufficient time has passed to observe acute toxic effects for patients treated at lower doses. Cohorts of three to six patients are treated at each dose level. Usually, if no dose-limiting toxicity (DLT) is seen at a given dose level, the dose is escalated for the next cohort. If the incidence of DLT is 33%, then three more patients are treated at the same level. If no further cases of DLT are seen in the additional patients, then the dose level is escalated for the next cohort. Otherwise, dose escalation stops. If the incidence of DLT is >33% at a given level, then dose escalation also stops. The phase 2 recommended dose often is taken as the highest dose for which the incidence of DLT is <33%. Usually, six or more patients are treated at the recommended dose.

The dose levels themselves are commonly based on a modified Fibonacci series. The second level is twice the starting dose, the third level is 67% greater than the second, the fourth level is 50% greater than the third, the fifth is 40% greater than the fourth, and each subsequent step is 33% greater than that preceding it. Escalating doses for subsequent courses in the same patient are generally not done, except at low doses before any DLT has been encountered.

Accelerated Titration Designs

There is no compelling scientific basis for the approach just outlined, except that experience has shown it to be safe. Traditional phase 1 trials have three limitations:

1. They sometimes expose too many patients to subtherapeutic doses of the new drug.
2. The trials may take a long time to complete.
3. They provide very limited information about interpatient variability and cumulative toxicity.

New trial designs have been developed to address these problems.⁴ The *accelerated titration designs*⁵ permit within-patient dose escalation and use only one patient per dose level until grade 2 or greater toxicity is seen. Doses are titrated within patients to achieve grade 2 toxicity. The analysis consists of fitting a statistical model to the full set of data that includes all grades of toxicity for all courses of a patient's treatment. The model includes parameters

Study chairperson, collaborating participants, addresses, and telephone numbers

that represent the steepness of the dose-toxicity curve, the degree of interpatient variability in the location of the dose-toxicity curve, and the degree (if any) of cumulative toxicity. All these parameters are estimated from the data.

Several variants of the accelerated titration design were studied. Design A uses conventional 40% dose steps during the initial accelerated phase, whereas designs B and C use 100% dose steps until one patient experiences DLT or two patients experience grade 2 toxicity. At that point, acceleration ceases and standard cohorts of three to six patients with 40% dose-step increments are used. These designs were compared to a control design using cohorts of three to six patients with 40% dose-step increments and no intrapatient dose escalation.

In the 20 phase I trials initially evaluated, only three showed any evidence of cumulative toxicity. The average number of patients required was reduced from 39.9 for the control design to 24.4, 20.7, and 21.2 for designs A, B, and C, respectively. The average number of patients who had grade 0 to 1 toxicity as their worst toxicity grade over three cycles of treatment was 23.3 for the control but only 7.9, 3.9, and 4.8 for designs A, B, and C, respectively. The average number of patients with a worst toxicity grade of 3 increased from 5.5 for the control to 6.2, 6.8, and 6.2 for designs A, B, and C, respectively. The average number of patients with a worst toxicity grade of 4 increased from 1.9 for the control to 3.0, 4.3, and 3.2 for designs A, B, and C, respectively. Accelerated titration designs appear to be effective in reducing the number of patients necessary for finding the maximum tolerated dose, for reducing the number who are undertreated, and for providing increased information. They do not necessarily reduce the length of time necessary for completion of the trial. They increase the information yield if investigators analyze the results of the trial using the model developed by Simon et al.⁵ Software for fitting the model is available at <http://brb.nci.nih.gov>. Software for determining dose assignments and for recording the data in a spreadsheet format are also available at that website. The model of Simon et al.⁵ uses actual worst grade toxicity for each course of treatment of each patient, and it enables one to determine whether there is cumulative toxicity and to estimate the variability among patients in toxic effects. The use of the accelerated titration design has been reviewed.^{6,7}

Continual Reassessment Methods

O'Quigley, Pepe, and Fisher⁸ used a dose-toxicity model to guide the dose escalation, as well as to determine the maximum tolerated

dose. A Bayesian prior distribution is established for the steepness of the dose-toxicity curve and the distribution is updated after each patient is treated. The model is based on using only first-course treatment data and whether the patient experiences DLT. This approach is called the *continual reassessment method*. For each new patient, the model is used to determine the dose predicted to cause DLT to a specified percentage of the patients. That dose is assigned to the next patient. Many modifications of the original continual reassessment method have been subsequently proposed.^{9–11}

For some tumor vaccines and molecularly targeted drugs, toxicity may not be dose limiting,¹² and the dose selected may be based on preclinical findings or on practical considerations. For some molecularly targeted drugs, preclinical studies provide a target serum concentration of the active moiety necessary to maximally inhibit the target, and drug administration can be titrated for each patient to the targeted serum concentration. This approach can be complex because it involves developing a population pharmacokinetic model relating dose to concentration as the study progresses. A simpler approach is to have separate cohorts of patients who are treated at each of several dose levels without intrapatient dose titration. A population pharmacokinetic model relating dose to concentration is fit to the data.

Ideally, a trial design should provide the smallest dose that gives maximum biologic effect. For molecularly targeted therapeutics, the biologic effect might be a measure of the degree of inhibition of the target. Because it can be very difficult to obtain tumor samples before and after treatment, biologic effect is sometimes measured in an accessible surrogate tissue, such as peripheral blood lymphocytes or skin, or by using functional imaging.¹³ For therapeutic vaccines, the biologic effect might be a measure of stimulation of tumor reactive T cells.

Finding the dose that provides maximum biological effect is often not practical in a phase I trial, as it may require a large number of patients. For example, to have 90% power for detecting a one standard error difference in mean response between two dose levels at a one-sided 10% significance level requires 14 patients per dose level. A more limited objective is to identify a dose that is biologically active. Korn et al.¹⁴ developed a sequential procedure for finding such a dose when the measure of biologic response is binary. During an initial accelerated phase, they treat one patient per dose level until a biologic response is seen. Then, they treat cohorts of three to six patients per dose level. With zero to one biologic responses among three patients at a dose level, they escalate to the next level. With two to three responses among three patients, they expand the cohort to six patients. With five to six biologic responses from the six patients, they declare that dose to be the biologically active level and terminate the trial. With four or fewer biologic responses at a level, they continue to escalate.

Designs have also been developed for phase zero proof of concept trials.^{15,16} Patients are treated with single doses of a new drug at very low concentrations not expected to cause toxicity. This enables the investigator to obtain an early assessment of whether the molecular target of the drug is being inhibited by measuring a pharmacodynamic end point before and after drug administration. These trials require prior development of an assay for measuring the pharmacodynamic end point and an adequate database for estimating the variability of measurement for independent tissue samples of the same patient. This estimate should reflect variability of tissue sampling as well as technical variability of the assay. The approach developed depends on having a good estimate of assay variability and in having assay sufficiently reproducible to be able to reliably classify individual patients as responders or nonresponders based on the observed change in the level of the pharmacodynamic end point. The designs described by Rubinstein et al.¹⁶ utilize a small numbers of patients for establishing whether the drug causes target inhibition in a substantial proportion of patients.

PHASE 2 CLINICAL TRIALS

Patient Selection

Phase 2 trials have traditionally been performed separately by tumor type in patients with the least amount of prior therapy for whom no effective therapy is available. With cytotoxics, full-dose chemotherapy is often impossible in patients debilitated by prior treatment, and lack of chemotherapeutic activity in previously treated patients may not indicate lack of clinical usefulness in earlier disease. The development of molecularly targeted drugs has introduced new complexities with regard to selection and evaluation of patients for phase 3 trials. When the target of the drug is clearly known, it may be more appropriate to select patients based on target expression than based on primary site of disease. Even if target expression is not used as an eligibility criterion, the drug should be evaluated in an adequate number of patients whose tumors express the target. Consequently, it is important to have an adequate assay for the target available at the time that phase 2 development begins.

In many cases, the drug will have multiple targets; there may be several candidate assays available for each target. Expression of the target will often prove to be only part of the relevant genomic information. For example, the effectiveness of anti-epidermal growth factor receptor antibodies cetuximab and panitumumab turned out to depend on whether the tumor had an activating K-RAS mutation.¹⁷⁻¹⁹

Whereas the major objective of phase 2 trials has traditionally been to identify the primary tumor sites in which a new drug was active, a new important objective is to develop promising predictive biomarkers that identify the patients whose tumors are most (or least) likely to respond to the drug. The phase 2 development stage is also the time to select the assay(s) that will be used in the phase 3 trials of the new drug and to define the criteria that will be used to either select patients for such trials or to structure the analysis, as will be described later in this chapter.

It is often undesirable to restrict entry to phase 2 trials based on what one thinks one knows about the drug target, at least in cases where this knowledge is uncertain. It is important, however, to ensure that the activity of the drug is not missed because the phase 2 trials did not accrue enough of the right kinds of patients. The decision of whether to restrict entry based on the presumed mechanism of action will depend in part on the adverse effects of the drug.

If tumor specimens are archived for the patients entered on broad eligibility phase 2 trials, then one avoids the need to develop assays in advance for all candidate targets, but it is not possible to ensure adequate accrual for subsets of patients whose tumors are positive for the candidate markers. Puztai, Anderson, and Hess²⁰ described a hybrid approach that begins with conducting a standard single-arm two-stage design for evaluating whether the overall response rate for unrestricted patients is sufficiently large. If the overall response rate is sufficient in the first stage of the standard phase 2 trial, then the second stage is completed with accrual of additional unrestricted patients. If there are too few responses overall in the first stage, then one starts a two-stage phase 2 study restricting entry to patients who are marker positive. If there are multiple markers of interest, then one restricts entry to patients positive for one of the markers and ensures that each marker has sufficient number of positive patients for evaluation. LeBlanc et al.²¹ have described how multiple primary sites can be incorporated in a single phase 2 trial.

In some cases, the list of candidate targets can be narrowed using mRNA transcript expression profiling of the pretreatment specimens. By comparing pretreatment expression levels of responders to nonresponders, one can potentially prioritize targets for assay development. If one does not have a good list of candidate targets, genomewide expression profiling can be used to develop

a classifier of the tumors likely to respond to the drug. Dobbin, Zhao, and Simon²² have provided sample size guidelines for genomewide expression profiling studies and generally recommend at least 20 responders for developing a classifier. Puztai, Anderson, and Hess²⁰ performed a computer simulation study to indicate that HER-2 transcript overexpression would have been missed as a predictive biomarker for treatment of advanced breast cancer with trastuzumab in whole genome expression profiling with only five responders to analyze. They recommend analysis based on candidate genes if the number of responders are very limited.

Single-Arm Phase 2 Trials

Single Agents

For most single-agent phase 2 trials, the objective is simply to determine whether the drug has activity against the tumor type in question. For this objective, response rate based on the response evaluation criteria in solid tumors guidelines may provide a satisfactory approach.²³ A variety of statistical accrual plans and sample size methods have been developed for single-arm phase 2 trials. One of the most popular approaches is the optimal two-stage design.²⁴ n_1 evaluable patients are entered into study in the first stage of the trial. If no more than r_1 responses are obtained among these n_1 patients, then accrual terminates and the drug is rejected as being of little interest. Otherwise, accrual continues to a total of n evaluable patients. At the end of the second stage, the drug is rejected if the observed response rate is less than or equal to r/n , where r and n are determined by the design used.

Tables 36.2 and 36.3 illustrate some of these optimized designs, and a web-based interactive computer program is available at <http://linus.nci.nih.gov/brb>. To select a design, the investigator specifies the target activity level of interest, p_1 , and also a lower activity level, p_0 , representing inadequate activity. The first row of each triplet of optimal designs provides designs with probability 0.10 of accepting drugs worse than p_0 and probability 0.10 of rejecting drugs better than p_1 . Subject to these two constraints, the optimal designs minimize the average sample size. The average sample size is calculated at the lower activity level p_0 to optimize protection of patients from exposure to inactive drugs. The tables show for each design the optimal values of r_1 , n_1 , r , and n ; the average sample size; and the probability of stopping after the first stage for a drug with activity level p_0 .

These tables also show the “minimax” designs, which provide the smallest maximum sample size n that satisfies the two constraints just described. Although minimax designs have somewhat larger average sample sizes than do optimal designs, in some instances, they are preferable because the small increase in average sample size is more than compensated for by a large reduction in maximum sample size.

The designs shown in Tables 36.2 and 36.3 are two-stage designs with the potential for early stopping for lack of activity. Optimized three-stage designs have been described by Ensign et al.²⁵ Others have extended the design to incorporate toxicity or tumor progression information.²⁶⁻²⁸

Some authors have recommended use of progression-free survival instead of response²⁹ for evaluating molecularly targeted drugs that may be cytostatic. Single-arm phase 2 trials can be designed using Tables 36.2 and 36.3 for testing whether the proportion of patients with stable disease at a specified landmark time like 12 months after the start of treatment is greater than a specified value p_0 , but that is only meaningful if the value p_0 is a stable, robust, and well-characterized stable disease rate that results from multiple large studies with control regimens. Single-arm studies using stable disease are rarely planned or analyzed with that care and hence conclusions of single-arm phase 2 trials claiming that molecularly targeted agents cause disease stabilization are often dubious.³⁰ Vidauurre et al.³⁰ have questioned, however, whether

^a For each value of (p_0, p_1) , designs are given for three sets of error probabilities (α, β) . The first, second, and third rows correspond to error probability limits (0.10, 0.10), (0.05, 0.20), and (0.05, 0.10), respectively. α is the probability of accepting a drug with response probability p_0 . β is the probability of rejecting a drug with response probability p_1 . For each design, EN (p_0) and PET (p_0) denote the expected sample size and the probability of early termination when the true response probability is p_0 .

molecularly targeted drugs are any more cytostatic than conventional chemotherapy drugs. El-Maraghi and Eisenhauer³¹ have also recommended that objective response is a useful end point for screening molecularly targeted agents.

Combination Regimens

Determination whether a new drug adds anticancer activity to an active regimen is inherently comparative. In using Tables 36.2 and 36.3 to design a single-arm trial, p_0 should represent the level of activity of existing standard regimens. If this response probability is not well determined, however, because it varies among studies and varies based on patient prognostic factors, then a single-arm trial based on an assumed known p_0 may not be appropriate.

Several approaches to single-arm study design have been developed that attempt to either account for or control the variability in p_0 . One approach to controlling this variability is to base the analysis of the single-arm trial on comparison to a specific set of control patients, matched for prognostic factors, and treated at the same institution as those for the new study. This can be a better approach than just using an assumed known value of p_0 as described previously, but it still assumes that adjustment for known prognostic factors is sufficient to ensure comparability. Although such historic control comparisons are not considered reliable enough to eliminate the need for phase 3 trials, if done carefully, they may provide an adequate basis for decisions about which new regimens are worthy of phase 3 evaluation.

For comparative trials of response rates using specific historic controls, the sample size should be planned using the formulas appropriate for randomized clinical trials. By inserting the number of historic controls to be used, one can compute the number of patients needed to treat on the new regimen in the single-arm phase 2 trial.³² For binary end point data, the results of these calculations are presented in Table 36.4 for 80% power with a one-sided 10% significance level. The tabulated entries indicate that a 25 percentage-point difference can be detected with <40 new patients if there are at least 30 appropriate historic controls. The table entries indicate that detecting a 15 percentage-point difference is almost never feasible with this single-arm approach and that detecting a 20 percentage-point difference generally requires at least 50 appropriate historical controls and ≥ 60 new patients.

Thall and colleagues^{33,34} have developed and used Bayesian methods for planning and conducting single-institution trials comparing one or more new regimens to a specific set of historic controls who received a control treatment at the same institution. The Bayesian designs provide for continual analysis of results with either tumor response or time to event end points or for joint monitoring of efficacy and toxicity. Their methods require a substantial number of patients who have been treated on protocol with an appropriate control regimen and who have been staged comparably to the patients to be treated with the new regimen.

Korn et al.³⁵ developed an approach for using historic control data in phase 2 multicenter trials of metastatic melanoma. They

^a For each value of (p_0, p_1) , designs are given for three sets of error probabilities (α, β) . The first, second, and third rows correspond to error probability limits (0.10, 0.10), (0.05, 0.20), and (0.05, 0.10), respectively. α is the probability of accepting a drug with response probability p_0 . β is the probability of rejecting a drug with response probability p_1 . For each design, EN (p_0) and PET (p_0) denote the expected sample size and the probability of early termination when the true response probability is p_0 .

reviewed 42 previous phase 2 trials in melanoma conducted by US cancer cooperative oncology groups. They found that after adjustment for performance status, sex, presence of visceral disease, and presence of brain metastases, there was little interstudy variability in survival among the arms of the phase 2 trials. Consequently, for any single-arm phase 2 trial of metastatic melanoma, one can use their results in conjunction with the prognostic makeup of the patients in the new study to synthesize a benchmark overall survival curve or a benchmark 1-year overall survival rate for use in evaluating the new regimen. They provide an example of planning a phase 2 trial using this approach that required 72 patients to have 85% to 90% power for detecting a 15 percentage-point improvement in the 1-year overall survival rate with a one-sided type 1 error of 10%. They found that this approach was less satisfactory for use with progression-free survival because interstudy variability remained substantial after adjustment for prognostic factors.

Mick, Crowley, and Carroll³⁶ proposed that the time to progression of a patient on a phase 2 trial be compared to the time to progression of the same patient on his/her previous trial. The ratio of these times was called a *growth modulation index*, and the agent was considered active if the index was >1.3 on average. In practice, however, follow-up intervals on various protocols are different, and there may be substantial variability and bias in computing

the ratio of progression times. As tumors grow larger, the doubling time may increase and hence in some cases the chance of false-positive findings may be inflated.³⁷

Randomized Phase 2 Trials

Time to tumor progression or disease-free survival has been recommended for evaluation of single-agent phase 2 trials of drugs that may be cytostatic and for trials adding a new drug to an active regimen. Even single-agent phase 2 trials of cytotoxics have been criticized on the basis that they do not provide much evidence that the drug will be able to prolong survival when incorporated into a regimen with other active drugs. Demonstrating that the regimen incorporating the new drug prolongs progression-free survival compared to the control regimen may provide a stronger basis for conducting a phase 3 trial of the new regimen.

Simon et al.¹² suggested two key design differences between such randomized phase 2 designs and phase 3 designs. A randomized phase 2 design may use an end point that is a sensitive indicator of antitumor effect, although it may not be an acceptable phase 3 end point that directly reflects patient benefit. Such an endpoint does not need to be "validated." It is not claimed to be a valid surrogate for survival; no regulatory approval or practice standard decisions should be based on the phase 2 trials using such an intermediate

^c Number of required new patients exceeds 1,000.

end point. The purpose of the phase 2 trial is merely to determine whether to conduct a phase 3 trial that will evaluate the new regimen with an accepted phase 3 end point. The phase 2 trial may also serve to optimize the regimen that might be carried forward to phase 3 and to provide information about the best target population. The second key difference noted by Simon et al.¹² is that the type I error “alpha level” for planning and analyzing the phase 2 trial can be increased from the two-sided 5% level used for phase 3 trials. By letting this alpha level increase to a one-sided 10%, meaningful savings in number of patients required can be achieved.

How large should a randomized phase 2 design comparing a new treatment to a control regimen be? Consider, for example, a randomized phase 3 trial comparing a new regimen to a control in a patient population in which the median time to progression on the control is 6 months and the median survival is 2 years. A 25% reduction in the hazard of death amounts to a 4-month prolongation of median survival with exponential distributions. A phase 3 trial with 90% statistical power for detecting this effect at a two-sided 5% significance level would require about 510 deaths (see Table 36.7). With an average follow-up time of 2 years, 50% of the patients would have events and so the number of patients required for randomization would be just in excess of 1,000. A randomized phase 2 trial with 90% power for detecting a 33% reduction in hazard of progression corresponding to a 2-month increase in median progression-free survival at a one-sided 10% significance level would require observing 164 progression events (Table 36.5). With an average follow-up time of 2 years, >90% would have progression events and so a sample size of 180 total randomized patients would suffice. Accrual to the randomized phase 2 study could potentially be stopped early based on futility monitoring if results are not promising for the new regimen. The results in Table 36.5 show that if an imbalanced randomization is used in which two-thirds of the patients are randomized to the new treatment, the number of progression events needed increases to 185 instead of 164. So although a larger total sample size would be required, somewhat fewer patients would receive the control regimen.

The randomized phase 2 design with control regimen has also been discussed by Korn et al.³⁸ and by Rubinstein et al.³⁹ Randomized phase 2 trials can require fewer patients than phase 3 trials, but they generally require more patients than single-arm phase 2 trials. Nevertheless, they are generally necessary for evaluating time to event end points or for evaluating combination regimens. Table 36.6 shows number of patients required for randomized phase 2 trials where the primary end point is either response rate or the proportion of patients without progression by a specified landmark time.

Randomized Screening Designs

Phase 2 trials are generally viewed as a means of determining whether a particular regimen is worthy of phase 3 evaluation. They can, however, be viewed as way to screen a wide range of new regimens in order to select the most promising for phase 3 evaluation. Traditional single-arm phase 2 designs are problematic for screening when there is substantial interstudy variation in patient selection and outcome evaluation. Simon, Wittes, and Ellenberg⁴⁰ proposed the randomized phase 2 design in which multiple new regimens are randomized against each other as one way of

TABLE 36.5

avoiding such interstudy variability in prioritizing the candidate regimens.⁴⁰ This randomized design can provide more interpretable results if it also incorporates a control arm. This design is more efficient than separate randomized phase 2 trials because the control arm does not have to be replicated in all of the randomized phase 2 trials. Using the example described previously, if it takes 90 patients per arm to conduct a randomized phase 2 trial, instead of $180 \times 5 = 900$ patients to conduct randomized phase 2 trials of five new regimens, one would require only $90 \times 6 = 540$ patients, a savings of 40%. The savings in number of patients can be even more dramatic if one takes the position that the objective is not to evaluate all five new regimens, but rather to select the best one and determine whether it is worthy of phase 3 evaluation. For this selection objective, one does not require 90 patients per arm.⁴⁰ These designs have been discussed and extended by others.⁴¹⁻⁴⁴

Simon et al.¹² showed that one can take advantage of the non-toxic nature of some molecularly targeted drugs to efficiently evaluate multiple regimens in the same study. They propose using a factorial design in which concurrent randomizations are made for each drug. For example, if there are three drugs (A, B, C) being evaluated, then some patients will receive all three, some will receive pairs (AB, AC, or BC), some will receive single drugs (A, B, C), and one group will receive none of the drugs. In evaluating each drug, the time to progression for all patients receiving that drug are compared to the times for all patients not receiving that drug. The trial can be sized as if it were a single two-arm trial. The design is effective as long as there are not negative interactions among drugs. Negative interactions would result from the toxicity of one drug interfering with the full-dose administration of other drugs, which may not be a problem for many molecularly targeted drugs. The design is also useful for attempting to identify combinations that are therapeutically synergistic, a circumstance of particular importance with molecularly targeted drugs.

Rosner, Stadler, and Ratain⁴⁵ describe a “randomized discontinuation design” for phase 2 studies of therapeutically targeted drugs. All eligible patients are started on the drug and given two to four courses of treatment. Patients are then evaluated: Those with progression are removed from study, those with objective tumor response are continued on treatment, and the remaining patients are randomized to either continue or discontinue the drug. The continued and discontinued groups of randomized patients are compared with regard to time to progression. Freidlin and Simon⁴⁶ evaluated and further developed this design. It may require as large a number of patients started on treatment as a straightforward randomized phase 2 design. The advantage of the design is that

because all patients start on the new regimen, accrual rate may be better with the randomized discontinuation design.

Seamless Phase 2/3 Designs

Hunsberger, Zhao, and Simon⁴⁷ developed a design for a seamless phase 2/3 design. Patients are randomized between a new regimen and control. An interim analysis is performed using a phase 2 end point such as response rate or time to progression to decide whether the results with the new treatment as sufficiently promising to continue to a phase 3 sample size. If accrual continues, then the final analysis is performed using an acceptable phase 3 end point. A similar approach was described by Goldman LeBlanc, and Crowley.⁴⁸ Phase 2/3 designs using Bayesian methods have been reviewed by Thall.⁴⁹ Sher and Heller⁵⁰ proposed conducting phase 3 trials with multiple experimental regimens, a control arm, and early termination of all experimental arms that are not promising. They used the statistical design of Schaid, Wieand, and Therasse⁵¹ for time to event data. Thall, Simon, and Ellenberg⁵² had studied such designs when the end point was binary. A similar approach was recommended by Parmar et al.⁵³ Freidlin et al.⁵⁴ have discussed statistical and practical aspects of conducting clinical trials with a control arm and multiple new treatment arms. Freidlin, McShane, and Polley⁵⁵ have also introduced a design for a randomized phase 2 design of a new drug with a candidate predictive biomarker for determining whether the drug is entirely inactive, active only in the marker positive group, or active regardless of the biomarker status. This design enables investigators to appropriately plan whether to continue biomarker development into phase 3 development.

DESIGN OF PHASE 3 CLINICAL TRIALS

Good therapeutic research requires asking important questions and getting reliable answers. The most important clinical trials are often the most difficult to conduct.⁵⁶ They may involve withholding a treatment established by tradition, transferring patient management responsibility across specialties, standardizing procedures among physicians, and sharing recognition with a large group of collaborators.

End Points

Phase 3 trials attempt to provide guidance to practicing physicians to help them make treatment decisions with their patients.

Consequently, the trials should provide reliable information concerning end points of relevance to the patients. The major end points for evaluating the effectiveness of a treatment should be direct measures of patient welfare. Survival and symptom control are two such end points. The latter is not routinely used because of the difficulty of measuring it reliably and because it may be influenced by concomitant treatments.

Although durable complete regression of metastatic disease is usually a good surrogate for prolonged survival, partial tumor shrinkage usually is not an appropriate end point for phase 3 trials. Torri et al.⁵⁷ performed a meta-analysis of the relationship between difference in response rates and difference in median survivals for randomized clinical trials of advanced ovarian carcinoma. They found that large improvements in response rates corresponded to very small improvements in median survival. Hence, use of response rate as an end point may result in giving patients increasingly intensive and toxic therapy with little or no net benefit to them. Proper validation of an end point as a surrogate for clinical benefit requires a series of randomized clinical trials in which treatment differences with regard to the candidate surrogate are related to treatment differences with regard to clinical benefit.⁵⁸⁻⁶⁰ It is not sufficient to show that clinical outcome is related to the candidate surrogate measured on the same treatment arm as this may just reflect the known responder versus nonresponder bias.

Disease-free survival is often accepted as an important measure of clinical benefit to be used as an end point for adjuvant treatment trials. There is more controversy, however, about the use of time to progression in metastatic disease trials. The controversy relates to whether prolonged time to progression provides clinical benefit and whether it can be measured without bias. With unblinded evaluation of time to progression, there could be a reduced threshold for declaring progression for control patients so that they can cross over to the new treatment.⁶¹ Central party blinded review of progression is often used to avoid such potential bias. Because the review is not performed in real-time, however, it can introduce additional biases of “informative censoring.” Freidlin et al.⁶² proposed an approach to adjusting for increased surveillance of the control group. Dodd et al.⁶³ proposed that central review be performed only for a subset of patients to evaluate whether local assessments were biased, not to replace local assessments.

Patient Eligibility

To ensure that the results of phase 3 trials are applicable to patients seen in the community outside of clinical research settings, the trials often involve numerous centers and extensive community participation. In order to ensure broad generalization of conclusions, most multicenter phase 3 trials have employed broad eligibility criteria. In the United Kingdom, many trials have been designed using the *uncertainty principle*, an approach that leaves much of the decision making about eligibility to the treating physician. There may be guidelines for eligibility, but the ultimate decision is made by the treating physician; if he or she is uncertain about which treatment is more appropriate for the patient, the patient is eligible.

There is a growing recognition, however, that the one of the key hallmarks of cancer is intertumor heterogeneity. Tumors that arise in the same primary site are often quite different with regard to their oncogenesis, pathophysiology, and drug sensitivity. Consequently, conducting broad eligibility clinical trials with drugs only expected to be effective for an identifiable subset of patients is often no longer an appropriate research strategy.⁶⁴⁻⁶⁶ Particularly with molecularly targeted drugs, effectiveness is likely to be limited to a sensitive subset of tumors that may be characterized based on whether the molecular target of the drug is deregulated in the tumor. Even with cytotoxics, many patients are generally treated for each patient who benefits. The high costs of many molecularly targeted drugs make the traditional broad eligibility trial approach increasingly unsustainable.

Clinical trials can be conducted with fewer patients if patients are selected based on assays that identify the tumors likely to be sensitive to the drug in question. Simon and Maitournam^{67,68} and others^{69,70} have evaluated the efficiency of such targeted designs. When fewer than half of the patients “test positive” and when the new treatment has little benefit for patients who test negative, the required sample size can be dramatically reduced by restricting eligibility to patients who test positive. Simon and Zhao have made available a web-based computer program to enable investigators to compare such designs to standard broad eligibility designs (<http://linus.nci.nih.gov/brb>).

This targeted approach was effectively used for the development of trastuzumab in patients with metastatic breast cancer. In that case, about 450 patients whose tumors overexpressed HER-2 participated in a randomized clinical trial that provided convincing evidence that trastuzumab prolonged survival. Had the study been conducted without evaluating HER-2 expression, >8,000 patients would have been needed for similar statistical power.⁶⁷ Even had a huge study of unselected patients been conducted and given a statistically significant result, the size of the benefit would have been very small as the benefit in the 25% of patients with HER-2 overexpression would have been diluted by lack of benefit from the remaining 75%. It is questionable whether such a small benefit overall would have justified approval or use of a drug with clear and serious toxicities.

In many cases where the biologic credentials of a predictive biomarker are less compelling, one will want to include patients who are both marker positive and marker negative but to require that all patients have the marker evaluated, to size the trial so that there is adequate statistical power for evaluating treatment effect separately in the patients who are marker positive and to use a multiple testing method that ensures that the study-wise type I error level does not exceed 5%. Simon and others have described “all comers” designs of this type.⁷¹⁻⁷⁴ Zhao and Simon provide web-based computer programs at <http://linus.nci.nih.gov/brb> to facilitate use of such designs in clinical trials. Freidlin, McShane, and Korn⁷⁵ have described the use of biomarker designs in cancer clinical trials. These enrichment and all-comers designs presume that a single predictive biomarker with an analytically validated test and a threshold of positivity has been developed prior to the start of the phase 3 clinical trial. Because of the complexity of cancer biology, this is not always possible. Several adaptive designs have been developed to enable some aspects of biomarker specification to be included in the phase 3 trial while also rigorously evaluating the statistical significance of the treatment effect in the “biomarker positive” population. The “adaptive threshold design” avoids the requirement that the threshold of positivity be prespecified,⁷⁶ and the “adaptive signature design” enables multiple candidate biomarkers to be evaluated.^{77,78} Hong and Simon⁷⁹ developed a run-in design that permits a pharmacodynamic, immunologic, or intermediate response end point measured after a short run-in period on the new treatment to be used as the predictive biomarker. Simon, Paik, and Hayes⁸⁰ described a prospective-retrospective approach to using archived tumor specimens for a focused re-analysis of a randomized phase 3 trial with regard to a predictive biomarker. The approach requires that archived specimens be available on most patients, and that an analysis plan focused on a single marker be developed prior to performing the blinded assays. This approach was used in establishing that a K-RAS mutation was a negative predictive biomarker for response of patients with colorectal cancer to anti-epidermal growth factor receptor antibodies.

Randomization

To determine whether a new treatment cures any patients with a disease that is uniformly and rapidly fatal, history is a satisfactory control. Once we leave this setting of complete determinism, however, the definition of an adequate nonrandomized control group becomes problematic. In comparing outcomes for patients

receiving two different treatments when the treatment assignment was not randomized, often diagnostic and staging procedures and other factors used explicitly or implicitly for selecting patients for each treatment are different. Some of these factors may be difficult to quantify but strongly prognostic. Some of the factors may be previously unsuspected as being of prognostic importance. Also, supportive care, secondary treatments, and methods of evaluation and follow-up may be different for the two treatment groups. In comparisons of a new treatment to a historic control, patients receiving the new treatment are often much more highly selected than the control group. Often, there is inadequate information to determine whether prognostic differences are present, and current known prognostic factors may not have been measured for the controls. It generally is difficult or impossible to determine whether the controls would have been eligible for the current study and in what way they represent a selection of all eligible patients.

Formation of the control group by random treatment assignment as an integral part of the planned study can avoid most of the systematic biases just mentioned. Randomization does not ensure that the study will include a representative sample of all patients with the disease, but it does help to ensure an unbiased evaluation of the relative merits of the two treatments for the types of patients entered.

It is sometimes said that randomization is unnecessary because matched historic or concurrent controls can be selected. However, matching can be done only with regard to known prognostic factors, and those factors often do not account for enough of the variation in patient outcome to assure that an unbiased historic control group can be constructed. It also is sometimes said that randomization is not effective in ensuring that the treatment groups are similar with regard to unknown prognostic factors unless the number of patients is large. This is true but reflects a misunderstanding of the purpose of randomization. Randomization does not ensure that the groups are medically equivalent, but it distributes the unknown biasing factors according to a known random distribution so that their effects can be rigorously allowed for in significance tests and confidence intervals. This is true regardless of the study size. A significance level represents the probability that differences in outcome can be the result of random fluctuations. Without a randomized treatment allocation, a "statistically significant difference" may be the result of a nonrandom difference in the distribution of unknown prognostic factors.

In many cases, there is a role for both randomized and nonrandomized trials in drug development. The nonrandomized format can in some cases be used for determining which regimens are sufficiently promising for randomized phase 3 evaluation and in clinical settings in which outcome is uniformly poor. For major questions of public health importance, unless the expected treatment effect on outcome is very large, the need for reliable answers dictates the use of randomized phase 3 trials.

Randomization of a patient should be performed after the patient has been found eligible and has consented to participate in the trial and to accept either of the randomized options. A truly random and nondiscernible randomization procedure should be used and implemented by calling a central randomization office staffed by individuals who are independent of participating physicians.

Stratification

When important prognostic factors are known for patients in a randomized trial, it is often advisable to stratify the randomization to ensure equal distribution of these factors. This is usually accomplished by preparing a separate randomization list for each stratum of patients. Each list must be balanced so that after each block of 4 to 10 patients within the stratum, the treatment groups contain equal numbers of patients. Within the blocks, the sequence of treatment assignments is random. The stratification factors must be known for each patient at the time of randomization.

It is generally best to limit stratification to those factors definitely known to have important independent effects on outcome. If two factors are closely correlated, only one needs to be included. Many clinical trialists believe that stratification is an unnecessary complication because adjustment for imbalances of known factors can be made in the analysis and has negligible effect on statistical power. Stratification may help to ensure balance for interim analyses when the sample sizes may be limited and provides the medical audience with confidence in the results, which often is not available when depending on complex adjustment methods to deal with prognostic imbalances. Stratification also is a convenient way of specifying a priori what are considered the important prognostic factors.

Many clinical trials use dynamic stratification methods. The most popular such method is that conceived by Pocock and Simon,⁸¹ which permits effective balancing with regard to many prognostic factors. There has been some concern about the effect of adaptive stratification on analysis of treatment differences. Multiple studies, including those by Kalish and Begg,⁸² have demonstrated that if the stratification factors are included in the model used for final analysis, the effect of adaptive stratification is to make the true type I error less than the nominal rate, hence the analyses are slightly conservative. Simon and Simon⁸³ showed that model-based analyses are not necessary to use with adaptive stratification methods. One can define a linear test statistic that reflects the treatment effect difference on the outcome adjusted for the stratification variables, and generate the null distribution of the test statistic by reapplying the adaptive stratification method. The Pocock-Simon⁸¹ method of adaptively stratified treatment assignment is not deterministic. Consequently, one can replicate the stratified treatment assignments, holding fixed the order of patient registrations and the stratification variables of the patients, recompute the value of the test statistic for the rerandomized treatment assignment, repeat this process a thousand times, and thereby generate the null distribution of the test statistic. Consequently, although the use of adaptive stratification methods, like the use of all stratification methods, are not essential, the criticisms of their effect on final analyses are unjustified.

Sample Size

The protocol for a phase 3 trial should specify the number of patients to be accrued and the duration of follow-up after the close of accrual when the final analysis will be performed. Methods of sample size planning are usually based on the assumption that at the conclusion of the follow-up period, a statistical significance test will be performed comparing the experimental treatment to the control treatment with regard to a single primary end point. A statistical significance level of 0.05 means that if there is no true difference in treatment effectiveness, the probability of obtaining a difference in outcomes as extreme as that observed in the data is 0.05. The significance level does not represent the probability that the null hypothesis is true; it represents a probability of an observed difference, assuming that the null hypothesis is true. Conventional statistical theory ascribes no probabilities to hypotheses, only to data.

A one-sided significance level represents the probability, by chance alone, of obtaining a difference as large as and in the same direction as that actually observed. A two-sided significance level represents the probability of obtaining by chance a difference in either direction as large in absolute magnitude as that actually observed. The two-sided significance level is usually twice the one-sided significance level. Controversy exists over the appropriateness of one-sided or two-sided significance levels. Although this is a somewhat trivial issue, a two-sided significance level of 0.05 has become widely accepted as a standard level of evidence.

The probability of obtaining a statistically significant result when the treatments differ in effectiveness is called the *power* of the trial. As the sample size and extent of follow-up increases, the power increases. The power depends critically, however, on the

TABLE 36.7

Number of Events Needed for Comparing Survival Curves

50	2.0	88

^aTotal number of deaths in both groups to have power = 0.90 for detecting ratio of median survival. Type I error α = 0.05 (two-sided).

size of the true difference in effectiveness of the two treatments. Generally, one sizes the trial so that the power is either 0.80 or 0.90 when the true difference in effectiveness is the smallest size that is considered medically important to detect.

Statisticians have developed useful methods for planning sample size to compare survival curves or disease-free survival curves in phase 3 trials. Table 36.7 shows the number of total events needed assuming that the *hazard ratio*—the ratio of forces of mortality for the two treatment groups—is constant over time.⁵⁴ Table 36.7 shows the total number of events that must occur in a given cohort to provide 90% power for detecting a specified reduction in the hazard for the experimental treatment relative to the control

treatment. For exponential distributions, the percentage reduction in hazard of death can be expressed as a ratio of median survivals, which is displayed in the second column of Table 36.7. When the primary end point is overall survival, the events are deaths; for disease-free survival curves, events are deaths or recurrences. The translation of the number of deaths or events required to the number of patients required depends on the actual shape of the survival distributions, the rate of accrual, and the duration of follow-up after close of accrual. Generally, however, it is best to specify the time of the final analysis as the time when the specified number of deaths or events is obtained—not in terms of absolute calendar time.

In some cases, it may be convenient to think in terms of the proportion of patients without progression or death beyond some landmark time, such as 5 years. Tables 36.8 and 36.9 provide required numbers of patients for clinical trials planned on this basis. This approach is less flexible for studies in which survival or disease-free survival is the end point, as it presumes that all patients will be followed for the landmark time as a minimum. These tables can, however, be used generally for detecting differences in a binary end point, denoted *success rate* in the tables. For comparing treatments in phase 3 trials, differences of >15 to 20 percentage-points usually are considered unrealistic. Establishing a sample size that provides good statistical power for detecting realistically expected treatment improvements is important. Many published “negative” results are actually uninterpretable because the sample sizes are too small.⁸⁵

FACTORIAL DESIGNS

The 2^k factorial design was described in the section on randomized phase 2 trials, but it can also be used for phase 3 trials. The two-by-two factorial design is the version most often used. There are four treatment groups: one receiving neither of the two drugs

A or B, one receiving A, one receiving B, and one receiving both. Although there are four treatment groups, the average effect of each treatment factor can be evaluated using all of the patients. To evaluate the effect of A, you compare outcomes for patients receiving A to outcomes for those not receiving A, ignoring B. Usually, the sample size for a two-by-two factorial trial is computed assuming that there is no interaction between the effects of the two drugs. The sample size is approximately the same as for a simple two-arm trial. The factorial design offers the possibility of answering two questions for the cost of one, but there is a risk of ambiguity in the interpretation of results.⁸⁶ For situations in which negative interactions are unlikely or in which it is unlikely that both factors will have substantial effects, the factorial design can provide a substantial improvement in the efficiency of clinical trials.

Simon and Freedman⁸⁷ developed a Bayesian method for the design and analysis of factorial trials. Their approach avoids the need to dichotomize one's assumptions that interactions either do or do not exist, and provides a flexible approach to the design and analysis of such clinical trials. The Bayesian approach also avoids a preliminary test of interaction; such tests have poor power and basing the analysis on such tests is problematic. The Bayesian model suggests that in planning a factorial trial in which interactions are unlikely but cannot be excluded, the sample size should be increased by approximately 30%, as compared to a simple two-arm clinical trial for detecting the same size of treatment effect. The 30% figure allows for a 5% prior probability of a medically important, qualitative interaction between the treatment effects.

Noninferiority Trials

Noninferiority trials often compare a standard treatment to a less invasive or more convenient therapy that is not expected to be superior to the standard treatment with regard to the primary end point.

For such trials, the secondary benefits of the new regimen, while important, is not worth reductions in effectiveness in the primary end point. Unfortunately, it is not possible to establish that the two treatments are completely equivalent with regard to the primary end point. The usual approach is to plan the trial to have high statistical power for detecting small reductions in effectiveness, and this requires a large sample size. Because failure to reject the standard null hypothesis of no treatment difference results in adoption of a new, and potentially inferior, regimen, misinterpretation of the results of noninferiority trials can result in serious problems. For the analysis of such trials, confidence intervals rather than statistical significance tests should be emphasized.⁸⁸ The confidence interval for the true difference of effectiveness gives a much clearer picture of which differences are consistent with the data. Makuch and Simon⁸⁹ and Durrleman and Simon⁹⁰ discuss this approach for planning and monitoring therapeutic equivalence trials.

Noninferiority trials are generally planned to distinguish the null hypothesis that the treatments are equivalent from the alternative that the new treatment is inferior by an amount δ . One of the key problems in designing a noninferiority trial is specification of δ . A small value of δ leads to a large trial. A large value of δ can lead to a small but meaningless trial. The reduction in effectiveness that the trial will be able to detect should be some fraction of the effectiveness of the standard treatment. For example, suppose the standard treatment is 12 months of a chemotherapy regimen that increases 5-year survival by 10 percentage-points relative to no chemotherapy and the new regimen of interest is use of the same regimen for only 6 months. If we want to have high power for detecting a reduction in effectiveness by half, then δ should represent a difference of 5 percentage-points in 5-year survival. If we want high power for detecting a reduction in effectiveness by one-quarter, then δ should represent a difference of 2.5 percentage-points in 5-year survival. An appropriate value of δ can only be determined based on a careful review of the studies that established the

effectiveness of the standard treatment. If those studies do not exist or are not adequate, a noninferiority trial may not be appropriate.

Another problem in the design of noninferiority trials is the lack of internal validation of the assumption that the control treatment is actually effective for the patient population at hand. If the effectiveness of the standard treatment is highly variable among studies, there is the risk that a new regimen will be found noninferior to the standard because the standard is not effective in the current study. Consequently, noninferiority trials are only appropriate when the standard regimen is highly and reproducibly effective.

None of the conventional frequentist approaches to the design and analysis of therapeutic equivalence trials satisfactorily account for the uncertainty in estimation of the effectiveness of the standard treatment. Simon⁹¹ developed a Bayesian approach that addresses this problem. The effectiveness of the control treatment C relative to the previous standard (P) is represented by a parameter β . Information about the effectiveness of C relative to P is summarized by a prior distribution, which is normal with mean μ_β and standard deviation σ_β . These values are obtained from a random-effects meta-analysis of the previously conducted randomized trials comparing C to P. The result of the noninferiority trial is summarized by an estimate $\hat{\delta}$ with standard error of the effectiveness of test regimen E relative to C. With some simplifying assumptions, the posterior distribution of the effectiveness of E relative to P is a normal distribution with mean $\mu_\beta + \hat{\delta}$ and variance $\sigma_\beta^2 + \sigma^2$. Simon⁹⁰ also shows how the sample size of the therapeutic equivalence trial may be planned and how the size depends critically on the strength and consistency of the evidence that the active control C is superior to P and on the size of that difference in effectiveness.

Bayesian Methods

Conventional statistical methods (i.e., *frequentist method*) regard the data collected in an experiment as being random; they test hypotheses about parameters that represent fixed but unknown treatment effects. For example, frequentist methods derive probability statements about differences in observed response rates under an assumed null hypothesis that the true response probabilities are equal. *Bayesian* statistical methods consider the parameters, as well as the data, as being random and selected from *prior distributions*. What does the assumption that the true treatment effect is a random draw from a prior distribution mean? One interpretation is that we regard the prior distribution as expressing our subjective beliefs about the value of the treatment effect based on previous experience with this treatment and other similar treatments. Such subjective prior distributions would vary among individuals based on their experience, biases, circumstances, and perhaps economic interests. Bayesian methods use Bayes' theorem to update the prior distributions of the parameters based on data from the study to produce the posterior distributions of the parameters. Using the posterior distributions, hypotheses about whether the treatments are equivalent can be tested. Consequently, Bayesian methods can derive direct probability statements about the parameters, such as "the probability that the treatment effect is 0.04." The probability statements about the parameters seem to tell us what we want to know, but the results may depend as much on our prior distributions as on the data.

Many Bayesian statisticians use "noninformative" prior distributions. For example, a noninformative prior distribution for the difference in response probabilities might be constant for all differences between -1 and $+1$. That noninformative prior represents the belief that huge differences are just as likely as small differences, positive differences as likely as negative differences. Consequently, methods based on apparently innocuous noninformative prior distributions may not be appropriate for real-world studies. In some cases, the treatment being evaluated can be considered "exchangeable" with other treatments that have been previously evaluated and a prior distribution can be defined based on that

previous experience. Spiegelhalter, Freedman, and Parmar⁹² have suggested analysis of a clinical trial with regard to both an "enthusiastic" prior and a "skeptical" prior. The former might be held by a developer of the treatment and the later by a regulator. Robust conclusions are obtained when the data is so extensive and strong that the posterior distributions are little changed regardless of whether you use an enthusiastic or skeptical prior. Unfortunately, such robustness generally requires a very large sample size, much larger than indicated by use of standard frequentist methods. For some parameters, there may be a consensus prior distribution. For example, for evaluating cytotoxics there was generally broad consensus that large treatment-effect by patient-subset interactions were unlikely, and Simon⁹³ used this in a Bayesian approach to subset analysis. Generally, however, there is no meaningful prior consensus about the effect of treatment. Randomized clinical trials are done because the opinions of experts are often wrong. The subjective nature of the prior distribution is problematic for the interpretation of phase 3 clinical trials.

There are several important misconceptions about the use of Bayesian methods for clinical trials. First, some people believe that Bayesian methods provide an adequate alternative to randomized treatment assignment. In fact, however, randomization is just as important for the validity of Bayesian methods as for frequentist methods.⁹⁴ Second, some people mistakenly believe that Bayesian clinical trials require fewer patients than frequentist trials. Bayesian sample size calculations depend on the prior distribution used. Using *skeptical priors*, the sample size needed with Bayesian methods may be much larger than the conventional sample size. Third, some statisticians believe that the main impediment to use of Bayesian methods in clinical trials has been the difficulty of computing posterior distributions. The main limitation has, however, been the fact that subjectivity of analysis is problematic for phase 3 clinical trials.

Bayesian methods can be very useful for phase 1 and phase 2 trials. For such trials, the prior distribution need only be appropriate for the investigator or sponsor. For phase 3 trials, the situation is more complex. Bayesian methods are applicable to phase 3 problems in which a consensus prior is appropriate. Such priors are possible for parameters representing interaction effects,⁹⁵ for the effectiveness of active controls in noninferiority trials,⁹¹ and for unexpected findings with multiple safety end points.⁹⁵ As indicated previously, however, subjective opinion of the investigator or sponsor should have no role in testing the primary hypothesis of whether the new treatment is better than the control for the prespecified target population. Once the basic effectiveness of the treatment is established, however, there are many other analyses that can help physicians decide how to use the new treatment. Those analyses generally cannot be answered as precisely or with as little chance of error as the testing of the primary null hypothesis. Different physicians may have varying prior beliefs about the treatment and how its effectiveness might vary among patients; Bayesian methods may be useful for physicians in determining how to implement the results in the context of the patients they see. One must recognize, however, that Bayesian models can be overfit to data like any other models and can produce poor predictions.

ANALYSIS OF PHASE 3 CLINICAL TRIALS

Intention-to-Treat Analysis

The *intention-to-treat* principle indicates that all randomized patients should be included in the primary analysis of the trial. For cancer trials, this has often been interpreted to mean all "eligible" randomized patients. Excluding patients from analysis because of treatment deviations, early death, or patient withdrawal can severely distort the results.⁹⁶⁻⁹⁸ Often, excluded patients have poorer outcomes than do those who are not excluded. Investigators

frequently rationalize that the poor outcome experienced by a patient was due to lack of compliance to treatment, but the direction of causality may be the reverse. For example, in the Coronary Drug Project, the 5-year mortality for poor adherents to the placebo regimen was 28.3%, significantly greater than the 15.1% experienced by good adherents to the placebo regimen.⁹⁹ In randomized trials, there may be poorer compliance in one treatment group than the other, or the reasons for poor compliance may differ. Excluding patients, or analyzing them separately (which is equivalent to excluding them), for reasons other than eligibility is generally considered unacceptable. The intention-to-treat analysis with all eligible randomized patients should be the primary analysis. If the conclusions of a study depend on exclusions, these conclusions are suspect. The treatment plan should be viewed as a policy to be evaluated. The treatment intended cannot be delivered uniformly to all patients, but all eligible patients should generally be evaluable in phase 3 trials.

Interim Analyses

If statistical significance tests are performed repeatedly, the probability that the difference in outcomes will be found to be statistically significant (at the 0.05 level) at some point may be considerably $>5\%$. This probability is called the *type I error* of the analysis plan. Fleming, Green, and Harrington¹⁰⁰ have shown that the type I error can be as great as 26% if a statistical significance test is performed every 3 months of a 3-year trial that compares two identical treatments. Some trials are published without stating the target sample size, without indicating whether a target sample size was stated in the protocol, and without describing whether the published analysis represented a planned final analysis or was one of multiple analyses performed during the course of the trial. In such cases, one must suspect that the investigators were not aware of good statistical practices and of the dangers of informal multiple analyses.

Interim analyses can be very misleading and interfere with a physician's attempt to state honestly to the patient that there is no reliable evidence indicating that one treatment option or the other is preferable. Consequently, it has become standard in phase 3 multicenter clinical trials to have a data-monitoring committee review interim results, rather than having the monitoring done by participating physicians. This approach helps to protect patients by having interim results carefully evaluated by an experienced group of individuals and helps to protect the study from damage that ensues from misinterpretation of interim results.^{101,102} Generally, interim outcome information is available to only the data-monitoring committee. The study leaders are not part of the data-monitoring committee, because they may have a perceived conflict of interest in continuing the trial. The data-monitoring committee determines when results are mature and should be released. These procedures are used only for phase 3 trials.

A number of useful statistical designs have been developed for monitoring interim results. The simplest is due to Haybittle.¹⁰³ Interim differences are discounted unless the difference is statistically significant at the two-sided $p < 0.0025$ level. If the interim differences are not significant at that level, the trial continues until its originally intended size. The final analysis is performed without regard to the interim analyses, and the type I error is almost unaffected by the monitoring. Many others have developed group-sequential methods for interim monitoring based on a prespecified number of planned interim analyses. One of the most commonly used methods is that of O'Brien and Fleming.¹⁰⁴ The critical p value for determining whether an interim difference should be judged statistically significant depends on the number of analyses that will be performed during the trial. For a five-stage trial—four interim analyses and one final analysis—the critical p values are shown in Table 36.10.¹⁰⁵ The experience of the US

cancer cooperative groups with interim analysis of phase 3 clinical trials was reviewed by Korn, Freidlin, and Mooney.¹⁰⁶

Extreme treatment differences at an interim analysis are less usual in cancer clinical trials than finding that interim results do not support the hypothesis that the experimental treatment is substantially better than the control. Futility analyses are important in order to avoid exposing patients to a more toxic and debilitating new treatment E once the essential outcome of the trial is well assured.¹⁰⁷ Data-monitoring committees are charged with helping to make these difficult judgments. A variety of statistical approaches to “futility monitoring” have been developed.¹⁰⁸ Goldman, LeBlanc, and Crowley⁴⁸ have shown that futility analyses based on intermediate end points like disease-free survival can be particularly effective even in trials where the primary endpoint is survival.

The method of stochastic curtailment¹⁰⁹ is widely used for “futility analyses.” At any interim analysis, the probability of rejecting the null hypothesis at the end of the trial is computed. This probability is calculated as being conditional on the data already obtained and on the assumption that the alternative hypothesis of superiority of the experimental treatment used initially in planning the sample size for the trial is true. If this conditional power is less than approximately 0.20, then the trial may be terminated with acceptance of the null hypothesis. The 0.20 cutoff can be raised substantially to at least 0.40 if this type of interim analysis is performed only a few times during the course of the trial. With stochastic curtailment, interim analyses need not be equally spaced, and the number of interim analyses need not be specified in advance.

Significance Levels, Hypothesis Tests, and Confidence Intervals

Medical decision making is complicated, and clinicians frequently misinterpret statistical significance tests in search of clear-cut answers from ambiguous data. A statistical significance level for comparing outcomes represents the probability of obtaining a difference as large as that actually observed if the treatments were actually of equal efficacy and differences occur merely by chance. After significance tests had been used for many years, Neyman and Pearson formalized a mathematical theory of hypothesis testing. In this theory, a study must prespecify a null hypothesis, an alternative hypothesis, and a decision rule for accepting one hypothesis and rejecting the other based on the data obtained. The theory has appealed to clinicians because it simplifies complex medical decision making by providing yes or no answers: either the difference is statistically significant or it is not. The distinction between one- and two-sided decision rules becomes crucial because a one-sided $p = 0.05$ is simply nonsignificant if a type I error of 0.05 based on a two-sided decision rule is prespecified.

The concept of prespecification of hypotheses is important for medical experimentation. However, the accept–reject nomenclature of the Neyman-Pearson theory provides an oversimplified and sometimes misleading interpretation of the data. Significance levels can serve as useful aids to interpretation of results, but quibbling about whether a one-sided $p = 0.04$ is significant makes little sense. Significance levels are influenced by sample sizes, and failure to reject the null hypothesis does not mean that the treatments are equivalent. There is no simple index of truth for interpreting results. Some attempt to use the notion of statistical significance in this way, but thorough presentation, skeptical evaluation, and cautious interpretation of results always are required.

Confidence intervals are generally much more informative than are significance levels. A confidence interval for the size of the treatment difference provides a range of effects consistent with the data. The significance level tells nothing about the size of the treatment effect because it depends on the sample size. However, it is the size of the treatment effect, as communicated by a confidence interval, that should be used in weighing the costs and benefits of clinical decision making. Many so-called negative results are actually noninformative, and confidence intervals help to determine when this is the case. Simon⁸⁸ has presented a non-technical discussion of how to calculate confidence intervals for treatment differences with the types of end points commonly used in cancer clinical trials.

Calculation of Survival Curves

Most cancer clinical trials display results by showing survival curves or disease-free survival curves. Survival curves display the probability of surviving beyond any specified time, with time shown on the horizontal axis. In disease-free survival curves, it is the time until recurrence or death that is shown. Other time-to-event distributions can be similarly represented using the same methods. The usual statistical methods are not appropriate for analyzing survival because they ignore the fact that surviving patients have a limited follow-up period after which their survivals are “censored.”

The most satisfactory way of representing such data is to estimate the survival function $S(t)$. This function represents the probability of surviving more than t time units. Time t is measured from diagnosis, start of treatment, or some other meaningful time point. For randomized studies, it is best to measure time from the date of randomization. There are basically two satisfactory methods for estimating $S(t)$. The first is the life table or actuarial method^{110,111} and is appropriate when the number of patients is large. The other method is the product limit method of Kaplan and Meier.¹¹² This method is appropriate for any number of patients, but it involves

more effort than the life table method when the number of patients is large.

The first step in the application of either method is the calculation of survival time for all patients. Survival is the duration from the chosen baseline (e.g., date of randomization) until death or date last known to be alive for patients who are not known to have died. To use the life table method, intervals for the grouping of survival times are determined. The life table, shown in Table 36.11, is then filled out. This sample life table is prepared with yearly intervals in the first column. The number of patients alive at the beginning of the interval is entered in column 2. The number who died in the interval is entered in column 4. Patients dying exactly at a time that represents a boundary between two intervals (e.g., 365 days) are considered to have died in the preceding interval (e.g., 0 to 1 year). Column 3 contains the number of patients who are lost to follow-up during the interval or who are alive with maximum follow-up duration included in the interval. These latter patients are referred to as *withdrawn alive* in the conventional life table terminology. The life table method assumes that patients lost to follow-up or withdrawn alive during the interval are at risk of death for one-half of the interval. Hence, column 5—the number alive at the start of the interval minus half the number lost or withdrawn during the interval—represents an approximate number of patients at risk of death during the interval. Column 6 gives the ratio of the number of patients who died during the interval to the number at risk during the interval. Column 7 gives the estimated probability of surviving the interval for patients alive at the start of the interval.

Column 8 should be studied carefully, because it provides the life table estimate of the survival distribution and indicates the logic behind the method. The probability of surviving >3 years after randomization, for example, equals the entry in the third row of column 8 (0.50). The logic is as follows: To survive 3 full years, the patients must survive through the first year; and given that they have survived the first year, they must survive the second year; and given that they have survived the second year, they must survive the third year. Consequently, the probability of surviving for at least 3 years is estimated by the product $p_1 \times p_2 \times p_3$ of factors in column 7. By using this product, the life table method takes maximal advantage of the mortality experience of patients with limited follow-up. The entry S_x in column 8, row x , represents the life table estimate of the probability of surviving more than x years from randomization. Computational shortcuts to observe are those for column 8 ($S_x = p_x = S_{x-1}$) and for column 2 ($l_{x+1} = l_x - w_x - d_x$).

The product limit method of Kaplan and Meier¹¹² is similar in concept to the life table method. With the Kaplan-Meier approach, however, the intervals are defined by the actual survival times of patients who have died. Suppose, for example, that the survivals are 3, 3, 3+, 5, 6, 8+, 8+, 10, 10, and 12+ months,

TABLE 36.11

where a plus sign follows survivals for patients still alive. Then the intervals are 0 to 3, 3 to 5, 5 to 6, and 6 to 10 months, as shown in Table 36.12. With the Kaplan-Meier method, deaths occur only at the ends of intervals. The entry in column 5 equals $l_x - w_x$ rather than $l_x - 2w_x$ for the life table method. This is because deaths occur only at the ends of intervals here, and the number of patients at risk of death just before the interval end is $l_x - w_x$. In the entry w_x in column 3 for the Kaplan-Meier method, patients who are lost to follow-up or withdrawn alive at the end of an interval are considered not lost or withdrawn until the following interval. These differences between the Kaplan-Meier and life table methods render the former more appropriate for studies with fewer patients.

Once the values S_x have been calculated for the Kaplan-Meier method, they may be graphed with time on the horizontal axis. The graph is a step function that starts at time zero and ordinate 1.0. It drops to value S_x at time x , where x is the time at the right end of an interval. The survival curve corresponding to Table 36.12 is shown in Fig. 36.1. The tic marks are placed on the curve at 3, 8, and 12 months to represent the follow-up times of living patients. The step function can be extended horizontally out to 12 months to represent follow-up of the last patient, but the right-hand end of the curve usually is very imprecisely estimated, and concluding that a plateau exists at the level shown on the curve is often erroneous.

For any time t , the Kaplan-Meier curve is an estimator of the true unknown value of $S(t)$. The estimator is approximately normally distributed in large samples. If m patients remain alive at time x ,

Figure 36.1 Example of estimated survival distribution.

the standard error of the estimate can be conservatively estimated⁴⁴ as the Kaplan-Meier estimate of a survival distribution is based on the assumption that censoring is noninformative, which means that the censoring time is independent of the prognosis of the patient. Most censoring in a randomized clinical trial results from the fact that some patients are alive and still being followed at the time of analysis. This is noninformative censoring. However, if patients are lost to follow-up—if they fail to return to clinic when they are too sick to travel—then the censoring is informative and all the usual methods of survival analysis are invalidated. Consequently, it is essential to obtain follow-up information actively on *all* patients before analysis. If some patients have not been contacted for many months and their status is unknown, that information should be obtained before any analysis is performed. Examining the distribution of time since the last contact for patients not known to have died is a good way to examine the adequacy of follow-up.

The issue of informative censoring also arises in considering end points other than death. For example, one may be attempting to estimate the distribution of time until tumor recurrence in the central nervous system (CNS) in a pediatric leukemia trial. How should one handle patients whose disease recurs in the marrow without evidence of CNS recurrence? One may be tempted to censor the time to CNS recurrence of such patients at their time of marrow recurrence, but that implicitly assumes that the censoring is noninformative. Because CNS and marrow recurrence may be biologically linked, the assumption of noninformative censoring may not be valid. Other issues of informative censoring can be similarly problematic. Clearly, one should never censor patients because of lack of compliance with therapy, as this can severely bias results. More extensive discussions of statistical methods for the analysis of clinical trial data are given by Marubini and Valsecchi.¹¹³

Multiple Comparisons

Table 36.13 shows the probability of obtaining one statistically significant ($p < 0.05$) difference by chance alone as a function of the number of independent comparisons of two equivalent treatments. With only five comparisons, the chance of at least one false-positive conclusion is 22.6%. When the number of end points, interim analyses, and patient subsets are considered in the analysis of clinical trials, these results are disturbing.¹¹⁴ The comparisons performed in clinical trials are not entirely independent, but this does not have much effect on ameliorating the problem. Fleming and Watelet¹¹⁵ performed a computer simulation to determine the chance of obtaining a statistically significant treatment difference when two equivalent treatments in six subsets determined by three dichotomous variables are compared. The chance of a statistically significant difference between treatments in at least one subset was 20% at the final analysis and 39% in the final or one of the three interim analyses. Subset analysis, comparison of treatments

TABLE 36.13

Probability of Obtaining at Least One Statistically Significant ($P < 0.05$) Difference by Chance Along in Multiple Comparisons of Two Equivalent Treatments

Comparisons	Probability of at Least One "Significant" Difference (%)

2	9.7
3	14.3
4	18.5
5	22.6
10	40
20	64.1

with regard to multiple end points, and multiple interim analyses are common sources of erroneous conclusions. The primary end point should be defined in the protocol. Subset analyses and analyses with regard to secondary end points should be specified in advance, and statistical significance should be declared only for significance levels much defined in advance to limit the study-wise type I error to 5%.

Generally, it is not valid to adjust the analysis by characteristics measured after the start of treatment (e.g., compliance, dose delivered, toxicity). New approaches to subset analysis and multiple end point analysis using Bayesian methods have been described by Dixon and Simon.^{93,116} Qualitative interaction tests are described by Gail and Simon.¹¹⁷

REPORTING RESULTS OF CLINICAL TRIALS

Effective reporting of results is an integral part of good research. Unfortunately, numerous reviews have indicated that the quality of reporting of clinical trial results is poor.^{98,118,119} Pocock et al.¹²⁰ concluded that "overall, the reporting of clinical trials appears to be biased toward an exaggeration of treatment differences." Tanock and Murphy^{98,114} have given clear illustration of how this is easily done. The guidelines summarized in Table 36.14 are adapted from those proposed by Simon and Wittes.¹²¹

FALSE POSITIVE REPORTS IN THE LITERATURE

Many of the positive results reported in the literature for small clinical trials are probably false positive results.¹²²⁻¹²⁴ In 100 trials, suppose that there are 10 in which the experimental treatment is sufficiently better than the control such that there is a 90% chance of the difference being detected in a small or moderate-sized clinical trial. Of these 10 trials, obtaining a statistically significant difference is expected in 9. Of the remaining 90 trials, we assume that the treatments are approximately equivalent to the control. A statistically significant difference could be expected in 5% (4.5) of these. Hence, of the 13.5 (9 + 4.5) trials that yield statistically significant results, the finding is false positive in 4.5 or 33% of the cases. The 33% false discovery rate is striking but it depends on the assumption that only 10% of the trials study new treatments with large treatment effects. For large clinical trials, the size of treatment effect that can be detected with high statistical power is likely to be larger. The Eastern Cooperative Oncology Group reported that about one-third of their phase 3 clinical trials resulted in statistically significant results.¹²³ Assuming that most of these trials are

TABLE 36.14

Summary of Guidelines for Reporting Clinical Trials¹¹⁶

- Quality control of data and response evaluations should be discussed.
- All patients registered on study should be accounted for.
- Inevaluability rate for major end points should not exceed 15%.
- No exclusions of eligible patients in comparing outcomes by treatment group.
- The sample size should be large enough to establish or conclusively rule out effects of clinically important magnitude. Confidence limits for size of treatment versus control effectiveness should be given.
- Publication should provide protocol-specified sample size and interim analysis plan as well as actual timing of analyses.
- Claims of therapeutic effectiveness should not be based on phase 2 trials.
- Generalizability of conclusions should be carefully discussed. Subset-specific claims should be justified based on prospective planning and statistical control of study-wise type I error.

conducted with 90% power and a 5% statistical significance level, the false positive discovery rate is about 9%.

An additional factor to consider is that of publication bias,¹²⁵ which denotes the preference of journals to publish positive rather than negative results. A negative result may not be published at all, particularly from a small trial. If it is published, it is likely to appear in a less widely read journal than it would if the result were positive.

These observations emphasize that results in the medical literature often cannot be accepted at face value. It is important to recognize that "positive" results need confirmation, particularly positive results of small studies, before they can be believed and applied to the general population.

META-ANALYSIS

A *meta-analysis* is a quantitative summary of research on a topic. It is distinguished from the traditional literature review by its emphasis on quantifying results of individual studies and combining results across studies. Key components of this approach for therapeutics are to include only randomized clinical trials, to include all relevant randomized clinical trials that have been initiated (regardless of whether they have been published), to exclude no randomized patients from the analysis, and to assess therapeutic effectiveness based on the average results pooled across trials.¹²⁶

Attention is restricted to randomized trials, because the bias from nonrandomized comparisons may be larger than the small to moderate therapeutic effects likely to be present. Including all relevant randomized trials that have been initiated in a geographic area (e.g., the world, or the Americas and Europe) represents an attempt to avoid publication bias. Avoiding exclusion of any randomized patients also functions to avoid bias. Assessing therapeutic effectiveness based on average pooled results is an attempt to make the evaluation on the totality of evidence rather than on extreme isolated reports. In calculating average treatment effects, a measure of difference in outcome between treatments is calculated separately for each trial. For example, an estimate of the logarithm of the hazard ratio can be computed for each trial. A weighted average of these study-specific differences is then computed, and the statistical significance of this average is evaluated. This approach to meta-analysis requires access to individual patient data for all randomized patients in each trial. It also requires collaboration of the leaders of all the relevant trials and is very labor-intensive. Nevertheless, it represents the gold standard for meta-analysis methodology.

A major issue of concern in meta-analyses is whether the individual trials are sufficiently similar to make calculation of average effects medically meaningful. If the therapeutic interventions or control treatments differ too greatly or if the patient populations are too different, the results may not be medically meaningful as a basis for making treatment decisions for individual patients. Often in cancer therapeutics, the studies will not be identical in their treatment regimens or their patient populations, but they will not be so different as to make the results meaningless. In this case, the meta-analysis may be useful for answering important questions about a class of treatments that the individual trials cannot address reliably. For example, trials evaluating adjuvant treatment of primary breast cancer often are designed to detect differences in disease-free survival, and a meta-analysis is often required to

evaluate survival. Similarly, subset analysis can usually be meaningfully evaluated only in the context of a meta-analysis, because individual trials are not sized for this objective.

Meta-analysis is not an alternative to properly designed and sized randomized clinical trials. Some have suggested that one need not be concerned about computing sample size in the traditional ways, as small, randomized trials can be pooled for meta-analysis. Because most investigators would prefer to "do their own thing," this would lead to a proliferation of diverse trials of inconsequential individual size that may be too heterogeneous to permit a meaningful meta-analysis. Given that sufficient large, randomized clinical trials of very similar treatment regimens have been conducted, meta-analysis can provide supplemental information about a given class of treatments that is not available from the individual trials.

37 Molecular Biology of Head and Neck Cancers

Thomas E. Carey and Mark E. P. Prince

INTRODUCTION

Incidence, Risk Factors, and Etiology

Head and neck squamous cell carcinoma (HNSCC) accounts for 90% of all malignant disease in the head and neck region of the body. With 550,000 new cases diagnosed worldwide each year, HNSCC is a major public health problem. In the United States, there are 40,000 new cases and roughly 14,000 deaths from HNSCC each year. Historically, HNSCC has been a disease of older males with heavy lifelong tobacco use, high alcohol consumption, poor diet, and bad dentition. As smoking increased among women, the male to female ratio of 5:1 observed in the 1960s declined to 3:1 in the 1990s. Most mucosal squamous cancers of the head and neck, particularly those of the oral cavity, larynx, and hypopharynx are still associated with these etiologic factors as well as other cultural habits, such as oral tobacco use, and in other countries, betel and areca nut chewing.^{1,2} A small but mysterious segment of head and neck tumors arise in individuals under 40 years of age who have no known etiologic factors. In the past 10 years, we noted that at our institution, HNSCC patients under age 35 included more women than men, and during this period, four cases of tongue cancer in pregnant women were also observed.³ The etiology of the cancers in the men and women in the young age group is unknown. A small percentage of HNSCC have a familial origin; however, when corrected for tobacco and alcohol use, most associations lose statistical significance.⁴ Nevertheless, familial head and neck cancers associated with inherited defects of the *CDKN2A* locus causing loss of function of the cyclin-dependent kinase inhibitor p16INK4A⁵ and the *hMDM2* regulator p14ARF occur. Two members of a family were treated recently for HNSCC in our department. An analysis revealed that each had the same somatic *CDKN2A* mutation. Families with inherited mutations of cancer-related genes tend to have multiple types of malignant tumors, and second primary tumors of different histologic types.⁶ In fact, *CDKN2A* was originally called multiple tumor suppressor gene 1 (*MTS-1*)^{7,8} because it was so frequently mutated in multiple tumor types, including melanoma, pancreatic cancers, breast cancers, and head and neck cancers. The genes associated with an inherited predisposition to head and neck cancer include the master regulator, *TP53* (Li-Fraumeni syndrome),⁹ and Fanconi anemia genes, the *FANC* family of DNA repair genes that are also associated with the development of HNSCC.^{10,11} Head and neck cancers arising in young patients and others that are independent of tobacco exposure provide a rich area for an in-depth molecular assessment to determine the underlying genetic factors.

High-Risk Human Papillomaviruses

As smoking has declined in the United States, so has the incidence of smoking-related head and neck cancer, particularly

those of the oral cavity and larynx, while at the same time there has been a steady increase in tonsillar cancers.¹² Trends for head and neck cancer incidence by site in the United States and Canada indicate that oropharynx cancers have increased continuously over the past 25 years.^{9,13} The oropharyngeal cancer increase began in the late 1970s and is attributed to increased rates of infection with high-risk human papillomaviruses (hrHPV) secondary to changing sexual mores that are traceable to widespread use of oral contraceptives, reduced use of condoms, and freedom to have more sexual partners, without the fear of an unwanted pregnancy. Studies in the United States, Canada, and Western Europe clearly show a trend for increasing incidence of hrHPV, notably, HPV16 in oropharyngeal cancers by year of diagnosis.^{14–22} At our institution, there was a steady increase in the proportion of HPV-positive oropharynx cancer in three clinical trials done over the past decade (Table 37.1). Surveillance, Epidemiology, and End Results (SEER) data illustrate the decline in smoking-related cancers of the larynx, the increase in oropharyngeal cancer, and the remarkable decline in cervical cancer that is attributable to an early diagnosis with Pap smears, hrHPV testing, and colposcopy of cervical lesions (Fig. 37.1). In 2013, the incidence of new oropharyngeal cancer cases was expected to surpass that of cervical cancer. Unfortunately, no early detection and treatment for HPV-induced oropharynx cancer is available, but this is a rich area for investigation.

HPV is the most common sexually transmitted disease with an overall genital HPV prevalence of 42.5% in females 14 to 59 years of age as determined in the National Health and Nutrition Examination Survey (NHANES) (2003–2006).²³ In the oral cavity and oropharynx, the lymphoid-rich tissue of the tonsils is the likely reservoir of HPV. To replicate, HPV must infect the basal epithelial cell. The thin epithelium of the tonsillar crypts serves as an ideal location for the virus to infect (Fig. 37.2). HPV infection may be facilitated by concurrent inflammation within the tonsil due to other microorganisms. D'Souza et al.²⁴ conducted a hospital-based case control study of 100 patients with newly diagnosed oropharynx cancer to 200 noncancer patients to evaluate associations between HPV infection and oropharyngeal cancer. A high lifetime number of vaginal sex partners (≥ 26) and oral sex partners (≥ 6) was significantly associated with oropharyngeal cancer as was seropositivity for antibodies to the viral L1 protein or oral infection with any hrHPV type, most frequently HPV16. However, other high-risk HPV types are also found in roughly 10% of oropharynx tumors and in other head and neck cancer locations, notably the nasopharynx and the oral cavity; the proportion of other high-risk HPV types is much higher.^{25,26} Oral and vaginal HPV infections in a series of HIV-positive and HIV-negative women revealed a significant but lower incidence of oral HPV (15%) compared to vaginal HPV (51%).²⁷ Oral HPV infection incidence in the general U.S. population was evaluated in the NHANES study.²⁸ The prevalence of oral HPV infection shows a biphasic distribution with one peak in the 30- to 34-year-old age group and a second

TABLE 37.1

Changing HPV Involvement in Oropharynx Cancers: Over 10 Years of Study Accruals: University of Michigan Head and Neck Oncology Program

HPV Positivity by Clinical Trial and Time Period			
HPV Status	UMCC 9921 1999–2001	UMCC 0221 2001–2005	UMCC 0221–like 2005–2011
HPV negative	14 (34%)	8 (10%)	6 (8%)
HPV positive	27 (66%)	75 (90%)	71 (92%)

UMCC, University of Michigan Cancer Center.

peak in the 60- to 64-year-old age group. Overall, oral HPV infection was (6.9%), with high-risk HPV types in 3.7%. Men had a higher prevalence than women (10.1% versus 3.6%), and blacks had a higher prevalence of oral HPV (10.5%) than whites (6.5%), although this difference did not reach statistical significance. It is not yet certain how oral HPV infection relates to the risk of developing HPV-induced head and neck cancer.

Fortunately, HPV-positive oropharyngeal cancers show improved response to therapy when compared to HPV-negative cancers of the same site.^{29–32} Patients presenting with HPV-positive oropharyngeal cancers also tend to be younger, healthier, and have a much lower frequency of smoking and alcohol abuse.³³ However, some studies have shown that a history of smoking in patients with HPV-positive oropharynx cancer may increase the likelihood of recurrence or metastasis after treatment.^{21,34} This has prompted many to consider reducing the intensity of treatment to decrease treatment-related morbidity.^{35,36} In contrast to

the excellent prognosis of HPV-positive oropharynx cancers, in HPV-positive oral cancers,³⁷ and HPV-positive nasopharyngeal cancers,³⁸ the outcome may be worse than HPV-negative cancers arising in these sites.

At the University of Michigan, 80% to 90% of oropharyngeal tumors (see Table 37.1) that present are HPV positive,^{21,25} and >80% of patients with HPV-positive oropharynx cancer are responders to concurrent carboplatin and taxol with intensity-modulated radiation treatment (chemoRT).³⁹ Critical questions for the future are to determine which patients can benefit from less intensive treatment, which patients need the intensive concurrent chemoRT treatment, and which patients need a different treatment because they fail to be cured by chemoRT. Spector et al.^{40,41} showed that nodal status and, in particular, matted nodes (defined as three nodes abutting one another with loss of an intervening fat plane replaced with evidence of extracapsular spread) defines a group of patients with a greatly increased risk of distant metastasis and poor overall and disease-free survival. The molecular correlates of these highly malignant HPV-positive tumors are yet to be defined fully, but in work submitted for publication, Walline et al. have shown that integration of hrHPV into cancer-related genes is common in tumors of patients who suffer from recurrent disease and poor survival, whereas integration of the viral genome into intragenic sites was more commonly associated with good response to therapy and prolonged progression-free survival. Immune responses to HPV antigens have also been suggested to be a cause of the good response to therapy among HPV-positive oropharyngeal cancers. However, failure of a potent immune response in some cases may occur because of frequent alterations affecting the tumor necrosis factor (TNF) receptor *TRAF3*, which participates in the activation of the immune response and nuclear factor kappa B (NF- κ B) signaling (TCGA Head and Neck Cancer Consortium).⁴² These changes may provide a mechanism for HPV-positive tumors to

Figure 37.1 Changing incidence rates of larynx, cervix, and oropharynx cancers. Adapted by R. Meza, from Surveillance, Epidemiology, and End Results (SEER) Program Populations (1969–2011) (www.seer.cancer.gov/popdata), National Cancer Institute, Division of Cancer Control and Population Sciences (DCCPS), Surveillance Research Program, Surveillance Systems Branch, released January 2013.

Figure 37.2 Human papillomavirus (HPV) infection and replication in the oropharynx, with the tonsil as the primary target for HPV infection and carcinogenesis. HPV detection can be carried out in oral rinses, normal tonsils, and tumors and lymph nodes.

evade antiviral immune responses.⁴² As a group, HPV-positive head and neck cancers have fewer gross genetic changes than HPV-negative tumors and share specific similarities, such as wild-type *TP53* and intact p16ink4a (*CDKN2A*), both of which are rare in HPV-negative HNSCC. Nearly all HPV-positive HNSCC express the HPV E6 and E7 viral oncogenes and exhibit low or absent expression of the HPV E2 gene that serves as a negative regulator of E6 and E7 expression (Walline et al. submitted). Viral integration⁴³ appears to be a requirement for carcinogenesis. Integration typically disrupts E2, which results in the unregulated expression of the E6 and E7 oncoproteins and includes the expression of the alternate HPV E6 transcripts E6**I* and E6**II*.⁴⁴ It appears that viral integration also causes a significant disruption of the host genome at sites of viral integration.⁴⁵ When significant disruption occurs leading to other genomic damage, this could also be a factor in the subset of nonresponsive HPV-positive tumors.

MOLECULAR MECHANISMS IN HEAD AND NECK SQUAMOUS CELL CARCINOMA

Early molecular studies of head and neck cancers revealed that amplification of the epidermal growth factor receptor (EGFR) gene with associated EGFR overexpression are common among head

and neck cancers and are associated with poor prognosis.^{46,47} It is puzzling that only about 10% of HNSCC cases respond to treatment that targets EGFR.⁴⁸ Alternate driver pathways are suspected as an explanation for this observation. Early molecular studies of HNSCC also revealed that mutations, loss of heterozygosity, and methylation of the *CDNK2A* locus is very common and occurs early in HNSCC development.^{49–51} Mutation and overexpression of p53 was also identified in early studies of HNSCC.⁵² CyclinD1 amplification and overexpression has also been identified as an important biomarker that is associated with outcomes and responses to treatment.⁵³ In the landmark VA larynx trial, a biomarker analysis revealed that overexpressed p53 predicted the response to induction chemotherapy and radiation (RT).⁵⁴ Because p53 overexpression is nearly always associated with mutant p53, this suggested that tumors with wild-type p53 were less responsive to chemotherapy and RT, even though normal cells containing wild-type p53 are very sensitive to chemotherapy or RT. Thus, it was unclear why tumors with wild-type p53 were more resistant to chemotherapy and RT. Subsequent studies revealed that the combination of wild-type p53 and overexpression of Bcl-xL resulted in cisplatin resistance.⁵⁵ This suggested that Bcl-xL blocks p53-induced apoptosis, and that wild-type p53 mediates cell cycle arrest and repair mechanisms, allowing tumor cells to escape from treatment-induced damage.

In spite of our awareness of EGFR overexpression and its potential value as a target for therapy, it is still impossible to predict which head and neck cancers will respond and which will not. The same is true for many other molecular markers when only one molecular target is addressed. It is now becoming clear that it will be necessary to identify the driver pathways and target more than one cancer driver. It was postulated many years ago that a certain number of “hits” is necessary to drive a tumor. Knudsen correctly explained the tumor suppressor nature of the retinoblastoma gene by comparing the kinetics of tumor development in children with an inherited predisposition and in children who developed sporadic retinoblastoma. When time to tumor development in affected children was plotted against months from birth, there was a straight line for children who inherited a mutant allele from an affected parent. However for children with sporadic retinoblastoma the line had a plateau for several months and then fell linearly. From this he reasoned that two hits were necessary for tumor development. For children who inherited one normal and one mutant gene he observed first-order kinetics, and for children who did not inherit a mutant gene he observed second-order kinetics. Thus only one additional event was necessary for tumor development in the inherited disease, but two events were necessary in the sporadic cases, i.e. acquisition of a mutation in a cell and then a second event in the same cell, resulting in loss of the healthy gene. For tumors that arise in adult epithelial tissues, the situation is more complex. It was estimated many years ago using a similar mathematical approach in cancers that develop with aging that it is likely that four to five events are necessary for a tumor to develop.

To attempt to identify cancer drivers, we characterized chromosomal abnormalities in two cell lines derived from a patient with recurrent laryngeal cancer. One portion of the tumor was within the endolarynx. From this, the UM-SCC-17A cell line was established, and from a second portion of the tumor that had invaded through the thyroid cartilage into the soft tissues of the neck, UM-SCC-17B was established. There were a total of 22 chromosome rearrangements in the two cell lines, of which 8 were unique to the UM-SCC-17A cell line from the endolarynx and 9 were unique to the UM-SCC-17B cell line from the invasive lobe of the tumor. Of interest, however, were the five rearrangements that were common to both cell lines, which could represent the loci of genetic events associated with tumor initiation, whereas the others represent either random events or events associated with progression.⁵⁶ It will be of interest to use modern sequencing methods to identify the genetic aberrations linked to these five early chromosome rearrangements to test this hypothesis. Hahn and Weinberg tested what steps were necessary to transform normal human bronchial epithelial

cells into tumor cells. They targeted a small but consistent set of specific pathways based on the observed abnormalities of many epithelial cancers. The necessary pathways include: ectopic expression of the catalytic unit of human telomerase, human telomerase reverse transcriptase (hTERT), to stabilize telomeres over many cell divisions; abrogation of the Rb pathway with SV40 large T oncoprotein to induce continuous cell cycle entry; inhibition of *TP53* with large T oncoprotein to facilitate cell cycle progression and to inhibit *TP53*-mediated induction of apoptosis; and introduction of the activated (oncogenic) allele of *HRAS*, to provide continuous signaling through the RAS, RAF, mitogen-activated protein kinase (MEK), extracellular signal-related kinase (ERK) kinase cascade to trigger the expression of transcription factors associated with proliferation.^{57,58} This demonstration is critical to our thinking of how we will develop precision medicine for cancer because, similar to the chromosome rearrangements observed in the UM-SCC-17A and UM-SCC-17B cell lines mentioned previously, each epithelial cancer is likely to have multiple abnormalities, of which some are primary driver events and others are passenger events that have developed incidentally due to genomic destabilization. The knowledge that a limited number of events are sufficient for the conversion of a normal human epithelial cell to an immortalized, invasive tumor cell population suggests that a series of principles can be developed that control the conversion of normal to malignant behavior and that we should be able to develop strategies that will target the two or three critical pathways of an individual tumor that serve as the primary drivers of neoplastic behavior.

THE CANCER GENOME ATLAS PROJECT

Most studies have looked at individual target genes in isolation or in small combinations of genes to identify tumor driver events; however, these have largely been thwarted by the range of mechanisms that a tumor cell might acquire stochastically to become malignant. This limited our ability to assess the drivers of individual cancers and has complicated the assessment of the efficacy of pathway-targeted agents. The development of modern molecular analysis techniques has made it possible to analyze nearly all of the abnormalities in an individual tumor. Furthermore, The Cancer Genome Atlas (TCGA) project has provided us with an impressive collection of data from multiple tumors of the same types that can be used to bring us closer to developing knowledge of the types of oncogenic drivers and tumor suppressors that characterize each tumor type. By examining individual tumors in similar detail to identify the aberrant pathways, we can deduce the primary drivers and propose effective combinations of targeted therapies that can work against that individual tumor.

The Head and Neck Cancer Consortium assessed 279 previously untreated HNSCC tumors (35 of which contained HPV) for genomic alterations.⁴² Sequence (exome, RNA, miRNA, some whole genome sequence), structural, epigenetic (DNA methylation), and copy number analyses as well as protein expression were carried out. The genomic gains and losses of the smoking-related HNSCC strongly resembled those in the squamous cancers of the lung⁵⁹; however, those HNSCC tumors containing HPV had less complex genomic signatures and lacked *TP53* mutations, *HRAS*-activating mutations, and *CDKN2A* deletions and mutations, but had more frequent *PIK3CA* mutations. Also of interest was the identification of a subset of HPV-negative HNSCC that had relatively fewer *TP53* mutations and more frequent *PIK3CA* and *HRAS* mutations. Interestingly the tumors with *HRAS* mutations tended to correlate with wild-type *TP53*-containing tumors. This set was also notable for a less complex pattern of chromosome rearrangements and better survival than the other HPV-negative HNSCC tumors. In the entire HNSCC set, the most commonly mutated genes were *TP53*, *FAT1*, *CDKN2A*, *PIK3CA*, *NOTCH1*, and *MLL2*, with mutation frequencies ranging from 72% to 18%. Amplifications of receptor tyrosine kinases (RTK) were common. *EGFR* amplification was identified in 16% of tumors. Other smaller subsets of

tumors lacked *EGFR* amplification but contained amplification of fibroblast growth factor receptor (FGFR) 1, 2, or 3. A few tumors had more than one RTK amplification, but mostly subsets could be categorized by amplification of one RTK. CyclinD1 (*CCND1*) amplification was very common, occurring in 30% of all tumors. *CCND1* amplification was observed in some tumors with RTK amplification and in a subset of tumors with *CMYC* amplification, although there was also a subset that had either *CCND1* or *CMYC* amplification, but not both. *HRAS* mutations were found in 5%, *PIK3CA* mutations were found in 18%, *PTEN* mutations in 12%, whereas *TP53* mutations were present in 83%.

The tumor subsets defined by each of these distinct categories offers promise for better response when the correct amplified or mutated gene is targeted in those categories. Inhibitors for *EGFR*, *FGFR*, and *PIK3CA* are all now available and suggest that the appropriate matching of the tumor characteristics with the correct inhibitor is a fruitful area for study. Although *CCND1* inhibitors are not yet available, several companies have cyclin-dependent kinase inhibitors (CDK4/6), and use of these agents is being tested in tumors with a loss of *CDKN2A* and might also be applicable in tumors with *CCND1* amplification. *NOTCH1* mutations found in 18% of HNSCC are a recently appreciated feature of a subset of HNSCC and are typically loss-of-function mutations, suggesting that *NOTCH1* is a tumor suppressor in this cancer type. In normal squamous epithelium, *NOTCH1* acts to drive squamous differentiation by feeding back on the Wnt/ β -catenin signaling pathway active in the proliferating basal cell. Loss of the *NOTCH1* tumor suppressor function allows unopposed activity of the Wnt pathway, allowing this to become a target for therapy. Liu et al.⁶⁰ recently reported the development of a novel inhibitor of the Wnt pathway that targets Wnt secretion by inhibiting porcupine, the enzyme required for Wnt secretion. This inhibitor, LGK974, was more effective in tumor cell lines shown to have *NOTCH1* loss of function mutations, suggesting that this may be a useful agent in HNSCC tumors with *NOTCH* pathway abnormalities.

The next horizon for targeted agents is to find the correct combinations of targeted compounds for individual tumors. For this effort, it will be necessary to identify targets in different pathways for which effective agents exist. Such a combination might include inhibitors of RTKs, together with a CDK4/6 inhibitor or a Wnt pathway inhibitor and *PIK3CA* inhibitor. Many combinations are possible, and the literature will be replete with combinations of multiple targeted agents within the next few years as precision medicine approaches evolve. Rapid and comparatively inexpensive targeted or exome sequencing is now becoming available at the lab bench, with bioinformatics software and cloud computing to provide results within days. This will be an exciting era.

CANCER STEM CELLS

The isolation of highly tumorigenic subpopulations of cancer cells from solid cancers, commonly referred to as cancer stem cells (CSC), has generated a great deal of interest in the relevance of these cells to cancer progression and treatment failure. CSCs have been shown to be critical in the growth and development of primary tumors and for the development of regional and distant metastatic disease in HNSCC. CSCs are also believed to be highly resistant to conventional therapy and, therefore, likely responsible for disease recurrence and treatment failures when they occur.

CSCs were first isolated from lymphomas. A subsequent investigation of solid tumors has revealed the presence of highly tumorigenic cancer cells in essentially every solid cancer type. These highly tumorigenic cells fit the current criteria for being classified as CSCs: they are tumorigenic; they are able to reproduce the original tumor heterogeneity, including the tumorigenic and nontumorigenic cell subpopulations; and they are self-renewing. CSCs generally represent a very small subpopulation of the cancer cells. In the majority of solid tumors, they typically represent less than 10%

of the entire cancer cell population. A variety of surface markers and biologic markers have been used to isolate the CSC population from the other cancer cells in HNSCC, including CD 44, CD 133, ESA, and aldehyde dehydrogenase activity. So far, no single marker or combination of markers has proven useful for isolating CSCs from every tumor site. Additionally, none of these stem cell markers has been found to be a useful or effective target for cancer therapy.

The term *cancer stem cell* refers to the biologic behavior of the cells and not their cell of origin. Although CSCs exhibit many of the properties of normal stem cells, their cell of origin has yet to be determined. Likely, CSCs can originate from normal stem cells, early progenitor cells, and possibly more differentiated cells if they undergo the correct combination of mutations and epigenetic changes required to achieve the CSC phenotype.

Many normal stem cell genetic pathways are expressed in CSCs and are important regulators of their behavior. These genes include the transcription factors responsible for maintaining pluripotency, epithelial to mesenchymal transition, self-renewal, xenobiotic efflux, and quiescence. Embryonic stem cells are believed to be dependent on at least three critical pathways that regulate their activity: NANOG, Oct-4, and Sox-2. NANOG has been shown to inhibit differentiation, and Oct-4 is critical to self-renewal. Oct-4 and NANOG have also been recognized as important transcription factors in the reprogramming of pluripotency in adult cells. NANOG, Oct-3/4, and Sox-2 have been found to be upregulated in CSC-enriched cells derived from HNSCC grown as spheroids. Oct-4, which is known to be an important stem cell gene in epithelial stem cells, has been found to be unregulated in aldehyde dehydrogenase (ALDH)-positive HNSCC cells.⁶¹ The overexpression of NANOG and Oct-4 has been correlated with chemotherapy resistance and the stage of cancer, suggesting that these genes play a role in treatment outcomes and in the prognosis in HNSCC.

BMII is a gene that is believed to be an essential stem cell-related gene that maintains the self-renewal of stem cells. To date, although *BMII* has not been shown to be a reliable marker for CSCs in HNSCC, its potential to induce tumorigenic changes has made it an attractive target for study in CSCs. *BMII* is expressed in CSCs from a variety of tumor types, including HNSCC, and is an important component of the polycomb complex 1, an epigenetic regulator of stem cell self-renewal and carcinogenesis.⁶² Through repression of the *CDKN2A* locus and inhibition of p16Ink4A expression, *BMII* is believed to promote cellular proliferation by blocking p16Ink4A-induced cellular senescence. *BMII* knockdown

resulted in a significant reduction in HNSCC CSC renewal and in chemotherapy and radiation resistance.⁶³ Conversely, overexpression of *BMII* in the non-CSC population of HNSCC resulted in the acquisition of self-renewal and stem cell-like properties.

Epithelial to mesenchymal transition is required to allow for cancer cell migration to occur and for the subsequent development of metastasis. Snail and Twist have been identified as critical transcription factors regulating epithelial to mesenchymal transition in stem cells and cancer cells. Increased expression of Twist has been found in both CD44-positive and ALDH-positive HNSCC, and increased Snail expression has been confirmed in ALDH HNSCC CSCs.⁶⁴ Snail expression in HNSCC CSCs has been correlated with metastasis, local recurrence, and prognosis. Increased Twist expression increases HNSCC CSC motility and loss of E-cadherin-mediated cell-to-cell contact.

Normal cells and CSCs express high levels of adenosine triphosphate (ATP)-binding cassette (ABC) transporter genes, including *ABCB1*, which encodes P-glycoprotein, and *ABCG2*. The drug-effluxing property of stem cells conferred by ABC transporters is the basis for the side-population phenotype that arises from the exclusion of the fluorescent dye Hoechst 33342 and has been used to isolate CSCs from HNSCC.⁶⁵ CSCs are likely to share many of the properties of normal stem cells that provide for a long lifespan, including resistance to drugs and toxins through the expression of ABC transporters. Therefore, tumors might have a built-in population of drug-resistant pluripotent cells—the CSCs—due to their expression of the ABC-transported genes that can survive chemotherapy and repopulate the tumor.

The Wnt/ β -catenin pathway is known to be important to organogenesis and embryonic development. The major function of this pathway is to regulate β -catenin function by its phosphorylation and proteasomal degradation. Abnormalities in the pathway can lead to β -catenin accumulation, which, in turn, results in the activation of several pathways such as cyclin D1 and CMYC, which control the G1 to S phase transition in the cell cycle. Wnt signaling is also involved in the critical cell migration process known as the epithelial-mesenchymal transition. These effects contribute to the importance of the Wnt/ β -catenin in determining the CSC phenotype.

The expression of CSC genes in primary HNSCC has been found in some studies to be associated with the prognosis and response to therapy. The role of CSCs in the treatment resistance and recurrence is still being elucidated. Gaining a better understanding of the molecular pathways that regulate CSC behavior will be essential to developing therapies that target this critical population of cells.

38 Cancer of the Head and Neck

William M. Mendenhall, John W. Werning, and David G. Pfister

INCIDENCE AND ETIOLOGY

The estimated number of new head and neck cancer cases (excluding skin cancer) in the United States in 2013 is 53,640; this represents 3.2% of the total new cancer cases.¹ Approximately 27% of these patients are women.¹ African Americans have a higher age-adjusted incidence than other ethnic groups. The usual time of diagnosis is after the age of 40, except for salivary gland and nasopharyngeal cancers (NPCs), which may occur in younger age groups. For many primary sites, tobacco use is associated with an increased risk. Alcohol has also been implicated as a causative factor; the effects of alcohol and tobacco may be synergistic.² Head and neck cancer patients have an increased risk for developing a second primary tumor (SPT), both within the head and neck and elsewhere (e.g., esophageal and lung cancers),³ attributed to the field effect associated with tobacco and alcohol use.⁴ Human papillomavirus infection (HPV; most commonly HPV-16) plays a role in the development of certain head and neck cancers, particularly those in the oropharynx.^{5,6} Patients with high-risk HPV (HR-HPV)-positive head and neck cancers tend to be younger and less likely to have a strong history of tobacco and ethanol use, have a history of multiple sex partners (particularly oral-genital sex), have a better prognosis, and appear to have a lower rate of SPTs.⁶⁻⁸ Prior tobacco exposure adversely affects the prognosis of HPV-related oropharynx cancers.^{8,9} An increasing incidence of oral tongue squamous cell carcinoma in nonsmoking Caucasian women has been reported that does not appear to be driven by prior HPV infection, whereas the incidence of other oral cavity cancers is declining.¹⁰ There is a long-standing association between Epstein-Barr virus (EBV) and NPC.¹¹ Occupational exposures are associated with the development of sinonasal tract tumors.¹²

ANATOMY AND PATHOLOGY

The anatomy pertaining to a particular primary site is described in subsequent sections. To facilitate communication, lymph nodes are organized into levels. Level I includes the submental and submandibular areas; levels II through IV include the internal jugular vein lymph nodes; level V includes the posterior triangle (Fig. 38.1).¹³ Furthermore, which lymph node levels are involved is predictive of the primary site. For example, lip, oral cavity, and facial skin tumors typically spread to levels I and II initially; larynx and pharynx cancers have a predilection for spread to levels II and III.

There are no capillary lymphatics in the epithelium. The tumor must penetrate the lamina propria before lymphatic invasion can occur. One can predict the richness of the capillary network in a given head and neck site by the relative incidence of lymph node metastases at presentation. The nasopharynx and pyriform sinus have the most profuse capillary lymphatic networks. The paranasal sinuses, middle ear, and vocal cords have few or no capillary lymphatics. Muscle and fat contain few capillary lymphatics, as do bone and cartilage within the periosteum

or perichondrium. There are no capillary lymphatics in the eye, and few in the orbit.

Most head and neck malignant neoplasms arise from the surface epithelium and are squamous cell carcinoma (SCC) or one of its variants, including lymphoepithelioma, spindle cell carcinoma, verrucous carcinoma, and undifferentiated carcinoma. Lymphomas and a wide variety of other malignant and benign neoplasms make up the remaining cases.¹⁴⁻¹⁶

Lymphoepithelioma is an SCC with a lymphoid stroma and occurs in the nasopharynx, tonsillar fossa, and base of tongue; it may also occur in the salivary glands. In the spindle cell variant, there is a spindle cell component that resembles sarcoma intermixed with SCC. It is generally managed like other high-grade SCCs. Verrucous carcinoma is a low-grade SCC found most often in the oral cavity, particularly on the gingiva and buccal mucosa. It usually has an indolent growth pattern and is often associated with the chronic use of snuff or chewing tobacco.

Small cell neuroendocrine carcinoma occurs rarely throughout the head and neck. Upper aerodigestive tract lymphomas almost always show a diffuse non-Hodgkin histologic pattern.

NATURAL HISTORY

Patterns of Spread

Primary Lesion

SCCs usually begin as surface lesions. Superficial tumors arising in the Waldeyer ring may be difficult to distinguish from normal lymphoid tissue. Very early surface lesions may show only erythema and a slightly elevated mucosa.

Spread is dictated by local anatomy, and thus varies by each site. Muscle invasion is common, and the tumor may spread along muscle or fascial planes a surprising distance from the palpable or visible lesion. The tumor may attach early to the periosteum or perichondrium, but bone or cartilage invasion is usually a late event. Bone and cartilage usually act as a barrier to spread; the tumor that encounters these structures will often be diverted and spread along a path of less resistance. Slow-growing gingival neoplasms may produce a smooth pressure defect of the underlying bone without bone invasion.

Tumor extension into the parapharyngeal space allows superior or inferior spread from the skull base to the low neck.

Spread inside the lumen of the sublingual, submandibular, and parotid gland ducts is uncommon. The nasolacrimal duct, however, is often invaded in ethmoid sinus and nasal carcinomas.

Perineural invasion (PNI) is observed in SCCs as well as salivary gland tumors, especially adenoid cystic carcinomas. When advanced, PNI may produce neurologic symptoms and is associated with a poorer rate of local control.¹⁷ Tumors may track along a nerve to the skull base and central nervous system (CNS) or peripherally.

Vascular space invasion is associated with an increased risk for regional and distant metastases.

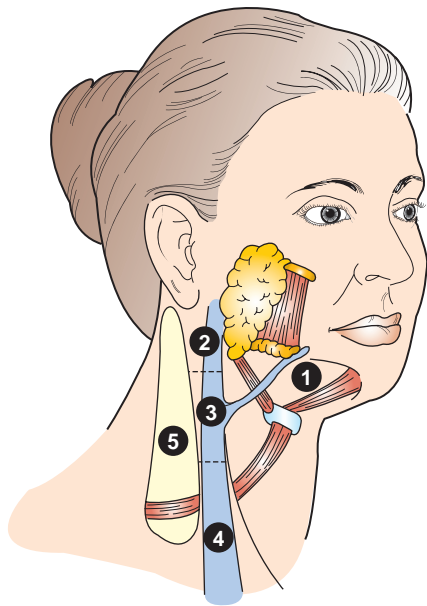

Figure 38.1 Head and neck lymph node levels.

Lymphatic Spread

The differentiation of the tumor, the size of the primary lesion, the presence of vascular space invasion, and the density of capillary lymphatics predict the risk of lymph node metastasis. Recurrent lesions have an increased risk. Histology also impacts the likelihood of lymphatic spread. Low-grade minor salivary gland tumors and sarcomas have a lower risk of lymph node metastases than SCCs arising in similar mucosal sites.

A patient may present with SCC in a cervical lymph node, and despite an extensive work-up, the site of origin may remain undetermined in approximately 50% of patients.¹⁸ If only the neck is treated, a primary lesion may appear later, but sometimes is never found.¹⁹

The relative incidence of clinically positive lymph nodes on admission is determined by primary site and T stage.²⁰ Well-lateralized lesions spread to ipsilateral neck nodes.²¹ Lesions on or near the midline, tongue base, and nasopharyngeal lesions (even when lateralized), may spread to both sides of the neck, although the risk is higher to the side occupied by the bulk of the lesion. Patients with clinically positive ipsilateral neck nodes are at risk for contralateral disease, especially if the nodes are large or multiple; obstruction of the lymphatic pathways by surgery or radiotherapy (RT) also shunts the lymphatic flow to the opposite neck.²¹ When lymph node metastases appear at an unusual site, a careful search must be made for a second primary. The likelihood of retropharyngeal adenopathy is related to the presence of clinically involved lymph nodes and the primary site, and is particularly high for NPCs.²²

Distant Spread

The risk of distant metastasis is related more to N stage and the location of involved nodes in the low neck, rather than to T stage.²³ The risk is less than 10% for N0 or N1 disease and rises to approximately 30% for N3 disease as well as N1 or N2 nodes with disease below the level of the thyroid notch. Distant metastases are found most often in the lung.²⁴

DIAGNOSIS

A general medical evaluation is performed, including a thorough head and neck examination. The location and extent of

the primary tumor and any clinically positive lymph nodes is documented. Almost all patients undergo contrast enhanced computed tomography (CT) and/or magnetic resonance imaging (MRI) to further define the extent of local-regional disease. The scan(s) should be obtained prior to biopsy so that biopsy changes are not confused with the tumor. A chest radiograph is obtained to determine the presence of distant metastases and/or a synchronous primary lung cancer. Patients with N3 neck disease, as well as those with N2 disease with nodes below the level of the thyroid notch, have a 20% to 30% risk of developing distant metastases and are considered for a chest CT or positron emission tomography (PET).

Tumors amenable to transoral biopsy may be biopsied using local anesthetics in the clinic. Otherwise, direct laryngoscopy under anesthesia is performed to determine the extent of the tumor and to obtain a tissue diagnosis. Given the risk of synchronous cancers, some advocate routine triple endoscopy (i.e., laryngoscopy/pharyngoscopy, bronchoscopy, and esophagoscopy). The additional yield is low, unless diffuse mucosal abnormalities or a malignant lymph node without an identified primary site, particularly in the low neck, are present. Patients presenting with a metastatic node from an unknown primary site undergo fine-needle aspiration (FNA) of the node. An excisional biopsy is not routinely performed unless lymphoma is suspected or FNA results are equivocal. If SCC is a consideration, the excision should be done in a manner to facilitate subsequent management, including neck dissection. Occasionally, the diagnosis may be made by clinical and radiographic evaluation, and a biopsy should be avoided in situations where the treatment is definitive for RT and where obtaining a tissue sample is risky (e.g., paragangliomas, juvenile nasopharyngeal angiofibromas).^{14,25}

Before the initial treatment, the patient should be evaluated by members of the team who may be involved in the initial management as well as possible salvage therapy. Head and neck surgeons, radiation oncologists, medical oncologists, diagnostic radiologists, plastic surgeons, pathologists, dentists, speech and swallowing therapists, and social workers may all play a role.

STAGING

The staging system of the American Joint Committee on Cancer (AJCC) is used.²⁶ In general, excisional biopsy (TX) indicates that the primary tumor cannot be assessed; T0 indicates no evidence of primary tumor; and Tis indicates carcinoma in situ. For tumors of the oral cavity and oropharynx, further staging of the primary lesion is based primarily on size criteria: 2 cm or less for T1; greater than 2 cm but no more than 4 cm for T2; greater than 4 cm for T3; and T4 tumors involve major invasion or encasement of surrounding structures (e.g., bone, carotid artery, deep musculature). For the other primary sites, further staging is less easily generalized because the anatomic extent of spread and/or functional criteria (e.g., vocal cord mobility) are used and, for certain sites, are combined with tumor size (e.g., hypopharynx, major salivary glands), and so will be given in the discussion of each respective primary site.²⁶ Neck staging is common to all head and neck sites, except the nasopharynx (Table 38.1).²⁶ Lesions may be clinically or pathologically staged. Clinical staging is more commonly used for treatment planning and the reporting of results. The format for combining T and N stages into an overall stage is depicted in Table 38.2 and is common to all sites except the nasopharynx.²⁶

Stage IV represents a wide spectrum of disease. One patient may have a T1, T2, or T3 lesion with low-volume N2 neck disease and a high probability of cure (stage IVA), whereas another may have a T4b primary cancer and/or N3 neck disease and a relatively poor prognosis (stage IVB)²⁷; distant metastases indicate stage IVC disease, and the treatment intent is typically palliative.

TABLE 38.1**2010 American Joint Committee on Cancer Stages of Regional Lymph Node Involvement**

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2	Metastasis in single ipsilateral lymph node, more than 3 cm but no more than 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, no more than 6 cm in greatest dimension
N2a	Metastasis in single ipsilateral lymph node, more than 3 cm but no more than 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3	Metastasis in a lymph node more than 6 cm in greatest dimension

PRINCIPLES OF TREATMENT FOR SQUAMOUS CELL CARCINOMA

General Principles for Selection of Treatment

Surgery and RT are the only curative treatments for head and neck carcinomas. Although chemotherapy alone is not curative, it enhances the effects of RT, and thus is routinely used as part of combined modality treatment in patients with stage III or IV disease.

The advantages of surgery compared with RT, assuming similar cure rates, may include the following: (1) a limited amount of tissue is exposed to treatment, (2) the treatment time is shorter, (3) the risk

TABLE 38.2**2010 American Joint Committee on Cancer Overall Stage Grouping**

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1–T3	N1	M0
Stage IVA	T4a	N0–N1	M0
	T1–T4a	N2	M0
Stage IVB	Any T	N3	M0
	T4b	Any N	M0
Stage IVC	Any T	Any N	M1

of immediate and late RT sequelae is avoided, and (4) RT is reserved for a head and neck SPT, which may not be as suitable for surgery.

The advantages of RT may include (1) the risk of a major post-operative complication is avoided, (2) no tissues are removed so that the probability of a functional or cosmetic defect may be reduced, (3) elective neck RT can be included with little added morbidity, and (4) the surgical salvage of RT failure is probably more likely than the salvage of a surgical failure.

Salvage of a surgical failure may be attempted by operation, RT, or both. Surgical recurrences usually develop at the resection margins, in or near the suture line. It is difficult to distinguish the normal surgical scarring from recurrent disease, and the diagnosis of recurrence is often delayed. Tumor response to RT under these circumstances is poor. Surgery, RT, or both, however, may salvage small mucosal recurrences and some neck recurrences. For bulkier recurrences treated with RT, concurrent chemotherapy is often incorporated.

MANAGEMENT

Primary Site

The management of the primary cancer will be considered separately for each anatomical site. Patients who are in poor nutritional condition may require a nasogastric (NG) tube or a percutaneous gastrostomy (PEG) before initiating RT, particularly if concomitant chemotherapy is used. Opinions vary regarding the role of prophylactic NG or PEG placement in anticipation of RT-based local toxicity in patients without significant baseline dysphagia or weight loss; a reactive strategy is preferred by many and may facilitate swallowing recovery.²⁸ If external-beam radiotherapy (EBRT) is selected, it may be given with either conventional once-daily fractionation, 66 to 70 Gy at 2 Gy per fraction, 5 days a week in a continuous course, or with an altered fractionation schedule. Whether an altered fractionation schedule is better than conventional fractionation depends on the altered fractionation technique that is selected. Two altered fractionation schedules shown to result in improved local–regional control rates are the University of Florida hyperfractionation and the M.D. Anderson concomitant boost techniques.²⁹ The results of a prospective randomized Radiation Therapy Oncology Group (RTOG) trial comparing these schedules with conventional fractionation and the Massachusetts General Hospital accelerated split-course schedule are shown in Table 38.3. Acute toxicity is increased with altered fractionation; late toxicity is comparable with conventional fractionation.³⁰

Conventional EBRT techniques and/or brachytherapy will be discussed in the subsequent site-specific sections. EBRT may also be delivered with intensity-modulated radiation therapy (IMRT) to produce a more conformal dose distribution and to reduce the dose to the normal tissues.^{31–33} The disadvantages of IMRT are that it is more time consuming to plan and treat the patient, the dose distribution is often less homogenous so that “hot spots” may increase the risk of late complications, the risk of a marginal miss may be increased because the fields are more conformal, the total body RT dose is higher because of increased “beam on” time and scatter irradiation, and it is more costly. Therefore, a clear reason for using IMRT versus conventional RT must be identified. The usual indication for IMRT is to reduce the dose to the contralateral parotid gland, and thus limit long-term xerostomia.³⁴ Another indication is to reduce the CNS dose in patients with NPC. Finally, it may be used to avoid a difficult low neck match in patients with laryngeal or hypopharyngeal cancers and a low-lying larynx. Proton therapy, which offers potential targeting and dosing advantages for selected tumors,³⁵ is useful for reducing the dose to the brain and the visual apparatus for patients with nasal cavity and paranasal sinus malignancies.

TABLE 38.3

Altered Fractionation: 5-Year Outcomes from the Radiation Therapy Oncology Group 90-03 Trial

Parameter	Fractionation Schedule			
	Conventional (70 Gy/35 Fx/7 wk)	Hyperfractionation (81.6 Gy/68 Fx/7 wk)	Accelerated Split Course (67.2 Gy/42 Fx/6 wk)	Accelerated Concomitant Boost (72 Gy/42 Fx/6 wk)
Number of patients	268	263	274	268
Local-regional failure	59.1%	51.2% (p = 0.037)	57.8% (p = 0.042)	51.7%
Disease-free survival	21.2%	30.7% (p = 0.013)	26.6% (p = 0.042)	28.9%
Overall survival	29.5%	37.1% (p = 0.063)	30.8%	33.5%
Cause-specific survival	42.9%	45.5%	40.9%	43.4%
Grade 3 late toxicity	25.2%	27.4%	26.8%	33.3% (p = 0.066)

Note: P values reflect comparison of the experimental arms with standard fractionation. Fx, fractions.

From Trotti A, Fu KK, Pajak TF, et al. Long term outcomes of RTOG 90-03: a comparison of hyperfractionation and two variants of accelerated fractionation to standard fractionation radiotherapy for head and neck squamous cell carcinoma. *Int J Radiat Oncol Biol Phys* 2005;63:S70-S71.

NECK

In a classic *radical neck dissection*, the superficial and deep cervical fascia with its enclosed lymph nodes (levels I to V) is removed in continuity with the sternocleidomastoid muscle, the omohyoid muscle, the internal and external jugular veins, cranial nerve XI, and the submandibular gland. The incisions used by the surgeon will be governed largely by the primary lesion. The radical neck dissection can be *modified* to spare certain structures with the intent of decreasing morbidity and improving functional outcome without compromising disease control. There are three main types of modified radical neck dissections: type I, CN XI is spared; type II, CN XI and the internal jugular vein are spared; and type III (functional), CN XI, the internal jugular vein, and the sternocleidomastoid muscle are spared. *Selective* neck dissections are more limited and include the resection of lymph node levels that are at greatest risk for nodal metastatic spread. Examples include the lateral, posterolateral, and supraomohyoid, which include resections of lymph node levels II through IV, II through V, and I through III, respectively.

A modified or selective neck dissection is recommended for the cN0 neck, for selected clinically positive necks (mobile, 1 to 3 cm lymph nodes), and for removing residual disease after RT when there has been excellent regression of N2 or N3 disease.^{36,37}

The more extensive the neck dissection, the higher the risk of complications. Complications after neck dissection include hematoma, seroma, lymphedema, wound infections and dehiscence, damage to the 7th, 10th, 11th, and 12th cranial nerves, carotid exposure, and carotid rupture. The last-mentioned complication can be minimized by covering the carotid artery with a dermal graft at the time of surgery.³⁶ Pain and dysfunction in the neck or shoulder may occur. Rehabilitation and anti-inflammatory medication are commonly utilized with varying benefits; acupuncture had demonstrated a benefit compared to the usual care in one randomized study.³⁸

Clinically Negative Neck

The estimated incidence of subclinical disease in the regional lymphatics when the neck is cN0 is presented in Table 38.4.³⁹ Both RT and neck dissection are approximately 90% efficient at eradicating subclinical regional disease.³⁶ Alternatively, a policy of close observation may be adopted for the cN0 neck to avoid unnecessary treatment, and the neck is managed by surgery and/or RT if cervical metastases develop. The salvage rate for patients developing clinically positive lymph nodes with the primary lesion controlled is 50% to 60%.³⁹

TABLE 38.4

Definition of Risk Groups for the Clinically N0 Neck

Group	Estimated Risk of Subclinical Neck Disease	T Stage	Site
I: Low risk	<20%	T1	Floor of mouth, oral tongue, retromolar trigone, gingiva, hard palate, buccal mucosa
II: Intermediate risk	20%–30%	T1 T2	Soft palate, pharyngeal wall, supraglottic larynx, tonsil Floor of mouth, oral tongue, retromolar trigone, gingiva, hard palate, buccal mucosa
III: High risk	>30%	T1–T4 T2–T4 T3–T4	Nasopharynx, pyriform sinus, base of tongue Soft palate, pharyngeal wall, supraglottic larynx, tonsil Floor of mouth, oral tongue, retromolar trigone, gingiva, hard palate, buccal mucosa

Adapted from Barkley HT Jr, Fletcher GH, Jesse RH, et al. Management of cervical lymph node metastases in squamous cell carcinoma of the tonsillar fossa, base of tongue supraglottic larynx, and hypopharynx. *Am J Surg* 1972;124:462–467.

Elective neck irradiation (ENI) and elective neck dissection are equally effective in the management of the N0 neck, with control rates exceeding 90%.^{39,40} Treatment of the entire neck is advised for primary lesions with a high rate of subclinical disease, such as the base of tongue, soft palate, supraglottis, and hypopharynx. Patients with lateralized T1 to T2 tonsillar cancers do not require elective treatment for the contralateral N0 neck⁴¹; T3 or T4 cancers or those with significant extension into the tongue and/or soft palate should receive bilateral neck treatment to the entire neck.

When the primary tumor is to be treated surgically, an elective neck dissection should be performed when the risk of regional lymph node metastasis is 10% to 15% or greater. Modified neck dissection has a good rate of disease control; patients who are found to have multiple positive nodes or extracapsular extension (ECE) are then referred for postoperative RT,⁴² and concurrent chemotherapy is recommended in the latter circumstance.^{43–46} If the primary lesion is to be treated with EBRT, ENI adds relatively little cost and modest morbidity.

Clinically Positive Neck Lymph Nodes

The rates of neck failure by N stage and treatment group reported from the M.D. Anderson Cancer Center and the University of Florida are shown in Tables 38.5 and 38.6, respectively.^{40,47} In general, RT precedes surgery if the primary site is to be treated by RT or if the node was fixed. The operation precedes RT if the primary site is to be treated surgically.

Modified neck dissection is sufficient treatment for the ipsilateral neck for patients with N1 or N2A disease without ECE. RT, often combined with concurrent chemotherapy, is added for those with more advanced neck disease.⁴²

When the primary lesion is to be managed by RT or chemoradiotherapy (chemoRT), then RT-based therapy alone is sufficient for patients in whom the node(s) regress completely as documented on CT obtained 4 weeks post-RT.^{37,48} RT is followed by a neck dissection for patients with residual nodes that are 1.5 cm or larger, as well as those that demonstrate focal defects, enhancement, and/or calcification.⁴⁸ A PET scan done 3 months after RT is completed is an alternative to CT to assess whether there is persistent disease.⁴⁹

McGuirt and McCabe⁵⁰ compared results of definitive surgery with and without a prior open neck biopsy and concluded the risks of neck failure, distant metastases, and complications were all increased. Ellis et al.⁵¹ studied the results of therapy following open biopsy of a lymph node before treatment. Patients received definitive RT to the primary site and neck; a subset of patients underwent a neck dissection after RT. Open biopsy had no adverse impact on these patients compared with those who did not undergo an open biopsy.⁵¹ Therefore, after open biopsy of the neck, RT-based therapy is recommended as the initial treatment, particularly if the primary tumor is to be managed by RT or chemoRT. Under these circumstances, no further neck treatment is needed if the neck node had been removed; if there was residual gross tumor in the neck after open biopsy, a planned neck dissection should be added depending on the results of radiologic reassessment.⁴⁸

TABLE 38.6

5-Year Rate of Neck Control According to the 1983 American Joint Committee on Cancer Stage and Treatment (459 Patients, 593 Heminecks^a)

Stage	RT Alone		RT + Neck Dissection		Significance
	No. of Heminecks	Control	No. of Heminecks	Control	
N1	215	86%	38	93%	p = 0.28
N2A	29	79%	24	68%	p = 0.60
N2B	138	70%	80	91%	p < 0.01
N3A	29	33%	40	69%	p < 0.01

Note: The University of Florida data, patients were treated October 1964 to October 1985; analysis occurred December 1988 by Eric R. Ellis, MD.

^a Excludes 67 heminecks that received incisional or excisional biopsies before treatment.

Lippincott Company; 1992: 790–805; and American Joint Committee on Cancer. *Manual for Staging of Cancer*. Philadelphia: J. B. Lippincott Company; 1983.

CHEMOTHERAPY

Drug therapy may be administered to prevent the development of SPTs (chemoprevention), to palliate symptoms in patients with incurable disease, to improve the odds of cure or organ preservation when combined with definitive local-regional therapy, or to decrease treatment toxicity. The first two indications are discussed here; the last two are discussed in a subsequent section.

Chemoprevention

Chemoprevention is the administration of natural or synthetic agents to reduce the risk of developing SPTs. Patients who have a head and neck SCC have an increased risk of developing an upper aerodigestive tract SPT because of exposure to carcinogens and/or genetic predisposition.³ The risk of developing an SPT is approximately 2.7% to 4% per year⁵² and may impact survival. Current data indicate the risk of SPTs is lower among patients with HR-HPV-related head and neck cancers.^{6,8} Analogs of vitamin A, particularly of the retinoids, have been a particular focus of clinical investigations. At present, there is no standard role for the use of chemopreventive agents in the management of head and neck cancer.

Retinoids and beta-carotene both may cause regression of oral leukoplakia; the former appear more efficacious.⁵³ Lesions commonly recur after cessation of drug therapy. Chemoprevention agents do not reduce the risk of recurrence of the index cancer.

High-dose 13-*cis*-retinoic acid (100 mg/m² daily for 12 months) has been shown in a randomized, placebo-controlled trial to reduce the risk of SPTs in patients previously treated for stage I to IV, M0, head and neck cancer.⁵⁴ However, a large, placebo-controlled, randomized trial in 1,190 survivors of stage I and II head and neck SCC found no difference in the rate of SPTs or survival after 3 years of a low-dose schedule of this agent (30 mg per day).⁵⁵ Outcomes were better among nonsmokers and those who quit compared to smokers, emphasizing the important role of tobacco cessation as part of head and neck cancer management and strategies to decrease SPTs. Similarly, etretinate was not shown to be efficacious in decreasing SPTs.⁵⁶

With regard to other agents, vitamin A, N-acetylcysteine, both, or neither were evaluated using a factorial design in the EU-ROSCAN study. No significant improvement in survival or SPTs was observed.⁵⁷ Bairati et al.⁵⁸ randomized head and neck cancer survivors to 3 years of therapy with alpha-tocopherol and beta-carotene versus placebo; the rate of SPTs was actually higher during the period of treatment, a difference that did not persist with longer follow-up. A randomized phase II, placebo-controlled trial demonstrated no significant benefit of celecoxib at 100 mg or 200 mg, both twice daily, on the control of oral premalignant lesions.⁵⁹

Targeting the epidermal growth factor receptor (EGFR) pathway is receiving attention, because there is an association between progressive EGFR dysregulation and the transition from normal mucosa to dysplasia to SCC.⁶⁰ The concept of bioadjuvant therapy,⁵⁵ whereby drug combinations intended to reduce both the risk of SPTs and relapse from the index cancer, as well as the potential role of natural extracts are also of interest.⁶¹

There is no standard role for the use of HR-HPV vaccination in the prevention of head and neck cancer at this time,⁶² although the impact of current vaccination programs on the incidence of head and neck cancer warrants follow-up.

Chemotherapy for Recurrent or Metastatic Disease

Single Agents

Patients with recurrent or metastatic head and neck SCCs have a median survival of 6 to 9 months, and a 1-year survival rate of 20% to 40% when treated with chemotherapy alone.^{63,64} Although

selected patients may derive apparent significant prolongations in survival, average survival improvements appear small at best. Morton et al.⁶⁵ reported a 2-month improvement in median survival after treatment with cisplatin, with or without bleomycin, compared to no treatment. The duration of responses is typically measured in weeks to months, not years; survival beyond 2 years is infrequent; and cures are anecdotal. Thus, the primary intent of chemotherapy in this setting is to achieve tumor regression with the hope that the potential palliative benefit and possible modest survival improvement will outweigh the side effects of treatment.

A number of drugs have been demonstrated in clinical trials to have activity in head and neck SCCs, and the list is well summarized in prior reviews.^{63,64} The most commonly used include methotrexate, cisplatin, carboplatin, 5-fluorouracil, paclitaxel, and docetaxel, with reported major response rates ranging from 15% to 42%. Among other drugs with reported major response rates of 15% or greater are bleomycin, cyclophosphamide, doxorubicin, hydroxyurea, ifosfamide, irinotecan, oral uracil, fltorafur (with leucovorin), pemetrexed, vinblastine, and vinorelbine. Some of these agents (e.g., cyclophosphamide, doxorubicin, hydroxyurea) have their activity based on reported assessments in a limited number of patients from over 2 decades ago, an era when methods and criteria for response assessments may have differed from current standards. Anticipated response rates and toxicity profiles may vary based on patient selection and drug schedule. A poor performance status is associated with both lower response rates and greater potential for toxicity. The larger the amount of prior treatment also adversely affects response rates.⁶⁴

Methotrexate is a historic standard drug used in the recurrent or metastatic disease setting. The typical standard dosing is 40 mg/m² intravenously weekly, with dose attenuation or increase (up to 60 mg/m²) based on toxicity, with mucositis being a frequent reason for dose adjustment. The favorable side effect profile and convenience of administration of methotrexate make it well-suited for use in this patient population in which medical comorbidity is common, as is more advanced age. In randomized trials, higher doses increase response rates and toxicity without a significant improvement in overall survival.^{66,67} Newer analogs of methotrexate (e.g., edatrexate) have not been shown to offer a therapeutic advantage in phase III trials.⁶⁸

Cisplatin is a cornerstone drug in the modern management of head and neck cancer. Cisplatin is customarily dosed at 75 to 100 mg/m² intravenously every 3 to 4 weeks. The potential for renal (i.e., increase in creatinine, electrolyte abnormalities), otologic (i.e., high frequency hearing loss, tinnitus), neurologic (i.e., peripheral neuropathy), and gastrointestinal (i.e., nausea and vomiting) toxicity are widely appreciated, but these risks are manageable if patients are appropriately screened for therapy, monitored closely, and state of the art supportive care measures are applied. Further dose escalation of cisplatin has not been established to improve outcome. A randomized trial comparing 60 mg/m² versus 120 mg/m² of cisplatin failed to demonstrate a significant improvement in response or survival.⁶⁹ Carboplatin is the best studied and most commonly used platinum analog in head and neck cancer. Although generally less toxic and easier to administer than the parent drug, it is more bone marrow suppressive and may be somewhat less active. This last issue is more of a concern in the definitive treatment setting in which cure is a central endpoint, as opposed to the palliative setting, when patients often seek a less toxic alternative treatment.

Although taxanes as a class have significant activity in head and neck SCCs, hopes of clinically significant improvement in survival in the palliative setting with the introduction of these agents have yet to be realized. Neither paclitaxel or docetaxel has been demonstrated in random assignment trials to be clearly superior to methotrexate with regard to survival as an endpoint.⁷⁰ Paclitaxel dosed at 250 mg/m² intravenously over 24 hours with growth factor support in an Eastern Cooperative Oncology Group (ECOG) trial, yielded a major response in 12 of 30 patients (40%) including

four complete responses; grade 3 or greater neutropenia occurred in 91% of patients, and there were two deaths.⁷¹ Less cumbersome to administer and less toxic schedules are commonly used in practice (e.g., 135 to 225 mg/m² intravenously over 3 hours every 3 weeks; 80 to 100 mg/m² weekly), although their relative efficacies have not been well evaluated. A paclitaxel schedule that provides more prolonged exposure to the drug may be more efficacious,⁷² although a phase II trial of 120 to 140 mg/m² over 96 hours yielded disappointing results even in treatment-naïve patients (major response rate, 13%).⁶⁵ Other toxicities besides myelosuppression include sensory neuropathy, alopecia, allergic reactions, and arrhythmia, although cardiac monitoring is not required.

Docetaxel appears less neurotoxic than paclitaxel, but fluid retention and hematologic toxicity may be more problematic. A typical dose is 60 to 100 mg/m² intravenously over 1 hour. Initial studies evaluated the efficacy of the 100 mg/m² dose level, with major response rates ranging from 21% to 42%⁷³; an excellent performance status is required for this higher dose. Lower doses may offer similar efficacy and better tolerance.⁷⁴ As with paclitaxel, weekly schedules are applied in practice, but the relative efficacy of weekly versus a schedule of every 3 weeks is not well-studied.

Although initial studies evaluated a bolus schedule for 5-fluorouracil, an infusional program of 1,000 mg/m² per day over 96 to 120 hours appears more efficacious in head and neck cancer.⁷⁵ Infusional 5-fluorouracil is associated with more mucositis and diarrhea than a bolus schedule, so the shorter infusion (i.e., 96 hours) is typically applied in patients who are pretreated and have received prior head and neck RT.

EGFR is highly expressed in most head and neck SCCs, and the degree of expression is inversely associated with prognosis.^{76–78} As such, there has been a keen interest in drugs that target the receptor itself or steps downstream. Cetuximab, a chimeric immunoglobulin G antibody that binds the receptor, has been approved by the U.S. Food and Drug Administration for use in patients with disease refractory to platin-based therapy. As summarized in Table 38.7, the response rates in this refractory setting are similar (10% to 13%) whether cetuximab is used alone or combined with platin-based therapy; median survivals remained disappointing, ranging from 5.2 to 6.1 months.^{79–82} Another EGFR antibody, zalutumumab, was compared in a randomized trial to best supportive care alone in patients with cisplatin-refractory squamous cell head and neck cancer. Among 286 entered patients, there was no significant improvement in the primary endpoint of overall survival (median 6.7 versus 5.2 months, $p = 0.0648$) although a significant difference was found on an exploratory post hoc analysis done 12 months after the last patient was randomized. Response rate (6.3% versus 1.1%) and progression-free survival (median 9.9 versus 8.4 weeks, $p = 0.0012$) were improved with zalutumumab.⁸³

The small molecule tyrosine-kinase inhibitors, gefitinib and erlotinib, offer no efficacy advantage in similar refractory patients.

Major response rates and median survivals ranged from 0% to 15% and 5.9 to 8.1 months, respectively.^{78,84–86} A large randomized trial (486 patients) compared gefitinib (250 or 500 mg daily) to methotrexate and demonstrated no survival improvement with either gefitinib dose.⁸⁷

With both of these classes of agents, the development of rash was associated with clinical benefit, but this association is not fully explained by simple pharmacokinetics.⁷⁸ There is no established molecular predictor of response to these agents currently in head and neck SCC.

The successful development and approval of cetuximab in head and neck SCC highlights the potential for therapies to exploit specific molecular pathways with therapeutic effect. A number of other new agents, often with multitarget capability, are entering clinical trials. There is a good rationale for agents that target angiogenesis in head and neck SCC.⁸⁸ However, the development of bevacizumab has been cautious given the reported toxicity concerns, specifically bleeding, in patients with squamous cell lung cancer.⁸⁹ Alterations in the PI3K/Akt/mammalian target of rapamycin (mTOR) pathway are common in head and neck cancer, and activation appears independent of EGFR activation, making targeting of this pathway of great interest.⁹⁰ Cancer gene therapy, whereby genetic sequences are introduced via viral or nonviral vectors, is well-suited to head and neck tumors given the local-regional character of head and neck tumors that facilitates direct injection and the monitoring of gene expression. The tumor suppressor gene p53 has been one target, because somatic mutations of it are common in head and neck cancers, particularly among patients who have smoked cigarettes and used alcohol.⁹¹ For example, in a phase II study of Onyx-015, a replication-competent adenovirus absent the E1B gene, major responses, including some complete regressions, occurred in 10% to 14% of treated patients.⁹² In other studies, treatment with Onyx-015, or a similar virus such as H101, improved the efficacy of chemotherapy.^{93,94}

Combination Therapy

Given the disappointing track record for single-agent therapy in the palliative setting, combinations of drugs have been extensively evaluated. In the early 1980s, investigators from Wayne State, building upon potential synergy between cisplatin and 5-fluorouracil, reported a major response rate of 70% with a complete response rate of 27% using a regimen of cisplatin 100 mg/m² intravenously and a 5-fluorouracil 1,000 mg/m² per day continuous infusion over 96 hours recycled every 3 weeks in patients with recurrent or disseminated disease.⁹⁵ Other investigators confirmed the significant activity of the regimen, albeit with a somewhat lower major and complete response rate on average (50% and 16%, respectively),⁹⁶ establishing it as the standard regimen to which new therapies are compared.

TABLE 38.7

Cetuximab for Recurrent or Metastatic Head and Neck Cancer: Selected Studies

Author	No. of Patients	Cancer	Chemotherapy	RR	Median PFS (Months)	Median OS (Months)
Herbst et al. ^{80,a}	79	SCC–POD on CDDP based	CDDP based + cetuximab	6%–20%	2.0–3.0	4.3–6.1
Baselga et al. ^{79,a}	96	SCC–POD on platin based	CDDP based + cetuximab	10%–11%	2.4–2.8	4.9–6.0
Trigo et al. ⁸¹	103	SCC–POD on platin based	Cetuximab	13%	2.3	5.9
Burtness et al. ^{82,b}	117	SCC No chemo for R/M	CDDP CDDP + cetuximab	10% 26%	2.7 4.2	8.0 9.2

^a Range related to how POD was defined in different subgroups.

^b Response rates were significantly different ($p = 0.03$): PFS ($p = 0.09$) and OS ($p = 0.21$) did not reach statistical significance.

RR, response rate; PFS, progressive-free survival; OS, overall survival; SCC, squamous cell cancer; POD, progression of disease; CDDP = cisplatin; R/M = recurrent or metastatic disease.

Despite an improvement in response rates associated with the use of combination therapies like cisplatin and 5-fluorouracil, demonstrating a statistically or clinically significant improvement in survival compared to single-agent therapy has proven elusive. Table 38.8 summarizes the results of three randomized trials that compared treatment with cisplatin and infusion 5-fluorouracil to that with different single agents.⁹⁷⁻⁹⁹ Treatment with combination chemotherapy led to a significant increase in response rate, albeit at the cost of greater toxicity. Overall survival did not significantly improve. The meta-analysis reported by Browman et al.¹⁰⁰ yielded similar conclusions. These data do not support the routine use of cisplatin-based combinations for patients with recurrent or metastatic SCC. Combination therapy seems most appropriate for patients with a good performance who have significant symptoms (e.g., pain) for which the higher anticipated response rate will translate into better palliation.

The activity of paclitaxel and docetaxel in head and neck cancer has fostered the development and evaluation of taxane and cisplatin combinations. Docetaxel with cisplatin is associated with a major response rate of 40% to 53%, with complete response rates approximating 6% to 18%^{101,102}; a weekly schedule of paclitaxel (80 mg/m²) and carboplatin (area under concentration [AUC] versus time curve, 2) appeared more efficacious than an every 3-week dosing (paclitaxel 175 to 200 mg/m² intravenously over 3 hours followed by carboplatin AUC 6) in two separate phase II studies.¹⁰³⁻¹⁰⁵ ECOG compared a high-dose (200 mg/m²) and moderate-dose (135 mg/m²) paclitaxel, both by 24-hour infusion and followed by the same dose of cisplatin (75 mg/m²) in a randomized study (E1393). No significant difference in response rate or survival was found between the arms.¹⁰⁶ Another randomized trial done under the auspices of ECOG compared standard cisplatin and 5-fluorouracil with paclitaxel 175 mg/m² intravenously over 3 hours and cisplatin 75 mg/m² (E1395).¹⁰⁷ Objective major response rates (27% versus 26%) and median survivals (8.7 versus 8.1 months) were no different between the arms. The reported quality of life was better on the paclitaxel arm over the first 16 weeks of treatment.¹⁰⁸

Attempts have been made to improve the efficacy of combination chemotherapy through the development of a variety of triplets. The addition of interferon-alpha2b (IFN-α2b) to cisplatin and 5-fluorouracil failed to significantly improve response or survival in

a randomized trial.¹⁰⁹ Phase II studies of a taxane with cisplatin or carboplatin and a third drug (e.g., 5-fluorouracil, ifosfamide), have yielded major response rates of 55% to 86%¹¹⁰⁻¹¹³; whether these regimens translate into better survival outcomes compared to a cisplatin-based doublet that may be less toxic await further evaluations.

There is great interest in the combination of standard chemotherapy with newer targeted agents. One ECOG study compared cisplatin versus cisplatin and cetuximab as first-line treatment in 123 patients. The arm including the cetuximab had a significantly higher response rate (10% versus 26%, $p = 0.03$), but no significant difference was found in the primary endpoint of progression-free survival (2.7 versus 4.2 months, $p = 0.09$) or in overall survival (8.0 versus 9.2 months, $p = 0.21$), although the trends favored the combination arm.⁸² In a larger trial (EXTREME),¹¹⁴ 442 patients were randomized to cisplatin or carboplatin and 5-fluorouracil with or without cetuximab for six cycles. Subsequent maintenance with cetuximab alone was allowed on the investigational arm, but there was no crossover to cetuximab on the standard arm. Both median progression-free (5.6 versus 3.3 months) and overall (10.1 versus 7.4 months) survivals were significantly improved on the triplet arm, at the cost of more sepsis (nine patients versus one patient; $p = 0.02$), grade 3 skin reactions (9%), and grade ≥3 infusion reactions. Quality of life outcomes were reported to not be significantly different between the treatment arms.¹¹⁵ Tumor EGFR copy number and degree of EGFR expression were not predictive of benefit with cetuximab.^{116,117} Of interest, data from Vermorken and colleagues¹¹⁸ suggests that the therapeutic effect of cetuximab, when combined with chemotherapy, is mainly additive rather than synergistic. Whether allowing patients to crossover to cetuximab on the doublet arm at progression would have decreased or eliminated the observed survival difference is of interest for future research. A similar but not identically designed randomized trial evaluated cisplatin and 5-fluorouracil with or without the EGFR antibody panitumumab in 657 patients. Response rate (36% versus 25%, $p = 0.0065$) and median progression-free survival (5.8 versus 4.6 months, $p = 0.0036$) were significantly improved with the incorporation of the panitumumab, but not the primary endpoint of overall survival (11.1 versus 9.0 months, $p = 0.1403$). Overall survival was improved in the p16-negative subgroup ($p = 0.0115$).¹¹⁹

With advances in RT techniques that facilitate reirradiation with acceptable morbidity, this approach has been increasingly

TABLE 38.8

Chemotherapy for Recurrent or Metastatic Head and Neck Cancer: Selected Phase III Trials of Cisplatin/5-Fluorouracil Versus Other Options

Study	No. of Patients	Agents	Response Rates ^a	Median Survivals ^b (Months)
Jacobs et al. ⁹⁸	249	CDDP/FU CDDP FU	32% 17% 13%	5.5 5.0 6.1
Forastiere et al. ⁹⁷	277	CDDP/FU CBDCA/FU MTX	32% 21% 10%	6.6 5.0 5.6
Clavel et al. ⁹⁹	382	CDDP/MTX/BLEO/VCR CDDP/FU CDDP	34% 31% 15%	8.2 6.2 5.3

Gibson et al. ¹⁰⁷	218	CDDP/FU CDDP/PAC	27% 26%	8.7 8.1

^aThe following response rate differences were statistically significant at $p < 0.05$: Jacobs et al., CDDP/FU versus both CDDP and FU; Forastiere et al., CDDP/FU versus MTX; Clavel et al., both combinations versus CDDP.

^bAll survival differences were not statistically significant.

CDDP, cisplatin; FU, 5-fluorouracil; MTX, methotrexate; CBDCA, carboplatin; BLEO, bleomycin; VCR, vincristine; IFN-α2b, interferon-alpha 2b; PAC, paclitaxel.

explored in patients with unresectable local or regional recurrence, often with integrated chemotherapy. The observed median survivals in these series are similar to those obtained in phase II trials of chemotherapy alone, but more durable responses occur in selected patients and there is a clearer plateau on the survival curve. In two larger series involving 169 and 115 patients, respectively, among patients treated with a variety of RT fractionation schedules and concurrent chemotherapy regimens, 2-year survival rates exceeded 20%.^{120,121} In two sequential RTOG studies, a regimen of daily paclitaxel (20 mg/m²) and cisplatin (15 mg/m²) added concurrently to split-course RT (total dose 60 Gy, 1.5 Gy twice-daily fractions; granulocyte colony-stimulating factor support during off weeks) (RTOG 96-11) yielded a better 2-year survival rate than concurrent 5-fluorouracil and hydroxyurea added to the same RT schedule (RTOG 96-10) (24.9% versus 16.9%, $p = 0.44$).^{122,123} The reported 2-year survival rates exceed the rate of 10.5%, which was observed in a subgroup of 124 patients with local disease only who had previously received RT and participated in E1393 or E1395.¹²⁴ Randomized trials comparing chemotherapy alone to reirradiation and chemotherapy are needed.

Nasopharynx Cancer

Many of the same drugs and regimens used in the treatment of head and neck SCC are also active in NPC. There are reports of a small proportion of patients with recurrent or metastatic disease being controlled long term with chemotherapy alone.¹²⁵ Available data support the use of cisplatin-based combination chemotherapy (e.g., cisplatin/5-fluorouracil; cisplatin/bleomycin/5-fluorouracil +/- epirubicin), although there is a lack of randomized studies to clarify the relative efficacies and toxicities of different options. Site-specific phase II studies report major response rates of 70% or higher with regimens containing cisplatin.¹²⁶⁻¹²⁸ In a review of the Princess Margaret Hospital experience, single-agent or noncisplatin-based combination chemotherapy was associated with a major and complete response rates of 25% and 8%, respectively, in 40 patients, whereas cisplatin-based combination therapy produced major and complete response rates of 70% and 23%, respectively, in 30 patients.¹²⁶ The substitution of carboplatin may be associated with less activity.¹²⁷

With regard to other agents, paclitaxel as a 175 mg/m² 3-hour infusion is active with a response rate of 22% in a series of 24 patients with undifferentiated NPCs.¹²⁸ The combination of it with carboplatin has yielded response rates consistently greater than 50%.¹²⁹⁻¹³¹ Gemcitabine is active in NPCs,^{132,133} and combinations including it appear promising, with response rates exceeding 70%.^{134,135} Capecitabine, prolonged 5-fluorouracil infusion, and cetuximab all have modest activity in the refractory setting, and no major responses were seen in one study with gefitinib.¹³⁶⁻¹³⁹ There is keen interest in looking to exploit the association NPCs have with EBV for therapeutic purposes. Potential gene therapy approaches are discussed elsewhere.^{140,141}

GENERAL PRINCIPLES OF COMBINING MODALITIES

Surgery Plus Radiation Therapy

RT may be administered preoperatively or postoperatively. An analysis of available data suggests there is no compelling difference in survival rates comparing the two sequences¹²; local-regional control may be improved with postoperative treatment.¹⁴²

Combined modality therapy should be avoided for lesions with a high cure rate (70% or greater) by either surgery or RT alone. The increased morbidity from combined treatment is not associated with a significantly improved control rate, and many patients with local or regional failure can be salvaged by secondary procedures.

The advantages of postoperative compared with preoperative RT include less operative morbidity, more meaningful margin checks at the time of the surgery, a knowledge of tumor spread for RT planning, safe use of a higher RT dose, and no chance the patient will refuse surgery. The disadvantages of postoperative RT include the larger treatment volume necessary to cover surgical dissections, a delay in the start of RT with possible progression, and the higher dose required to accomplish the same rates of local-regional control.

Preoperative Radiation Therapy

Preoperative RT should be considered for the following situations: (1) fixed-neck nodes, (2) delayed initiation of postoperative RT by >8 weeks, (3) use of the gastric pull-up for reconstruction, and (4) open biopsy of a positive neck node.

Postoperative Radiation Therapy

Postoperative RT is considered when the risk of recurrence above the clavicles exceeds 20%. The operative procedure should be one stage and of such magnitude that RT is started no later than 6 to 8 weeks after surgery. The operation should be undertaken only if it is believed to be highly likely that all gross disease will be removed and margins will be negative.

Although no definitive randomized trials have addressed the efficacy of postoperative RT in the treatment of head and neck cancer, excellent data that has bearing on this issue is available from the Medical College of Virginia. Two groups of surgeons operated on patients with head and neck cancer: general surgical oncologists who used surgery alone and reserved RT for treatment of recurrent disease, and otolaryngologists who routinely sent patients with locally advanced disease for postoperative RT.¹⁴³ Of 441 patients, 125 were treated surgically between 1982 and 1988 and had ECE and/or positive margins, 71 were treated with surgery alone, and 54 received postoperative RT. Local control rates at 3 years after surgery alone compared with surgery and RT were: for ECE, 31% and 66% ($p = 0.03$); positive margins, 41% and 49% ($p = 0.04$); and ECE and positive margins, 0% and 68% ($p = 0.001$). A multivariate analysis of local control revealed that the use of postoperative RT ($p = 0.0001$), macroscopic ECE ($p = 0.0001$), and margin status ($p = 0.09$) were of independent significance. Cause-specific survival rates at 3 years were 41% for surgery alone and 72% for surgery and postoperative RT ($p = 0.0003$). A multivariate analysis of cause-specific survival showed that postoperative RT ($p = 0.0001$) and the number of nodes with ECE ($p = 0.0001$) significantly influenced this endpoint.

In another series, Lundahl et al.¹⁴⁴ reported on 95 patients with node-positive SCC who were treated with a neck dissection and postoperative RT at the Mayo Clinic. A matched-pair analysis was performed using a series of patients treated with surgery alone; 56 matched pairs of patients were identified. The recurrence rates in the dissected neck (relative risk [RR] = 5.82, $p = 0.0002$), recurrence in either side of the neck (RR = 2.21, $p = 0.0052$), and death from any cause (RR = 1.67, $p = 0.0182$) were significantly higher for patients treated with surgery alone.

Thus, it appears that postoperative RT may significantly improve both local-regional disease control and survival for patients who are at high risk for failure after surgery.

Indications for postoperative RT include close (<5 mm) or positive margins, ECE, multiple positive nodes, invasion of the soft tissues of the neck, endothelial-lined space invasion, PNI, and more than 5 mm of subglottic invasion.⁴² The authors currently recommend 60 Gy in 6 weeks to 66 Gy in 6.5 weeks for patients with negative margins and fewer than three indications for RT. For patients with close (<5 mm) or positive margins, we recommend 70 Gy in 7 weeks or 74.4 Gy at 1.2 Gy twice a day. Concomitant cisplatin chemotherapy should be considered for patients with positive margins and/or ECE.⁴³⁻⁴⁵

Given the appreciation that HPV-related cancers have a better prognosis than HPV-unrelated disease, there is interest in potential deescalation of therapy with the intent of decreasing toxicity without compromise in survival.¹⁴⁵ Although this is an important area of future research, modification in standards of care based on the HPV status of the tumor is not recommended outside of a clinical trial at present.¹⁴⁶

CHEMOTHERAPY AS PART OF CURATIVE TREATMENT

Systematically designed and randomized studies have established a role for drug therapy as part of the standard combined modality management of head and neck SCC in several settings. These include the therapy of unresectable disease, for organ preservation, and for patients with poor risk pathologic features after surgery. Chemotherapy has been shown to improve the likelihood of disease control compared to RT alone in patients with advanced disease, albeit with increased acute toxicity. In certain circumstances, response to chemotherapy has been used to triage patients to different local–regional treatments.

Chemotherapy has been integrated with surgery or RT in a variety of ways including induction, concurrent with RT, and/or maintenance. Unlike outcome studies of surgery and/or RT in which site-specific results are reported, albeit typically using a retrospective methodology, many of the trials evaluating the role of chemotherapy enrolled patients with a variety of head and neck SCCs. Even when site specific, although prospective, subsites are combined. This is less of an issue for studies evaluating therapy for NPC.^{147,148} Nonetheless, important lessons have been learned from these studies, further enhanced by use of a random assignment methodology. In this section, general principles for the integration chemotherapy with local–regional treatment will be discussed with a focus on the results of randomized trials.

The Meta-Analysis of Chemotherapy on Head and Neck Cancer (MACH-NC) included 63 randomized trials published from 1965 through 1993, all of which compared local–regional treatment with or without chemotherapy.¹⁴⁹ Individual patient data was available on 10,741 patients. The absolute improvement in 5-year survival overall was 4% ($p < 0.001$). However, the significant improvement appeared limited to those patients who received concomitant treatment (absolute difference of 8% at 5 years, $p < 0.001$). Neither the difference seen at 5 years with induction (2%, $p = 0.10$), nor maintenance (1%, $p = 0.74$) chemotherapy was statistically significant.¹⁴⁹ In an update of this analysis, now including trials through 2000 and totaling 17,346 patients,¹⁴⁹ the superior efficacy of concurrent therapy was confirmed, and was greater than that seen with induction chemotherapy. Survival benefit diminished with patient age and, on subset analysis, was not significant in patients over 70 years of age.

Tumor HPV status has emerged as an important predictor of favorable treatment response and survival, particularly for patients with oropharynx cancer.⁷ In ECOG 2399, the response to chemotherapy to all protocol treatment, progression free-survival, and overall survival were all improved in the HPV-positive group.⁷ Subsequent analysis of RTOG 0129 demonstrated that tobacco use (> 10 pack-years) and the extent of nodal disease (N2b–N3) both adversely affect the prognosis associated with HPV-positive tumors.⁸

Induction Chemotherapy

In untreated patients with local or regionally advanced M0 head and neck SCC, treatment with cisplatin-based combination chemotherapy will yield major response rates approximating 90%, with clinical complete response rates in the 30% range.¹⁵⁰ Enthusiasm that response rates of this magnitude should translate into

survival benefit when induction chemotherapy was combined with surgery or RT is understandable. Yet, in the original report of the MACH-NC analysis, which included 31 induction studies, all but 2 suggested no survival benefit.¹⁴⁹

However, a more careful look at these and other data do provide grounds for continued interest in this approach. Many of the included studies had significant methodologic limitations by more contemporary trial standards. A subset analysis, limited to the 15 trials that used cisplatin and infusional 5-fluorouracil, suggested survival benefit (hazard ratio [HR], 0.88; 95% confidence interval [CI], 0.79 to 0.97).¹⁴⁹ Even in the absence of survival improvement, there seemed to be a correlation between response to chemotherapy and subsequent response to RT, which provided a basis for subsequent organ preservation initiatives.^{151,152} Finally, patterns of failure were affected with less distant metastases in certain studies when induction chemotherapy was incorporated. As local–regional control improves, the rate of clinically apparent distant metastases is increasing,¹⁵³ and induction chemotherapy is, on average, better tolerated than maintenance therapy as a way to give additional systemic therapy.

The study reported originally by Paccagnella et al.¹⁵⁴ is illustrative of these types of trials, and provides further insights.¹⁵⁵ Two hundred and thirty-seven patients with stage III or IV head and neck cancer were randomized to four cycles of induction cisplatin and infusional 5-fluorouracil followed by standard local–regional treatment (i.e., surgery plus RT if resectable, RT alone if unresectable). Resectability was assessed pretreatment, not after chemotherapy, and was a stratification criteria. Overall, there was no significant difference between the arms with regard to overall survival or local–regional control, although the incidence of distant metastases was lower among patients treated with chemotherapy. On a subset analysis, however, patients with unresectable disease benefitted from the incorporation of induction chemotherapy for all outcomes, including local–regional control, distant control, and overall survival (3-year survival 24% versus 10%, $p = 0.04$). Among resectable patients, improvement in distant control was offset by a decrement in local–regional control with the integration of induction chemotherapy, and reported survival rates in this subgroup were similar on both treatment arms.

Historically, then, there was no established role for induction chemotherapy prior to planned surgery and postoperative RT, and a limited role only in selected settings prior to RT. However, with the incorporation of taxanes into induction regimens containing cisplatin and 5-fluorouracil, newer data suggest that the indications for induction chemotherapy may further evolve.

Three randomized trials have compared the relative efficacies of induction chemotherapy with standard cisplatin and 5-fluorouracil versus a triplet including a taxane and these same two drugs with one or both being dose adjusted.^{156–158} All three studies randomized patients with advanced M0 head and neck cancer to either cisplatin and 5-fluorouracil or a triplet, followed by the same RT-based treatment. In one study, this was RT alone, whereas, in the other two, concurrent therapy with carboplatin and cisplatin, respectively, were employed. In general, the taxane-containing triplet was associated with a higher response rate to induction chemotherapy, and improved both progression-free and overall survival. More neutropenia was observed with triplet therapy but, overall, it was as well-tolerated as standard cisplatin and 5-fluorouracil.

These studies were designed to determine which induction chemotherapy was more efficacious, and provide convincing evidence that the triplet of a taxane with cisplatin and 5-fluorouracil is superior to standard cisplatin and 5-fluorouracil alone as induction therapy. However, an alternative design is necessary to define the role of induction with such triplets in standard practice. For this population, as discussed in the next section, concurrent chemotherapy and RT alone without induction chemotherapy is the more established standard therapy. Randomized studies are necessary to determine whether a sequential approach using induction with a

triplet followed by RT-based treatment (typically with concurrent chemotherapy), is superior to concurrent chemotherapy and RT alone such that the added duration of treatment and potential toxicity is justified.

To date, available randomized trials have failed to demonstrate a clear overall survival benefit with the incorporation of induction chemotherapy. The combination of docetaxel, cisplatin, and 5-fluorouracil has been the focus of these investigations. One study available only in abstract form was confounded by the lack of an intention to treat an analysis with unequal exclusions among treatment arms. Even with those methodologic limitations, it failed to demonstrate a significant improvement in overall survival with the incorporation of induction docetaxel, cisplatin, and 5-fluorouracil or cisplatin, and 5-fluorouracil.¹⁵⁹ In the PARADIGM study, 145 patients with local or regionally advanced SCC were randomized to induction docetaxel, cisplatin, and 5-fluorouracil followed by carboplatin or docetaxel concurrent with RT versus concurrent cisplatin with concomitant boost radiation. Patients could have unresectable disease or be resectable, with the intent of therapy being organ preservation. The study was closed early because of slower than expected accrual, so it was somewhat underpowered. There was no difference in overall or progression-free survival between the arms with a median follow-up of 49 months; the 3-year overall survival rates were 73% on the induction arm and 78% on the concurrent arm ($p = 0.77$); and the 3-year progression-free survival rates were 67% and 69%, respectively ($p = 0.82$). A subset analysis of the group with advanced neck disease (N2b/N2c, N3), felt to be at increased risk of distant metastases, demonstrated no advantage with the incorporation of induction chemotherapy.¹⁶⁰ The DECIDE trial used a similar design, but only patients with N2/N3 were eligible and, for the concurrent therapy, hydroxyurea and 5-fluorouracil was used. Among 280 patients accrued with minimum 24-months follow-up, there was no significant difference between the sequential and concurrent arms with regard to overall survival (75% versus 73%, $p = 0.70$) or disease-free survival (69% versus 64%, $p = 0.39$); the cumulative incidence of distant failure, however, was lower in the induction arm (10% versus 19%, $p = 0.025$).¹⁶¹ Finally, in 256 enrolled patients with stage III or IVA oral cavity cancer, induction with docetaxel, cisplatin, and 5-fluorouracil prior to surgery and postoperative radiation failed to improve overall survival ($p = 0.918$) or disease-free survival ($p = 0.897$) compared to proceeding directly to surgery and postoperative radiation alone.¹⁶²

The optimal role of induction chemotherapy is currently controversial. A review of the National Comprehensive Cancer Network (NCCN) guidelines highlights this reality, because concurrent chemoRT alone and induction followed by RT-based therapy are both listed as treatment options for certain disease scenarios.¹⁴⁶ Although concurrent chemoRT alone remains the standard to which new treatments are compared for local or regionally advanced disease and generally receives the higher category rating in these guidelines, induction is well-suited for certain settings in patients who are medically fit. Examples include when immediate therapy is needed in the hope of avoiding a tracheostomy or PEG, in organ preservation settings where the degree of response affects the decision to proceed with surgery versus RT-based therapy, or in patients with advanced neck disease at higher risk for distant metastases.

After induction chemotherapy, there is some controversy as to whether to proceed with RT alone or concurrent chemoRT, and if the latter, which drug to use.¹⁵⁶⁻¹⁵⁸ Concern exists regarding the tolerance to high-dose cisplatin after cisplatin-based induction treatment. In a randomized phase II trial, concurrent cetuximab and RT was compared with high-dose cisplatin and RT after induction docetaxel, cisplatin, and 5-fluorouracil in 116 patients with advanced hypopharynx or larynx cancer. Toxicity was substantial on both arms, but treatment compliance was better with cetuximab therapy. There was no significant difference in larynx

function preservation and overall survival between the arms; more local failures occurred on the cetuximab arm.¹⁶³

Concurrent Chemotherapy and Radiation for Gross Disease

Although there are a number of ways to integrate chemotherapy with RT, available data most strongly support concurrent chemotherapy. Given proven efficacy in patients with poor prognostic and unresectable disease, more recent investigations have applied the approach in better prognostic, organ preservation, and adjuvant settings.

Concurrent chemoRT programs vary in many ways, of which the type of chemotherapy (i.e., specific agents, single, combination) and RT schedule (i.e., dose, fractionation) are the most apparent variables. In general, three main approaches can be discerned: single-agent or combination chemotherapy with continuous-course RT; combination chemotherapy with split-course RT, often with altered fractionation; and chemotherapy alternating with RT.¹⁶⁴ Although continuous course RT may be desirable and more attractive from a radiobiologic perspective, local toxicities may preclude it depending on the concurrent agents used. The first two approaches are the most common.

A variety of drugs and combinations have been utilized concurrently with RT. When only one drug is used, the MACH-NC indicates that the impact is largest with a platin, of which cisplatin is the predominant one studied, a conclusion shared in another meta-analysis reported by Browman and colleagues.¹⁶⁵ Of interest, platin plus 5-fluorouracil (HR, 0.75) offered no clear advantage compared to platin alone (HR, 0.74).¹⁶⁶ The results of a three-arm randomized study comparing concurrent cisplatin and RT, concurrent cisplatin, 5-fluorouracil and split-course RT (with possible resection depending on response), and definitive RT alone in patients with unresectable disease reported by Adelstein et al.,¹⁶⁷ in the E1392 study, are consistent with this assessment. Although daily,¹⁶⁸ weekly,^{46,169} and every 3 week schedules of cisplatin intravenously concurrent with RT have been applied, the last schedule is the one most studied and is a widely accepted standard. If weekly dosing is used, 20 mg/m² weekly appears too low because it did not significantly improve overall survival or failure-free survival in one randomized study.¹⁶⁹ Attempts to improve the efficacy of concurrent cisplatin through intra-arterial administration^{170,171} did not prove more efficacious in a randomized trial when compared to intravenously delivered cisplatin, although toxicity profiles differed.¹⁷² In absence of a proven efficacy advantage with intra-arterial delivery, intravenous cisplatin is preferred because it is logistically easier to administer.

Most randomized trials to date have compared chemoRT to RT alone. As such, studies evaluating the efficacy of different chemoRT programs are limited. For example, for purposes of the MACH-NC analysis, "platin" included both cisplatin and carboplatin. Yet the relative efficacy of these agents, when given concurrently, is not well-studied. In one three-arm randomized study by Jeremic et al.¹⁶⁸ using a daily schedule for each drug with RT and a control arm of RT alone, both the cisplatin (6 mg/m² per day) and carboplatin (25 mg/m² per day) arms appeared comparable, and superior in efficacy to RT alone. However, in a randomized study reported by the Hellenic Cooperative Oncology Group using an every 3 week schedule for each drug (cisplatin 100 mg/m², carboplatin AUC, 6), their equivalence seemed less clear.¹⁷³ The RTOG reported a randomized phase II study comparing three different chemotherapy regimens, all delivered concurrently with 70 Gy in 2 Gy fractions: ARM 1, cisplatin 10 mg/m² per day and 5-fluorouracil 400 mg/m² per day continuous infusion for the final 10 days of treatment; ARM 2, hydroxyurea 1 g every 12 hours and 5-fluorouracil 800 mg/m² per day continuous infusion every other week; or ARM 3, weekly paclitaxel 30 mg/m² and cisplatin 20 mg/m². Among 231 analyzable patients, 2-year disease-free and overall survival rates were for ARM

1, 38.2% and 57.4%; for ARM 2, 48.6% and 69.4%; and for ARM 3, 51.3% and 66.6%, respectively.¹⁷⁴

Because anemia may adversely affect the efficacy of RT, the integration of an appropriate hematopoietic growth factor has been investigated. In a multicenter, double-blind, randomized, placebo-controlled trial, the addition of erythropoietin 300 IU/kg three times weekly during postoperative RT was evaluated in 351 patients with head and neck SCC.¹⁷⁵ Although target hemoglobin levels were reached in 82% of patients receiving erythropoietin compared to 15% receiving placebo, local–regional progression-free survival (adjusted RR, 1.62 [95% CI, 1.22 to 2.14]; $p = 0.0008$), local–regional progression (RR, 1.69 [CI, 1.16 to 2.47]; $p = 0.007$), and survival (RR, 1.39 [CI, 1.05 to 1.84]; $p = 0.02$) were all inferior on the erythropoietin arm. Consistent with the current FDA alert, an erythropoietin-stimulation agent is contraindicated during curative-intent RT-based therapy.¹⁷⁶ Transfusion then, is the preferred approach to address potential radiation resistance attributed to anemia, but a recent analysis of two randomized trials failed to demonstrate that prophylactic transfusion improved overall survival or other disease control endpoints.¹⁷⁷ Use of a hypoxic radiosensitizer represents another strategy to potentially address tumor hypoxia. The results of one meta-analysis were consistent with potential benefit¹⁷⁸; recent randomized trials, however, have not been convincing in terms of improved disease control with such a strategy.^{179,180}

An important question is whether the use of newer, more efficacious, and altered fractionated RT programs¹⁸¹ obviates the benefits accrued with the addition of chemotherapy. A single institution study reported by Brizel et al.¹⁸² compared a more aggressive RT schedule with or without concomitant 5-fluorouracil and cisplatin. Patients who underwent RT alone received 75 Gy in 60 twice-daily fractions; those who underwent concomitant chemotherapy received 70 Gy in 56 twice-daily fractions with a 7-day split. Chemotherapy consisted of two cycles of concomitant cisplatin 12 mg/m² per day and 5-fluorouracil 600 mg/m² per day each for 5 days, followed by two cycles of maintenance chemotherapy. Among the 116 patients included, chemoRT was associated with improved 3-year rates of local–regional control (70% versus 40%, $p = 0.01$), relapse-free survival (61% versus 41%, $p = 0.08$), and overall survival (55% versus 34%, $p = 0.07$). In another randomized study reported by Jeremic et al.,¹⁸³ the addition of daily cisplatin to hyperfractionated RT also leads to incremental benefits. The results of these studies are consistent with the MACH-NC analysis, which demonstrated significant HRs, that are consistent with benefits among patients receiving postoperative RT (HR, 0.79), conventional RT (HR, 0.83), or altered fractionated RT (HR, 0.73), suggesting a benefit for adding concomitant chemotherapy regardless of the type of RT schedule.¹⁶⁶

Of note, the converse—once concurrent chemotherapy is added, does an altered fractionation RT schedule further improve outcome compared to that seen with standard fractionation—has not been established in randomized trials. Neither RTOG 0129 (standard versus concomitant boost RT both with concurrent high-dose cisplatin)⁸ nor GORTEC 99-02 (accelerated RT with or without concurrent carboplatin and 5-fluorouracil, standard fractionated RT with concurrent carboplatin and 5-fluorouracil)¹⁸⁴ demonstrated improved overall survival with the incorporation of altered fractionated RT with concurrent chemotherapy versus standard fractionation with concurrent chemotherapy to justify the added logistical complexity and potential added toxicity.

For patients who are not cisplatin candidates, using a carboplatin-based program (e.g., carboplatin/5-fluorouracil)¹⁴⁷ or other concurrent programs that have different side effect profiles and that withstood the scrutiny of a randomized trial is recommended. There has been great interest in cetuximab and concurrent RT in this regard.¹⁸⁵ In a randomized study reported by Bonner et al.,¹⁸⁶ patients with local–regionally advanced head and neck cancer were randomized to RT alone (213 patients) or combined with weekly cetuximab dosed in a standard fashion (211 patients);

median follow-up was 54 months. The median duration of survival was 49 months after combined therapy compared with 29 months after RT alone ($p = 0.03$). Other than an acneiform rash and infusion reactions, grade 3 or greater complications were similar in the two groups of patients. The results of this trial have been confirmed with longer follow-ups.¹⁸⁶ Patients with oropharynx cancer appeared to derive the largest benefit with the integration of cetuximab, suggesting that HPV-related disease may have an improved outcome with the use of this agent; other studies, however, suggest greater activity of EGFR-directed antibody therapy in HPV-negative disease.^{114,119} Randomized data comparing cetuximab and RT to other chemoRT programs are not available. One RTOG study evaluating concurrent cisplatin and RT versus cetuximab and RT in patients with HPV-related cancers is currently in progress. Investigators at Memorial-Sloan Kettering reported a phase II trial of cisplatin and cetuximab concurrent with RT in patients with local–regionally advanced head and neck SCC. Efficacy was impressive, although there were toxicity concerns.¹⁸⁷ The RTOG completed accrual to a large randomized trial (RTOG 0522, $n = 895$ evaluable patients) intended to assess the efficacy and safety of this regimen compared to concurrent cisplatin and RT. With a median follow-up of 2.4 years among surviving patients, the incorporation of cetuximab failed to significantly improve 2-year progression-free survival (63% versus 64%, $p = 0.66$) or overall survival (83% versus 80%, $p = 0.17$), but mucosal and skin toxicity were increased.¹⁸⁸

Choosing among the numerous concurrent programs can be difficult. In the NCCN guidelines,¹⁴⁶ concurrent cisplatin with RT is the preferred choice, although several other options are listed. It is important to emphasize that concurrent chemoRT may be associated with significant toxicity; treatment-related mortality, albeit infrequent (<5% in the cooperative group setting), may occur. Morbidity from chemotherapy (dependent on the agent chosen) and RT are possible, and there are both acute (e.g., mucositis, blood count suppression) and chronic (e.g., dry mouth, swallowing dysfunction, fibrosis) toxicities. Selected studies have begun to report long-term, not just acute, toxicities.¹⁸⁹ Appropriate infrastructure, an experienced multidisciplinary team, and a cooperative patient are necessary to optimize both efficacy and safety.

Nasopharynx Cancer

Current practice has been particularly affected by the Intergroup Study 0099 (Table 38.9).¹⁹⁰ In it, 147 patients with stage III or IV NPC were randomized to definitive RT (70 Gy, 35 fractions over 7 weeks) versus cisplatin 100 mg/m² intravenously on days 1, 22, and 43 concurrent with the same dose of RT followed by three planned cycles of cisplatin and infusional 5-fluorouracil. Although only 63% and 53% of patients received all the planned concurrent and maintenance treatments, respectively, local–regional control, distant control, progression-free, and overall survivals were all significantly improved with chemoRT.

One of the potential limitations of the Intergroup Study was how generalizable its results would be to endemic NPCs, because 24% of patients entered in the trial had World Health Organization (WHO) type I histology. However, subsequent reports of randomized trials in which WHO types II and III predominated have similarly shown a survival advantage with concurrent cisplatin-based concurrent chemotherapy without^{191–193} or with maintenance chemotherapy.^{194,195}

One relatively small randomized trial ($n = 206$) with a median follow-up of 26.3 months, suggested that weekly carboplatin dosed at 100 mg/m² concurrent with RT when compared to standard high-dose cisplatin, did not yield inferior disease-free or overall survival. Both arms received adjuvant platinum and 5-fluorouracil.¹⁹⁶ However, another randomized study involving 408 patients who received concurrent carboplatin at AUC 6 every 3 weeks after induction chemotherapy failed to demonstrate an improvement

TABLE 38.9

Selected Randomized Trials Evaluating Concurrent Chemoradiotherapy Versus Radiotherapy for Advanced Nasopharynx Cancer

Study	No. of Patients	Maintenance Chemotherapy	Treatment Arms	PFS ^{a,b} (p value)	OS ^a (p value)
Al-Saraff et al. ¹⁹⁰	147	Yes, on CDDP/RT arm	RT CDDP/RT	24% 69% (<0.001)	47% 78% (0.005)
Lin et al. ¹⁹¹	284	No	RT CDDP/FU/RT	53% 72% (0.0012)	54% 72% (0.0022)
Chan et al. ¹⁹⁸	350	No	RT CDDP/RT	52% 60% (0.06)	59% 70% (0.049)
Wee et al. ¹⁹⁴	221	Yes, on CDDP/RT arm	RT CDDP/RT	53% 72% (0.0093)	65% 80% (0.0061)
Lee et al. ¹⁹⁵	348	Yes, on CDDP/RT arm	RT CDDP/RT	62% 72% (0.027)	78% 78% (0.97)

^b Disease-free rate provided for Wee et al., and failure-free rate for Lee et al.

PFS, progression-free survival; OS, overall survival; CDDP, cisplatin; FU, 5-fluorouracil; RT, radiation therapy.

in overall survival at 5 years or other disease outcomes compared to patients receiving radiation alone after the same induction regimen.¹⁹⁷

Another limitation of the Intergroup Study was that it was not designed to delineate the proportional benefits of concurrent and maintenance chemotherapy. Although current NCCN guidelines recommend concurrent and maintenance chemotherapy in M0 patients with a more advanced disease based on the Intergroup experience,¹⁴⁶ in reviewing available data, the benefits of maintenance chemotherapy appear more controversial. As noted, other randomized studies have demonstrated a survival improvement with concurrent therapy alone.^{191,198} Earlier randomized trials, summarized elsewhere, failed to demonstrate a survival benefit when either maintenance or induction chemotherapy was added to definitive RT.^{199,200} Furthermore, a meta-analysis of updated individual patient data on 1,753 patients enrolled in eight randomized trials, besides confirming an absolute survival benefit of 6% at 5 years with incorporation of chemotherapy with RT (HR, 0.82, 95% CI, 0.71 to 0.91; $p = 0.006$), also reported a significant association between the timing of chemotherapy and overall survival ($p = 0.005$), with the largest benefit being attributed to concomitant therapy.²⁰¹ A recently reported randomized trial involving 508 patients with nonmetastatic, stage III to IV nasopharyngeal cancer failed to demonstrate a significant difference in 2-year failure-free survival, overall survival, local-regional failure-free survival, or distant failure-free survival after a median follow-up of 37.8 months. Of note, the direction of each of the previous endpoint comparisons favored the adjuvant arm, albeit not significantly so, with associated p values of 0.13, 0.32, 0.10, and 0.12, respectively.²⁰² A longer term follow-up of this trial will be of interest. Currently, the NCCN guidelines list both concurrent chemoRT followed by maintenance chemotherapy and concurrent chemoRT alone as treatment options for advanced disease, with the former having the higher category rating.¹⁴⁶

Selected randomized studies have demonstrated evidence of a positive biologic effect with the use of induction chemotherapy, but no survival benefit has been documented.^{200,203–205} Such promising results have engendered interest in the potential for enhanced efficacy with newer drugs and combinations. A randomized phase II trial evaluating induction with docetaxel and

cisplatin prior to concurrent cisplatin and RT was consistent with a benefit compared with concurrent cisplatin and RT alone.²⁰⁰ Programs incorporating newer taxane- and cisplatin-based triplet induction regimens warrant further study.²⁰⁶ There is also interest in the role of plasma EBV-DNA assays as a way to assess disease and monitor response.¹⁹⁹

Organ Preservation

Organ preservation therapy is intended to control disease without compromise in survival while optimizing function or cosmesis.²⁰⁷ The term implies that the tumor is potentially resectable for cure, and that the morbidity from surgery is significant. Although conservation surgical procedures can achieve the same goals, the label of organ preservation is more commonly applied to nonsurgical approaches. In that regard, the role of chemotherapy integrated with RT is best established for more advanced primary tumors. In this setting, conservation surgical procedures become less feasible, and local control rates with RT alone are lower than seen with earlier stage disease.

Total laryngectomy is one of the surgical procedures most feared by patients.²⁰⁸ Thus, larynx preservation has been a central focus of many organ preservation studies, including those that established integrated chemotherapy and RT as a standard organ preservation treatment option. Studies commonly focused on patients with advanced tumors of the larynx, hypopharynx, and oropharynx (particularly the base of tongue), in whom primary surgical management would jeopardize the voice box.²⁰⁹

Initial chemoRT approaches to larynx preservation utilized induction chemotherapy. The response to initial chemotherapy was used to triage patients to either definitive RT (a partial response or better at the primary site; surgery to the primary site was reserved for salvage) or primary surgical management (lower than a partial response). The randomized and landmark Veterans Administration (VA) Larynx Preservation Study demonstrated that such an approach could be pursued in patients with advanced laryngeal cancer without compromise in survival when compared to primary treatment with surgery and RT.¹⁵¹ Over 60% of patients on the chemoRT arm avoided total laryngectomy. Among

long-term survivors, patients treated on the chemoRT arm had better emotional well-being, were less depressed, and also reported less pain.²¹⁰

A similarly designed randomized trial in patients with pyriform sinus and aryepiglottic fold tumors reported by the European Organization for Research and Treatment of Cancer (EORTC) confirmed these findings.¹⁵² However, a small randomized study (n = 68) limited to patients with T3 disease with a fixed cord done by the Groupe d'Etude des Tumeurs de la Tête et du Cou (GETTEC) reported that survival was superior on the primary surgery arm (84% versus 69% at 2 years, p = 0.006).²¹¹ When the MACH-NC performed a collective analysis of the VA, EORTC, and GETTEC studies, the rate of larynx preservation among survivors was 58%. A nonsignificant (6%) decrement in survival at 5 years was seen in the chemoRT group (39% versus 45%; pooled HR, 1.19; 95% CI, 0.97 to 1.46; p = 0.10).¹⁴⁹

The data reviewed in the prior section highlighting the therapeutic benefits of a concurrent chemoRT relative to an induction or RT alone approach have obvious implications for the larynx preservation setting. RTOG 91-11 was designed to assess the impacts of adding chemotherapy to RT and its timing (concurrent versus induction) with regard to achieving larynx preservation. Four hundred and ninety-seven patients with larynx cancer were randomized to one of three arms: primary RT, 70 Gy to the primary site, 50 to 70 Gy to nodes; induction chemotherapy with cisplatin and infusional 5-fluorouracil for three cycles followed by RT in responders, surgery in nonresponders; and cisplatin 100 mg/m² on days 1, 22, and 43 concurrent with RT. Surgical salvage was an option on all three arms. The recently updated 10-year results are summarized in Table 38.10.^{148,212} As anticipated, the rate of grade 3 or 4 mucosal toxicity was highest on the concurrent arm; however, this did not translate into more significant speech or swallowing impairment at 2 years compared to the other treatment arms. Noteworthy is that, although the larynx preservation rate and local–regional control was highest and statistically superior with concurrent treatment, there was no significant difference in overall survival rates among the arms. Deaths not attributed to larynx cancer were highest in the concurrent arm (30.8%) versus 20.8% on the induction arm and 16.9% in the RT alone group, raising concern regarding the long-term morbidity of concurrent therapy. However, late effects were similar among the groups, and there were no substantial differences in speech or swallowing function reported.²¹²

In another randomized larynx-preservation study, induction chemotherapy followed by RT and alternating chemotherapy and RT approaches were compared in 450 patients with advanced larynx or hypopharynx cancer. Both treatment arms used cisplatin and 5-fluorouracil and allowed surgical salvage. Overall and progression-free survival rates were similar on both arms. Survival with a functional larynx in place was higher with alternating chemoRT,

although the difference was not statistically significant (median, 2.3 years versus 1.6 years; HR, 0.85; 95% CI, 0.68 to 1.06).²¹³

Available randomized phase III data support a concurrent chemotherapy–RT strategy administered with organ preservation intent for patients with advanced oropharynx cancer. A phase III study from the Groupe d'Oncologie Radiothérapie Tête et Cou (GORTEC) demonstrated improved local–regional control (66% versus 42% at 3 years, p = 0.03) in patients with advanced oropharynx cancer who received concurrent chemotherapy (carboplatin and 5-fluorouracil) and RT (70 Gy) compared to RT alone.¹⁴⁷ A non–site-specific trial from the Cleveland Clinic, which included a high proportion of patients with advanced oropharynx cancer, yielded similar results.²¹⁴

Although concurrent chemotherapy is the current cornerstone of organ preservation treatment of advanced disease, other paradigms deserve mention. In an Italian study, 195 patients with T2 to T4 oral cavity cancer were randomized to either primary surgical management or induction chemotherapy with cisplatin and 5-fluorouracil followed by a surgical procedure, which could be modified based on response. Overall survival was similar on both arms, but less postoperative RT was necessary (33% versus 46%) and fewer mandible resections were performed (31% versus 52%) on the chemotherapy arm.²¹⁵ As a further extension of this concept, Laccourreye and colleagues²¹⁶ have pioneered the selective observation without local–regional treatment of patients with laryngeal cancer who have a complete response to induction chemotherapy. Durable tumor control without the addition of surgery or RT has been reported in a small subset of patients with early stage tumors.²¹⁶ The University of Michigan has developed a larynx preservation program whereby the triage to RT-based treatment or surgery occurs after only one cycle of chemotherapy.²¹⁷ The intent is to improve survival and minimize morbidity through the timely selection of appropriate therapy, including referral to surgery if indicated. The implication is that induction chemotherapy has little other therapeutic benefit, and some patients who are slow to respond may be triaged unnecessarily to total laryngectomy.²¹⁸ Conversely, newer sequential strategies of induction chemotherapy followed by planned concurrent chemotherapy are looking to optimize both local–regional and distant control. Induction with more efficacious triplet chemotherapy, including a taxane combined with cisplatin and 5-fluorouracil, is already being incorporated into larynx preservation strategies with evidence of improved larynx preservation rates.²¹⁹

Adjuvant Therapy after Surgery

The use of maintenance chemotherapy after the completion of local–regional treatment has been evaluated in several randomized trials, but with disappointing results. Suboptimal compliance

From Forastiere AA, Zhang Q, Weber RS, et al. Long-term results of RTOG 91-11: a comparison of three nonsurgical treatment strategies to preserve the larynx in patients with locally advanced larynx cancer. *J Clin Oncol* 2013;31:845–852.

with maintenance treatment may in part explain the lack of benefit, because tolerance of chemotherapy can be poor after surgery and RT.²²⁰ Despite these limitations and the lack of convincing survival benefit, patterns of failure were affected in selected studies, with a decrease in distant metastases, consistent with a biologic effect of chemotherapy.^{220,221}

The results of Intergroup 0034 highlight these points. In this trial, 442 analyzable patients were randomized after definitive surgical therapy to either postoperative RT alone (50 to 60 Gy) or three cycles of standard dose cisplatin and 5-fluorouracil by infusion followed by the same RT-dosing scheme. The randomization was stratified by risk, with surgical margins less than 5 mm, cancer in situ (CIS) at the margins, and ECE being considered high-risk features. Overall, there was no significant difference in overall survival, disease-free survival, or local–regional control between the treatment arms, although there was a significant decrease in incidence of distant metastases on the investigational arm ($p = 0.03$). Interestingly, on a subset analysis, adjuvant chemotherapy had no significant impact in the low-risk group, but a more dramatic impact on survival and tumor control was seen among high-risk patients. Given the success of concurrent chemoRT as definitive treatment, its application in the adjuvant setting was a logical extension. A pilot study done by the RTOG demonstrated that concurrent high-dose cisplatin every 3 weeks with RT was feasible in the adjuvant setting.²²² Early randomized studies demonstrated an improvement in local–regional control with the incorporation of concurrent mitomycin.^{223,224} A study comparing weekly cisplatin concurrent with postoperative RT versus RT alone with ECE, yielded a significant improvement in both local–regional control and survival with combined modality treatment.⁴⁶

Two randomized studies, both published in 2004, have further clarified the indications for postoperative chemoRT in the poor risk adjuvant setting. RTOG 9501 and EORTC 22931 had very similar designs.^{43–45,209} Patients were randomized after surgery if they had poor risk features to either standard postoperative RT alone (60 to 66 Gy, over 6 to 6.5 weeks, standard fractionation) or the same RT with three planned cycles of concurrent cisplatin at 100 mg/m² every 3 weeks. What constituted poor risk differed somewhat between the studies: the RTOG required the presence of two or more positive lymph nodes, ECE, or positive margins; the EORTC required ECE, positive margins, pT3 or pT4 with any N, N2, or N3 disease, level IV nodes or stage IV disease in patients with oral cavity or oropharynx primaries, PNI, or vascular embolism.^{43–45} Both studies demonstrated a significant improvement in local–regional control and disease-free or progression-free survival with combined modality therapy. These improvements translated into a significant advantage in overall survival in the EORTC study ($p = 0.02$), but only a trend ($p = 0.19$) in the RTOG study. Neither study showed a significant impact on distant control with the addition of chemotherapy. Acute toxicity was greater with the addition of the cisplatin, but there was no difference in late toxicity.

A subsequent analysis of the EORTC and RTOG studies was performed to better understand which pathologic subgroups may benefit the most from the concurrent addition of cisplatin to RT.²⁰³ Patients having evidence of ECE or a positive margin derived the largest benefit from combined modality adjuvant therapy. Conversely, patients in whom their only poor risk factor was two or more positive lymph nodes without ECE seemed to do just as well with RT alone. Long-term follow-up of RTOG 9501 yielded results consistent with this conclusion.⁴⁵

The EORTC and RTOG studies focused on patients who were previously untreated with the exception of prior surgery. Janot et al.,²²⁵ on behalf of the GETTEC and GORTEC groups, addressed the potential role of concurrent chemotherapy and reirradiation after salvage surgery. In this randomized study enrolling 130 patients, the standard arm was salvage surgery alone. The combined modality treatment significantly improved disease-free survival (HR, 1.68 [95% CI, 1.13 to 2.5], $p = 0.01$), although overall survival was not significantly improved and both acute and chronic toxicities were worse.

Some investigators have questioned whether extracapsular nodal spread has the same adverse prognostic implications in patients with HPV-related disease.²²⁶ The related therapeutic question is whether this pathologic risk factor should drive the addition of concurrent chemotherapy to radiation in the postoperative setting for patients with HPV-related disease. These issues are the focus of ongoing investigations. For now, the NCCN does not recommend different approaches to treatment in the poor-risk adjuvant setting based on tumor HPV status.¹⁴⁶

Toxicity Reduction

Xerostomia is one of the most troubling side effects of RT-based treatment. Extra oral fluids, artificial saliva, other topical measures, and humidity are commonly utilized. Available data indicates that IMRT applied with salivary-sparing intent decreases this symptom.^{34,227,228} Historically, the emphasis has been on parotid sparing. Sparing other salivary glands when possible further improves salivary outcomes.^{229,230} Pharmacotherapy may also help. The cholinomimetic and muscarinic agent, pilocarpine, at a dose of 5 mg three times a day was shown in a randomized trial to improve the production of saliva as well as symptoms of dry mouth compared to placebo in patients treated with at least 40 Gy to the head and neck.²³¹ Excessive sweating was the most common side effect. Cevimeline, a similar agent with a more selective mechanism of action, was associated with a significant increase in unstimulated salivary flow at dosing of 30 to 45 mg three times a day.²³² Amifostine is a thiol with chemo- and radioprotectant properties. Objective and subjective measures of salivary function were improved in an open-label, randomized study among patients who received 200 mg/m² of amifostine intravenous daily 15 to 30 minutes before RT.²³³ Grade 3 toxicities were infrequent, but nausea, vomiting, hypotension, and allergic reactions were more common among patients treated with amifostine. The benefits when given with chemoRT are more controversial.²³⁴ There have been concerns regarding the potential of tumor protection by amifostine, but a recent meta-analysis did not demonstrate any adverse impact on progression-free or overall survival in patients treated with RT or chemoRT.²³⁴ Finally, acupuncture may be of benefit in the management of xerostomia in selected patients.^{38,235}

Mucositis is a troubling symptom typically exacerbated by aggressive altered fractionated RT programs and the use of concurrent chemoRT. A variety of rinses (e.g., topical anesthetics, antifungals) and systemic pain medications are used for symptomatic relief. Concurrent amifostine with RT has not been clearly shown to decrease mucositis.^{233,234} Isegan hydrochloride, a synthetic peptide with broad spectrum antibacterial activity, was evaluated in a multinational, double-blind, placebo-controlled trial among patients receiving definitive or postoperative RT-based therapy. No improvement in oral mucositis was found compared to placebo.²³⁶ Recombinant human keratinocyte growth factor has been shown to decrease the incidence and duration of mucositis in the transplant setting.²³⁷ Two randomized studies demonstrated improvement in observer-assessed mucositis with palifermin use, but no clear difference in patient-reported pain, opioid analgesic use, or treatment breaks when compared to placebo.^{238,239}

FOLLOW-UP

How to optimally follow-up with patients after treatment for head and neck cancer is less well studied than how to treat it. Approaches are informed by patterns of failure. Most relapses occur within the first 3 years and are front loaded, and relapses above the clavicles are potentially curable. The lung is the most common site of distant spread.

The schedule proposed in the NCCN practice guidelines is reasonable.¹⁴⁶ Patients are seen for follow-up head and neck examinations every 1 to 3 months during year 1, every 2 to 6 months during

year 2, every 4 to 8 months during years 3 to 5, and every 12 months thereafter. Thyroid function tests are obtained every 6 to 12 months if the neck was irradiated. Many practitioners obtain annual chest x-rays or other chest imaging to monitor for a second primary lung cancer and to document distant metastases. The impact of this imaging on outcomes is not well established, which is consistent with a vague recommendation from the NCCN of chest imaging “as clinically indicated.” Tobacco history should be considered for purposes of lung cancer screening.¹⁴⁶ Posttreatment baseline imaging within 6 months of therapy is recommended. Additional studies such as CT, MRI, and PET scans may subsequently be necessary to determine whether there is a recurrence or a complication, but otherwise are not routinely performed in surveillance. Speech and swallowing evaluations and rehabilitation are obtained as indicated. Counseling is indicated for patients in whom tobacco or alcohol contributed as a risk factor for tumor development.

ORAL CAVITY

The oral cavity consists of the lips, the floor of mouth, the anterior two-thirds of the tongue, the buccal mucosa, the upper and lower alveolar ridges, the hard palate, and the retromolar trigone.

The AJCC staging system is used.²⁶

LIP

The ratio between men and women with lip cancer is approximately 15:1.²⁴⁰ Persons with light-colored skin and/or prolonged exposure to sunlight are most prone to develop lip carcinoma.

Anatomy

The lips are composed of the orbicularis oris muscle with skin on the external surface and mucous membrane on the internal surface. The transition from skin to mucous membrane is the lip vermilion. The blood supply is from the labial artery, a branch of the facial artery. The motor nerves are branches of cranial nerve (CN) VII. The sensory nerve to the upper lip is the infraorbital branch of CN V (V 2), and the mental nerve (V 3) supplies the lower lip.

Pathology

The most common neoplasms are SCCs. Basal cell carcinomas arise on the skin of the lip and may secondarily invade the vermilion. Keratoacanthoma occurs on the skin of the lips and may be mistaken grossly and histologically for SCC.

Leukoplakia and CIS are common problems on the lower lip and may precede the appearance of carcinoma by many years. Primary lesions arising from the moist mucosa of the lip are considered under the section *Buccal Mucosa*.

Patterns of Spread

SCC can originate from the skin of the lip or the vermilion, which may invade the adjacent skin and orbicularis muscle. Advanced lesions invade the adjacent commissures of the lip, the buccal mucosa, the skin and wet mucosa of the lip, the adjacent mandible, and eventually the mental nerve. PNI occurred in 2% of the cases reported by Byers and coworkers²⁴¹ and was related to recurrent lesions, large tumor size, mandibular invasion, and poorly differentiated histology. Lymphatic spread is to the submental (IA) and submandibular (IB) lymph nodes and then to the jugular chain. The risk for lymph node metastases is approximately 5% at diagnosis and is increased by high-grade histology, large lesions, invasion of the mucosa of the lip, and for patients with recurrent disease.

Clinical Picture

The vermilion of the lower lip is the most common site of origin. SCC may present as an enlarging discrete lesion that is not tender until it ulcerates. Some lesions develop slowly on a background of leukoplakia or CIS and present as superficially ulcerated lesions with little or no bulk. Erythema of the adjacent skin suggests dermal lymphatic invasion. Palpation of the lip will reveal the extent of induration. Paresthesia of the skin of the lip indicates PNI.

Treatment

Selection of Treatment Modality

Early lesions may be cured equally well with surgery or RT. Surgical excision is preferred for the majority of lower lip lesions up to 2 cm in diameter that do not involve the commissure; the treatment is simple and the cosmetic result is satisfactory. Removal of more of the lip with simple closure usually results in a poor cosmetic and functional result and, therefore, requires reconstructive procedures. RT is often preferred for lesions involving the commissure, for lesions over 2 cm in length, and for upper lip carcinomas. Advanced lesions with bone, nerve, or node involvement frequently require a combined modality approach.

The regional lymphatics are not treated electively for early cases. Advanced lesions, high-grade lesions, and recurrent lesions should be considered for elective neck treatment. Clinically positive nodes are managed as previously discussed in *Clinically Positive Neck Lymph Nodes*.

Surgical Treatment

Surgical treatment for early lesions (0.5 to 1.5 cm) utilizes a V- or W-shaped excision, depending on the size of the defect, which facilitates cosmetic primary closure. If the vermilion is diffusely involved with little or no involvement of the muscle, a vermilionectomy may be performed and the mucosa from the labial vestibule of the oral cavity advanced to cover the defect.

Irradiation Technique

Lip cancer may be successfully treated by EBRT, interstitial brachytherapy, or a combination of both. Interstitial brachytherapy may be accomplished with removable sources such as iridium-192 (¹⁹²Ir). EBRT techniques use orthovoltage (55.8 Gy at 1.8 Gy per fraction) or electrons (60 to 66 Gy at 2 Gy per fraction) with lead shields behind the lip to limit exit EBRT. IMRT is not indicated except for the occasional patient with advanced neck disease and/or clinical PNI where it is necessary to extend the dose distribution to the skull base and reduce the dose to the contralateral parotid. For more advanced lesions, combining chemotherapy with EBRT is appropriately considered.¹⁴⁶

Results of Treatment

MacKay and Sellers²⁴² reviewed 2,864 patients with all stages of lip cancer, of whom 92% were managed initially by RT. The primary lesion was controlled by the initial treatment in 84% of cases; an additional 8% were salvaged by later treatment for an overall local control rate of 92%. Of those who presented with clinically involved nodes, 58% had control of disease, but only 35% had control of disease when neck nodes appeared later. The 5-year, cause-specific survival rate was 89%; the 5-year absolute survival rate was 65%.

Mohs and Snow²⁴³ reported the results for 1,448 patients treated with microscopically controlled surgery for SCCs of the lower lip between 1936 and 1976. Eighty-three percent had cancers less than 3 cm in diameter, with a 5-year cure rate of 96.6%. For 192 patients with cancers that measured 2 cm or more, the cure rate dropped to 60%.

Complications of Treatment

Oral competence, which permits patients to control oral secretions and effectively suck, speak, and swallow, requires the sphincteric function of an intact orbicularis oris muscle. Hence, disruption of the sphincteric function resulting from division of the orbicularis oris should be restored. Microstomia and drooling secondary to oral incompetence may occur after a large flap reconstruction. If the oral opening is too small, the patient may not be able to inset a denture.

There will be some atrophy of the irradiated tissues; this progresses with time. Soft tissue necrosis may occur, but this problem is reduced by plans that prolong the treatment.

FLOOR OF THE MOUTH

Anatomy

The floor of the mouth is a U-shaped area bounded by the lower gum and the oral tongue; it terminates posteriorly at the anterior tonsillar pillar. The paired sublingual glands lie immediately below the mucous membrane; the paired genioglossus and geniohyoid muscles separate them. Bony protuberances, the genial tubercles, occur at the point of insertion of these two muscle groups at the symphysis. The mylohyoid muscle arises from the mylohyoid ridge of the mandible and is the muscular floor for the oral cavity; it ends posteriorly at about the level of the third molars. The submandibular gland rests on the external surface of the mylohyoid muscle between the mandible and the insertion of the mylohyoid. The submandibular duct (the Wharton duct) is about 5 cm long. It courses between the sublingual gland and the genioglossus muscle and exits in the anterior floor of the mouth near the midline.

Pathology

Most neoplasms are SCC, usually of moderate grade. Adenoid cystic and mucoepidermoid carcinomas account for about 5% of malignant tumors in this area.

Patterns of Spread

Primary

Approximately 90% of neoplasms originate within 2 cm of the anterior midline floor of the mouth, penetrating early beneath the mucosa into the sublingual gland and eventually into the genioglossus and geniohyoid muscles. The mylohyoid muscle acts as an effective barrier until the lesion becomes advanced. Extension toward the gingiva and periosteum of the mandible occurs early. When the tumor reaches the periosteum, the tumor usually spreads along the periosteum rather than through it. Mandible invasion is a late manifestation. The skin of the lower lip may be involved in advanced cases. Posterior extension occurs in the muscles of the root of the tongue. One or both submandibular ducts are frequently obstructed by the tumor or after the biopsy; it may be difficult to distinguish between tumor extension and infection in an obstructed duct. The submandibular gland frequently enlarges, becoming firm and occasionally painful when the duct is obstructed. Extensive lesions may follow the anatomic plane of the mylohyoid muscle to its posterior extremity and emerge in the submandibular space of the neck.

Lymphatic

Approximately 30% of patients will have clinically positive nodes on presentation; 4% will have bilateral nodes. The reported incidence of conversion from N0 to N+ with no neck treatment varies

from 20% to 35%.^{39,244} For T1 or superficial T2 lesions, the risk for occult metastasis is probably 10% to 15%.^{39,244}

The first nodes involved are in levels IB and II; the risk for bilateral spread is fairly high.

Clinical Picture

On physical examination, the earliest lesions appear as a red area, slightly elevated, with ill-defined borders, and very little induration. As the lesion enlarges, the edges of the tumor become distinct, elevated, and "rolled," with a central ulceration and induration. Some lesions start with a background of leukoplakia. Bimanual palpation will determine the extent of the induration and the degree of fixation to the periosteum. Large lesions bulge into the submental space and rarely grow through the mylohyoid muscle into the soft tissues of the neck. Gross invasion of the mandible may be detected, especially when the anterior teeth have been removed. A tumor may grow through the mandible to involve the gingivolabial sulcus and lip. The submandibular duct and gland are evaluated by bimanual palpation.

Treatment

Selection of Treatment Modality

Early Lesions. Surgery or RT are equally effective treatments for T1 or T2 lesions. Most patients are treated surgically because of the risk of soft tissue or bone necrosis after RT.

A few patients are seen after excisional biopsy of a tiny lesion, and the only finding is a surgical scar with varying degrees of induration under the scar (TX). The margins are often equivocal. These patients are treated with reexcision or brachytherapy.

Moderately Advanced Lesions. The usual recommendation for moderately advanced anterior midline lesions is rim resection or segmental mandibulectomy and osteomyocutaneous free flap reconstruction; postoperative RT or chemoRT is added depending on the pathologic findings. The clinically N0 neck is usually managed by a bilateral functional neck dissection for midline lesions.

Advanced Lesions. Massive lesions have a poor prognosis with combined surgery and postoperative chemoRT. Only palliation can be offered in some cases.

Surgical Treatment

Wide Local Excision. Small lesions (5 mm or less in size) may be excised transorally with a 1-cm margin with primary closure or a skin graft. If the duct is involved, the submandibular gland and duct are removed in continuity.

Rim Resection. Rim resection of the mandible in continuity with excision of the primary lesion preserves the arch and may be combined with postoperative RT. Periosteal invasion is often an indication for this procedure. Patients who have been edentulous for a long time may have an atrophic mandible and are not suitable because the mandible is likely to fracture.

Segmental Mandibulectomy. A partial segmental mandibulectomy with resection of the floor of the mouth is done for lesions invading bone. An osteomyocutaneous flap is usually used to repair the defect.

Irradiation Technique

Superficial T1 cancers are treated with either brachytherapy or intraoral cone RT to approximately 65 Gy, and the neck is observed. Larger lesions are treated with EBRT to 45 to 50 Gy over 5 weeks followed by an interstitial implant for an additional 20 to 30 Gy. Lesions

that are suitable for intraoral cone RT may be boosted with this technique prior to EBRT of the primary lesion and upper neck. Use of EBRT alone results in suboptimal cure rates and is discouraged.²⁴⁵

External-Beam Irradiation. Opposed lateral EBRT portals are used to treat anterior floor of the mouth carcinomas. The entire width of the mandibular arch is included and the superior border is shaped to spare part of the parotid gland. The level I and level II nodes are included to the level of the thyroid notch if the neck is clinically negative; the lower neck may be electively irradiated. If the neck is clinically positive, the portals are enlarged to include all of the upper neck nodes, and an en face low neck field is added. IMRT may be useful to reduce the dose to the contralateral parotid in patients with positive nodes.

Interstitial Irradiation. The implantation of T1 to T2 lesions confined to the floor of the mouth with minimal extension to the mucosa of the tongue can be accomplished with iridium using the plastic tube technique.

Intraoral Cone Irradiation. Intraoral orthovoltage or electron cone RT requires daily positioning by the physician and is preferable to interstitial RT because there is little or no irradiation of the mandible.²⁴⁶ An intraoral cone can be used for well-circumscribed anterior superficial lesions and is easiest to perform in the edentulous patient.

Combined Treatment Policies

Postoperative RT is preferred, because the risk of bone complications and fistulae is higher with preoperative RT. Concurrent chemotherapy may be necessary based on pathologic findings.

Management of Recurrence

RT failures are treated by an operation. The salvage rate is good for patients with T1 to T2 lesions and poor for those with more advanced lesions.

Surgical treatment failures may be treated by a repeat operation and postoperative RT.

Results of Treatment

Rodgers et al.²⁴⁷ reported on 194 patients treated with surgery and/or RT at the University of Florida between 1964 and 1987. The local control rates after RT versus surgery alone or combined with RT were: T1, 32 out of 37 (86%) versus 10 out of 11 (91%); T2, 25 out of 36 (69%) versus 16 out of 19 (84%); T3, 11 out of 20 (55%) versus 9 out of 9 (100%); and T4, 2 out of 5 (40%) versus 6 out of 10 (60%).²⁴⁷ The 5-year cause-specific survival rates were comparable for the treatment groups.²⁴⁷ Mild-to-moderate and severe complications were observed as follows: RT alone, 49 out of 117 (42%) and 6 out of 117 (5%); surgery alone, 3 out of 36 (8%) and 6 out of 36 (17%); and surgery and RT, 8 out of 41 (20%) and 6 out of 41 (15%), respectively.²⁴⁷

Two hundred seven patients treated with RT alone at the Centre Alexis Vautin between 1976 and 1992 were reviewed by Pernot and colleagues.²⁴⁸ Local control and cause-specific survival rates at 5 years were as follows: T1, 97% and 88%; T2, 72% and 47%; and T3, 51% and 36%, respectively. Six percent of patients developed complications necessitating surgical intervention and one patient experienced a fatal complication.

Follow-Up

There are two major difficulties in follow-up after RT: soft tissue ulcers and enlarged submandibular glands. An ulcer in the floor of the mouth within 2 years of treatment can be either a recurrence or necrosis. If the lesion appears to be soft tissue necrosis, a trial of conservative therapy is adequate. Failure to stabilize or resolve is an indication for biopsy. A negative biopsy does not rule out recurrence,

and repeat deep biopsies may be necessary. An enlarged submandibular gland(s) may be a sequel to obstruction of the submandibular duct; a contrast-enhanced CT is useful to distinguish between an enlarged submandibular gland and a tumor in a lymph node.

The follow-up for surgical cases may be difficult if skin grafts or flaps have been used because of the associated induration and thickness of the flaps. If the submandibular ducts have been reimplanted, stenosis may occur with subsequent enlargement of the submandibular glands.

Complications of Treatment

Radiation Therapy. A small soft-tissue necrosis may develop, usually in the site of the original lesion where the dose is highest. These are moderately painful and respond to local anesthetics, antibiotics, and the tincture of time. Treatment with pentoxifylline 400 mg three times daily may be beneficial.

If the ulceration develops on the adjacent gingiva, the underlying mandible is exposed. These areas are mildly painful. They are managed by discontinuing dentures, local anesthetics, antibiotics, and smoothing of the bone by filing, if needed. These small bone exposures do not often progress to osteoradionecrosis (ORN) and either sequestrate a small piece of bone or are simply recovered by the mucous membrane. Severe ORN may require daily hyperbaric oxygen (HBO) treatments for 4 to 6 weeks, either alone or in conjunction with surgical intervention.

Surgical. These include bone exposure, orocutaneous fistula, and failure of osteomyocutaneous flaps. Salvage procedures after RT are associated with an increased risk of complications.

ORAL TONGUE

Anatomy

The circumvallate papillae locate the division between the oral tongue and the base of the tongue. The arterial supply is mainly by way of paired lingual arteries that are branches of the external carotid. The sensory pathway is by way of the lingual nerve to the gasserian ganglion.

Pathology

More than 95% of oral tongue lesions are SCCs. Coexisting leukoplakia is common. Verrucous carcinoma and minor salivary gland tumors are uncommon. Granular cell myoblastoma is a benign tumor of uncertain origin that occurs on the dorsum of the tongue and may be confused histologically with carcinoma.

Patterns of Spread

Primary

Nearly all SCCs occur on the lateral and ventral middle and posterior thirds of the oral tongue. They tend to remain in the tongue until large unless they originate near the junction with the floor of the mouth. PNI and vascular space invasion may occur.

Anterior third lesions usually are diagnosed early. Advanced lesions invade the floor of the mouth and root of the tongue, producing ulceration and fixation. Posterior third lesions grow into the anterior tonsillar pillar and base of tongue.

Lymphatics

The first-echelon nodes are the level Ib and II nodes.²⁰ The submental and level V lymph nodes are seldom involved. Rouvière¹³ describes lymphatic trunks that bypass the level I to II nodes and

terminate in the level III lymph nodes. Byers et al.²⁴⁹ evaluated nodal spread pattern in 277 patients treated surgically at the M.D. Anderson Cancer Center and observed skip metastases to the level III or IV nodes without involvement of levels I and II in 16% of patients. Of patients with oral tongue cancer, 35% have clinically positive nodes at diagnosis and 5% are bilateral. The incidence of occult disease is approximately 30%. The incidence of positive nodes increases with T stage. Patients with N1 or N2 ipsilateral nodes have a significant risk of developing node metastasis in the opposite neck.

Clinical Picture

Mild irritation of the tongue is the most frequent complaint. As ulceration develops, the pain worsens and is referred to the external ear canal. Extensive infiltration of the muscles of the tongue affects speech and deglutition and is associated with a foul odor.

The extent of disease is determined by visual examination and palpation. The tongue protrudes incompletely and toward the side of the lesion as fixation develops. Posterior oral tongue lesions may grow behind the mylohyoid and present as a mass in the neck at the angle of the mandible. Invasion of the hypoglossal nerve is rare.

Differential Diagnosis

The differential diagnosis includes granular cell myoblastomas, which are usually slow growing, nontender masses and 0.5 cm to 2.0 cm in size. The lesions are well circumscribed, firm, and slightly raised; they may be multiple. Aggressive behavior is rare, and wide local excision is preferred. Pyogenic granulomas mimic small exophytic carcinomas. Tuberculous ulcer and syphilitic chancre are rare.

Treatment

Selection of Treatment Modality

Both surgery and RT result in cure rates that are similar for similar stages. The disadvantages of surgery include removal of part of the tongue and the decision of whether to do a neck dissection for the N0 neck. The disadvantage of RT is the risk of necrosis.

Excisional Biopsy (TX). An excisional biopsy of a small lesion may show inadequate or equivocal margins. An interstitial implant or reexcision will produce a high rate of local control.

Early Lesions (T1 or T2). A partial glossectomy with primary closure or a skin graft may be done transorally and is usually the preferred therapy. Depending on the depth of invasion, an elective neck dissection may be indicated. Postoperative RT would only be added for indications previously discussed.

Moderately Advanced Lesions (T2 or T3). The preferred treatment for the majority of these patients is partial glossectomy, neck dissection, and postoperative RT-based treatment.

Advanced Lesions (T4). Bi- or trimodality treatment will cure a minority of these patients. Some patients are best treated with palliative intent.

Surgical Treatment

Early Lesions (T1 or T2). A partial glossectomy and primary closure is performed.

Moderately Advanced Lesions (T2 or T3). A partial glossectomy with primary closure, skin graft, or flap reconstruction is performed. Frozen section control is essential. Positive margins are an indication for excision of additional tissue.

Advanced Lesions (T4). Near total or total glossectomy and sometimes a laryngectomy is performed.

Irradiation Technique

The ability to control the primary lesion is enhanced by giving all or part of the treatment with an interstitial RT or by intraoral cone.²⁵⁰⁻²⁵² Superficial T1 tumors may be treated with ¹⁹²Ir brachytherapy alone using the plastic tube technique. Larger lesions that have an increased risk for subclinical neck disease may be treated with EBRT and a brachytherapy boost or with brachytherapy combined with an elective neck dissection. The time factor is critical for oral tongue cancer, and the EBRT part of the treatment is shortened (30 Gy in 10 once-daily fractions, or 38.4 Gy in 1.6 Gy twice-daily fractions) in order to increase the proportion of the RT given by either interstitial or intraoral cone therapy. The interstitial therapy is given after the EBRT; the intraoral cone therapy should be done prior to the EBRT. Elective neck RT is indicated for nearly all lesions.

Combined Treatment Policies

Postoperative RT or chemoRT is administered to the primary site and neck for indications previously outlined. IMRT may be useful to reduce the dose to one or both parotids.

Management of Recurrence

Local recurrence after RT or surgery is heralded by ulceration, pain, or increased induration. Recurrences have a slightly elevated or rolled border, whereas necroses do not. A biopsy should be done as soon as ulceration appears if it is within the original tumor site. Ulcers that appear on adjacent normal tissues are likely due to RT and not cancer.

RT failure is managed by surgery. Surgical failure occasionally is salvaged by re-resection and postoperative RT-based treatment. Recurrence in the soft tissues of the neck is rarely eradicated by any procedure.

Nodes appearing in a previously untreated neck are managed by neck dissection with or without postoperative RT or chemoRT.

Results of Treatment

The local control rates for 170 patients treated with RT alone versus surgery alone or with RT between 1964 and 1990 at the University of Florida included: for T1, 79% versus 76% ($p = 0.76$); for T2, 72% versus 76% ($p = 0.86$); for T3, 45% versus 82% ($p = 0.03$); and for T4, 0% versus 67% ($p = 0.08$).²⁵³ The differences in 5-year survival between the two treatment groups were not statistically significant.

The results of brachytherapy alone or combined with EBRT for 448 patients treated at the Centre Alexis Vautin were reported by Pernot et al.²⁵⁴ and revealed the following 5-year local control and survival rates: T1, 93% and 69%; T2, 65% and 41%; and T3, 49% and 25%, respectively. Shorter time intervals between brachytherapy and EBRT were associated with significantly improved local control and survival for those who received both modalities.

Complications of Treatment

Surgical. Orocutaneous fistula, flap necrosis, and dysphagia are the most common complications after surgery. Damage to the lingual nerve or the hypoglossal nerve is rare. Fistula and flap necrosis may result in carotid artery hemorrhage. Enunciation difficulties occur whenever the tongue is bound down by scarring. The incidence of complications increases for surgical salvage attempts after RT failure. Of 65 patients, 13 (20%) treated with surgery alone or combined with RT at the University of Florida developed significant complications.²⁵³

Radiation Therapy. A minor soft-tissue necrosis is fairly common and is treated with broad-spectrum antibiotics, local anesthetics such as viscous lidocaine, and analgesics. Pentoxifylline 400 mg three times daily may be beneficial. Hyperbaric oxygen treatment may be tried in difficult cases. If the necrosis is persistent and the pain is uncontrollable, it must be resected.

The edentulous person is less likely to develop bone complications compared with those who are dentulous.²⁵⁵ The most frequent problem involving the mandible is *bone exposure*. If the patient has dentures, they should be discontinued or altered to relieve the pressure over the exposed bone. If sharp bony edges appear, they are filed and the bone edge is lowered to speed healing. Healing may require months or even years.

If ORN develops, HBO has been used with some success. If conservative measures are unsuccessful, segmental mandibulectomy and an osteomyocutaneous flap reconstruction is performed.

Severe complications were observed in 9 of 105 patients (9%) treated with RT at the University of Florida.²⁵³ Pernot and colleagues²⁵⁴ observed the following soft tissue and/or bone complications in a series of 448 patients: Grade 1, 19%; Grade 2, 6%; and Grade 3, 3%.

BUCCAL MUCOSA

Epidemiology

SCC is relatively uncommon in the United States. In Southern India, it is common and is related to chewing a combination of tobacco mixed with betel leaves, areca nut, and lime shell.²⁵⁶

Anatomy

The buccal mucosa is the mucous membrane covering the inner surface of the cheeks and lips, ending above and below with a transition to the gingiva. It ends posteriorly at the retromolar trigone. The parotid duct opens into the buccal mucosa opposite the second upper molar. The buccal mucosa is innervated by a branch of the mandibular nerve.

Pathology

Most malignant tumors are low-grade SCCs that frequently appear on a background of leukoplakia or lichen planus. Verrucous carcinoma occurs. Minor salivary gland tumors and melanomas are rare.

Patterns of Spread

Early lesions are usually discrete and exophytic. As they enlarge, they penetrate the underlying muscles and eventually extend to the skin. Peripheral growth occurs into the gingivobuccal sulci and eventually onto the gingiva and into bone.

The lymphatic spread is first to the level I and level II nodes. The incidence of positive nodes on admission is 9% to 31%, and the risk of occult disease is 16%.^{20,244}

Clinical Picture

Small lesions produce the sensation of a lump that is felt with the tongue. Pain is minimal, unless there is posterior extension to involve the lingual and dental nerves. Pain may be referred to the ear. Obstruction of the Stensen duct will produce parotid enlargement. Extension posteriorly, behind the pterygomandibular raphe or into the buccinator and masseter muscles, causes trismus.

Differential Diagnosis

The differential diagnosis includes lues and tuberculosis; both are rare. If the first biopsy reveals chronic inflammation or pseudoepitheliomatous hyperplasia, a repeat biopsy may be necessary.

Treatment

Selection of Treatment Modality

Small lesions (≤ 1 cm) may be excised with primary closure; small lesions that involve the lip commissure are sometimes treated by RT. Lesions 2 cm to 3 cm in size can be treated with surgery or by RT (usually the former). Larger lesions are usually treated with surgery, and postoperative RT or chemoRT.

Surgical Treatment. Lesions that invade the mandible or maxilla require bone resection along with the soft tissues. Repair may require a maxillary prosthesis. A myocutaneous flap repairs full-thickness removal of the cheek.

Irradiation Technique. Buccal mucosa lesions are suited for treatment with electrons, an intraoral cone, and interstitial techniques to spare the contralateral normal tissues. When tumors extend into one of the gingivobuccal gutters or onto bone, treatment must be entirely by EBRT.

Results of Treatment

Diaz et al.²⁵⁷ recently reported the M.D. Anderson experience for 119 patients treated with surgery alone (84 patients) or combined with adjuvant RT (35 patients) between 1974 and 1993. Tumor recurrence developed in 54 patients (45%): local recurrence in 27 patients (23%); regional recurrence in 13 patients (11%); local and regional recurrence in 11 patients (9%); and distant metastases in 3 patients (3%). The 5-year survival rates versus stage were stage I, 78%; stage II, 66%; stage III, 62%; stage IV, 50%; and overall, 63%.

Nair and coworkers²⁵⁶ reported the definitive RT results for 234 cases of buccal mucosa cancer treated in southern India during the 1982 calendar year. The 3-year disease-free survival rates were stage I, 85%; stage II, 63%; stage III, 41%; and stage IV, 15%. Thirty-two patients had verrucous carcinoma, and the 3-year disease-free survival rate was 47%, similar to that for other grades of SCC.

Complications of Treatment

The buccal mucosa is tolerant of high-dose RT, and complications are uncommon. Bone exposure may appear on the mandible or maxilla. Trismus may develop if the muscles of mastication receive high doses.

Surgical injury of the Stensen duct may cause obstruction and parotitis. Injury to branches of the VII nerve may occur. Split-thickness skin grafts may shrink and produce a partial trismus. Resection of the lip commissure may produce oral incompetence.

GINGIVA AND HARD PALATE (INCLUDING RETROMOLAR TRIGONE)

Anatomy

The lower gingiva includes the keratinized masticatory mucosa covering the mandible from the gingivobuccal gutter to the origin of the nonkeratinized lining mucosa covering the floor of the mouth. The retromolar trigone lies behind the third molar and is contiguous superiorly with the maxillary tuberosity. Beneath the keratinized mucosa of the retromolar trigone is the tendinous pterygomandibular raphe, which is attached to the pterygoid hamulus and the posterior mylohyoid ridge of the mandible and serves

as the insertion of the buccinator, orbicular oris, and superior pharyngeal constrictor muscles. Behind the pterygomandibular raphe and between the medial pterygoid muscle and the ascending ramus is the pterygomandibular space, which contains the lingual and dental nerves and is related posteriorly to the deep lobe of the parotid and the parapharyngeal space. There are no minor salivary glands in the mucous membranes of the alveolar ridges.

Pathology

Most neoplasms are SCCs. Minor salivary gland tumors, usually adenoid cystic carcinomas, often occur on the posterolateral hard palate.²⁵⁸ Verrucous carcinomas usually occur on the lower gingiva. Melanoma has been reported.²⁵⁹

SCC may arise within the body of the mandible or maxilla either from the odontogenic epithelium or from epithelium trapped during embryonic development. It is more frequent in the mandible than the maxilla and is most common in the molar regions. It must be distinguished from metastatic SCC and ameloblastoma.

Ameloblastoma is a rare, benign locally aggressive odontogenic tumor with an incidence of about 1% of all tumors of the maxilla and mandible; about 80% of cases occur in the mandible with the molar–ramus region most commonly involved.

Patterns of Spread

Lower Gum

SCC invades the periosteum and the adjacent buccal mucosa and floor of the mouth. Low-grade lesions tend to produce a smooth, saucerized defect before invading the mandible. Moderate to high-grade lesions invade the bone directly or through recently opened dental sockets and produce a lytic defect.

Lymphatic spread is to the level I and level II nodes. Clinically positive nodes occur in 18% to 52% of diagnoses; occult disease occurs in 17% to 19%.^{20,244}

Ameloblastoma expands and destroys the bone and extends to adjacent areas by contiguous growth. Ameloblastic carcinoma, a rare malignant variant of ameloblastoma, may metastasize to regional nodes and distant sites.²⁶⁰

Upper Alveolar Ridge and Hard Palate

Most SCCs originate on the gingiva and spread secondarily to the hard palate, soft palate, buccal mucosa, and underlying bone. The maxillary antrum is invaded late unless there are recent extractions providing access. The risk for positive lymph nodes at diagnosis is 13% to 24%, and the incidence of occult disease is 22%.^{20,244}

Retromolar Trigone

Carcinomas spread to the adjacent buccal mucosa, the anterior tonsillar pillar, and the maxilla. Posterior spread occurs into the pterygomandibular space and the medial pterygoid muscle. Posterolateral spread occurs into the buccinator muscle and fat pad. The first echelon lymphatics are the level I and level II nodes. The incidence of clinically positive nodes on presentation is about 30%; the risk for occult disease is 15% to 25%.

Clinical Picture

The patient with SCC may present to the dentist first with ill-fitting dentures, pain, loose teeth, or a sore that will not heal. A history of inappropriate dental extractions or root canal therapy is common. Invasion into the mandible may involve the inferior alveolar nerve and produce paresthesia of the lower lip. A background of leukoplakia is frequently present.

Retromolar trigone lesions have pain referred to the external auditory canal and preauricular area. Invasion of the pterygoid

muscle produces trismus. Intra-alveolar SCC presents with a submucosal mass and dental symptoms. Roentgenograms show a lytic lesion in the mandible.

Ameloblastoma exhibits few symptoms in the early stages. Patients may notice a gradually increasing facial deformity or a loosening of teeth. An intraoral submucosal mass may be present initially; ulceration occurs as the mass increases in size. On roentgenograms, a radiolucent area is seen with the expansion of the overlying cortical plate, scalloped margins, a multilocular appearance, and/or resorption of the roots of adjacent teeth.

Minor salivary gland tumors present as a submucosal mass, enlarge slowly, and may develop a central ulceration.²⁶¹

Differential Diagnosis

The differential diagnosis includes dental disease and underlying bony cysts or tumors.

Treatment

Selection of Treatment Modality

Lower Alveolar Ridge. The majority of lesions are managed by surgery alone or followed by postoperative RT or chemoRT. Surgery entails a marginal mandibulectomy when there is, at most, saucerization of the underlying bone. Segmental mandibulectomy and free flap reconstruction is indicated for more advanced disease.

Ameloblastoma. The treatment is surgery; however, local recurrence is a problem. Sehdev and coworkers²⁶² reported curettage was followed by local recurrence in 90% of mandibular ameloblastomas and in all maxillary ameloblastomas. Subsequent resection controlled 80% of the mandibular but only 40% of the maxillary tumors. The initial use of segmental mandibular resection controlled 78% (18 of 23 patients), with subsequent resection controlling those that recurred. The use of partial maxillectomy as the first treatment controlled 100% (7 of 7 patients) of maxillary ameloblastomas as opposed to only 40% when a partial maxillectomy was performed for recurrence. Limited experience with RT suggests that it may reduce the probability of progression and result in long-term local control in the occasional patient with incompletely resectable disease.²⁶⁰

Retromolar Trigone. Surgery is preferred for discrete early lesions. RT is recommended for superficial lesions involving a large surface area.²⁶³ Advanced carcinomas are treated with surgery and postoperative RT or chemoRT

Upper Alveolar Ridge and Hard Palate. Resection alone or followed by RT or chemoRT is the usual treatment for most lesions. However, if the lesion is superficial and extensively involves the hard palate or involves a significant portion of the soft palate, then an RT-based approach should be considered for the initial therapy. If the lesion is small and discrete and there is no bone involvement, resection includes the periosteum or occasionally some underlying bone. Bone invasion requires a maxillectomy that is tailored to optimally resect the cancer. The resulting defect is usually rehabilitated with a removable prosthesis.

Irradiation Technique

Small lesions of the lower alveolar ridge and retromolar trigone may be treated by intraoral cone for all or part of their therapy. Well-lateralized lesions of the retromolar trigone and posterior alveolar ridge may be treated by either an ipsilateral mixed beam or IMRT; the latter is preferred. Parallel-opposed portals treat anterior gum lesions.

Carcinomas that involve a large surface area with little or no bone invasion may be treated by EBRT. T1 to T2 carcinomas are treated with altered fractionation; larger tumors are treated with chemoRT.

Management of Recurrence

RT failures are managed by operation. Surgical failures may be managed by surgery and postoperative RT or chemoRT²⁶⁴; Salvage procedures frequently are not attempted because of the advanced nature of the recurrence and the low chance of cure.

Results of Treatment

Mandibular Gingiva. Overholt and coworkers²⁶⁵ reported 155 patients with SCCs of the lower alveolar ridge treated at M.D. Anderson between 1970 and 1990. Surgery alone was used for 131 patients; the remainder received surgery and RT. Five-year survival for patients with T1 and T2 cancers were 85% and 84%, respectively, compared with 66% and 64%, respectively, for those with T3 and T4 malignancies. Local control at 2 years was impacted by tumor size ($p = 0.021$) and margin status ($p = 0.027$), whereas 5-year cause-specific survival was influenced by tumor size ($p = 0.001$), margin status ($p = 0.011$), mandibular invasion ($p \leq 0.05$), and the presence of lymph node metastases ($p < 0.001$).

Retromolar Trigone. Byers and coworkers²⁶⁶ reported the M.D. Anderson results for 110 previously untreated patients with SCC of the retromolar trigone treated between 1965 and 1977, with a minimum 5-year follow-up. Surgery was often selected for patients with leukoplakia, poor teeth, mandible invasion, large neck nodes, or trismus. RT was selected for poorly differentiated tumors, for mainly exophytic lesions, and lesions involving the faucial arch or soft palate or lesions having ill-defined borders, and for poor surgical risk cases. The local control rates were as follows: T1, 12 of 13 (92%); T2, 50 of 57 (88%); T3, 18 of 20 (90%); and T4, 15 of 20 (75%). Local control was similar after surgery and/or RT. The absolute 5-year survival rate was 26%.

Mendenhall and coworkers²⁶³ reported on 99 patients with retromolar trigone SCCs treated between 1966 and 2003 with RT alone (35 patients) or combined with surgery (64 patients). The 5-year local–regional control rates after RT versus surgery and RT were for stages I through III, 51% and 87%; for stage IV, 42% and 62%; and overall, 48% and 71%, respectively. The 5-year cause-specific survival rates after RT versus surgery and RT were for stages I through III, 56% and 83%; for stage IV, 50% and 61%; and overall, 52% and 69%, respectively. A multivariate analysis revealed that the likelihood of cure was better after surgery and RT compared with definitive RT.

Hard Palate. Shibuya and coworkers²⁶⁷ reported the results for 38 cases of carcinoma of the hard palate and 82 cases of carcinoma of the upper alveolar ridge treated between 1953 and 1982 in Japan. Sixty-six patients were managed initially by RT alone to the primary lesion, and 54 patients were managed by RT and surgery. The 5-year actuarial survival rate by stage was the following: for stage I, 56%; for stage II, 41%; for stage III, 32%; and for stage IV, 12%. There was no difference in survival when comparing hard palate versus upper alveolar ridge, SCC versus minor salivary gland tumors, or RT alone versus RT plus surgery as the initial therapy. The overall risk for metastatic lymph nodes was 47% for hard palate and 49% for the upper alveolar ridge. Thirty patients were recorded as having “slight bone invasion,” and no metastases had a 5-year survival rate of 75% when treated by RT.

Complications of Treatment

Surgical complications include orocutaneous fistula, bone exposure, extrusion of a metal tray, and loss of graft or flap.

The complications of RT include soft tissue necrosis, bone exposure, and ORN. The risk is greatest for patients with advanced lesions of the lower gum and retromolar trigone. Huang and colleagues²⁶⁸ reported the following rates of grade 3 bone and soft tissue complications in 65 patients treated for retromolar trigone carcinomas: preoperative RT, 0 of 10 patients (0%); surgery and postoperative RT, 5 of 39 patients (13%); and RT alone, 2 of 16 patients (13%).

OROPHARYNX

ANATOMY

The base of the tongue is bounded anteriorly by the circumvallate papillae, laterally by the glossotonsillar sulci, and posteriorly by the epiglottis. The vallecula is a strip of mucosa that is the transition from the base of the tongue to the epiglottis; it is considered part of the base of tongue. The musculature of the base of the tongue is contiguous with that of the oral tongue.

The tonsillar fossa is bounded anteriorly by the anterior tonsillar pillar (palatopharyngeal muscle), posteriorly by the posterior tonsillar pillar (palatopharyngeal muscle), and inferiorly by the glossotonsillar sulcus and pharyngoepiglottic fold. The pharyngeal constrictor muscle and its fascia, the mandible, and the lateral pharyngeal space bound the tonsillar region laterally. The tonsillar area is separated from the base of tongue by the glossotonsillar sulcus, which extends from the anterior tonsillar pillar to the pharyngoepiglottic fold. Beneath the mucous membrane of the sulcus are the styloglossal muscle and the stylohyoid ligament.

The soft palate is a thin, mobile muscle complex separating the nasopharynx from the oropharynx. The epithelium of the oral side of the soft palate is squamous; the epithelium of the nasopharyngeal surface is respiratory. It is contiguous laterally with the tonsillar pillars.

PATHOLOGY

SCC accounts for 95% of cancers. Lymphoepitheliomas occur in the tonsillar fossa and the base of tongue. Basaloid features suggest a HR-HPV related tumor. Lymphomas account for 5% of tonsillar and 1% to 2% of base of tongue malignancies. Minor salivary gland malignancies, plasmacytomas, and other rare tumors make up the remainder.^{269,270}

PATTERNS OF SPREAD

Base of Tongue

Primary

Base of tongue SCC usually remains in the tongue unless it begins at the peripheral margin. Lateral base of tongue cancers may invade the glossotonsillar sulcus and eventually escape into the neck, because there is no effective musculature barrier at this point. Vallecular lesions spread along the mucosa to the lingual surface of the epiglottis, laterally along the pharyngoepiglottic fold, and then to the lateral pharyngeal wall and anterior wall of the pyriform sinus. Vallecular lesions frequently penetrate through the hyoepiglottic ligament to enter the preepiglottic space.

Lymphatic

The first-echelon nodes are in level II; spread is then to the level III and level IV nodes. The level Ib nodes are at risk if the tumor extends into the oral tongue or if massive upper neck disease is present. The level V nodes are involved often enough to be included

in treatment plans. Approximately 75% of patients will have clinically positive neck nodes at diagnosis, and 30% will have bilateral nodes.²⁰ The risk of occult disease in the clinically negative neck is probably 40% to 50%.

Tonsillar Area

Anterior Tonsillar Pillar

Almost all malignancies are SCCs, and they tend to be diagnosed early when they are relatively superficial with indistinct borders. As the lesions progress, they may develop a central ulcer with a rolled margin and infiltrate the palatoglossus. The lesion may extend superiorly onto the soft palate and posterior hard palate, anterolaterally to the retromolar trigone and buccal mucosa, and inferomedially into the tongue. As these lesions advance, they eventually invade bone, extend to the skull base and nasopharynx, and invade the medial pterygoid muscle, causing trismus and temporal pain.

Tonsillar Fossa

The initial lesions tend to be exophytic with central ulceration plus an infiltrative component. As the tumor progresses, it extends into the posterior tonsillar pillar, the oropharyngeal wall, and the base of tongue. It eventually penetrates the parapharyngeal space and grows superiorly to the skull base.

Posterior Tonsillar Pillar

Posterior tonsillar pillar lesions may spread inferiorly along the palatopharyngeal muscle to its insertions into the middle pharyngeal constrictor, the pharyngoepiglottic fold, and the posterior border of the thyroid cartilage.

Lymphatic

Retromolar trigone/anterior tonsillar pillar lesions have a lower risk of clinically positive lymph nodes (45%) compared with the tonsillar fossa (76%). The distribution for the retromolar trigone/anterior tonsillar pillar on the ipsilateral side is to the jugular and level IB lymph nodes with a low risk for junctional and level V nodes. Contralateral spread is uncommon (5%) and is confined to the jugular chain. The risk of occult disease in the clinically negative neck (N0) is 10% to 15%. The incidence of positive nodes increases with T stage.

The lymph node distribution for tonsillar fossa lesions on the ipsilateral side includes the jugular, junctional, level V, and level IB lymph nodes. Contralateral spread occurs in 11% of patients and is mainly to the jugular chain lymph nodes. The risk of contralateral spread is related to invasion of the tongue near the midline of the soft palate and large ipsilateral lymph nodes that produce lymphatic obstruction. The incidence of occult disease is probably 50% to 60%.

Soft Palate

Primary

Nearly all SCCs occur on the oral side of the palate. The earliest tumors are red lesions with ill-defined borders. Spread occurs first to the tonsillar pillars and hard palate. Lateral spread may eventually penetrate the superior constrictor muscle and skull base and invade the lateral wall(s) of the nasopharynx.

Lymphatic

The spread pattern is first to the level II nodes and then to levels III and IV. Approximately 56% of patients have clinically positive nodes at presentation; 16% are bilateral.²⁰ The incidence of occult neck disease is approximately 20%.²⁷¹ The incidence of clinically positive nodes increases with T stage.²⁰

CLINICAL PICTURE

Base of Tongue

Often, the earliest symptom is a mild sore throat or a level II neck mass. Difficulty swallowing, a nasal voice quality, and ear pain occur as the lesion enlarges. Advanced lesions fix the tongue.

Flexible fiber optic endoscopy and digital palpation are necessary for the diagnosis of early lesions of the base of tongue.

Lymphomas are usually large, mostly submucosal masses. Minor salivary gland tumors are also usually submucosal, but more discrete and firm than lymphomas.

Tonsillar Area

Anterior Tonsillar Pillar

Early symptoms include sore throat, and pain is referred to the ear. As the lesion progresses, it may cause trismus and temporal pain.

Tonsillar Fossa

An ipsilateral sore throat is common. Detection by visual examination with a tongue depressor is sufficient for most lesions. Some patients present with a node in the neck. Lymphomas tend to be large submucosal masses, but may ulcerate and appear similar to carcinomas.

Soft Palate

Patients may present with a mild sore throat that is not well localized. Advanced lesions may cause swallowing dysfunction, voice changes, regurgitation of food into the nasopharynx, trismus, temporal pain, and, rarely, CN involvement.

STAGING

The AJCC staging system is used.²⁶ Invasion of the deep musculature of the tongue is diagnosed if the tongue is partially fixed. Lesions that produce trismus or CN palsy are classified as T4. Pathologic staging usually results in "upstaging." Stage migration renders a meaningful comparison of outcomes between clinically and pathologically staged patients nearly impossible.

TREATMENT: BASE OF TONGUE

Selection of Treatment Modality

Surgery and RT produce similar cure rates. Because excision of the base of tongue generally causes greater disability and because of the high risk for bilateral lymphatic involvement, RT or chemoRT is usually the treatment of choice.²⁷²

Surgical Treatment

Patients with a low-volume T1 or early T2 cancer may be suitable for transoral laser excision and a neck dissection.²⁷³ Transoral robotic surgery is increasingly used to facilitate resection with less morbidity. Otherwise, the surgical approach requires an incision, which splits the lip, and a mandibulotomy, which permits lateral rotation of the mandible. Suprahoid, transhyoid, and infrahyoid approaches also can be used to resect small lesions. After the tumor has been removed, the mandibular edges are reapproximated and stabilized with a titanium reconstruction plate. Only one lingual artery may be sacrificed. A neck dissection is done

in continuity with excision of the primary lesion. Removal of a large tumor requires the simultaneous removal of part of or the entire larynx.

Irradiation Technique

Parallel opposed EBRT portals encompass the primary site and bilateral cervical nodes. Interstitial brachytherapy with flexible sources, such as ^{192}Ir ribbons, may be used for part of the treatment if the lesion is relatively limited. In contrast to oral tongue cancer, there is no proven advantage in local control for interstitial boosts compared with EBRT alone.

One of the common errors in planning EBRT is a failure to recognize anterior tumor extension into the lateral floor of the mouth; this is usually appreciated on CT and/or MRI. The inferior border of the lateral portals is usually the thyroid notch unless the tumor has extended into the upper pyriform sinus or preepiglottic space.

The primary portals include the level I_B, II, and V nodes when the neck is N0. The superior border is approximately 2 cm above the tip of the mastoid even with clinically negative nodes to ensure coverage of the nodes near the skull base.

The bilateral lower neck nodes are always treated with a separate anterior portal. If the upper neck is clinically negative, the lower neck portals include the level 3 and 4 nodes. If the upper neck is clinically positive, the lower neck portals are more generous.

Patients are treated with 1.2 Gy per fraction twice daily to 74.4 to 76.8 Gy. An alternative is 70 Gy in 35 fractions over 30 treatment days using simultaneous integrated boost (SIB) and a concomitant boost. Most patients with a N0 neck or ipsilateral positive nodes are treated with IMRT to reduce the dose to the contralateral parotid.

Management of Recurrence

RT treatment failures are treated surgically; salvage is infrequent except for T1 and early T2 lesions. Surgical treatment failures are rarely salvaged, except for the early lesion with a discrete local recurrence. Palliative management is often preferred.

RESULTS OF TREATMENT: BASE OF TONGUE

The 5-year local control rates after definitive RT in a series of 333 patients treated at the University of Florida were for T1, 98% (n = 46); for T2, 92% (n = 125); for T3, 82% (n = 92); and for T4, 53% (n = 70).²⁷² The 5-year local–regional control, distant metastasis-free survival, and survival rates are depicted in Table 38.11. Severe, acute, late, and/or postoperative complications developed in 52 patients (16%).

TABLE 38.11

Base of Tongue: 5-Year Outcomes After Radiotherapy at the University of Florida (333 Patients)

Stage	No. of Patients	Local–Regional Control	Ultimate Local–Regional Control	Distant Metastasis-Free Survival	Cause-Specific Survival	Survival
I–II	26	100%	100%	92%	91%	67%
III	58	82%	87%	90%	77%	66%
IVA	124	87%	90%	92%	84%	67%
IVB	125	58%	62%	69%	45%	33%

From Mendenhall WM, Morris CG, Amdur RJ, et al. Definitive radiotherapy for squamous cell carcinoma of the base of tongue. *Am J Clin Oncol* 2006;29:32–39.

FOLLOW-UP: BASE OF TONGUE

RT failures may present as an ulcer and must be distinguished from necrosis. Deep biopsies usually must be done under general anesthesia to obtain adequate tissue and control bleeding.

COMPLICATIONS OF TREATMENT: BASE OF TONGUE

Surgical Complications

These include an operative mortality of about 5%. Other complications include fistula, mandibular necrosis, dysphagia, aspiration pneumonia, hoarseness, trismus, and carotid rupture.

Complications of Irradiation

Bone exposure and ORN are uncommon. Mild-to-moderate soft tissue necroses occur in approximately 10% of patients, and mild-to-moderate bone exposures occur in 5% of patients treated solely by EBRT. Necroses may persist for several months and may respond to pentoxifylline. Hypoglossal nerve palsy occurs rarely.

Occasionally, patients may have difficulty swallowing due to fibrosis of the base of the tongue compounded by xerostomia. Significant aspiration is unusual. It is uncommon for a patient to develop severe swallowing disability requiring a PEG.²⁷⁴

TREATMENT: TONSILLAR AREA

Selection of Treatment Modality

The cure rates are similar after definitive RT-based treatment compared with surgery alone or combined with adjuvant RT.²⁷⁵ Because morbidity is generally higher after surgery, definitive RT or chemoRT is often preferred.

Surgical Treatment

Surgery for early cancers consists of a transoral wide local excision. Transoral robotic surgery is increasingly used for surgical procedures of this site to facilitate resection with less morbidity. Larger lesions may require removal of the adjacent mandible as well as a portion of the tongue and soft palate. Depending on the size of the defect, a tongue, deltopectoral, or osteomyocutaneous flap may be required. Speech may be impaired if a significant portion of the tongue or palate has been removed.

Irradiation Technique

The portal arrangement depends on the extent of local–regional disease. If the risk for contralateral lymph node metastases is low, an ipsilateral IMRT technique is employed to reduce xerostomia.

More advanced lesions are treated with parallel opposed photon portals, usually weighted 2 to 1 or 3 to 2 to the involved side. If there are positive contralateral nodes or extension across the midline, the portals usually are equally weighted. The inferior border is placed 2 cm below the primary tumor. IMRT may be employed to irradiate both sides of the neck and reduce the dose to the contralateral parotid in patients with a N0 neck or ipsilateral positive neck nodes. The low neck is treated with a separate anterior field with a thin midline block over the larynx. Small, discrete lesions of the anterior tonsillar pillar may have part of the RT by intraoral cone.

The dose for tonsillar lesions is 74.4 to 76.8 Gy (1.2 Gy twice daily) for T1 to T3 lesions, and 76.8 Gy for T4 lesions. An alternative is 70 Gy in 35 fractions over 30 treatment days using SIB and concomitant boost.

Management of Recurrence

Surgery will salvage a good portion of T1 or T2 RT failures, but only an occasional advanced lesion is salvaged.

RESULTS OF TREATMENT: TONSILLAR AREA

The 5-year local control rates after definitive RT in a series of 503 patients treated at the University of Florida between 1964 and 2003 for cancer of the anterior tonsillar pillar versus tonsillar fossa/posterior tonsillar pillar were for T1, 70% versus 94%; for T2, 74% versus 90%; for T3, 72% versus 79%; and for T4, 57% versus 62%.²⁷⁵ The local control rates are better for tonsillar fossa/posterior tonsillar pillar cancers compared with those arising in the anterior tonsillar pillar. The 5-year local–regional control, distant metastasis-free survival, and survival rates are depicted in Table 38.12.²⁷⁵

COMPLICATIONS OF TREATMENT: TONSILLAR AREA

Radiation Therapy

The risk for a severe complication, usually a bone or soft tissue necrosis, requiring surgical intervention is low. The probability of a fatal complication is remote. An occasional patient, usually one treated for advanced disease, may have long-term swallowing problems. Other complications include trismus, hypoglossal

nerve entrapment, and a remote risk of an RT-induced malignancy and/or myelitis. Severe late complications occurred in 46 of 503 patients (9%).²⁷⁵

SURGICAL TREATMENT

Complications of operation include impaired swallowing, fistula, flap failure, poor wound healing, and aspiration occasionally leading to laryngectomy. The risk of severe and/or fatal complications is higher after surgery compared with RT.²⁷⁵

TREATMENT: SOFT PALATE

Selection of Treatment Modality

Although small, well-defined lesions may be excised and the neck observed, the risk of subclinical regional disease is high. Therefore, definitive RT is indicated for nearly all soft palate carcinomas; neck dissection is added as needed. Concomitant chemotherapy is indicated for patients with T3 to T4 and/or N2 to N3 disease.

Surgical Treatment

Small, discrete lesions can be managed by transoral excision and repaired by a pharyngeal flap to prevent any velopharyngeal incompetence. A tonsillectomy may also be necessary in order to obtain an adequate margin. If full-thickness resection is performed, a prosthesis is often required.

Irradiation Technique

The RT technique involves equally weighted, parallel opposed EBRT portals that include the primary lesion and the bilateral first-echelon upper neck nodes. A separate anterior portal is used to treat the low neck. If the primary lesion is discrete and the neck is clinically negative, a portion of the treatment may be given with an intraoral cone prior to EBRT.

Patients are treated with 4 to 6 MV photons to 74.4 to 76.8 Gy at 1.2 Gy per fraction, twice daily, in a continuous course. Another option is 70 Gy in 35 fractions over 30 treatment days. IMRT using the concomitant boost technique may be used to reduce the dose to one or both parotids.

Management of Recurrence

A persistent ulcer after RT is indicative of recurrent disease. Patients with a limited local recurrence after RT for a T1 or T2 lesion may be suitable for surgical salvage.

TABLE 38.12

Tonsillar Region: 5-Year Outcomes After Definitive Radiotherapy at the University of Florida (503 Patients)

Stage	No. of Patients	Local–Regional Control	Ultimate Local–Regional Control	Distant Metastasis-Free Survival	Cause-Specific Survival	Survival
I	22	66%	92%	100%	100%	54%
II	83	75%	88%	95%	86%	61%
III	95	85%	88%	97%	84%	62%
IVA	184	76%	84%	85%	73%	57%
IVB	119	58%	66%	68%	46%	33%

From Mendenhall WM, Morris CG, Amdur RJ, et al. Definitive radiotherapy for tonsillar squamous cell carcinoma. *Am J Clin Oncol* 2006;29:290–297.

RESULTS OF TREATMENT: SOFT PALATE

Chera and coworkers²⁷⁶ reported on 145 patients treated with definitive RT at the University of Florida between 1963 and 2004. Local control rates at 5 years were for T1, 90%; for T2, 90%; for T3, 67%; for T4, 57%; and overall, 81%. The 5-year local–regional control and cause-specific survival rates were for stage I, 84% and 89%; for stage II, 85% and 87%; for stage III, 66% and 88%; for stage IVA, 59% and 57%; and for stage IVB, 43% and 0%, respectively.²⁷⁶

COMPLICATIONS OF TREATMENT: SOFT PALATE

Surgical Complications

Nasal speech and regurgitation of food into the nasopharynx are sequelae of full-thickness soft palate resection. A prosthesis is partially successful in correcting the functional deficit.

Complications of Irradiation

Soft-tissue necrosis is uncommon. The soft palate may become retracted following successful treatment of advanced lesions and may result in regurgitation into the nasopharynx and a slight alteration in speech. ORN requiring surgical management is rare. Severe late complications were observed in 8 of 145 patients (6%) treated with definitive RT.²⁷⁶

LARYNX

Cancer of the larynx is primarily related to cigarette smoking.²⁷⁷ The effect of alcohol remains unclear, but it is probably less impactful for the larynx than for the other head and neck sites.²⁷⁷

ANATOMY

The larynx is divided anatomically into the supraglottis, glottis, and subglottis. The supraglottis consists of the epiglottis, false vocal cords, ventricles, aryepiglottic folds, and arytenoids; the arytenoids are cartilages that articulate on the cricoid. The glottis includes the true vocal cords and the anterior commissure. The subglottis is 2 cm long and extends from 5 mm below the free edge of the true vocal cords to the lower margin of cricoid cartilage.

The preepiglottic space is bounded by the epiglottis posteriorly, the hyoepiglottic ligament and vallecula superiorly, and the thyroid cartilage and thyrohyoid membrane anteriorly and laterally. It can be seen as a low-density area on a CT scan.

The supraglottis has a moderately rich capillary lymphatic plexus. The lymphatic trunks pass through the preepiglottic space and the thyrohyoid membrane to the level II nodes. A few trunks drain directly to the level III or level IV nodes. There are essentially no capillary lymphatics of the true vocal cords. The subglottis area has relatively few capillary lymphatics. The lymphatic trunks pass through the thyrocricoid membrane to the midline pretracheal (Delphian) node(s) in the region of the thyroid isthmus and/or to the level IV nodes. The subglottis also drains posteriorly through the cricotracheal membrane with some trunks going to the paratracheal (level VI) nodes, whereas others pass to the level IV nodes.

PATHOLOGY

Nearly all laryngeal cancers arise from the surface epithelium and are SCCs. Minor salivary gland tumors are rare; even rarer are soft-tissue sarcomas, lymphomas, neuroendocrine carcinomas, and

plasmacytomas. Hemangiomas, chondromas, and osteochondromas are reported, but their malignant counterparts are rare.

Distinguishing between CIS and invasive SCC is often challenging because focal biopsies of the vocal cords can miss an area of microinvasion and mucosal stripping of a vocal cord lesion results in a disoriented specimen that precludes a complete evaluation of the basement membrane region. However, both CIS and microinvasive SCC are treated the same, with either endoscopic transoral laser resection or RT.

Most vocal cord SCCs are either well or moderately well differentiated. In a few cases, SCCs with a spindle cell component may be observed. Verrucous carcinoma occurs on the vocal cords in about 1% to 2% of patients with carcinoma. Supraglottic SCCs are less differentiated; verrucous cancers are rare.

PATTERNS OF SPREAD

Supraglottic Larynx

Lesions may exhibit an exophytic growth pattern with little tendency to destroy cartilage or spread to adjacent structures. Others may infiltrate and destroy cartilage and eventually amputate the tip of the epiglottis. They tend to invade the vallecula, preepiglottic space, lateral pharyngeal walls, and the remainder of the supraglottis.

False vocal cord cancers are often submucosal. Those arising from the aryepiglottic fold tend to invade the medial wall of the pyriform sinus. An inferior invasion of the vocal cords is usually a late phenomenon, and subglottic extension occurs only in advanced lesions. Lesions that extend onto or below the vocal cords are at a high risk for cartilage invasion, even if the cords are mobile.²⁷⁸

Vocal Cord

The majority of lesions begin on the free margin and upper surface of the vocal cord. About two thirds are confined to one cord, usually the anterior two thirds of the cord. Extension to the anterior commissure is frequent. As the lesion enlarges, it extends to the ventricle, false cord, vocal process of the arytenoids, and subglottis. Cancers then invade the vocal ligament and thyroarytenoid muscles, eventually reaching the thyroid cartilage where they tend to grow up or down the paraglottic space rather than invade cartilage. The conus elasticus initially acts as a barrier to subglottic extension. Advanced lesions eventually invade through the thyroid cartilage or thyrocricoid membrane to enter the neck and/or thyroid gland.

Subglottic Larynx

Subglottic cancers involve the cricoid cartilage early, and cord fixation is common.

Lymphatic

Supraglottic

Lymphatic drainage is initially to the level II nodes, and then to levels III and IV.²⁰ The incidence of clinically positive nodes is 55% at diagnosis; 16% are bilateral.²⁰ Elective neck dissection will show pathologically positive nodes in 16% to 26% of cases; observation of the neck will be followed by the appearance of positive nodes in approximately 33% of cases.

Glottic

The incidence of clinically positive nodes at diagnosis varies with T stage: T1, $\leq 1\%$; T2, $\leq 5\%$; and T3 and T4, 20% to 30%.²⁷⁹ Supraglottic spread is associated with metastasis to the level II nodes. Anterior commissure and subglottic invasion is associated with level III, level IV, and Delphian node involvement.²⁸⁰

Subglottic

Lederman²⁸¹ reported a 10% incidence of clinically positive lymph nodes on admission. Spread is primarily to the Delphian nodes and the level IV nodes.

CLINICAL PICTURE

Presenting Symptoms

Vocal Cords

Carcinoma initially causes hoarseness. Pain, dysphagia, and airway obstruction may be observed with advanced cancers.

Supraglottic Larynx

Pain on swallowing, referred to the ear by the vagus nerve and the auricular nerve of Arnold, is a frequent initial symptom. A neck mass may be the first sign of a supraglottic cancer. Late symptoms include hoarseness, weight loss, foul breath, dysphagia, and aspiration.

Physical Examination

A determination of laryngeal mobility with a laryngeal mirror or fiber optic scope frequently requires multiple examinations

because the subtle distinctions between mobile, partially fixed, and fixed cords are often difficult. Preepiglottic space invasion is best appreciated on CT.

Postcricoid extension may be suspected when the laryngeal “click” disappears on physical examination. Localized pain or tenderness to palpation over the thyroid cartilage is suggestive of invasion. Advanced tumors may penetrate through the thyroid ala and be felt as a bulge on the cartilage. A CT scan may detect cartilage invasion, but irregular calcification of the cartilage, coupled with volume averaging of the CT slice, creates technical problems in appreciating early cartilage invasion.

DIFFERENTIAL DIAGNOSIS AND STAGING

The differential diagnosis includes papillomas, polyps, vocal nodules, fibromas, and granulomas. Papillomas generally occur in children and young adults, and may persist into adulthood. Vocal polyps and nodules occur at the junction of the middle and anterior one third of the true vocal cords. There is usually a history of voice abuse followed by hoarseness. Vocal cord granulomas usually occur as a result of intubation and are located on or near the posterior commissure. Endoscopic removal may be necessary if medical therapy for gastroesophageal reflux provides no improvement, although this is rare.

The staging system for the primary tumor is depicted in Table 38.13.

TABLE 38.13

2010 American Joint Committee on Cancer Staging for Laryngeal Cancer

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Supraglottis	
T1	Tumor limited to one subsite of supraglottis with normal vocal cord mobility
T2	Tumor invades mucosa of more than one adjacent subsite of supraglottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx
T3	Tumor limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, preepiglottic tissues, paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex)
T4a	Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Glottis	
T1	Tumor limited to one (T1a) or both (T1b) vocal cord(s) (may involve anterior or posterior commissure) with normal mobility
T2	Tumor extends to supraglottis and/or subglottis, and/or with impaired vocal cord mobility
T3	Tumor limited to the larynx with vocal cord fixation, and/or invades paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex)
T4a	Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, esophagus)
T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Subglottis	
T1	Tumor limited to the subglottis
T2	Tumor extends to vocal cord(s) with normal or impaired mobility
T3	Tumor limited to larynx with vocal cord fixation
T4a	Tumor invades cricoid or thyroid cartilage and/or tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

TREATMENT: VOCAL CORD CARCINOMA

Selection of Treatment Modality

Carcinoma In Situ

Vocal cord stripping may sometimes control CIS. Recurrence is frequent, and the vocal cord may become thickened and the voice hoarse with repeated stripping. We recommend RT for patients with multiple recurrences.²⁸²

Early Vocal Cord Lesions (T1, T2)

In most centers, RT is the initial treatment, with operation reserved for salvage of RT failures.²⁸³ Although an open partial laryngectomy will produce comparable cure rates for selected T1 or T2 vocal cord lesions, RT is generally preferred because it is less expensive and voice quality is better. An endoscopic transoral laser resection is increasingly being used.²⁸³ Using this technique, small midcord lesions may be treated. Voice quality depends on the extent of tissue removal and whether surgical resection involves the anterior commissure. An open partial laryngectomy or a total laryngectomy may be used as a salvage operation after RT failure.

Verrucous carcinomas are treated with a transoral laser resection or an open partial laryngectomy. Definitive RT is employed if the alternative is a total laryngectomy.

Advanced Vocal Cord Lesions (T3, T4)

Low volume cancers (≤ 3.5 mL) with stage III to IV disease are treated with definitive RT and concomitant chemotherapy.^{284,285} Higher volume carcinomas are usually treated with a total laryngectomy, neck dissection, and postoperative RT or chemoRT.

Surgical Treatment

Stripping the cord implies transoral removal of the mucosa of the edge of the cord.

A cordectomy is an excision of the vocal cord and is usually performed via a transoral laser. The major advantages of laser excision are that it requires a day, as opposed to the 5.5 weeks that are necessary for RT, and RT may be reserved if the patient develops a second head and neck cancer.

A hemilaryngectomy is a partial laryngectomy allowing the removal of limited cord lesions with voice preservation. Restrictions include the involvement of one cord and up to 5 mm of the opposite cord, a partial fixation of one cord, and up to 9 mm of subglottic extension anteriorly and 5 mm posteriorly (to preserve the cricoid cartilage). Extension to the supraglottic or interarytenoid area is a contraindication. One arytenoid may be sacrificed; the reconstructed vocal cord must be fixed in the midline to prevent aspiration. The patient must have adequate pulmonary function. More extensive open partial laryngectomies have been described, such as the supracricoid partial laryngectomy.²⁸⁶

The last surgical alternative is a total laryngectomy with or without a neck dissection. The entire larynx is removed, the pharynx is reconstituted, and a permanent tracheostoma is created.

There are several options to accomplish voice rehabilitation after a total laryngectomy. Prosthetic devices (e.g., the Blom-Singer Voice Prosthesis) have been developed for insertion into a tracheoesophageal fistula, which permits the patient to speak without aspiration.²⁸⁷ Voice rehabilitation was evaluated in 173 patients who underwent a total laryngectomy and postoperative RT at the University of Florida; 118 patients were evaluable 2 to 3 years after treatment and 69 patients were evaluated for 5 years or longer.²⁸⁷ Methods of voice rehabilitation at 2 to 3 years and 5 years or more after surgery included: tracheoesophageal speech, 27% and 19%; artificial ("electric") larynx, 50% and 57%; esophageal, 1% and 3%; nonvocal, 17% and 14%; and no data, 5% and 7%, respectively.²⁸⁷

Irradiation Technique

RT for early vocal cord cancer is delivered by portals including only the primary lesion. Portals for T1 lesions extend from the thyroid notch superiorly to the inferior border of the cricoid; the posterior border depends on posterior extension of the tumor. Portals for T2 lesions are slightly larger, depending on the extent of the lesion. Patients receive 2.25 Gy per fraction once daily to 63 Gy (T1 and T2a) or 65.25 Gy (T2b).^{279,288}

RT for T3 and T4 lesions include the primary lesion and the level II through IV and Delphian lymph nodes. The initial treatment is delivered at 1.2 Gy per fraction twice daily to 45.6 Gy. The portals are then reduced to include only the primary lesion; the final tumor dose is 74.4 Gy. Another option is 70 Gy in 35 fractions in over 30 treatment days. The low neck is treated through a separate anterior portal. IMRT may be useful to avoid a difficult low neck match in patients with a low-lying larynx.

Management of Recurrence

Worsening laryngeal edema suggests recurrence. Cord fixation usually implies local recurrence; fixation may rarely develop in the absence of recurrent disease.

RT failures (T1 to T2) are almost always salvaged by a cordectomy, a partial laryngectomy, or a total laryngectomy. The salvage rate for T3 lesions recurring after RT is approximately 60%.²⁸⁵

Salvage by RT-based treatment for recurrences or new tumors appearing after partial laryngectomy is about 50%. Isolated tracheostomal recurrences may be managed by RT, chemoRT, or surgery and postoperative RT-based treatment; the chance of cure is relatively low.²⁸⁹ A multi-institutional surgical experience in the management of stomal recurrence was reported by Gluckman and coworkers.²⁸⁹ Forty-one patients came to operation. The 2-year cause-specific survival was 24%. Patients with localized recurrences had a 5-year survival rate of 45%.

TREATMENT: SUPRAGLOTTIC LARYNX CARCINOMA

Selection of Treatment Modality

T1, T2, and low-volume (≤ 6 mL) T3 lesions are favorable and can be treated with definitive RT or a supraglottic laryngectomy. It is seldom necessary to combine RT and surgery for the management of the primary lesion; however, combined treatment may be indicated to control neck disease.

Patients who are candidates for a supraglottic laryngectomy must have lesions that are anatomically suitable, a resectable neck disease, and adequate pulmonary reserve to withstand aspiration. Because the likelihood of local control after RT is related to primary tumor volume, lesions >6 mL are treated with a partial laryngectomy.^{290,291} The anatomic constraints include: no extension inferior to the apex of the ventricle, minimal or no involvement of the medial wall of the pyriform sinus, mobile cords, no cartilage invasion, and limited lateralized extension to the tongue base. Patients who are not candidates for the supraglottic laryngectomy are treated with RT; concomitant chemotherapy is added for those with stage III through IV disease.

When a patient presents with an early-stage primary lesion and N2B to N3 neck disease, a combined treatment is necessary to produce a high rate of neck control. Thus, the primary lesion is preferably treated with chemoRT, with neck dissection(s) added to the involved side(s) of the neck if necessary. If the patient has N1 or N2A neck disease and surgery is elected for the primary site, postoperative RT or chemoRT is only added because of unexpected findings (e.g., positive margins, multiple positive nodes, ECE). The probability of a good functional result is improved if the dose to the remaining larynx is limited to 55 Gy at 1.8 Gy per

once-daily fraction. The involved neck may be boosted to a higher dose without irradiating the larynx.

Selected unfavorable T3 and T4 lesions that are mainly exophytic can be treated by chemoRT. Lesions unsuitable for RT are endophytic, high-volume cancers often associated with vocal cord fixation, which are managed by a total laryngectomy.

Surgical Treatment

Supraglottic Laryngectomy

The incision is usually an apron flap. The neck dissection is completed and left attached to the thyrohyoid membrane. The perichondrium of the larynx is elevated in continuity with the strap muscles and used to close the surgical defect. Saw cuts are made through the thyroid cartilage, and the pharynx is entered above the hyoid bone through the vallecula so the preepiglottic space is included in the specimen. The arytenoids and true vocal cords are preserved. If one arytenoid is sacrificed, the vocal cord is fixed in the midline to prevent aspiration. Suturing the perichondrium and muscle to the base of tongue closes the defect. The extended supraglottic laryngectomy may include resection of the base of tongue to the level of the circumvallate papillae as long as one lingual artery is spared.

Total Laryngectomy

The entire larynx and the preepiglottic space are resected en bloc and a permanent tracheostoma is fashioned. A portion of the thyroid gland is also removed if there is extralaryngeal or subglottic extension. The pharyngeal defect is closed, reestablishing a conduit from the pharynx into the esophagus.

Irradiation Technique

The primary lesion and both sides of the neck are included with opposed lateral portals. The inferior border of the portals depends on the inferior extent of the primary tumor; it is usually at the inferior border of the cricoid. The dose is 74.4 Gy in 62 twice-daily fractions; the lower neck nodes are irradiated through a separate anterior portal. Patients with ipsilateral positive nodes may be treated with IMRT to reduce the dose to the contralateral parotid and/or to avoid a difficult low neck match. An alternative is 70 Gy in 35 fractions over 30 treatment days.

Patients develop a sore throat, loss of taste, and moderate dryness during RT. Arytenoid edema may occur and produce the sensation of a lump in the throat. A tracheostomy is seldom necessary before the start of RT. Laryngeal edema may persist for up to a year. Neck dissection increases the degree of lymphedema; a bilateral neck dissection should be avoided, if possible.²⁹²

Combined Treatment Policies

If a total laryngectomy is required and the lesion is resectable, postoperative RT is preferred. The high-risk areas are usually the base of tongue and neck. The stoma is at risk when subglottic extension is present or if there is tumor in the low neck lymph nodes.

Management of Recurrence

Failures after supraglottic laryngectomy or RT frequently can be salvaged by further treatment. The salvage of recurrences that develop after total laryngectomy and adjuvant RT is uncommon.

TREATMENT: SUBGLOTTIC LARYNX CARCINOMA

Early lesions are treated with RT; advanced lesions are usually managed by a total laryngectomy and postoperative RT or chemoRT.

Results of Treatment

Vocal Cord Cancer

Surgical Results. Garcia-Serra et al.²⁸² reviewed 10 series containing 269 patients with CIS of the vocal cord treated with stripping; the weighted average 5-year local control and ultimate local control rates were 71.9% and 92.4%, respectively. Similarly, 10 series containing 177 patients treated with carbon dioxide laser revealed the following weighted average 5-year local control and ultimate local control rates: 82.5% and 98.1%, respectively.²⁸²

Thomas and coworkers²⁹³ reported on 159 patients who underwent an open partial laryngectomy at the Mayo Clinic between 1976 and 1986. Of 159 patients, 17 had CIS; the remaining were T1 SCCs. Local recurrence developed in 11 patients (7%), and 9 eventually required a laryngectomy. Ten patients developed recurrent cancer in the neck, and distant metastases were observed in 10 patients.

A hemilaryngectomy, including the ipsilateral arytenoid, was reported by Som²⁹⁴ for 130 cases of vocal cord carcinoma extending to the vocal process and face of the arytenoid. The cure rate was 74% for 104 patients with T2 lesions, and 58% for 26 patients with T3 cancers.

Foote and coworkers²⁹⁵ reported on 81 patients who underwent a laryngectomy for T3 cancers at the Mayo Clinic between 1970 and 1981. Seventy-five patients underwent a total laryngectomy and six underwent a near-total laryngectomy; 53 received a neck dissection. No patient underwent adjuvant RT or chemotherapy. The 5-year rates of local–regional control, cause-specific survival, and absolute survival were 74%, 74%, and 54%, respectively.

Radiation Therapy Results. Garcia-Serra et al.²⁸² reviewed 22 series containing 705 patients with CIS of the vocal cord treated with RT and observed that the weighted average 5-year local control and ultimate local control rates were 87.4% and 98.4%, respectively.

The results of RT for 585 patients with T1 and T2 N0 SCC of the glottis treated by RT are presented in Table 38.14. The 5-year rates of neck control for the overall groups and for the subsets of patients who remained continuously disease free at the primary site were for T1a, 98% and 100%; for T1b, 99% and 100%; for T2a, 96% and 98%; and for T2b, 88% and 94%, respectively.²⁷⁹

The 5-year outcomes after RT alone (53 patients) versus surgery alone or combined with RT (65 patients) in a series of 118 patients with T3 fixed-cord glottic carcinomas treated at the University of Florida were for local–regional control, 62% versus 75% ($p = 0.10$); for ultimate local–regional control, 84% versus 82% ($p = 0.95$); for cause-specific survival, 75% versus 71% ($p = 0.26$); for overall survival, 55% versus 45% ($p = 0.119$); and for severe complications, 16% versus 15% ($p = 0.558$), respectively.²⁸⁴ Hinerman et al.²⁹⁶ recently updated the University of Florida experience and reported a 5-year local control rate of 63% for 87 patients with T3 fixed-cord glottic carcinomas. The likelihood of local control after RT is related to primary tumor volume and cartilage sclerosis.²⁹⁷

The probability of cure after treatment for T4 glottic carcinomas after surgery with or without adjuvant RT or definitive RT varies from 30% to 50% depending on patient selection.^{296–303}

TREATMENT: SUPRAGLOTTIC LARYNX CANCER

The 5-year local control rates after definitive RT in a series of 274 patients treated between 1964 and 1998 at the University of Florida were for T1, 100% ($n = 22$); for T2, 86% ($n = 125$); for T3, 62% ($n = 99$); and for T4, 62% ($n = 28$).³⁰⁴ The likelihood of local control and local control with a functional larynx is related to tumor volume; those with tumors ≤ 6 mL have a more favorable outcome

TABLE 38.14

T1 to T2N0 Glottic Larynx: 5-Year Outcomes After Radiotherapy in 585 Patients

Stage	No. of Patients	Local Control	Ultimate Local Control	Local Control With Larynx Preservation	Cause-Specific Survival	Survival
T1A	253	94%	98%	95%	97%	82%
T1B	72	93%	97%	94%	99%	83%
T2A	165	80%	96%	81%	94%	76%
T2B	95	70%	93%	74%	90%	78%

Data from Chera BS, Amdur R, Morris CG, et al. T1N0 to T2N0 squamous cell carcinoma of the glottic larynx treated with definitive radiotherapy. *Int J Radiat Oncol Biol Phys* 2010;78:461–466.

than those with larger primary tumors.²⁹¹ The 5-year rates of local–regional control and cause-specific survival were for stage I, 100% and 100%; for stage II, 86% and 93%; for stage III, 64% and 81%; for stage IVA, 61% and 50%; and for stage IVB, 28% and 13%, respectively.³⁰⁴ Of 274 patients, 12 (4%) experienced a severe acute or late complication, and 2 patients (1%) died as a consequence.

Lee and coworkers³⁰⁵ reported on 60 patients who underwent a supraglottic laryngectomy and modified neck dissection at the M.D. Anderson Hospital between 1974 and 1987, of which 50 patients (83%) received postoperative RT. Local control was 100% and local–regional control was obtained in 56 of 60 patients (93%). The 5-year disease-free survival rate was 91%. Three of 60 patients (5%) required a complete laryngectomy for intractable aspiration.

Ambrosch and colleagues³⁰⁶ reported on 48 patients treated with transoral laser resection for T1N0 (12 patients) and T2N0 (36 patients) supraglottic carcinoma. Twenty-six patients underwent a unilateral (11 patients) or bilateral (15 patients) neck dissection. Postoperative RT was administered to two patients (4%). The 5-year local control rates were 100% for pT1 cancers and 89% for pT2 malignancies. The 5-year recurrence-free survival and overall survival rates were 83% and 76%, respectively. No patient developed severe aspiration.

Complications of Treatment

Surgical Treatment

Repeated stripping of the cord may result in vocal cord fibrosis and hoarseness. Neel and coworkers³⁰⁷ reported a 26% incidence of nonfatal complications for cordectomy. Immediate postoperative complications included atelectasis and pneumonia, severe subcutaneous emphysema in the neck, bleeding from the tracheotomy site or larynx, wound complications, and airway obstruction requiring a tracheotomy. Late complications included the removal of granulation tissue by a direct laryngoscopy to exclude recurrence, extrusion of cartilage, laryngeal stenosis, and obstructing laryngeal web.

The postoperative complications of hemilaryngectomy include aspiration, chondritis, wound slough, inadequate glottic closure, and anterior commissure webs.

The complication rate following supraglottic laryngectomy is about 10%, including fistula formation, aspiration, chondritis, dysphagia, dyspnea, and carotid rupture.³⁰⁴

The postoperative complications of a total laryngectomy may include perioperative death, hemorrhage, fistula, chondritis, wound breakdown, carotid rupture, dysphagia, and pharyngo-esophageal stenosis.

Radiation Therapy

Soft-tissue necrosis leading to chondritis occurs in about 1% of patients. Soft-tissue and cartilage necroses mimic recurrence with hoarseness, pain, and edema; a laryngectomy may be recommended

for fear of recurrent cancer, even though biopsies show only necrosis. Chera et al.²⁷⁹ recorded severe complications after definitive RT in 10 (1.7%) of 585 patients treated for T1 to T2N0 glottic SCCs.

Combined Treatment

The major late effects of combined treatment are an increased fibrosis of soft tissues, stomal stenosis, and pharyngeal stricture.

HYPOPHARYNX: PHARYNGEAL WALLS, PYRIFORM SINUS, AND POSTCRICOID PHARYNX

Both the oropharyngeal and hypopharyngeal walls will be considered together because there is no distinct difference in the presentation or treatment. The majority of hypopharyngeal lesions originate in the pyriform sinus. Postericoid carcinomas are uncommon.

ANATOMY

The epithelium of the pharyngeal mucous membrane is squamous. The dividing point between the nasopharynx and posterior pharyngeal wall is the Passavant ridge, a muscular ring that contracts to close the nasopharynx during swallowing. Between the constrictor muscles and the prevertebral fascia covering the longitudinal prevertebral muscles is a thin layer of loose areolar tissue, the retropharyngeal space. The entire thickness of the posterior pharyngeal wall from the mucous membrane to the anterior vertebral body is no more than 1 cm in the midline. Lateral to the pharyngeal wall are the vessels, nerves, and muscles of the parapharyngeal space. The constrictor muscles are relatively thin and do not present much of an obstacle to tumor penetration. There is a variable weak spot in the lateral pharyngeal wall just below the hyoid where the middle and the inferior constrictor muscles fail to overlap. The lateral wall in this area is composed of the thin thyrohyoid membrane, which is penetrated by the vessels, nerves, and lymphatics of the laryngopharynx.

The pharyngeal walls are continuous with the cervical esophagus below; the transition to cervical esophagus is below the arytenoids (C4). The transition zone, which is 3 cm to 4 cm in length, is the postericoid hypopharynx.

The lateral pharyngeal wall is a narrow strip of mucosa that lies behind the posterior tonsillar pillar in the oropharynx, is partially interrupted by the pharyngoepiglottic fold, and then continues into the hypopharynx, where it becomes the lateral wall of the pyriform sinus. The posterior pharyngeal wall is 4 cm to 5 cm wide and 6 cm to 7 cm in height.

The superior margin of the pyriform sinus is the pharyngoepiglottic fold and the free margin of the aryepiglottic fold. The superolateral margin of the pyriform sinus is an oblique line along the lateral pharyngeal wall opposite the aryepiglottic fold. Thus,

the pyriform sinus has three walls: the anterior, lateral, and medial (there is no posterior wall). The pyriform sinus tapers inferiorly to the apex and terminates variably at a level between the superior and inferior borders of the cricoid cartilage. The superior limit of the pyriform sinus is opposite the hyoid. The thyrohyoid membrane is lateral to the upper portion of the pyriform sinus, and the thyroid cartilage, cricothyroid membrane, and cricoid cartilage are lateral to the lower portion. The internal branch of the superior laryngeal nerve, a branch of the vagus, lies under the mucous membrane on the anterolateral wall of the pyriform sinus. The auricular branch is sensory to the skin of the back of the pinna and the posterior wall of the external auditory canal.

The postcricoid pharynx is funnel shaped to direct food into the esophagus. The superior margin begins just below the arytenoids. The anterior wall lies behind the cricoid cartilage and is the posterior wall of the lower larynx. The posterior wall is a continuation of the hypopharyngeal walls. The recurrent laryngeal nerve ascends in the tracheoesophageal groove, entering the larynx posterior to the cricothyroid articulation at the junction of the hypopharynx and esophagus. Internal branches of the superior laryngeal nerve extend inferiorly anterior to the mucosa of the pyriform sinuses.

PATHOLOGY

More than 95% of malignant tumors are SCCs. CIS is commonly seen at the edge of pharyngeal wall SCCs; multifocal skip areas of CIS may make it difficult to obtain clear margins if excision is done. Minor salivary gland tumors are rare.

PATTERNS OF SPREAD

Posterior Pharyngeal Wall

SCCs of the posterior wall have a tendency to remain on the posterior wall, grow up or down the wall, and infiltrate posteriorly; they seldom spread circumferentially to the lateral walls. Early lesions are red and ulcerate as they progress. The tumor may spread up the pillars, eventually reaching the palate and nasopharynx. Advanced lesions tend to terminate inferiorly at the level of the arytenoids. Direct invasion of the cervical vertebrae or skull base is uncommon.

Lateral Pharyngeal Wall

Early tumors may be well-defined exophytic lesions. As they advance, they tend to penetrate laterally through the constrictor muscle, thus entering the lateral pharyngeal space or the soft tissues of the neck.

Pyriform Sinus

Early lesions usually appear as nodular mucosal irregularities. Medial wall lesions may grow superficially along the aryepiglottic fold and arytenoids, or invade directly into the false cord and aryepiglottic fold. Medial wall lesions also extend posteriorly to the postcricoid region, cricoid cartilage, and to the opposite pyriform sinus. Extensive submucosal spread is characteristic. There is frequently an area of central ulceration. The vocal cord becomes fixed because of infiltration of the intrinsic muscles of the larynx, the cricoarytenoid joint or muscle, or less commonly, the recurrent laryngeal nerve. Spread into the cervical esophagus is a late event.

Lesions arising on the lateral wall tend toward early invasion of the posterior thyroid cartilage and the posterior superior cricoid cartilage and, eventually, invade the thyroid gland. Involvement of the pyriform sinus apex is associated with an increased risk of thyroid cartilage invasion.³⁰⁸ Lesions of the lateral walls tend to spread submucosally to the posterior pharyngeal wall.

Postcricoid Pharynx

Early postcricoid lesions are rare. Lesions arising from the posterior wall tend to remain on the posterior wall. Lesions arising from the anterior wall tend to invade the posterior cricoarytenoid muscle and the cricoid and arytenoid cartilages. Advanced tumors eventually encircle the lumen.

Lymphatics

Pharyngeal Walls

The lymphatics of the pharyngeal walls terminate primarily in the jugular chain and secondarily in the level V nodes. The level II nodes are most often involved. Lindberg²⁰ reported 59% clinically positive nodes at diagnosis; 17% were bilateral. Retropharyngeal lymph node involvement is frequent.

Pyriform Sinus

The drainage is mainly to the jugular chain with a relatively small proportion to the level V nodes. The level II nodes are most commonly involved, but level III involvement occurs without level II metastases. At diagnosis, 75% of patients have clinically positive nodes, and at least 10% have bilateral nodes. There is no difference in the risk of lymph node metastases by T stage. The incidence of subclinical neck disease probably exceeds 50%.³⁰⁹

CLINICAL PICTURE

Tumors that are lateralized to the lateral pharyngeal wall or pyriform sinus produce a unilateral sore throat. Dysphagia, ear pain, and voice changes occur later. A neck mass may be the presenting complaint.

Lesions of the apex of the pyriform sinus or postcricoid area produce a pooling of secretions, indicating obstruction of the gullet. Arytenoid edema and an inability to see into the apex of the pyriform sinus may be observed.

STAGING

The staging system for the primary tumor is depicted in Table 38.15.

TABLE 38.15

Hypopharynx: 2010 American Joint Committee on Cancer Staging System for the Primary Tumor

T1	Tumor limited to one subsite of hypopharynx and 2 cm or less in greatest dimension
T2	Tumor invades more than one subsite of hypopharynx or an adjacent site, or measures more than 2 cm but not more than 4 cm in greatest diameter without fixation of the hemilarynx
T3	Tumor more than 4 cm in greatest dimension or with fixation of the hemilarynx or extension to esophagus
T4a	Tumor invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, or central compartment soft tissue ^a
T4b	Tumor invades the prevertebral fascia, encases the carotid artery, or involves mediastinal structures

^a Central compartment soft tissue includes the prelaryngeal strap muscles and subcutaneous fat.

TREATMENT

Selection of Treatment Modality

Posterior Pharyngeal Wall

RT produces cure rates similar to those produced by surgery alone or combined with RT, and with less morbidity. Thus, almost all cancers are treated with RT.

Lateral Pharyngeal Wall

The preferred treatment is definitive RT.

Pyriform Sinus

T1 and low-volume (≤ 6 mL), exophytic T2 cancers with normal cord mobility can be treated either by RT or a partial laryngopharyngectomy.³¹⁰ RT is preferred because it is associated with less morbidity.

Selected high-volume endophytic T2 and T3 lesions with normal or reduced mobility may be suitable for chemoRT. The swallowing outcomes after concurrent chemoRT may be less optimal than those seen in the oropharynx and larynx.³¹¹

The remainders are best treated with a total laryngopharyngectomy, neck dissection, and postoperative RT or chemoRT. Patients presenting with an extensive primary lesion and extensive neck metastases are frequently offered palliative therapy.

Surgical Treatment

Posterior Pharyngeal Wall

If the lesion is high on the posterior wall, a transoral approach can be used. Lower lesions were traditionally accessed via a transhyoid approach, a lateral pharyngotomy, or a midline mandibulolabial glossectomy. More recently, transoral laser microsurgical resection has been employed to reduce the morbidity associated with open approaches, which also frequently require tracheotomy. Dissection extends deep to the tumor down to the prevertebral fascia; smaller defects heal by secondary intention without a skin graft, whereas larger defects may require a radial forearm free flap.

Pyriform Sinus

Partial Laryngopharyngectomy. A partial laryngopharyngectomy removes the false cords, epiglottis, aryepiglottic fold, and pyriform sinus; one arytenoid may be removed when necessary. The vocal cords are preserved. The following findings contraindicate a partial laryngopharyngectomy: extension to the apex of the pyriform sinus, a fixed cord, extension to contralateral arytenoid, poor pulmonary function, and large, fixed lymph nodes.

Total Laryngopharyngectomy. A total laryngopharyngectomy removes the larynx and varying amounts of the pharyngeal wall. Advanced lesions require excision of nearly the entire circumference. The pharynx is reestablished by primary closure after a partial pharyngectomy; reconstruction is accomplished with a pectoralis major myocutaneous flap or a radial forearm free flap.

Postcricoid Pharynx

A total laryngopharyngectomy with reconstruction, generally using a pectoralis major myocutaneous flap or free flap, is performed. If the lesion extends into the cervical esophagus, a gastric pull-up or jejunal free flap may be necessary.

Irradiation Technique

Posterior Pharyngeal Wall

The RT technique is opposed lateral fields to include the primary lesion and the regional nodes. Because these lesions tend to “skip” areas, the entire posterior pharyngeal wall is included initially. If the lesion extends near the arytenoids, the postcricoid pharynx, pyriform sinuses, and upper cervical esophagus are included. The retropharyngeal nodes are included even if the neck is N0. When the field is reduced at 45 Gy to avoid the spinal cord, the posterior border of the portal is placed just anterior to the spinal cord.³¹² The dose is 74.4 to 76.8 Gy, at 1.2 Gy per fraction twice daily, in a continuous course. Another option is 70 Gy in 35 fractions over 30 treatment days. IMRT is useful to reduce the dose to one or both parotids. Concomitant chemotherapy should be included for stage III through IV cancers.

Pyriform Sinus

Parallel-opposed lateral portals are used to encompass the primary lesion and regional nodes on both sides. The superior border is placed 2 cm above the tip of the mastoid to cover the most superior jugular chain and the retropharyngeal lymph nodes. The posterior border encompasses the level V nodes. Clinically positive nodes behind the plane of the spinal cord require an electron boost. The anterior border is usually placed about 0.5 to 1 cm behind the anterior skin edge if it is possible to do so and adequately encompass the tumor. The inferior border is 2 cm below the inferior border of the cricoid. The remaining lower neck lymph nodes are treated through an en face portal. The doses are the same as for the posterior pharyngeal wall. IMRT is an option if the tumor can be adequately encompassed while sparing the contralateral salivary gland(s) and/or to avoid a difficult low neck match.

Combined Treatment Policies

Posterior Pharyngeal Wall

An operation should usually precede RT when a combination is selected, unless a gastric pull-up is planned.

Pyriform Sinus

Following a total laryngopharyngectomy with or without neck dissection, RT is usually recommended for indications previously outlined. RT or chemoRT is used prior to operation for patients with a large fixed node. The dose to the primary tumor ranges from 45 to 50 Gy; the fixed node(s) is boosted to 60 to 75 Gy.

Management of Recurrence

Posterior Pharyngeal Wall

Recurrence after RT may be limited to the posterior pharyngeal wall and may be suitable for surgical excision, with occasional salvage. There is frequently a persistent ulcer after RT for advanced lesions; it should be considered evidence of persistent disease if it does not heal. Surgical excision is limited posteriorly by the prevertebral fascia. RT salvage of a surgical failure is unusual.

Pyriform Sinus

The hallmark of local recurrence after RT is persistent edema, pain, and fixation of laryngeal structures. A direct laryngoscopy is required, but the biopsy may be negative. A CT and/or PET scan is often helpful for distinguishing local recurrence from necrosis. It may be necessary to recommend a total laryngopharyngectomy for salvage without a positive biopsy.

Recurrence after a total laryngopharyngectomy is usually in the soft tissues of the neck, the untreated opposite neck, the base of tongue, or stoma. Surgical failures after a partial laryngopharyngectomy for early lesions may be salvaged by a total laryngopharyngectomy. Failures after a total laryngopharyngectomy are rarely salvaged.

RESULTS OF TREATMENT

Pharyngeal Wall

The 5-year local control rates and ultimate local control rates after RT at the University of Florida for 170 patients were for T1 (n = 14), 93% and 93%; for T2 (n = 51), 84% and 91%; for T3 (n = 75), 60% and 62%; and for T4 (n = 30), 44% and 44%, respectively.³¹² The 5-year local–regional control and cause-specific survival rates were for stage I, 88% and 88%; for stage II, 85% and 89%; for stage III, 49% and 44%; and for stage IV, 44% and 35%, respectively.³¹²

Pyiform Sinus

The results of treatment for 80 patients with carcinoma of the pyriform sinus treated at Washington University by preoperative RT followed by a partial laryngopharyngectomy are shown in Table 38.16.³¹³ Seventy patients had the equivalent of AJCC T1 lesions (disease limited to the pyriform sinus), 10 patients had disease extending beyond the pyriform sinus, and none had invasion of the apex of the pyriform sinus. The cause of death was cancer in 26%, complications of treatment in 14%, and intercurrent disease in 20%. The 5-year absolute survival was 25 of 66 patients (38%) (JE Marks, Personal communication, 1979).

The results of treatment for 57 patients from the same institution who were treated by preoperative RT followed by total laryngectomy and partial pharyngectomy are depicted in Table 38.16.³¹³ Thirty-five patients had lesions confined to the pyriform sinus (AJCC T1) and the remainder had extension beyond the pyriform sinus (AJCC T2 to T4). The cause of death was cancer in 56% of patients, complications of treatment in 11% of patients, and intercurrent disease in 18% of patients.

TABLE 38.16

Carcinoma of the Pyriform Sinus: Results of Treatment by Low Dose Radiation Therapy Plus Partial Laryngopharyngectomy or Total Laryngectomy and Partial Pharyngectomy (Washington University, St. Louis, 1964–1974)

Result	PLP (80 Patients) ^a	TLP (57 Patients) ^b
Local recurrence ± neck recurrence	14% ^c	14%
Neck recurrence ± distant metastases (primary controlled)	9%	23%
Distant metastases alone	11%	21%
5-year actuarial survival (no evidence of disease)	40%	22%

^aT1, 70 patients; T2–T4, 10 patients (AJCC staging).

^bT1, 35 patients; T2–T4, 22 patients (AJCC staging).

^cFour patients salvaged.

PLP, partial laryngopharyngectomy; TLP, total laryngopharyngectomy. Data from Marks JE, Kurnick B, Powers WE, Ogura JH. Carcinoma of the pyriform sinus: an analysis of treatment results and patterns of failure. *Cancer* 1978;41:1008–1015.

The 5-year local control rates for 123 patients treated with definitive RT for T1 (23 patients) and T2 (100 patients) pyriform sinus SCCs were for T1, 85%; and for T2, 85%, respectively.³¹¹ The 5-year rates of local–regional control and cause-specific survival were for stage I to II, 86% and 85%; for stage III, 65% and 73%; for stage IVA, 83% and 62%; and for stage IVB, 24% and 22%, respectively.³¹¹ The 5-year distant metastasis-free survival rates were for N0, 96%; for N1, 88%; for N2, 68%; and for N3, 55%.

COMPLICATIONS OF TREATMENT

Posterior Pharyngeal Wall

Surgical Treatment Complications

Marks and coworkers³¹⁴ reported a 14% operative mortality plus major complications including pharyngocutaneous fistula (31%) and carotid rupture (14%) for patients treated with preoperative RT, 25 to 30 Gy.

Radiation Therapy Complications

Mendenhall and coworkers³¹² observed 9 fatal complications (5%) in 170 patients who were treated at the University of Florida. Twenty-five patients (15%) experienced nonfatal severe complications including permanent feeding tube (17 patients), soft tissue and/or bone necrosis (7 patients), and permanent tracheostomy (1 patient).

Pyiform Sinus

Surgical Treatment Complications

The complications of a partial laryngopharyngectomy included a 12% operative mortality, fistula, aspiration, and dysphagia.³¹³ The complications of total laryngopharyngectomy included a treatment-related mortality of 11%, fistula, and pharyngeal stenosis.³¹³ The complication rate is increased by the addition of RT.

Radiation Therapy Complications

The major RT complication is laryngeal necrosis. Rabbani et al.³¹¹ reported the following rates of moderate-to-severe complications in 123 patients: acute (2%); late (9%); and postoperative (5%).

Complications of Salvage Treatment

Attempted surgical salvage of RT failures has a significant operative morbidity and mortality; few patients are cured.

NASOPHARYNX

NPCs are uncommon in the United States. The Chinese have a high frequency; American-born second-generation Chinese maintain the risk of NPC. NPC has been shown to have an association with elevated titers of EBV, which is independent of geography.³¹⁵ There is a 3 to 1 ratio of predominance in men. The age distribution for NPC is younger than for other head and neck sites; about 20% of patients are younger than 30 years of age.

ANATOMY

The nasopharynx is roughly cuboidal in shape. It is contiguous with the nasal cavity, inferiorly with the oropharynx, and laterally with the middle ears by way of the eustachian tubes.

The mucosa of the roof and posterior wall is often irregular because of the pharyngeal bursa, adenoids, and pharyngeal hypopharynx; it tends to become smooth with age.

The lateral walls include the eustachian tube openings with the fossa of Rosenmüller, located behind the torus tubarius. The superolateral muscular wall of the nasopharynx is incomplete. The floor of the nasopharynx is incomplete and consists of the upper surface of the soft palate.

Lymphatics

There is an extensive submucosal lymphatic capillary plexus. The tumor spreads along three different pathways: the jugular chain, the spinal accessory chain, and the retropharyngeal pathway.³¹⁶ The lateral retropharyngeal nodes lie in the retropharyngeal space medial to the carotid artery. Directly behind the nodes are the lateral masses of C1 and C2. Inconstant lymphatic vessels may drain directly to the level III and V nodes.¹³

PATHOLOGY

Carcinomas compose about 85% and lymphomas about 10% of the malignant lesions. NPCs are classified as follows: keratinizing squamous cell carcinoma (WHO type I); nonkeratinizing carcinoma (WHO type II), and undifferentiated (WHO type III) basaloid SCC. Lymphoepithelioma is included in the WHO type II and III categories. A miscellaneous group of malignant tumors includes melanoma, plasmacytoma,²⁷⁰ juvenile angiofibroma,¹⁴ carcinosarcoma, sarcomas, nonchromaffin paragangliomas, and minor salivary gland tumors.

PATTERNS OF SPREAD

Primary

Inferior extension along the lateral pharyngeal walls and tonsillar pillars occurs in almost one third of patients. Extension into the posterior nasal cavity is frequent but is usually limited to less than 1 cm. Invasion of the posterior ethmoids, maxillary antrum, and/or orbit occurs fairly often. Skull base invasion is recognized radiographically in at least 25% of patients. The sphenoid sinus frequently is invaded. The tumor may erode through the foramen ovale, lacerum, and/or spinosum. The tumor eventually reaches the cavernous sinus and has access to CNs II to VI.

The lateral muscular wall of the nasopharynx is incomplete superiorly. The defect, termed the sinus of Morgagni, is transversed by the cartilaginous eustachian tube and the levator palatine muscle, providing access for NPCs to the lateral pharyngeal space and skull base.

Lymphatics

There is an 80% to 90% incidence of metastatic neck nodes on presentation; approximately 50% are bilateral. Low-grade SCCs produce fewer metastases (73%) than high-grade carcinomas (92%). Metastases to submental and occipital nodes may appear when there is blockage of the common lymphatic pathways either by massive neck disease or by an untimely neck dissection.

CLINICAL PICTURE

The most common presenting complaint is a painless upper neck mass. Nasal obstruction, epistaxis, sore throat, and otitis media may be observed. Facial pain may be referred from any of the three divisions of the trigeminal nerve, usually V3. Occipital or temporal headaches frequently are seen. Proptosis occurs with posterior orbital invasion. Trismus is due to the invasion of the pterygoid region.

Neurologic symptoms and signs occur in about 25% of patients. Involvement of CNs II to VI indicates extension into the cavernous sinus. CNs IX to XII and the sympathetic chain are involved in the lateral pharyngeal space.

An examination of the nasopharynx will show a lesion on the lateral wall or roof. Early lesions may be submucosal. Lymphomas tend to remain submucosal until quite large. The tumor infrequently grows very far down the posterior pharyngeal wall. The posterior tonsillar pillars may bulge into the oropharynx if an enlarged node develops in the lateral pharyngeal space. CN VI is the one most commonly involved.

STAGING

The AJCC staging system is depicted in Table 38.17.

TREATMENT

Selection of Treatment Modality

The treatment of almost all NPCs is RT-based because complete surgical resection is usually not feasible. Neck dissection is used less often in the management of neck disease because of the relatively high success rate with RT or chemoRT alone. A small adenocarcinoma or sarcoma may be excised. Juvenile angiofibromas are preferably excised because of the young age of the patient, although the tumors are quite successfully cured by RT when a complete resection is unlikely or dangerous.¹⁴ Patients with advanced disease should receive concomitant chemotherapy.^{190,192,201,317,318}

Irradiation Technique

If the tumor is thought to be limited to the nasopharynx or to have minimal soft-tissue extension, the following areas are included in the treatment volume: (1) the nasopharynx, (2) the posterior 2 cm of the nasal cavity, (3) the posterior ethmoid sinuses, (4) the entire sphenoid sinus and basioccipital bone, (5) the cavernous sinus, (6) the base of skull (7 to 8 cm width encompassing the foramen ovale, carotid canal, and foramen spinosum laterally), (7) the pterygoid fossae, (8) the posterior one third of the maxillary sinus, (9) the oropharyngeal wall to the level of the mid tonsillar fossa, (10) the retropharyngeal nodes, and (11) the neck nodes on both sides.

Extension to the skull base or involvement of CNs II to VI requires the superior border be raised to include the entire pituitary, the base of the brain in the suprasellar area, the adjacent middle cranial fossa, and the posterior portion of the anterior cranial fossa. Patients with anterior invasion into the orbit, ethmoids, or maxillary sinus require an individualized plan to produce a satisfactory dose distribution. The use of 3-dimensional CT-based treatment planning allows for the use of more conformal fields. IMRT is useful to improve coverage of the poststyloid parapharyngeal space and to reduce the dose to the parotid glands and the temporal lobes to reduce long-term morbidity. We currently treat patients to 74.4 at 1.2 Gy per fraction twice daily.

Neck Nodes. The entire neck is irradiated to the level of the clavicles. The retropharyngeal nodes are included in the treatment of the primary lesion. The upper neck nodes are included in the primary fields to the level of the thyroid notch. In the case of an N0 neck, the posterior margin is placed about 1 to 2 cm behind the posterior border of the sternocleidomastoid to encompass the high level V nodes and level 2 nodes. The portals are extended to include the submental area only if there is disease in the level IB nodes or if the patient had a neck dissection prior to RT. The lower neck is treated through an anterior portal with a shield over the larynx.

TABLE 38.17

2010 American Joint Committee on Cancer Staging for Nasopharyngeal Cancer

Primary Tumor (T)

T1	Tumor confined to the nasopharynx, or tumor extends to oropharynx and/or nasal cavity without parapharyngeal extension ^a
T2	Tumor with parapharyngeal extension ^a
T3	Tumor involves bony structures of skull base and/or paranasal sinuses
T4	Tumor with intracranial extension and/or involvement of cranial nerves, hypopharynx, orbit, or with extension to the infratemporal fossa/masticator space

^a Parapharyngeal extension denotes posterolateral infiltration of tumor.

Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original source for this material is the *AJCC Cancer Staging Handbook*, Seventh Edition (2010) published by Springer Science and Business Media LLC, www.springerlink.com.

Regional Lymph Nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Unilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa and/or unilateral or bilateral, retropharyngeal lymph nodes, 6 cm or less, in greatest dimension ^a
N2	Bilateral metastasis in cervical lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa ^a
N3	Metastasis in a lymph node(s), ^a >6 cm and/or to supraclavicular fossa
N3a	Greater than 6 cm in dimension
N3b	Extension to the supraclavicular fossa ^b

^a Midline nodes are considered ipsilateral nodes.

^b Supraclavicular zone or fossa is relevant to the staging of nasopharyngeal carcinoma and is the triangular region originally described by Ho. It is defined by three points: (1) the superior margin of the sternal end of the clavicle, (2) the superior margin of the lateral end of the clavicle, and (3) the point where the neck meets the shoulder. Note that this would include caudal portions of levels IV and VB. All cases with lymph nodes (whole or part) in the fossa are considered N3b.

Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original source for this material is the *AJCC Cancer Staging Handbook*, Seventh Edition (2010) published by Springer Science and Business Media LLC, www.springerlink.com.

Stage Grouping

0	Tis	N0	M0
I	T1	N0	M0
II	T1	N1	M0
	T2	N0	M0
	T2	N1	M0
III	T1	N2	M0

Acute Sequelae. A sore throat begins at the end of the second week of therapy and persists for 2 to 3 months after the completion of RT. A xerostomia is always present. Loss of taste and appetite is often profound; both return 1 to 6 months after completion of RT. Obstruction of the eustachian tubes may occur with secondary otitis media and hearing loss. Polyethylene tubes inserted through the eardrums to drain the middle ears can correct this condition. The obstruction often improves after a few months. Severe nausea and vomiting are uncommon.

Management of Recurrence

The majority of recurrent SCCs are diagnosed within 2 years, but lymphoepithelioma may recur many years after treatment. Headache and CN palsies usually indicate recurrence. Retreatment for local recurrences with limited RT portals and/or intracavitary brachytherapy may be rewarding, particularly if the recurrence is due to a marginal miss or low dose.^{319,320}

Results of Treatment

Lee and co-workers³²¹ reported the following 10-year outcomes in a series of 5,037 patients treated with RT at the Queen Elizabeth Hospital, Hong Kong, between 1976 and 1985: local control, 61%; regional control, 64%; distant metastasis-free survival, 59%; and survival, 42%. Leung et al.³²² reported the following 5-year local control rates in a series of 1,070 patients: T1, 88%; T2A, 87%; T2B, 82%; T3, 69%; and T4, 69%. Chua et al.³²³ evaluated 290 patients and found that primary tumor volume of more than 60 mL was associated with a lower likelihood of local control after RT. Teo and colleagues³²⁴ evaluated a series of 903 patients treated at the Prince of Wales Hospital, Hong Kong, and observed that local control was adversely affected by advanced patient age, skull base invasion, and CN involvement. Prognostic factors associated with an increased rate of distant metastases and poor survival were male sex, skull base and CN(s) involvement, advanced neck stage, nodal fixation, and bilateral neck nodes.³²⁴ The 5-year outcomes for 82 patients treated at the University of Florida were for local control, 78%; for regional control, 90%; for local–regional control, 76%; for distant metastasis-free survival, 80%; for cause-specific survival, 66%; and for survival, 57%.³²⁵ Table 38.9 summarizes the results of selected randomized trials comparing chemoRT versus RT alone.

Follow-Up

The follow-up includes careful observation and laboratory testing for possible thyroid and/or pituitary hypofunction. Dental care must be closely monitored because of xerostomia.

Complications of Treatment

Primary or secondary hypopituitarism (from a hypothalamic lesion) has been reported. Brain necrosis is rare. Hypothyroidism may result from either a direct effect on the thyroid gland or an indirect effect on the pituitary. A transient CNS syndrome may appear 2 to 3 months after RT and would require several months to resolve. General weakness and extreme fatigue may be symptoms of low serum cortisol levels. Radiation myelitis of the cervical cord or brain stem is the most severe CNS complication. IMRT may be used to reduce the dose to the CNS, particularly the temporal lobes.

Trismus may occur because of fibrosis of the pterygoid muscles. Palsy of CNs IX to XII may occur several years after RT and is related to nerve entrapment in the lateral pharyngeal space. Eye complications (e.g., retrobulbar optic neuritis) may develop owing to RT of the optic nerve.³²⁶ RT of the posterior eyeball to high doses may produce a retinopathy.³²⁷

NASAL VESTIBULE, NASAL CAVITY, AND PARANASAL SINUSES

Tumors of the nasal vestibule are considered separately from nasal cavity tumors because they are essentially skin cancers and have a different natural history. Primary tumors arising from the nasal cavity and paranasal sinuses are considered together because the lesions are frequently advanced when first seen and it is not always possible to determine the site of origin.

Cancer of the nasal cavity or paranasal sinuses is a relatively rare problem, with a yearly risk factor estimated at approximately one case for every 100,000 people. They occur more often in men and usually appear after the age of 40 except for minor salivary gland tumors and esthesioneuroblastomas, which may appear before the age of 20.³²⁸ Nasal cavity and ethmoid sinus adenocarcinomas have been linked to occupations associated with wood dust, such as the furniture industry, sawmill work, and carpentry. Other occupations with dust-filled work environments, such as shoe making, baking, and the flour milling industry, also have been implicated.¹²

Carcinomas of the sphenoid and frontal sinuses are rare.

Anatomy

The nasal vestibule is the entrance to the nasal cavity. It is lined by skin in which there are numerous hair follicles and sebaceous glands. The vestibule is a three-sided, pear-shaped cavity about 1.5 cm in diameter that ends posteriorly at the limen nasi. The alar cartilages form the anterolateral wall. The medial wall is the columella, formed by the medial wing of the alar cartilage and the anterior portion of the cartilaginous septum. The floor is the maxilla.

The nasal cavity begins at the limen nasi and ends at the posterior nares, where it communicates with the nasopharynx. The lateral walls are composed of thin bony folds that project into the nasal cavity: the inferior, medial, and superior turbinates. The nasolacrimal duct enters the nasal cavity beneath the inferior turbinate. The frontal sinus and ethmoid bullae connect to the nasal cavity with openings that lie under the middle turbinate. The sphenoid sinus communicates with the nasal cavity by an opening on the anterior wall of the sinus. Approximately 20 branches of the olfactory nerves enter the nasal cavity through the cribriform plate; nerve fibers are distributed over the upper one third of the septum and the superior nasal turbinate. The epithelium is nonciliated columnar. The lower half of the nasal cavity is the respiratory portion, and the epithelium is ciliated columnar. There are numerous collections of lymphoid tissue and mucous glands beneath the epithelium.

The maxillary sinuses are single pyramidal cavities. The medial wall is the lateral wall of the nasal cavity and has one or two openings communicating with the middle meatus under the medial turbinate. The inferior wall is the hard palate. The posterolateral wall is related to the zygomatic process and the pterygomaxillary space. The superior wall is the orbital floor.

The frontal sinuses are two irregular, asymmetrical air cavities separated by a thin bony septum. They connect to the middle meatus of the nasal cavity by the frontonasal duct. They are separated from the anterior ethmoid cells by thin bony walls. The posterior wall separating the frontal sinus from the anterior cranial fossa is relatively thick.

The ethmoid sinuses consist of a number of air cells lying between the medial walls of the orbits and the lateral wall of the nasal cavity. The lateral wall is the thin porous lamina papyracea. Medially, the ethmoid air cells bulge into the lateral wall of the nasal cavity. The ethmoid cells communicate with the nasal cavity in the middle meatus. These bony walls are thin and easily traversed by the tumor. The ethmoid air cells extend far anteriorly; the lacrimal bone covers the anterior cells laterally. The midline perpendicular plate of the ethmoid separates the right and left ethmoid cells anatomically. There is no anatomic barrier between the anterior, middle, and posterior ethmoids.

The sphenoid sinus is a midline structure in the body of the sphenoid bone. The pituitary lies above, the cavernous sinuses laterally, the nasal cavity and ethmoid sinuses in front, and the nasopharynx beneath. The clivus and brain stem lie posteriorly. The pneumatization is variable and can extend into all portions of the sphenoid bone. The right and left sinuses are partially separated by an incomplete septum. The sphenoid sinus connects anteriorly with the nasal cavity in the sphenoidal recess.

Lymphatics

Nasal Vestibule. The lymphatic trunks run to the level IB nodes. There is a small risk for involvement of the intercalated facial nodes just behind the commissure of the lip along the course of the facial neurovascular bundle.

Nasal Cavity and Paranasal Sinuses. The lymphatics of the nasal cavity are separated into the olfactory group and the respiratory group. According to Rouvière,¹³ they do not communicate with each other. There is a connection between the lymphatic network of the olfactory region and the subarachnoid spaces, which allows some absorption of cerebrospinal fluid (CSF) into the lymphatic system. The lymphatics of the olfactory region of the nasal cavity run posteriorly to terminate in lymph nodes alongside the jugular vein at the skull base in the lateral pharyngeal space. The lymphatics of the respiratory nasal cavity terminate in the lateral retropharyngeal nodes or the level II nodes. The capillary lymphatic plexus of the nasal mucosa is probably not very profuse, judged by the relatively low incidence of metastatic nodes.

The mucosa of the paranasal sinuses has either no or very sparse capillary lymphatics.

Pathology

Benign Tumors

Inflammatory polyps, giant cell reparative granulomas, benign odontogenic tumors, and necrotizing sialometaplasia may appear in this area. Inverted papilloma is a benign, aggressive neoplasm that is associated with carcinoma in 5% to 15% of cases.³²⁹

Malignant Tumors

Nasal Vestibule. Almost all malignant tumors are SCCs; basal cell carcinomas and adnexal carcinomas are also reported.

Nasal Cavity and Paranasal Sinuses. SCC or one of its variants is the most common neoplasm. Minor salivary gland tumors account for about 10% to 15% of neoplasms in this region. Lymphoma and melanoma account for approximately 5% and 1% of cases, respectively. Esthesioneuroblastoma is a neuroendocrine carcinoma that originates from the olfactory mucosa. Sinonasal undifferentiated carcinoma—a more aggressive neuroendocrine malignancy—is sometimes encountered.³³⁰ Soft tissue and bone sarcomas may occur in the nasal cavity and paranasal sinuses, including chondrosarcoma, osteosarcoma, and Ewing sarcoma.³³¹

Midline lethal granuloma is a nonkiller (NK) nasal T-cell lymphoma. Unchecked, the disease is fatal. Death results from extension to the CNS, hemorrhage, sepsis, or inanition. Treatment is usually RT, which is often combined with chemotherapy.³³²

Patterns of Spread

Nasal Vestibule

Primary. Lesions of the nasal vestibule invade the alar and septal cartilages and may extend to the nasal skin. The upper lip is frequently invaded. Posterior growth into the nasal cavity is frequent.

Early cancers originating on the columella and anterior septum are often superficial lesions that ulcerate and produce a crust or scab and often present with septal perforation.

Lymphatic. Lymph node spread is usually to a solitary ipsilateral level IB node, but may be bilateral. The facial, preauricular, and submental nodes are at small risk. Wallace et al.³³³ reported only 4 of 79 patients (5%) with clinically positive lymph nodes at diagnosis, but 9 patients (11%) later developed positive lymph nodes.

Nasal Cavity and Paranasal Sinuses

Nasal Cavity. The routes of spread are essentially the same for various histologies, with the exception of esthesioneuroblastoma and minor salivary gland tumors. The latter have a greater propensity for PNI.

Lesions arising in the olfactory region invade the ethmoids and the orbit, spread through the cribriform plate to the anterior cranial fossa, and spread between bone and dura. Eventually, they penetrate the dura and invade the frontal lobes. These lesions also tend to destroy the septum and may invade through the nasal bone to the skin. Lesions arising on the lateral wall of the nasal cavity invade the maxillary sinus, ethmoids, and orbit.

Esthesioneuroblastomas may show submucosal spread and may grow along olfactory nerves and penetrate through an intact dura to the frontal lobes.

The nasopharynx and sphenoid sinus are secondarily invaded in advanced lesions. The tumor may follow nerves posteriorly and superiorly toward the sphenopalatine ganglion near the skull base or along V2.

Maxillary Sinus. All walls of the sinus may be penetrated by the tumor; the pattern of spread and bone destruction is dependent on the site of origin within the sinus. Lesions arising in the anterolateral infrastructure tend to invade through the lateral inferior wall or grow through dental sockets, causing loosening of the teeth or improper seating of a denture. Ulceration follows, with the development of an oral-antral fistula. Lesions arising on the medial infrastructure readily extend into the nasal cavity.

Posterior infrastructure lesions erode through the posterolateral wall and into the infratemporal fossa and extend superiorly to the skull base. Orbital extension occurs either through the roof of the maxillary sinus, through the ethmoids and lamina papyracea, or by way of the infratemporal fossa and then through the infraorbital fissure.

Tumors arising in the suprastructure of the antrum have two general patterns of development. One group extends laterally, invades the malar bone, and produces a mass below the lateral floor of the orbit that may ulcerate through to the skin. The orbit is invaded laterally and displaces the eye superomedially. The temporal fossa is often involved, as is the zygomatic bone in advanced lesions. Suprastructure cancers that extend medially invade the nasal cavity, the ethmoid and frontal sinuses, the lacrimal apparatus, and the medial inferior orbit.

Ethmoid Sinuses. Depending on the location of the tumor, it may invade the medial orbit through the lamina papyracea, the inner canthus, and the nasal cavity. More advanced lesions invade the maxillary antrum, the nasopharynx, the sphenoid sinus, and the anterior cranial fossa.

Sphenoid Sinus. The sphenoid sinus is closely related to the CNs in the cavernous sinus: III, IV, V1, V2, and VI (Fig. 38.2). CN palsies and headaches are frequently the first clinical evidence of a sphenoid sinus tumor. A diagnosis is usually made, however, when the tumor eventually breaks through into the nasopharynx or nasal cavity where it can be seen.

Inverted Papilloma. A report of 223 cases of inverted papillomas showed the lateral nasal wall was the most commonly involved site (68%), with ethmoid and maxillary sinus involvement also being

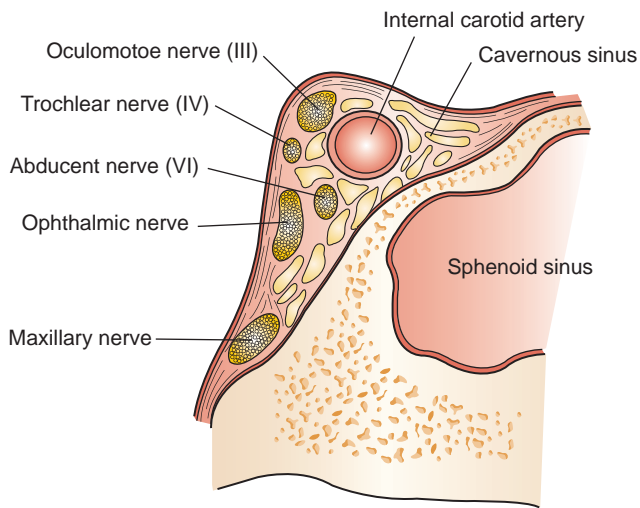

Figure 38.2 Coronal section of the cavernous sinus. (Mendenhall WM, Million RR, Mancuso AA, Stringer SP. *Nasopharynx*. In: Million RR, Cassisi, eds. *Management of Head and Neck Cancer: A Multidisciplinary Approach*, 2nd ed. Philadelphia: J. B. Lippincott; 1994: 606, Fig. 23-10).

common (57%), as was involvement of the septum (28%). However, ethmoid and maxillary sinus involvement without a tumor of the lateral nasal wall occurred in 4%. Intracranial extension was usually associated with a carcinoma. The tumor occurred bilaterally when there was spread through the nasal septum; multicentric sites of origin were observed.³³⁴

Lymphatic. The incidence of lymphatic metastases at diagnosis is 10% to 15% for nasal cavity and ethmoid sinus SCCs and probably lower for antral and sphenoid tumors. Maxillary sinus tumors that invade the oral cavity and involve the buccal mucosa, maxillary gingiva, or hard palate may spread to the level IB and level II nodes. Lesions that invade the nasal cavity or nasopharynx spread posteriorly to the parapharyngeal nodes and then to the level II nodes. The risk of cervical node involvement for esthesioneuroblastoma is approximately 20%.³²⁸

Clinical Picture

Nasal Vestibule

These lesions present with symptoms of a slow-growing mass with attendant crusting and occasional, minor bleeding. Septal perforation may occur.

Nasal Cavity and Paranasal Sinuses

Nasal Cavity. The earliest symptoms are a low-grade chronic infection with discharge, obstruction, and minor, intermittent bleeding. Lesions arising in the olfactory region may cause unilateral or bilateral nasal expansion of the bridge of the nose; a mass may appear near the inner canthus and eventually ulcerate. Obstruction of the nasolacrimal system may be a presenting complaint. Extension through the cribriform plate or into the ethmoid sinuses is accompanied by a frontal headache. The aberration of smell is rare. Invasion of the medial orbit produces proptosis and diplopia; a mass may be palpated in the orbit.

Maxillary Sinus. These cancers develop silently when they are confined to the sinus and produce symptoms after extension through the walls. If the tumor invades toward the oral cavity, the presenting symptoms include pain and loosening or loss of teeth. Palpation

and observation of the face may show a mass. A posterior invasion of the orbit will produce proptosis, diplopia, and conjunctival edema. Invasion of V2 in the floor of the orbit may cause paresthesia. Nasal obstruction and bleeding are common, and trismus and headaches are associated with invasion posteriorly into the pterygopalatine fossa, pterygoid muscles, infratemporal fossa, and skull base.

Cancers developing in the medial suprastructure of the antrum present with nasal symptoms of discharge or bleeding, mild infra-orbital pain, an infected lacrimal sac, and displacement of the eye superolaterally with proptosis, diplopia, and conjunctival edema.

Cancer developing in the lateral suprastructure produces a mass below the lateral canthus with associated pain. The eye may be deviated medially and upward when orbital invasion occurs, producing diplopia and proptosis. The tumor may extend to the temporal fossa, producing a diffuse fullness.

Ethmoid Sinuses. Mild-to-moderate sinus pain referred to the frontal-nasal area is an early symptom. A painless mass may present near the inner canthus. Diplopia and proptosis develop with invasion of the medial orbit. Nasal discharge, epistaxis, and obstruction are frequent. Paresthesia may occur over the distribution of sensory nerves.

Staging

The AJCC staging system for the nasal cavity and paranasal sinuses is depicted in Table 38.18. Nasal vestibule tumors are staged according to the AJCC staging system for skin cancers.

Treatment

Selection of Treatment Modality

Nasal Vestibule. RT is usually the preferred treatment because of the deformity produced by excision.³³³ Surgery alone is preferred for the occasional very small lesion, the removal of which will not produce cosmetic deformity or require reconstruction. A subset of patients best treated by surgery and adjuvant RT or chemoRT are those with invasion of the premaxilla.

Surgical Treatment. Excision of lesions in the nasal vestibule usually involves removal of cartilage as well as skin. Depending on the site of the lesion, the columella, the septum, or the alar cartilages will have to be removed, with a resulting cosmetic deformity that is difficult to reconstruct. If the alar cartilage has been sacrificed, either a composite graft consisting of skin and cartilage from the ear or a nasolabial flap can be used to repair the defect. If the entire external nose is resected, a prosthesis is used.

Irradiation Technique. EBRT, brachytherapy, or a combination of both may be used. EBRT is usually administered with a single anterior portal technique, which uses a combination of photons and electrons; a wax bolus ensures a homogenous dose. The dose ranges from 66 to 70 Gy at 2 Gy per fraction, once daily in a continuous course.

Interstitial brachytherapy of the nasal vestibule and nasal cavity is highly individualized and employs afterloaded ¹⁹²Ir needles. The implant is usually composed of two, three, or four planes of sources inserted perpendicularly through the skin surface of the external nose with crossing needles placed in the dorsum of the nose, the floor of the nasal cavity, and the upper lip. The dose varies depending on the size of the lesion.³³³

Inverted Papilloma. An inverted papilloma is treated initially by surgery. Depending on the procedure, the local recurrence rate may be fairly high, and subsequent excisions may be required. When the lesion begins to act aggressively with rapid recurrences and invasion of the sinuses, orbit, and anterior cranial fossa, it

TABLE 38.18

2010 American Joint Committee on Cancer Staging System for Nasal Cavity and Paranasal Sinus Cancers

Maxillary Sinus	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor limited to the maxillary sinus mucosa with no erosion or destruction of bone
T2	Tumor causing bone erosion or destruction including extension into the hard palate and/or middle nasal meatus, except extension to posterior wall of maxillary sinus and pterygoid plates
T3	Tumor invades any of the following: bone of the posterior wall of maxillary sinus, subcutaneous tissues, floor or medial wall of orbit, pterygoid fossa, ethmoid sinuses
T4a	Tumor invades anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
T4b	Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V2), nasopharynx, or clivus
Nasal Cavity and Ethmoid Sinus	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor restricted to any one subsite, with or without bony invasion
T2	Tumor invading two subsites in a single region or extending to involve an adjacent region within the nasoethmoid complex, with or without bony invasion
T3	Tumor extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate
T4a	Tumor invades any of the following: anterior orbital contents, skin of nose or cheek, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses
T4b	Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than V2, nasopharynx, or clivus

should be considered a low-grade cancer and treated by a more radical removal. RT is recommended for lesions that are incompletely resected, for multiple recurrences, and for those in whom carcinoma is found.³²⁹

Nasal Cavity. Surgery is the preferred treatment if a gross total resection is likely; postoperative RT or chemoRT is usually indicated.³³⁵ Definitive RT is used for incompletely resectable tumors.

Surgical Treatment. A lateral rhinotomy provides the best access for resection of lesions of the nasal cavity. Generally, reconstruction

is not necessary unless the entire cartilaginous septum has been removed, in which case there will be a saddle deformity of the nose. The lateral wall of the nose may be removed by this approach for resection of an inverted papilloma and other localized neoplasms. More advanced lesions require the removal of involved sinuses and orbit. A craniofacial procedure may be required.

Irradiation Technique. The EBRT technique emphasizes an anterior portal with one or two lateral portals. Contiguous structures such as the maxillary sinus, ethmoid sinus, medial orbit, nasopharynx, skull base, and sphenoid sinus are generally included in the initial treatment volume as required. The treatment volume is reduced after 50 Gy to include the original gross disease with a margin. IMRT may be employed and usually produces a more conformal dose distribution.

Advanced lesions may require inclusion of an entire orbit and loss of vision usually occurs, but an operation would require visual loss in any case. Treatment planning should protect the opposite eye and optic nerve.

Combined Treatment Policies

If a combined treatment is planned, we prefer surgery first. RT or chemoRT is started 4 to 6 weeks afterward. The dose is usually 60 to 65 Gy for clear margins; patients with positive margins or for a gross residual tumor after operation receive 74.4 Gy at 1.2 Gy per twice-daily fraction.

Management of Recurrence

Once the patient has had surgery or RT, it is difficult to determine the extent of recurrent disease because of changes from the previous therapy. The most common situation for salvage is RT or surgical failure that can be treated successfully by a craniofacial resection. Tumor extension to the sphenopalatine fossa with definite destruction of a pterygoid plate is a relative contraindication to craniofacial resection. CN involvement, posterior invasion near the optic chiasm, and sphenoid sinus or cavernous sinus invasion are contraindications to resection. An MRI can distinguish between exudate and a gross tumor in a sinus. The anterior wall of the sphenoid sinus may be removed, but the sinus itself cannot be completely resected. Postoperative RT should be considered whether or not margins are positive.

Maxillary Sinus

Selection of Treatment Modality. Surgery gives the best results. Early infrastructure lesions may be cured by surgery alone, but, for most other cases, RT is given postoperatively even if margins are negative. ChemoRT should be considered for a positive margin. The extension of cancer to the skull base, nasopharynx, or sphenoid sinus contraindicates excision. The pterygoid process below the foramen rotundum may be removed along with the attached pterygoid muscles, but destruction of the sphenoid bone above this point is a contraindication to operation. Procedures to resect portions of the skull base are described for special situations.

Surgical Treatment. Surgery for maxillary sinus carcinoma depends on which walls are involved. If the floor of the orbit is free of disease, then the eye and orbital rim may be left undisturbed. If, however, there is involvement through the orbital floor, then a maxillectomy with resection of the floor with or without an orbital exenteration must be performed. If the posterior wall or the pterygoid plates are involved, they too must be included in the resection. A split-thickness skin graft is used to line the cavity, and a removable dental prosthesis is then used to fill the resulting deformity in the palate. An interim prosthesis is constructed prior to surgery so it can be placed at the time of operation and act as a stent. The permanent prosthesis is constructed about 6 months after the operation.

Irradiation Technique. RT treatment planning includes the entire maxilla, the adjacent nasal cavity, the ethmoid sinus, the nasopharynx, and the pterygopalatine fossa. All or part of the orbit is included in patients with extension into or near the orbit. Target volume definition is aided by the use of treatment planning CT combined with image-fusion MRI. The prescribed dose is 74.4 Gy at 1.2 Gy per fraction twice daily for RT alone. The dose for preoperative RT varies from 50 to 60 Gy, and the dose for postoperative RT varies from 60 to 74.4 Gy.

Ethmoid Sinus

Selection of Treatment Modality. Surgery is preferred if a gross total resection is likely. Postoperative RT or chemoRT is usually indicated. Unresectable tumors are treated with chemoRT.

Surgical Treatment. Localized lesions require resection of the ethmoids with or without the ipsilateral maxilla and/or orbit. Extensive lesions require a craniofacial procedure. Endoscopic resection of selected malignant tumors involving the nasal cavity, ethmoid sinuses, and anterior skull base is being performed with increasing frequency with promising outcomes.

Irradiation Technique. RT treatment is entirely by EBRT, emphasizing treatment through an anterior field combined with one or two lateral fields. This field arrangement, weighted 2:1 or 3:1 in favor of the anterior field, provides adequate treatment of the tumor volume while avoiding excessive RT to the contralateral eye and optic nerve. Wedges are added to achieve a satisfactory dose distribution. Electrons should not be used for the anterior portal. IMRT should be considered because a more conformal dose distribution can usually be achieved.

Management of Recurrence. Recurrent disease is heralded by recurrent pain and CN palsies. Localized recurrence after surgery only may be managed by chemoRT or craniofacial resection and postoperative RT or chemoRT. RT failures may be suitable for maxillectomy or craniofacial resection.

Sphenoid Sinus

The treatment is with RT, and the technique is similar to that used for advanced NPC.

Results of Treatment

Nasal Vestibule

Goepfert and coworkers³³⁶ reviewed the M.D. Anderson Cancer Center experience of 26 patients with nasal vestibule SCCs. The absolute 5-year survival was 78%. Ten patients were treated initially by surgery; one developed a local recurrence and was salvaged by RT. Sixteen patients were treated by RT; three developed local recurrence, and two were salvaged by an operation.

Wallace et al.³³³ reviewed 71 patients treated by RT at the University of Florida for SCC of the nasal vestibule. The 5-year local control and cause-specific survival rates were for T1 to T2 (n = 43), 95% and 95%; for T4 (n = 28), 71% and no data; and overall, 86% and 91%.³³³ Eight additional patients with unfavorable T4 cancers were treated with resection and adjuvant RT. All eight patients treated with surgery and RT were locally controlled; three of eight experienced severe complications.

Nasal Cavity and Ethmoid Sinus

Inverted Papilloma. Weissler and coworkers³³⁴ reported 233 cases of inverting papilloma seen over a 35-year period. One hundred thirty-four patients had at least 1 year of follow-up. The risk of recurrence was 71% in patients who had an intranasal

procedure and 56% for those having a Caldwell-Luc approach. Patients having a lateral rhinotomy had the lowest incidence of recurrence (29%).

Weissler and coworkers³³⁴ also reported six patients who received RT for benign inverting papilloma and nine for inverting papilloma associated with malignant disease. Twelve of the 15 patients had a complete response to RT and were free of disease for long periods of follow-up. Gomez et al.³²⁹ reported 10 patients with advanced and/or recurrent inverting papillomas who were treated with definitive RT. Local recurrence developed in four patients (40%) at 1.5, 6.5, 12, and 13 years after treatment. Six patients remained continuously disease-free at 7, 8.5, 8.5, 9, 9, and 20.5 years after RT.

Carcinoma. Mendenhall et al.³³⁵ reviewed 109 patients treated at the University of Florida for carcinomas of the nasal cavity (69 patients), ethmoid sinus (33 patients), sphenoid sinus (6 patients), and frontal sinus (1 patient). Fifty-six patients were treated with definitive RT, 45 with surgery and postoperative RT, and 8 with preoperative RT and surgery. The 5-year local control rates were for T1 to T3, 82%; for T4, 50%; and overall, 63%. Local control at 5 years was 43% after definitive RT and 84% after surgery and adjuvant RT (p < 0.0001). A multivariate analysis revealed that both overall stage and treatment group (definitive RT versus surgery and adjuvant RT) impacted this endpoint. Cause-specific survival rates at 5 years were for stages I to III, 81%; for stage IV, 54%; and overall, 62%. A multivariate analysis of cause-specific survival revealed that T-stage, N-stage, and treatment group significantly impacted this endpoint. Of 109 patients, 31 (20%) sustained severe complications; 17 (16%) of 56 patients after definitive RT, and 14 (25%) of 53 patients after surgery and adjuvant RT.

Esthesioneuroblastoma. Elkon and coworkers³³⁷ reviewed the literature on esthesioneuroblastoma and compiled the results of 78 cases. They concluded that either RT or surgery was sufficient treatment for early-stage disease, but that combined treatment might be advantageous for late-stage presentations. The 5-year absolute survival rate was 75% for lesions confined to the nasal cavity, 60% for those involving the nasal cavity and paranasal sinuses, and 41% for tumors extending beyond the nasal cavity and paranasal sinuses.

Monroe and coworkers³²⁸ reported on 22 patients treated with curative intent at the University of Florida and observed the following 5-year outcomes: local control, 59%; cause-specific survival, 54%; and survival, 48%. The 5-year cause-specific survival rate was lower after definitive RT (17%) compared with craniofacial resection and postoperative RT (56%). Cervical metastases occurred in 6 of 22 patients (27%). Recurrence in the neck was observed in 4 of 9 patients, who were initially N0 and who did not receive elective neck RT compared with zero of 11 patients who were electively treated (p = 0.02).

Maxillary Sinus

Waldron and coworkers³³⁸ reported on 110 patients treated with curative intent at the Princess Margaret Hospital with definitive RT (83 patients) or surgery and adjuvant RT (27 patients). The 5-year rates of local control and cause-specific survival were 42% and 43%, respectively. Sixty-three patients developed a local recurrence, and 25 of 63 underwent salvage surgery with a subsequent 5-year cause-specific survival of 31%.

Complications of Treatment

Surgery

Complications of a maxillectomy include failure of the split-thickness skin graft to heal, trismus, CSF leak, and hemorrhage.

Complications of ethmoid sinus surgery include hemorrhage, meningitis, CSF leak, cellulitis and pansinusitis, brain abscess, and stroke. Complications of craniofacial resection includes meningitis, subdural abscess, CSF leak, diplopia, and hemorrhage.

Radiation Therapy

The most frequent and significant complications of RT involve the eye.^{335,339,340} When only a portion of the ipsilateral eye is irradiated (the medial one third), it is possible to preserve vision in the majority of patients. When there is extensive disease in the orbit, however, the entire eye is irradiated to a high dose with almost certain loss of vision; however, these same patients would require orbital exenteration if treated by surgery. The risk for bilateral blindness can be reduced by the use of CT and MRI scans for improved treatment planning and knowledge of the tolerance of the optic nerve.

A few patients will experience a transient CNS syndrome that includes vertigo, headaches, decreased cerebation, and lethargy. This syndrome usually appears 2 to 3 months after the completion of treatment and lasts 1 to 2 months. Aseptic meningitis, chronic sinusitis, or serous otitis media can occur. High-dose RT of the nasal cavity can cause narrowing and synechiae of the nasal cavity. Douching with salt water and daily self-dilations with petrolatum-coated cotton swabs will reduce the problem. Septal perforations occur when tumor has destroyed part of the septum; these do not usually require treatment. Destruction of the nasal bone and septum by the tumor may result in cosmetic deformity. Maxillary necrosis may develop, particularly if teeth are extracted.

PARANGLIOMAS

Parangliomas are an uncommon group of neoplasms that may originate anywhere glomus bodies are found. The lesions are rare before the age of 20; there is a female predominance in some series; and the lesions may occur in multiple sites in about 10% to 20% of cases, especially in patients with familial history. Carotid body tumors are associated with conditions producing chronic hypoxia, such as high-altitude habitation.

Anatomy

The normal glomus bodies in the head and neck vary from 0.1 to 0.5 mm in diameter. Tumors arising in glomus bodies (i.e., parangliomas) arise most often from the carotid and temporal bone glomus bodies, with rare reports of tumors arising in the orbit, nasopharynx, larynx, nasal cavity, paranasal sinuses, tongue, and jaw. The temporal bone glomus bodies are not found consistently in any location. At least one half of the glomus bodies are found in the general region of the jugular fossa; the remaining are distributed along the course of the nerve of Jacobson (a branch of CN X). Approximately 20% of all temporal bone glomus bodies lie in the tympanic canaliculus, and approximately 10% are in relation to the cochlear promontory. The carotid bodies are located adjacent to the bifurcation of the common carotid. Orbital bodies are in relation to the ciliary nerve, and vagal bodies are adjacent to the ganglion nodosum of the vagus nerve.

Pathology

Parangliomas are histologically benign tumors resembling the parent tissue and consist of nests of epithelioid cells within stroma-containing, thin-walled blood vessels and nonmyelinated nerve fibers. Although the tumor is well circumscribed, a true capsule is not seen. The criterion of malignancy is based on the development of metastases rather than the histologic appearance.

Patterns of Spread

These lesions usually grow slowly; it is usual to have a history of symptoms for a few years and, occasionally, for 20 years or longer.

Carotid Body Tumors

Carotid body tumors are usually located at the common carotid bifurcation and, as they expand, tend to displace and encircle the internal and external carotid vessels. The tumor begins in the adventitia of the artery and initially derives its blood supply from the vaso vasorum. An accessory blood supply may come from branches of the vertebral artery and the ascending cervical artery. The tumor is usually closely adherent to the wall of the carotid adjacent to the vascular pedicle, and there may be thinning of the arterial wall owing to pressure by the mass. Large masses extend toward the cervical spine, skull base, angle of the mandible, and the lateral pharyngeal space.

Temporal Bone Tumors

Glomus tympanicum lesions tend to be small when diagnosed because they produce symptoms early in their course. The tumor may involve the ossicles, the tympanic membrane, the mastoid, the external auditory canal, the semicircular canal, and the 7th, Jacobson, and Arnold nerves.

Glomus jugulare tumors invade the skull base, petrous apex, jugular vein, middle ear, and middle and posterior cranial fossae. CNs V to XII may be involved.

Lymphatic

Lymphatic metastases occur in about 5% of carotid body tumors but are very rare for temporal bone tumors. An upper neck mass may be an inferior extension of a jugular fossa or vagal tumor rather than a lymph node metastasis.

Distant Metastases

Distant metastases have rarely been reported for temporal bone tumors; carotid body tumors have a low risk for distant metastases, probably in the range of 5% or less.

Clinical Picture

Carotid Body Tumors

The most common presenting symptom is an asymptomatic, slow-growing mass in the upper neck near the carotid bifurcation. Large masses may encroach on the parapharyngeal space and produce dysphagia, pain, and CN palsies. Carotid sinus syndrome may occur because of the pressure of the mass.

On examination, the mass usually lies deep to the sternocleidomastoid muscle and is tethered to surrounding structures. Fixation occurs only in large tumors extending to the spine and skull base. Glomus vagale tumors occur more superiorly and produce a submucosal bulge in the tonsillar area.

Temporal Bone Tumors

A tumor arising in or near the middle ear presents with an insidious conductive hearing loss, pulsatile tinnitus, vertigo, and headache. Patients with lesions developing in or around the jugular fossa develop headaches, often pulsatile in nature, referred to the orbit or temple. CNs V to XII and the sympathetic nerves become affected. Lesions developing in the facial canal present with facial nerve symptoms.

A characteristic blue-red mass may be seen bulging the tympanic membrane. A mass may be appreciated in the upper neck between the mandible and mastoid. Paralysis of CNs V to XII and sympathetic nerves may occur.

Differential Diagnosis

Carotid Body Tumors

The differential diagnosis includes enlarged lymph nodes, a carotid artery aneurysm, a branchial cleft cyst, benign tumors (e.g., lipoma), and direct extension of a lateral pharyngeal wall or pyriform sinus cancer into the soft tissues of the neck.

A CT and/or MRI scan with contrast provides the diagnosis. A biopsy usually produces serious hemorrhage and is not recommended.

Temporal Bone Tumors

The differential diagnosis includes an internal carotid artery in the middle ear either as an aberrant vessel or as an aneurysm. These patients also present with hearing loss, pulsatile tinnitus, and a pulsatile mass behind the eardrum. A high jugular bulb may present as a vascular mass in the middle ear and mimic a glomus tumor. Other possibilities include an ear canal polyp, an NPC with extension to the temporal bone, acoustic neuroma, middle ear carcinoma, metastatic carcinoma, cholesteatoma, histiocytosis, chronic serous otitis, and mastoiditis.

Staging

There is no accepted staging system for paragangliomas.

Treatment

Selection of Treatment Modality

Temporal Bone Tumors. Excision is satisfactory for small lesions that can be removed without a risk of operative death or damage to normal structures. Stereotactic radiosurgery is an option for early lesions.

Early lesions of the tympanic cavity are managed successfully by excision without a loss of hearing or vestibular function. The remainder of the lesions are managed best by RT, with a very high success rate and minimal morbidity with current techniques. Partial removal of the tumor prior to RT does not improve the results and only increases the overall morbidity. Local control after RT is defined as stable disease or partial regression with no evidence of growth.

Carotid Body Tumors. Small lesions (1 to 5 cm) may be successfully removed with little risk to the patient. However, if resection of the carotid vessels is anticipated or if a large lesion is fixed or unresectable because of size, RT is the preferred initial treatment.

Surgical Treatment

Temporal Bone Tumors. Small glomus tympanicum lesions are approached through the eardrum or mastoid area and are removed. Hearing loss may occur from the operation, but if there is conductive hearing loss from the tumor, it may be correctable.

For the glomus jugulare tumors, surgery is reserved for RT failure, in which case a radical mastoidectomy or a subtotal temporal bone resection would be required. Some surgeons advocate a skull base approach.

Carotid Body Tumors. A standard neck incision is made in a skin crease at the level of the carotid bulb, and the carotid sheath and its contents are identified. The tumor is usually lying at the bifurcation of the internal and external carotid arteries, often displacing these vessels. Marked drops in blood pressure and bradycardia can be avoided by injecting the bulb area with lidocaine. Bleeding may be avoided by using the bipolar electrode before excising the mass. The mass is then removed, preserving the carotid arteries.

Preoperative embolization of feeder vessels is frequently employed to minimize intraoperative blood loss.

Irradiation Technique

RT consists of 45 Gy of 25 fractions over 5 weeks. The dose is below the tolerance of the normal tissues included in the treatment volume. Patients are treated with IMRT.

Acute RT sequelae are almost nil. The patient will have temporary hair loss in the entrance and exit areas beginning about the 3rd week. Mild nausea may occur. Late sequelae are few. The patient may develop otitis media, especially if tumor involves the middle ear.

Management of Recurrence

Patients have follow-up with annual CT or MRI scans. Recurrence after surgery usually is treated by RT. Recurrence after RT should be treated by operation if feasible; if surgery is not possible, re-RT may be considered.

Results of Treatment

Woods and coworkers³⁴¹ observed a local control rate of 89% in 71 patients with temporal bone paragangliomas who were treated surgically and followed from 1 to 22 years. Green and coworkers³⁴² reported a local control rate of 89% after surgery for 18 patients who had a mean follow-up of 8 years.

Hinerman et al.²⁵ reported on 104 patients with 121 paragangliomas who were treated with RT (115 tumors) or radiosurgery (6 tumors) and followed for a median of 8.5 years. The 10-year actuarial local control and cause-specific survival rates were 94% and 95%, respectively.

Complications of Treatment

Surgery

The major risks during operation are hemorrhage and injury to the CNs. Other complications include hemiparesis, spinal fluid leak, and hearing loss.

Irradiation

Complications include cholesteatoma and sequestrum of the mastoid and otitis media. Detectable damage to the hearing mechanism and vestibular apparatus is unlikely after 45 Gy of 25 fractions.³⁴³

MAJOR SALIVARY GLANDS

Tumors of the major salivary glands account for 3% to 4% of all head and neck neoplasms. The average age of patients is 55 years for malignant neoplasms, and about 40 years for benign tumors. Approximately 25% of parotid tumors and 50% of submandibular tumors are malignant.

Anatomy

The parotid gland is formed by the muscles, bones, vessels, and nerves that come in contact with the gland. The bulk of the parotid gland is superficial, extending superiorly to the zygomatic arch and anterior aspect of the external auditory canal. The anterior border does not extend beyond the opening of the parotid duct into the oral cavity opposite the second molar. Inferiorly, the gland extends between the mastoid and the angle of the mandible. The gland lies in front of and below the external auditory canal. A deep lobe extends into the parapharyngeal area, where it is in

relationship to the lateral process of C1, the styloid process, and the parapharyngeal space.

The parotid gland is encompassed by fascia that is sufficient to contain most parotid infections in addition to benign tumors and low-grade malignancies. However, the fascia between the parotid gland and the conchal and tragal cartilages is thin and quickly penetrated by tumor. The fascia separating the deep lobe from the parapharyngeal space (stylomandibular fascial membrane) may be sufficiently thin to allow the tumor or infection to access the parapharyngeal space and pharynx.

The sensory nerve supply to the parotid area and part of the pinna is from the greater auricular nerve (C2 to C3). The facial nerve (VII) penetrates the parotid gland almost immediately upon leaving the stylomastoid canal and forms an extensive anatomic network within the gland and gives off branches to the muscles of expression.

The parotid gland is richly supplied from several arteries that freely anastomose and create arteriovenous bleeding during a parotidectomy. The external carotid, the internal maxillary and superficial temporal arteries, and the posterior facial vein lie deep to CN VII.

The superficial preauricular nodes lie outside the fascia of the parotid gland and immediately in front of the tragus and drain the skin of the anterior ear, temple, and upper face, including the eye and nose. They are involved most frequently by metastatic skin cancer and lymphoma, but not usually from parotid neoplasms. The preauricular nodes empty into the external jugular chain nodes, or they may communicate with the internal jugular chain nodes.

There are two nodal groups within the parotid fascia. Within the substance of the parotid gland are numerous lymph follicles and 4 to 10 small lymph nodes scattered along the posterior facial and external jugular veins. Thus, they may lie deep to CN VII. Outside the gland but within the fascia are subparotid nodes that lie in front of the tragus and between the inferior aspect of the parotid tail and the anterior border of the sternocleidomastoid muscle.

Pathology

Benign Tumors

Benign Mixed Tumors. Also called pleomorphic adenoma, these slow-growing neoplasms are surrounded by an imperfect pseudocapsule traversed by fingers of tumor. The age of appearance begins in the early 20s with a mean age of 40 years.

Papillary Cystadenoma Lymphomatosum. Also called a Warthin tumor, it is encased by a thin but complete capsule, occurs predominantly in older men, is bilateral in approximately 10% of cases, and may be multiple on one or both sides.

Benign Lymphoepithelial Lesions. Benign lymphoepithelial lesions account for about 5% of benign lesions. The tumor may be bilateral and is more common in women.

Oncocytoma. Oncocytoma is a benign, slow-growing tumor found mostly in the older age group. The encapsulated tumor has a dark appearance similar to melanoma.

Basal Cell Adenoma. The basal cell adenoma is an uncommon benign lesion, usually appearing in older people. It is cured by a simple excision. Basal cell adenoma must be distinguished from basal cell carcinoma of the skin metastatic to parotid lymph nodes.

Malignant Tumors

Low-Grade Malignancy

Acinic cell carcinoma. Acinic cell carcinomas typically are indolent low-grade neoplasms appearing in all age groups and are most

common in women. Metastases occur in a small percentage of cases and cannot be predicted by the histologic picture.

Mucoepidermoid carcinoma, low grade. Most mucoepidermoid carcinomas are indolent lesions readily cured by adequate excision. They may appear in any age group and grow slowly; there is little or no capsule. They are usually well circumscribed, but they may widely infiltrate the normal gland or become fixed to skin.

High-Grade Malignancy

Mucoepidermoid carcinoma, high grade. High-grade mucoepidermoid carcinomas behave aggressively, widely infiltrating the salivary gland and producing lymph node and distant metastases. They may be difficult to distinguish from SCCs.

Adenocarcinoma, poorly differentiated carcinoma, anaplastic carcinoma, and squamous cell carcinoma. These histologies tend to appear late in life and behave aggressively. Almost all of the so-called SCCs of the parotid are metastatic from skin cancer, especially from the temple area.³⁴⁴

Malignant mixed tumor. A small percentage of benign mixed tumors may develop into a frank malignancy (carcinoma ex pleomorphic adenoma).

Adenoid cystic carcinoma. This is uncommon in the major salivary glands. Its growth rate is variable. Metastases to regional lymph nodes and distant sites occur; PNI is characteristic; and recurrences may appear many years after initial treatment.

Lymphoepithelioma (malignant lymphoepithelial lesion, "eski-moma"). Lymphoepithelioma occurs rarely in the parotid and submandibular gland. The histologic picture is that of lymphoepithelioma with varying degrees of nonmalignant lymphoid stroma.

Patterns of Spread

Benign Mixed Tumors

Benign mixed tumors of the parotid gland grow by expansion and local infiltration. Most tumors begin in the superficial lobe. Because of their slow growth, they rarely cause CN VII palsy. When incompletely excised, multiple tumor nodules develop within the tumor bed. Skin invasion may occur in recurrent lesions; bone invasion does not occur.

Malignant Tumors

Malignant neoplasms infiltrate the parotid gland, invade CN VII and the auriculotemporal nerve, and spread along nerve sheaths. The tumor may invade the adjacent skin, muscles, and bone. Deep lobe lesions invade the parapharyngeal space, the infratemporal fossa, and the skull base and compromise additional CNs.

Malignant tumors of the submandibular gland invade the gland, fix the tumor to the adjacent mandible, and invade the mylohyoid muscle and hypoglossal nerve.

Sublingual gland neoplasms usually present as a submucosal mass in the floor of the mouth. The advanced lesions show an ulcerated mass in the floor of the mouth with extension to the tongue, the mandible, and the submental soft tissues.

Lymphatic Spread

Lymph node metastases may occur from all of the malignant neoplasms. Approximately 20% to 25% of patients with malignant tumors will have clinically positive or occult metastases in lymph nodes at the time of diagnosis. Low-grade mucoepidermoid carcinoma and acinic cell adenocarcinoma have a low rate of lymph node metastasis, as do adenoid cystic cancers. The risk for lymph

node metastasis increases with recurrent disease and an increased size of the primary lesion.

Clinical Picture

Parotid Gland

The majority of patients with either benign or malignant parotid tumors present with a mass. Mild, intermittent pain is occasionally present, but does not distinguish between benign and malignant tumors. Facial nerve palsy is an infrequent presenting complaint and indicates malignancy. Deep lobe tumors may produce dysphagia. Fixation or reduced mobility may occur in both benign and malignant neoplasms. Tumors presenting in the deep lobe may cause bulging of the palate and tonsil. Advanced malignant lesions may rarely affect CNs IX to XII and the sympathetic chain if the parapharyngeal space is invaded. CN V3 may be involved when tumor tracks along the auriculotemporal nerve to the skull base; pain is an associated finding.

Submandibular Gland

Both benign and malignant neoplasms present as a mass usually associated with mild pain. Nerve palsy is rarely present. The skin may be infiltrated in advanced lesions. The tumor mass usually is partially fixed to the mandible unless quite small. Loss of mobility occurs with both benign and malignant lesions.

Sublingual Gland

Sublingual gland lesions are clinically similar to floor of the mouth SCCs. They produce a mass, which is submucosal at first, that may be felt by the tongue. There is mild discomfort, if any, in the early stages.

Differential Diagnosis

Parotid Gland

Gallia and Johnson³⁴⁵ reviewed 140 patients who eventually underwent a parotidectomy for diagnosis. Only 11% had malignant masses; the remainder had benign neoplasms (62%) or nonneoplastic conditions (27%). Conditions that may be confused with a parotid tumor include: (1) metastatic cancer, lymphoma, or leukemia involving parotid-area lymph nodes; (2) fatty replacement, tail of parotid; (3) chronic parotitis; (4) a Boeck sarcoid; (5) a stone in the duct; (6) cysts (branchial cleft, dermoid); (7) hypertrophy associated with diabetes; (8) hypertrophy of masseter muscle; (9) mandibular neoplasms; (10) prominent transverse process of C1; (11) penetrating foreign bodies; (12) hemangiomas/lymphangioma; and (13) a lipoma.

Submandibular Gland

The differential diagnosis of a submandibular mass includes inflammatory disease, SCC metastatic to a lymph node, and a primary neoplasm of the submandibular gland.

Gallia and Johnson³⁴⁵ reviewed 110 submandibular lesions in patients who underwent biopsy. Ninety-three lesions (85%) were nonneoplastic, usually inflamed glands, and nine lesions (8%) were benign tumors. Eight patients (7%) had malignant lesions, of which three lesions were lymphoma, three were metastatic carcinoma, and two were primary submandibular gland carcinoma.

Biopsy Technique

Parotid Gland. The biopsy and definitive surgical treatment are often the same for parotid masses. Lesions lying in the superficial lobe are best biopsied by performing a superficial parotidectomy. Lesions involving both the superficial and deep lobes or just the deep lobes are “biopsied” by a total parotidectomy. An incisional

and excisional biopsy may contaminate the tumor bed, thus increasing the risk of tumor recurrence and facial nerve damage as well as increasing the extent of the definitive surgical procedure by necessitating the wide removal of the biopsy site.

An FNA cytology can be performed for diagnosis. A negative FNA does not necessarily mean that there is no tumor, therefore surgical decisions often rely heavily on clinical and radiographic findings. An FNA can be used in the inoperable or recurrent lesions when RT is the initial treatment.

Submandibular Gland. An FNA is helpful when positive for a tumor, but may delay diagnosis when falsely negative. When needle biopsy is negative, but history, physical examination, and radiographic studies suggest neoplasm, and a careful search of the head and neck area fails to reveal a primary mucosal lesion, the submandibular triangle is dissected as the biopsy procedure.

Staging

The AJCC staging system is depicted in Table 38.19.

Treatment

Selection of Treatment Modality

Parotid Gland. The initial management of resectable superficial lobe parotid masses is an en bloc superficial lobectomy. The tumor usually can be dissected free of the facial nerve. If the tumor involves the deep portion of the gland, the nerve is retracted and the deep portion excised (i.e., total parotidectomy). Skin, bone, and muscle may also be resected as needed.

Low-grade malignant neoplasms are usually managed by operation only. RT is given postoperatively for nearly all high-grade lesions. RT is advised for low-grade malignant lesions that are recurrent and those with close or positive margins on the facial nerve. Postoperative RT is advised for selected benign mixed tumors when there is microscopic residual disease after operation, and for nearly all patients after surgery for recurrent disease. RT alone is unlikely to control gross disease, and if possible, resection of any gross residual benign mixed tumor should be performed prior to RT. Inoperable malignancies are treated by definitive RT.

TABLE 38.19

2010 American Joint Committee on Cancer Staging for Major Salivary Gland Primary Tumors (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 2 cm or less in greatest dimension without extraparenchymal extension ^a
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension without extraparenchymal extension ^a
T3	Tumor more than 4 cm and/or tumor having extraparenchymal extension ^a
T4a	Tumor invades skin, mandible, ear canal, and/or facial nerve
T4b	Tumor invades skull base and/or pterygoid plates and/or encases carotid artery

^a Extraparenchymal extension is clinical or macroscopic evidence of invasion of soft tissues. Microscopic evidence alone does not constitute extraparenchymal extension for classification purposes. Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original source for this material is the *AJCC Cancer Staging Handbook*, Seventh Edition (2010) published by Springer Science and Business Media LLC, www.springerlink.com.

Submandibular Gland. If a frozen section diagnosis shows a malignant lesion and there is no involvement of nerves, mandible, or soft tissues, submandibular triangle dissection is performed and postoperative RT is given to the submandibular bed and ipsilateral neck. If there is PNI, bone invasion, a clinically positive node, or extension to contiguous soft tissues, resection is enlarged to encompass the necessary areas. Postoperative RT is added in nearly all cases.

Surgical Treatment

Superficial Parotidectomy. The incision is made in the preauricular crease and then curves under the earlobe posteriorly, and extends into the neck. The facial nerve is identified and the dissection is carried out between the mass and the facial nerve. Ideally, a 1-cm circumferential cuff of “normal” parotid tissue should be resected along with the tumor. However, close margins of less than 1 mm are frequently encountered because most parotid gland tumors lay close to branches of the facial nerve. In such cases, completely encapsulated tumors can frequently be resected with confidence. On the other hand, facial nerve sacrifice must be considered if the nerve branch courses directly through the tumor or when there is gross extracapsular extension into the parotid gland. The adequacy of resection is determined by frozen sections.

Total Parotidectomy. A superficial parotidectomy is performed, the nerve is dissected free from the underlying deep lobe, and the deep lobe and tumor are removed. Occasionally, the mandible must be divided to gain access to the retromandibular portion of the deep lobe. A partial mandibulectomy is required when the mandible is invaded by tumor.

The intraparotid nodes are removed with the primary lesion. If the nodes are positive, a neck dissection is added. Neck dissection is always included for clinically positive nodes. Elective neck dissection is not done for low-grade lesions.

A radical parotidectomy implies removal of the entire parotid, the facial nerve, and other involved tissues such as skin, bone, or muscle. Part or all of CN VII must be sacrificed, and an immediate autologous nerve graft may be done. If a frozen section examination of the facial nerve is positive at the stylomastoid foramen, a mastoidectomy may be required to complete the resection. Postoperative RT is delayed for 6 weeks, and the chance of successful function is reported to be good.³⁴⁶

Radiation Therapy

The minimum treatment volume for parotid lesions includes the parotid bed and upper neck nodes. PNI indicates enlargement of the portals to cover the nerve pathways. The entire ipsilateral neck is included for high-grade lesions or for clinically positive nodes in the neck dissection specimen. The tumor dose to the primary area is 60 to 65 Gy over 6 to 7 weeks if there is no gross residual disease. Higher doses employing altered fractionation are used for patients with microscopically positive margins or gross disease.

Submandibular space EBRT portals are tailored to the extent of disease found in the surgical dissection. The entire ipsilateral neck is included. The postoperative dose is 65 to 70 Gy because the rate of recurrence, even with combined treatment, is substantial. Neutron therapy has been used in the management of unresectable salivary gland cancers.³⁴⁷

Chemotherapy for Salivary Gland Cancers

Historically, chemotherapy has been primarily used for patients with incurable disease or on prospective clinical trials. The safety and dosing of concurrent chemotherapy and RT has been established for this body region from the experience in patients with upper aerodigestive tract SCCs, and as such, this approach is sometimes applied to patients with unresectable disease or in the

poor risk adjuvant setting. Available efficacy data for such an approach in this setting are limited.^{348,349}

Results of Treatment

Parotid Gland

Benign Mixed Tumors. Enucleation or excision with a narrow rim of normal tissue will eventually result in a local recurrence rate of approximately 20% after 10 to 15 years of follow-up. A superficial parotidectomy will result in a recurrence rate of approximately 5%.³⁵⁰ The surgical success rate for recurrent lesions depends on the number of previous operations and the size and extent of recurrence. It may be necessary to sacrifice one or several branches of CN VII and to repair the defect with a nerve graft. Postoperative RT of 66 to 70 Gy is added in selected cases in which there are close margins or microscopic residual disease, or in cases in which a subsequent recurrence would be almost impossible to manage surgically or would result in loss of the facial nerve.³⁵¹ Death because of benign mixed tumors is unlikely.

Malignant Tumors. The likelihood of cure after surgery alone for low-grade tumors is high, and adjuvant RT is usually unnecessary. The local recurrence rate for operation alone is approximately 50% to 60% for high-grade tumors.^{352,353}

Garden and coworkers³⁵⁴ reported 166 patients treated with surgery and postoperative RT for parotid malignancies at the M.D. Anderson Hospital between 1965 and 1989. Forty patients (24%) developed a recurrent disease that was local in 9% and regional in 6%. The histologic type did not significantly influence the likelihood of local control ($p = 0.36$). Twenty-five patients (15%) developed distant metastases with disease control above the clavicles. The 10- and 15-year survival rates were 60% and 52%, respectively.

Submandibular Gland

Byers and coworkers³⁵⁵ reported the results of treatment for 22 malignant tumors of the submandibular gland with no prior therapy. Treatment was resection followed selectively by postoperative RT. The local control rate was 64%, and the survival rate was 50%.

Spiro³⁵⁰ reported the results of surgery for 129 malignant submandibular gland carcinomas seen between 1939 and 1973. All patients had a minimum of 10 years of follow-up. Adenoid cystic carcinoma occurred in 35%, mucoepidermoid carcinoma in 29%, and malignant mixed tumor in 19%. Cervical lymph nodes were malignant in 28%. The local-regional control rate was 40%, and the cause-specific cure rate was 31% at 5 years and 22% at 10 years.

Benign tumors of the submandibular gland were resected in 106 patients, and only 2 developed a local recurrence.³⁵⁰

Chemotherapy Results

The heterogeneity and relative rarity of malignant salivary gland tumors have complicated the evaluation of systemic therapies. Prospective clinical trials are infrequent; different histologies are often combined, as are the results for major and minor salivary gland tumors. Over the last 2 decades, less than 500 patients with adenoid cystic cancer have been the subject of studies evaluating drug therapy.^{356,357} Drugs like doxorubicin and 5-fluorouracil with reported activity have this claim largely based on retrospective case series, not prospective clinical trials.

Cisplatin, paclitaxel, vinorelbine, epirubicin, and mitoxantrone have major response rates in the 10% to 20% range in prospective studies in the recurrent or metastatic disease setting.³⁵⁸⁻³⁶² The potential importance of histology in trial design is well illustrated with the case of paclitaxel, where 3 out of 12 and 4 out of 17 patients with mucoepidermoid and adenocarcinoma responded, respectively, yet zero of 14 with adenoid cystic cancer responded.³⁶³ Treatment with gemcitabine also did not yield any major response

in patients with adenoid cystic carcinoma.¹³⁹ Cisplatin- or anthracycline-containing combinations (e.g., cyclophosphamide/doxorubicin/cisplatin; cisplatin/vinorelbine; cisplatin/5-fluorouracil, cisplatin/mitoxantrone) may increase this rate, but a major response still occurs in the minority of patients, and toxicity is increased.^{356,357} The relative efficacies of single-agent versus combination chemotherapies have not been well studied. It should be emphasized that the natural history of some salivary gland cancers, of which the adenoid cystic subtype is perhaps the best example, can be quite indolent, making initial observation a prudent course.

Given these response rates, clinical trials are often an attractive option for patients, and there has been interest in the potential utility of newer targeted agents. Expression of potential molecular targets vary by pathologic subtype. For example, c-kit is commonly expressed in adenoid cystic cancer, but variably or not at all in other salivary cancer subtypes.³⁵⁶ Although there have been reported responses to imatinib in case reports,^{364,365} demonstrating objective responses in clinical trials where the agent has proved elusive, and so the drug remains investigational for this disease.^{366,367} Data thus far for EGFR pathway and Her-2 targeted agents are limited and not compelling.³⁶⁸ Of note, the androgen receptor is commonly expressed in patients with salivary duct carcinoma, and there are reports under these circumstances of response to anti-androgen therapy.³⁶⁹ The oncogenic transcription factor c-myc is overexpressed in adenoid cystic cancer³⁷⁰ and is informing further drug development in the disease. Dovitinib, which is designed to block fibroblast growth factor receptor (FGFR)- and vascular endothelial growth factor receptor (VEGFR)-mediated angiogenesis demonstrated activity in a phase II trial in patients with adenoid cystic cancer.³⁷¹

Complications of Treatment

Surgery

Facial paralysis is the most important complication associated with parotid surgery. Temporary facial nerve palsy may occur due to manipulation of the nerve during operation, and function will gradually return over a few months' time. Isolated persistent weakness of the lower lip may occur due to division of the platysma muscle. Incomplete eyelid closure requires protective measures such as artificial tears, Lacri-Lube (Allergan Inc., Irvine, CA), and eye patches to prevent corneal abrasion. A variety of surgical techniques can be employed to address facial nerve deficits if functional recovery is not expected, including nerve grafting, a brow lift, gold weight implantation into the upper eyelid, lower eyelid tightening, and facial suspensory procedures. Gustatory sweating (Frey syndrome) occurs in about 10% of patients after parotidectomy and rarely requires treatment. A persistent salivary fistula is rare.

Radiation Therapy

Xerostomia is avoided by techniques that spare the contralateral salivary tissues. There may be trismus due to fibrosis of the masseter and pterygoid muscles and the temporomandibular joint. Otitis media may occur if the ear is irradiated. Localized hair loss may occur with some techniques. Osteoradionecrosis may rarely occur with high doses.

MINOR SALIVARY GLANDS

Tumors of the minor salivary gland origin are uncommon, accounting for about 2% to 3% of all malignant neoplasms of the upper aerodigestive tract. They may appear at any age, but are uncommon before age 20 and rare under age 10. They tend to occur most often in the hard palate, nasal cavity, and paranasal sinuses—areas infrequently involved by SCCs. Thus, the site of origin is related to the density of the minor salivary glands in a particular tissue.

Anatomy

Minor salivary glands are ubiquitous in the mucosa of the upper aerodigestive tract with the exception of the gingivae and the anterior portion of the hard palate, which are free of minor salivary glands. They are distributed on the undersurface of the anterior and lateral oral tongue and the base of the tongue. Aberrant salivary tissue sometimes is seen in lymph nodes, in the body of the mandible just behind the third molar teeth, and in the vestigial remnant of the nasopalatine canal in the anterior maxilla, middle ear, lower neck, sternoclavicular joint, thyroglossal duct, and other sites.

Pathology

Approximately one half of minor salivary gland tumors are malignant. The histologic varieties of malignant tumors include adenoid cystic carcinoma, mucoepidermoid carcinoma, adenocarcinoma, and malignant mixed, acinic cell, and oncocytic carcinomas. About two thirds are adenoid cystic. Mucoepidermoid carcinomas and adenocarcinomas arise predominantly in the oral cavity.

The benign tumors are pleomorphic adenomas in the great majority of cases, with a few cases of intraductal papillomas, papillary cystadenomas, basal cell adenomas, and benign oncocytomas.

Patterns of Spread

There are no minor salivary glands in the anterior half of the hard palate, so tumors arise on the posterolateral hard palate and all of the soft palate. The site of origin for floor of mouth salivary gland tumors is either the sublingual gland or a minor salivary gland.

These tumors grow by local infiltration with eventual invasion of muscle, bone, and cartilage. PNI is a common feature, particularly for adenoid cystic carcinoma. The tumor may track both centrally and peripherally along nerves, but the central spread is the more common event. Extension along nerves eventually may traverse the skull base and surface intracranially, although this spread pattern may not become manifest for several years after the original treatment. Tumor growth along a nerve may be characterized by skip areas, so that a normal nerve segment is no assurance of free margins.

The risk of positive lymph nodes is related to the site of origin and the histology. Lymph node metastases are most likely from sites with a dense capillary lymphatic network, similar to the pattern for SCC. Adenoid cystic carcinoma, low-grade mucoepidermoid carcinoma, and acinic cell carcinoma are at low risk to spread to lymph nodes; about 20% of adenoid cystic carcinomas spread to lymph nodes, but this low incidence may be related partly to their frequent site of origin in the hard palate and paranasal sinuses, areas that infrequently produce lymph node metastases. The high-grade tumors carcinomas have a 30% incidence of lymph node involvement on presentation, and eventually half will develop lymph node metastases.

Clinical Picture

The clinical picture depends on the site of origin. The signs and symptoms differ from those of SCCs arising in the same area. Many of the lesions are indolent, and the history may go back many months or even years. Because lesions develop under the epithelium, the initial lesion is a submucosal mass that is often painless until ulceration develops. PNI is expressed as pain or paresthesias. Otherwise, the clinical picture resembles that for SCCs for a given size and site. Lymph node metastases occur at predictable sites. The clinically positive nodes are usually small and mobile, but neck dissection on such a patient may show numerous small, clinically undetectable positive nodes. The same staging systems applied to SCCs may be used.

Treatment

Selection of Treatment Modality

Benign, mixed-grade tumors are managed by operation; postoperative RT sometimes is advised in cases in which margins are close or positive.³⁷²

The low-grade carcinoma is treated initially by an operation when feasible, but RT is sometimes used as the primary treatment for inaccessible lesions or where the functional loss would be considerable. Postoperative RT is added for close margins or for those lesions that have recurred more than once. If the patient presents after excisional biopsy of a small lesion, RT is an alternative to reexcision, particularly if the procedure would produce significant cosmetic or functional loss.

The treatment of high-grade lesions varies immensely, depending on the site of origin, stage of disease, and willingness of the patient to accept a major cosmetic or functional change subsequent to an operation. Surgery and postoperative RT are preferred; RT alone is used for unresectable cancers. There are data that support the use of neutron therapy.³⁴⁷

Surgical Treatment

Benign tumors are removed by a wide local excision that includes a cuff of normal tissue. Small, low-grade lesions with a long history of slow growth may be treated with a wide local excision including a shell of normal tissue. Large, low-grade lesions and high-grade lesions require a more radical resection. When PNI is present, it is not possible to remove all the nerves potentially involved, but the nerves that are involved should be sacrificed wherever it is reasonable to do so. As an alternative, postoperative RT may be used to cover the perineural routes of spread.

Irradiation Technique

The RT techniques and doses are similar to those for SCCs of the same anatomic site and similar tumor size, with the exception that nerve pathways must be covered for adenoid cystic carcinomas.

Subclinical PNI for adenoid cystic carcinomas must be considered to be present even if it is not seen on the biopsy or surgical sections.

Results of Treatment

Spiro and coworkers³⁷³ reported the Memorial Sloan-Kettering Cancer Center results for 434 malignant minor salivary gland tumors, of which 90% were treated surgically. The cause-specific 5-, 10-, and 15-year cure rates were 44%, 32%, and 21%, respectively; 51% died of the original cancer. Patients with adenoid cystic carcinoma had the poorest prognosis, with about 20% surviving without recurrence. Those with adenocarcinoma had an intermediate outlook—about 35% surviving without recurrence—and mucoepidermoid carcinomas had the best control rate, with about 70% long-term cures.

Cianchetti et al.¹⁸ reported on 140 patients treated at the University of Florida for minor salivary gland carcinomas between 1966 and 2006. The 10-year local control rate was 66%; a multivariate analysis revealed that treatment group and T-stages significantly influenced this endpoint. Patients treated with RT alone had a lower local control rate compared with those treated with surgery and RT. The 10-year outcomes were for distant metastasis-free survival, 67%; for cause-specific survival, 56%; and for overall survival, 45%.

Benign mixed tumors of minor salivary gland origin have a good prognosis. Spiro³⁵⁰ reported on 81 benign tumors; 60 occurred on the palate and 13 on the lip or cheek. With a minimum follow-up of 10 years, the local recurrence rate was 6%.

Wallace et al.³⁷⁴ reported on 25 patients treated with RT alone (2 patients) or combined with surgery (23 patients) for pleomorphic adenoma and followed the patients for a median of 10.5 years. Local control was obtained in 13 of 16 patients (75%) with subclinical disease and 5 of 9 patients (56%) irradiated for gross disease. The 10-year overall local control rate was 76%.

In a small randomized trial of inoperable primary or recurrent salivary gland cancers (both major and minor salivary gland cancers were allowed), neutron therapy (n = 25) improved local-regional control significantly (p = 0.009) but at the expense of more severe morbidity.³⁴⁷

39 Rehabilitation After Treatment of Head and Neck Cancer

Douglas B. Chepeha, Teresa H. Lyden, and Marc Haxer

INTRODUCTION

Progress has been made in the past several years with survival for patients with head and neck cancer.¹ The current challenge is how to balance intensity of treatment and preserve function. Conservation surgery, radiation strategies, autogenous revascularized tissue transplantation, and treatment selection protocols continue to be used in an attempt to maintain or reestablish functional speech, voice, and swallowing in head and neck cancer patients. The ideal multidisciplinary team requires interaction among the surgical oncologists, radiation oncologists, medical oncologists, reconstructive surgeons, speech pathologists, physical therapists, occupational therapists, maxillofacial prosthodontists, dental oncologists, nutritionists, nurse oncologists, psychologists, audiologists, and social workers during pretreatment assessment and posttreatment intervention. Because radiation and chemotherapy protocols are being initiated in smaller centers, steps must be taken to ensure that the patient benefits from a multidisciplinary approach to treatment.

This chapter will focus on the rehabilitation of the *patient as a whole*. Pretreatment counseling is essential for all patients with aerodigestive tract cancer. Patients benefit from discussions regarding swallowing, voice, and speech difficulties that can result from radiation and chemotherapy regimens. Regrettably, patients who undergo radiation and chemotherapy protocols often are inadequately counseled, if at all. For rehabilitation to be effective, the patient's social, psychological, and addictive behaviors must be assessed and treated. Many of these patients have addictions to tobacco and/or alcohol at presentation and may lack social support. All these issues should be comprehensively addressed, and in so doing, the provider and the patient are often rewarded by the productive role the patient assumes for him or herself, as well as within his or her family and in the workplace.

PRETREATMENT COUNSELING

The education process begins during the initial consultation with the physician. Each team member has a specific, yet overlapping, role in preparing the patient for his or her intervention. The physicians are essential for providing information to the patient with respect to diagnosis, prognosis, and treatment options. This includes providing education to the patient on his or her specific treatment plan. Patients who are previously untreated and receive single modality treatment are going to do much better than patients who are recurrent or are going to undergo multimodality therapy. In order to design the best intervention for the patient, the physicians must also remain flexible and integrate feedback from the team. Once the plan is established, the physician team has to clearly communicate the treatment plan to the remaining members of the team so they can provide appropriate counseling.

Nursing will provide education on feeding tube and tracheotomy management. The placement of a gastrostomy or a tracheotomy tube is associated with the poorest patient-reported quality of life.² The patient will have little or no familiarity with these

interventions; therefore, a specific explanation of the anatomy and postoperative care is important.

Preoperative counseling with the speech pathologist is another essential part of patient education and shaping expectations. The speech pathologist is often regarded by the patient as the individual who will restore communication and swallowing function posttreatment. The greatest counseling challenge for the team when working with this patient group is overcoming poor coping skills.³ Quality of life assessments have correlated low scores in emotional well-being domains with increased *overall bother* scores.⁴ The speech pathologist and other rehabilitation specialists must contend with the patient's coping mechanisms in order to facilitate rehabilitation. Speech pathologists often provide psychological counseling on an ad hoc basis, and this has shown to benefit head and neck cancer patients when compared to controls.⁵ The speech pathologist must show interest in the patient's welfare, describe the expected long-term functional outcomes, and discuss the mechanics of communicative and swallowing strategies.

The patient must also be counseled on smoking and alcohol cessation. This is a central piece of the rehabilitation efforts that ideally should be handled by a cessation specialist. Smoking cessation interventions, particularly those that take into consideration alcohol intake and depression, have been shown to be efficacious for this patient population.⁶ This is encouraging because smoking is highly correlated with alcohol intake and depression. An addicted patient is unlikely to be effectively rehabilitated. Therefore, the patient must understand that continuation of addictive behaviors represents the greatest risk to patient survival and future function. It is important to emphasize to the patient that there are many different ways to quit smoking. The patient should understand that alcohol is a facilitator and nicotine is a lower level carcinogen than tobacco products. Involvement of social work is important to address psychosocial and economic issues that impact cancer treatment and rehabilitation.

The use of patient volunteers who have completed treatment is an invaluable resource. They provide education and experience with regard to what one may experience during treatment, post-treatment recuperation, and long-term quality of life to patients who are preparing for treatment.

SUPPORT DURING TREATMENT AND REHABILITATION OF THE CHEMORADIATION PATIENT

Radiation alone, with concurrent chemotherapy or adjuvant after surgery, is a common treatment approach.¹ Swallowing and the voice are affected by radiation, but the effect is variable and depends on the radiation field, the radiation dose, and the concomitant chemotherapy agents. After treatment, there can be stiffness, edema, fibrosis, xerostomia, and stenosis. The severity of these effects is proportional to the aggressiveness of the treatment. To help reduce the effects of chemotherapy and radiation therapy, mobility of the aerodigestive tract should be maintained during treatment.⁷ Recent, small, randomized studies support both prophylactic use of feeding gastrostomies, together with oral feeding⁸ and swallow

exercises during therapy,⁹⁻¹¹ to improve long-term swallowing and quality of life. Newer radiotherapy techniques that spare the swallowing-related structures have resulted in substantial improvements of long-term dysphagia.¹² This is facilitated by good supportive care, which includes appropriate treatment of mucositis, adequate analgesia, management of depression, maintenance of nutrition, and monitoring by the treatment team. The treatment of mucositis involves the use of mouthwash and oral care. There are many different *recipes* for mouthwashes, but the common components are an antifungal such as nystatin (Mycostatin), an antihistamine such as diphenhydramine (Benadryl), and a barrier agent such as an antacid. The approach to analgesia is a sustained release agent that covers 80% to 90% of the analgesia needs and a shorter acting agent to cover breakthrough pain. Recent efforts to identify newer agents that may reduce mucositis during radiotherapy include amifostine¹³ and palifermin (keratinocyte growth factor).¹⁴ None of these agents can yet be recommended for routine use based on the published data. To address issues relating to depression, the creation of an environment where depressive emotions or issues can be addressed is important. At present, serotonin reuptake inhibitors are the first-line antidepressants, and modafinil is added if the patient has significant symptoms of fatigue. Clonazepam is added to the antidepressant regimen if there is a significant component of anxiety or to support the withdrawal of alcohol. Transdermal testosterone is also useful for symptoms of fatigue. A free testosterone serum level should be obtained to verify that testosterone levels are low. If unable to maintain adequate nutrition orally, particularly for the patient who is receiving radiation therapy, supplemental or primary nutrition can be met via a temporary gastrostomy tube. It is important to keep the patient swallowing even if the patient is only able to take sips of liquids. If a patient is unable to swallow anything, then a nasogastric feeding tube should be inserted as a stent for the pharynx. Removal of the stent is recommended only when the lumen is patent and the patient is able to swallow again. A possible consequence of *resting* the digestive tract during chemoradiation is pharyngeal stenosis or a nonfunctional upper aerodigestive tract. If pharyngeal stenosis occurs, management is achieved through dilation in the operating room, clinic, or with a program of self-dilation.

Rehabilitation after treatment usually focuses on relief from xerostomia, maintenance of mobility of the oropharyngeal musculature, improved swallowing function (including reducing the risk of aspiration), and improvement with communication or voice. The posttreatment examination usually reveals edema, decreased sensation, and thick secretions. The thick secretions and xerostomia are managed with the regular intake of liquids. In addition, medications designed to improve salivary flow, such as pilocarpine and cevimeline, can be taken daily. Pilocarpine is indicated in the radiated patient, but a minority of patients report subjective efficacy.¹⁵ Cevimeline is indicated for Sjögren disease but is often used off label for xerostomia, with few patients using this medication long term. Artificial saliva can be taken as a gel, spray, or a lozenge and contains methylcellulose as a lubricating agent. However, in lieu of using salivary substitutes, most patients choose to take frequent sips of water to thin secretions and keep their aerodigestive tract lubricated. The most important advance to reduce the incidence of xerostomia is intensity modulated radiation therapy (IMRT), which is a radiation delivery technique that uses selective targeting to spare salivary tissue. In cases where it is safe to spare the parotid from radiation, it has been shown that there is improved salivary flow, relief from xerostomia, and improved quality of life.¹⁶⁻¹⁸ Even with better salivary flow, patients frequently need to use liquid washes to improve swallowing function by moistening dry foods and lubricating the aerodigestive tract to allow for easier bolus passage. The reduction of aspiration is facilitated by aggressive swallowing exercises⁷ and the use of strategies, postures, or maneuvers. The incidence of aspiration can increase during and after treatment. Exercises are introduced focusing on improving strength, range of motion, and coordination of movement. Areas that are

commonly focused on include improving mandibular, labial, and lingual range of motion and improving strength and coordination of the lips, tongue (including base of tongue), palate, posterior pharyngeal wall, and laryngeal elevation. There are several strategies that may be of benefit that include, but are not limited to, a chin tuck, an effortful swallow, supra- and supersupraglottic swallows, and the Mendelsohn maneuver.¹⁹⁻²¹

There are several patient factors that also affect outcome. These include continued smoking, continued alcohol consumption, gastroesophageal reflux disease, and tissue reaction to the oxidative effects of radiation. As previously mentioned, in order to facilitate optimal rehabilitation, these factors need to be addressed by the medical team as part of the patient's rehabilitation.

Posttreatment Swallowing Assessment

The team should understand which aspects of communication and swallowing functions have been compromised by treatment. Because of their training in the areas of communication and swallowing, the speech pathologist assumes a leading role in the evaluation and treatment of deficits in these areas. The site of lesion, the extent of resection, the type of reconstruction, and the use of adjunct treatment modalities will influence the extent and severity of the communication and swallowing disorder. In addition, these factors will help guide the selection of assessment tools to be used, as well as which strategies may be of benefit to the patient. In order to better understand the rehabilitation process with respect to swallowing, it may be useful to briefly review the four phases or stages of the normal swallow. The oral preparatory phase involves mastication and bolus formation. During this phase, the lips are closed anteriorly while the posterior tongue is closed against the soft palate, which keeps the bolus from prematurely spilling into the pharynx. The bolus is formed, shaped, and readied for swallowing.²² During the oral phase, the bolus is propelled into the oropharynx as a result of the oral tongue rolling posteriorly. Once this occurs, the involuntary or pharyngeal phase of swallowing is initiated. There are multiple components to the pharyngeal phase. This phase involves palatal closure and bolus transport through the pharynx. In addition, laryngeal elevation occurs and, with this action, pharyngeal suction results along with coverage of the larynx by the base of the tongue. Glottic closure also occurs with the pharyngeal phase of the swallow and helps assist with the prevention of aspiration. Finally, relaxation of the upper esophageal sphincter facilitates the delivery of the bolus into the esophagus, and this completes the pharyngeal phase of the swallow. When the bolus enters the esophagus, this is the initiation of the esophageal phase of the swallow.²¹ Any alteration of the normal aerodigestive physiology will result in compromised swallowing. Normal transit times for the oral and pharyngeal phases of the swallow are 1.5 seconds or less. These increase slightly as bolus viscosity increases.²¹ Transit times for the esophageal phase of the swallow vary between 8 and 20 seconds.²¹

Swallowing can be assessed subjectively or objectively. A subjective assessment is a clinical examination that involves an evaluation of oral motor skills along with the presentation of various consistencies of foods or liquids. Observations are made with regard to oral competency, timeliness of the swallow, laryngeal elevation, and clinical signs or symptoms of aspiration. Objective measures include fiber optic endoscopic evaluation of swallowing (FEES) and videofluoroscopic swallow study (VFSS).^{21,23} VFSS is performed using x-rays (cineradiography or fluoroscopy) with barium as a contrast agent to visualize swallowing movements. VFSS is an objective evaluation of swallowing function that includes all stages of the swallow during presentation of varying food consistencies. This procedure allows measured amounts of barium boluses to be followed from the lips to the stomach and, if needed, can incorporate the effects of compensatory strategies, such as postural assists or maneuvers. VFSS is ideal for patients with oropharyngeal dysphagia because it allows for an assessment of strategies and a diagnosis

of aspiration severity. VFSS is expensive and time consuming. It requires at least 30 minutes to perform, involves radiation exposure, and requires both a radiologist and a speech pathologist.²¹ FEES utilizes a fiber optic nasendoscope to observe the pharyngeal and laryngeal structures directly during the pharyngeal phase of the swallow. A bolus of contrasting color is used to note premature spillage into the hypopharynx or laryngeal vestibule before the swallow initiation along with the presence of residua in the hypopharynx and laryngopharynx after a swallow. Vocal fold movement patterns can be assessed during FEES but need to be visualized independent of swallows. This examination yields minimal information relative to the oral preparatory and oral phases of the swallow. However, there are advantages to FEES, including a shorter assessment time, the avoidance of radiation, and less expensive instrumentation. The Fiber optic Endoscopic Evaluation of Swallowing with Sensory Testing (FEESST)²⁴ combines FEES with a technique that determines laryngopharyngeal sensory discrimination thresholds by endoscopically delivering air pulse stimuli to the mucosa.

VFSS and FEES integrate a diagnosis and intervention. During these diagnostic interventions, the food bolus size, consistency, and maneuvers are all assessed to identify the safest and most efficient method for bolus transport and clearance and to reduce or eliminate aspiration events. At the most basic level, the assessment and intervention allows the patient to continue with oral intake and minimizes aspiration. At the most sophisticated level, efficient eating can only be accomplished if the patient understands the consistencies, the bolus size, and the maneuvers that are appropriate to the speed of consumption in particular social situations. As a result, the VFSS and FEES are only as good as the knowledge and training of the speech pathologist providing the rehabilitation to this patient group. If the speech pathologist lacks this experience and training in the completion or the interpretation of either the VFSS or FEES of head and neck cancer patients, the physician must recognize and manage this situation by encouraging the patient to make the effort to go to an institution where the assessment and plan will be appropriate to the patient's needs.

Posttreatment Swallowing Rehabilitation

The speech pathologist rehabilitates swallowing disorders with use of postural assists, maneuvers, control of bolus size or rate of intake, modification of bolus consistencies, and exercises.^{21,25} Postures are body positions that the patient utilizes to improve bolus control and transport. Most of the postures involve the alteration of head or body position to direct the bolus to sensate native tissue, to direct the bolus to more functional tissue, or to open the pharynx or close the larynx. Maneuvers are used to alter swallow physiology. These maneuvers are designed to improve laryngeal closure, increase the base of tongue contact with the posterior pharyngeal wall, elevate the larynx, and open the hypopharynx. Postural assists and maneuvers may be prescribed to reduce penetration (entry of the bolus into the supraglottis) and aspiration (entry of the bolus into the trachea), with the goal of achieving safe and efficient oral intake. Many patients who have been treated for advanced head and neck cancer and are in need of evaluation and rehabilitation are actively aspirating. A statistically significant correlation between aspiration detected on videofluoroscopy after chemoradiation of head and neck cancer and the risk of subsequent aspiration pneumonia has been observed, whereas patient-reported or observer-based dysphagia were not predictive of subsequent pneumonia.²⁶ These findings suggest that an objective evaluation of dysphagia, such as videofluoroscopy, should be performed routinely after chemoradiation, rather than limiting it to patients with symptoms of dysphagia. Successful rehabilitation is a reduction, not necessarily the elimination, of aspiration. Optimization of the bolus type and consistency is an art. The bolus size and type of consistencies consumed evolve during rehabilitation. Management of swallowing requires understanding of the pre- versus posttreatment physiology and the probability of improvement

during the first year following treatment. Swallowing exercises are important for strengthening, improving mobility, and improving coordination of movement. They involve both passive and active range of motion exercises. Exercises are designed to improve labial seal, mandibular movement or mouth opening, oral tongue mobility, base of tongue mobility, velopharyngeal closure, posterior pharyngeal wall strength or movement, and laryngeal elevation.

Posttreatment Speech Assessment

Speech generation involves an assessment of respiration, phonation, resonance, and articulation. For optimum phonatory function, there has to be adequate pulmonary reserve for breath support, an intact sound generator, and an intact vocal tract. Respiratory support is the driver of sound generation. Head and neck cancer patients frequently have impaired respiratory support secondary to chronic lung disease or pulmonary resection for second primary tumors. Reduced respiratory support decreases sound volume, increases vocal fatigue, and makes select consonants difficult to produce. Phonation can occur in the glottic or supraglottic larynx, the pharynx, or from an external source such as an artificial larynx. An important component of speech production is vocal resonance. If the soft palate and the lateral or posterior pharyngeal walls are not functioning properly, the voice may sound hyper- or hyponasal. Hyponasality is associated with too much sound (i.e., air leakage) into the nasopharynx during speech, whereas hyponasality is associated with inadequate nasal resonance during speech. For the sound to be shaped into intelligible speech, there must be coordination between and adequate contact of the articulators. Much of the shaping of speech occurs in the oral cavity. For articulation to be optimized, the patient has to have an intact oral sphincter, tongue tip to premaxilla contact, maxillary alveolar contact with the lateral tongue and a mobile tongue tip, obliteration of dead space within the oral cavity, and soft palate contact with the base of the tongue.

The assessment of speech after the treatment of head and neck cancer is varied depending on the site of the lesion, the treatment completed, the extent of surgical resection, and the type of reconstruction, if any. Speech deficits commonly occur in postsurgical patients but can also occur in postchemoradiation patients. Access to the surgeon's template of the surgical defect, including the involved muscles and nerves, is useful for the assessment of the postoperative patient.²⁷ For the assessment of resonance and velopharyngeal competence, a thorough evaluation includes an articulation assessment, an oral motor assessment, and a measurement of nasal airflow. A nasometer (Zoo Passage, Rainbow Passage, and Nasal Sentences) is used to measure nasal airflow during the recitation of standard passages. This is a relatively simple and noninvasive test. The results are compared to normative data. In addition, periodic retesting can be useful to monitor patient progress with interventions. VFSS and FEES can also be useful for the assessment of articulatory precision and velopharyngeal competency, but are better suited to the evaluation of swallowing. Articulation can be assessed by a number of survey instruments, including those that can be used for the assessment of intraoral prostheses.²⁸ These instruments are useful in the research setting and should be used in conjunction with the clinical examination. An interesting area of development is assessment using pressure-sensing electrode arrays. These electrodes are placed on the hard and soft palate to determine the exact location of tongue contact points during articulation. The contact points are then viewed as contrasting colored dots in a line drawing of the palate on a computer screen. This display can be used to assess and treat articulation problems particularly after tongue resection or reconstruction.

With regard to postlaryngectomy voice restoration, insufflation testing²⁹ is an available objective measure to assist with determining candidacy for tracheoesophageal puncture. This test provides information relative to the pressure generated within the pharyngo-esophageal segment during production of structured speech tasks but has never gained widespread use among speech pathologists.

Rehabilitation of the Neck

Neck dissection is performed for the diagnosis or treatment of neck metastasis. The clinical sequelae are secondary to postoperative weakness of the trapezius muscle, which include neck stiffness, shoulder girdle weakness, and chronic pain. The extent of the neck dissection (selective versus modified), radiation, age, and weight all affect the patient's ability to rehabilitate after neck dissection.² Patients who undergo selective neck dissection have significantly better shoulder function than patients who undergo modified radical neck dissection with the same regional control rates.^{30,31} To reduce pain and discomfort and improve mobility, passive and active range of motions have been shown to significantly improve long-term function and quality of life.³²

Rehabilitation of the Oral Cavity

Surgery and postoperative radiation therapy remain the most common treatment approach in the oral cavity. Reconstructive surgeons must be versed in the optimization of oral function. The general approach for oral cavity reconstruction is to perform an anatomic reconstruction (Figs. 39.1 and 39.2). The goals of oral cavity reconstruction include:

- Obliteration of the oral cavity. This is achieved when all oral cavity mucosal surfaces are in contact with one another when the mouth is closed. This goal is important because it should decrease the likelihood of food getting lost in a *dead space* in the oral cavity. Additionally, it should improve the handling of secretions by bringing the revascularized free tissue transfer in contact with the remaining native mucosa.
- Maintain premaxillary contact. This is an extension of the goal of obliteration of the oral cavity. In terms of speech generation, premaxillary and palatal contact is important for maintaining the precision of articulation for a number of speech sounds. Generally, reduced precision of linguadental, alveolar, palatal, and velar sounds will occur if adequate contact is not achieved. The surgeon needs to ensure that some of the volume of the reconstructive flap is concentrated anteriorly to allow for the obliteration of the oral cavity.
- Maintain the *finger function* of the tongue. This is the ability of the tongue to sweep and clear the buccal, labial, and alveolar sulci and protrude past the coronal plane of the incisors.
- Maintain movement of secretions from the anterior to the posterior aspect of the oral cavity.
- Optimize sensation of the remaining native tissue and the revascularized free tissue transfer.

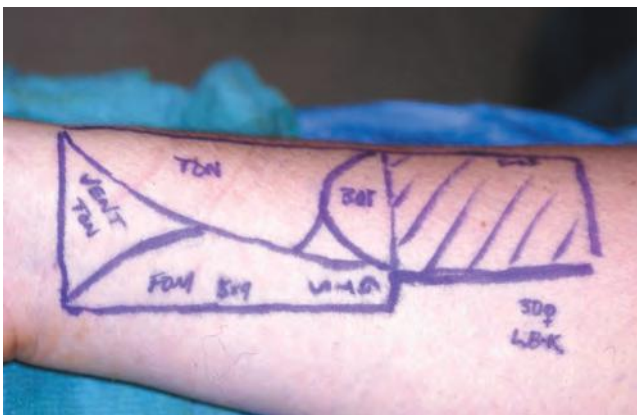

Figure 39.1 This is the preoperative *rectangle tongue* template for reconstruction of a hemiglossectomy defect. The template is marked out on the patient's forearm, will be excised, implanted, and revascularized to reconstruct the tongue.

Figure 39.2 A postoperative reconstructed hemiglossectomy defect 22 months after implantation.

In general, these goals are best met with local tissue and revascularized autogenous tissue reconstruction. Traditional regional flaps, such as the pectoralis flap, are less commonly used because they are associated with higher gastrostomy tube rates.³³ There are published studies that suggest that autogenous revascularized free tissue transplantation is a disadvantage.³⁴ These data are not generally representative of present day reconstruction because, in this historic cohort, free flaps were used for large defects and skin grafts were used for smaller defects. The differences related more to the size of the defect than the reconstructive approach.

For oral cavity rehabilitation, the speech pathologist will perform an oral motor assessment. An assessment includes an evaluation of oral sphincter competence, the patient's ability to handle secretions, tongue to premaxillary/palatal contact, anterior-posterior movement of the tongue, location of sensate tissue, and identification of areas where food will collect (i.e., dead space). A clinical swallow examination is used to assess swallowing function with a focus on the oral phase of the swallow. The patient's ability to remove the bolus from an eating utensil (e.g., a spoon), create a labial seal, manipulate the bolus, control the bolus, and clear the bolus is assessed. The challenge for the speech pathologist is to modify the treatment plan and strategies used to compensate for the changing reconstruction during the first year of rehabilitation.

During the immediate postoperative period, the reconstruction will frequently be bulky and edematous; with radiation, the reconstruction will become smaller and the native tissue will undergo fibrosis. The objective throughout the first year is to maximize and maintain mobility of the tongue, focusing on the use of the remaining native tissue. In this patient group, use of liquid washes to add moisture and to aid in bolus passage with dry and solid consistencies should be considered the norm and not a failure of oral rehabilitation.

Maintaining the remaining native dentition is important for communication, swallowing, and for general health; therefore, including a dentist as part of the treatment team is critical. The best approach is prevention, which involves a reduction of radiation dose to the mandible when possible, the removal or restoration of carious teeth prior to treatment, regular fluoride trays before and after treatment, and the treatment of inflamed gingival tissue. Should a patient develop osteoradionecrosis, surgical excision and reconstruction is the mainstay, because hyperbaric oxygen therapy has been shown to lack efficacy in controlled clinical trials.³⁵

The maxillofacial prosthodontist makes important contributions to the rehabilitation of the patient with an oral cavity defect. Dental rehabilitation with dental prostheses is important for function and cosmesis. When introducing dental prosthetics, it is important to consider the patient's ability to masticate and prevent bolus loss. The introduction of a dental prosthesis can impair bolus control by covering sensate tissue, preventing glossal-labial contact, and

decreasing the functional oral opening. It is also important to ensure that the patient can perform a *tongue sweep* of the labial sulci to clear food residue, especially if a lower (mandibular) dental prosthesis is introduced. If the patient is unable to perform this maneuver, then use of a digit may be required to clear food particles while eating. Even if the patient is a good candidate for a dental prosthesis, implants may be required to assist in the retention of a lower dental prosthesis. Implants can be placed in the native mandible or in an osseous free flap for the purpose of supporting and retaining a dental prosthesis. An individual knowledgeable of the use of implants in radiated bone is important because the rate of implant failure is high and there is a risk of osteoradionecrosis.³⁶ Prostheses can also be useful for the rehabilitation of soft tissue deficits. For example, if the patient does not have good palatal–maxillary contact, a *palatal drop* prosthesis can be fashioned, facilitating the obliteration of dead space within the oral cavity, which allows the tongue to contact the prosthetically reconstructed palate. This may result in improved clarity of speech sounds and, therefore, overall speech intelligibility. In addition, the palatal drop prosthesis may assist in improved bolus manipulation, control, and oral transfer.

Rehabilitation After Partial Laryngeal Procedures

Both the communication and swallowing functions can be adversely affected with a partial surgical resection of the larynx. Supraglottic laryngectomy, hemilaryngectomy, and supracricoid laryngectomy all result in some degree of compromised phonatory function. Following these surgical procedures, the swallowing function is generally adversely affected in the short term, but improvement can be anticipated with the process of healing and the implementation of swallowing therapy. Postoperative dysphagia after partial laryngeal procedures is common due to a decrease in sensation and alteration of normal laryngeal anatomy. As a result, the patient is at risk for penetration and aspiration secondary to the compromise in airway protection that completion of these procedures brings about. Postoperatively, the patient will be trained on swallowing

strategies to improve laryngeal closure in an attempt to prevent aspiration. In the early stages of recovery, liquids are usually the most difficult consistency to consume due to reduced sensation in and around the laryngeal complex and incomplete laryngeal closure, thus reducing airway protection. Therefore, consumption of a modified diet (thickened liquids and purees) with or without the use of alternative means of nutrition is not uncommon until adequate airway protection can be achieved. Implementation of swallowing maneuvers, such as the supra- and supersupraglottic swallow maneuvers, are helpful in facilitating airway protection.^{19–21}

Rehabilitation After Laryngectomy or Laryngopharyngectomy

After a total laryngectomy, the patient has a tracheostoma in the lower neck and a separated digestive tract. The stoma and lungs require management to prevent stomal stenosis, prevent stomal trauma, enhance humidification, and reduce tracheal crusting. There are a variety of products that prevent tracheostomal stenosis, protect the stoma from digital trauma, and enhance humidification (Fig. 39.3A, B). Many of these tracheal stomal products are designed to be used with or without tracheoesophageal (TE) prostheses.

Rehabilitation of speech after a total laryngectomy has improved. Options for alaryngeal communication are TE voice, voice generated by an artificial larynx, and esophageal voice. TE voice has become the gold standard for voice rehabilitation after a total laryngectomy. The challenge with prosthetic rehabilitation is customized solutions, because one size does not fit all. There are many different types of TE voice prostheses (Fig. 39.4A, B). An experienced speech pathologist is essential for long-term patient compliance. The artificial larynx is a device that produces mechanical sound. This sound is transferred into the oral cavity via the placement of the device to the cheek or neck. Additionally, there is an option for an intraoral adapter, allowing for direct transmission of sound into the oral cavity. This device can be used short term until a patient achieves functional esophageal or TE speech. In some cases, it is used long term as the primary means of alaryngeal communication. This device can

Figure 39.3 (A) Items 1 through 4 are for use in the trachea and are designed to retain the heat moisture exchange (HME) cartridge/cassette or hands-free speaking valve. Items 1 and 2 are laryngectomy tubes that are not self-retaining and are designed for use with ties. They are available in different diameters, lengths, and with or without fenestration. Items 3 and 4 are stoma buttons, are self-retaining, and are designed to be used by patients with a tracheal lip. If this lip of tissue is not circumferential, adequate retention is unlikely. Items 5 and 6 are examples of HME cassettes/cartridges and can be used with items 1 through 4. Items 7 and 8 are examples of hands-free speaking valves. The valves are open during restful breathing. During tracheoesophageal (TE) sound production, the valve closes, redirecting the air through a separate device, the TE voice prosthesis. The TE prosthesis diverts air into the esophagus creating a vibratory segment so the patient can produce a voice. (B) Item 1 is an example of a laryngectomy tube that is used to maintain stoma patency and can be supplied with fenestrations so that it can be used with a TE voice prosthesis. Item 2 is a foam adhesive filter that is placed over the stoma and acts as a partial barrier between the trachea and environment. Items 3 and 4 are types of tracheostoma (TS) base plates. These are adhesive and attach to the peristomal skin to allow for attachment of a HME system (see items 5 and 6) or a hands-free speaking valve. The base plates come in different shapes and adhesive strengths, but the HME attachment system is universal to facilitate the use of different brands. Items 5 and 6 are two types of HME cartridges/cassettes and must be inserted into a retention system such as a TS base plate, select laryngectomy tubes, and/or stoma buttons. The HME helps maintain the humidity and temperature of the pulmonary tract and should be worn 24 hours per day. Items 2 through 6 are single-use items and are meant to be discarded after use. Wear time of the TS baseplates can vary from several hours to several days.

Figure 39.4 (A) There are many different types of tracheoesophageal (TE) prostheses. This figure is a sample of some different types. Item 1 is a duckbill voice prosthesis. Item 2a is a low pressure voice prosthesis. These are patient changeable devices. The duckbill (1a) is shown attached to the insertion stick (1b). Item 2a would be attached to the insertion stick (2b) in the same manner. Items 3a and 5a are indwelling voice prostheses that are not patient changeable and are shown apart from their insertion sticks (3b and 5b, respectively). Item 4a is a gel cap that has been placed on the esophageal end of an indwelling prosthesis (4b), which is shown attached to the insertion stick (4c). Item 5a is an indwelling variation with large esophageal flange. This would be used in patients who experience reduced retention of their prosthesis in the TE puncture. (B) These are examples of TE prostheses with alternative insertion systems. Item 1a is a patient changeable nonindwelling voice prosthesis shown on its insertion stick (1b). Item 1c is a safety washer attached to the voice prosthesis, which allows for the easy removal of the voice prosthesis in the event of accidental prosthesis dislodgement. Item 2a is an insertion tube. The indwelling voice prosthesis (2b) is shown on its insertion stick (2c), which is intended to be placed into the insertion tube. Item 3b is a loaded indwelling voice prosthesis in its insertion tube. The voice prosthesis (3a) can be visualized on the left side of the insertion tube.

be difficult to use. Training of and practice by the patient are essential to become adept for daily communication requirements (Fig. 39.5). Another alaryngeal speech option is esophageal speech, which does not utilize devices or implants. It involves trapping air in the pharynx distal to the cricopharyngeus with a subsequent controlled release of air through the pharyngoesophageal segment to produce sound. Learning esophageal speech is time intensive and can take up to a year or longer to achieve a functional result. In some cases, fluent sound is never realized. As a result, esophageal speech is not commonly used. However, voice production with a TE voice prosthesis, in many instances, can be achieved on the day of insertion.

A wide variety of TE voice prostheses are available. Prosthesis selection is related to many factors. It is important to know that prostheses come in different diameters, lengths, amounts of valve resistance, and sizes of tracheal and esophageal retention collars.

Figure 39.5 An artificial larynx. This device is a sound generator. Item 1 is shown without an attachment/attenuator and can be used with neck placement or cheek placement. When used this way, sound is directed through the neck or cheek tissue into the oral cavity. Item 2 is shown with an intraoral attenuator (2a) and an attachment (2b). Together, the attachment and attenuator allow for the delivery of sound into the oral cavity, which can then be shaped into speech.

Additionally, there are standard prostheses and yeast-resistant prostheses. The type of voice prosthesis that is chosen will depend on the diameter, length, and integrity of the tissue that makes up the TE puncture. Candidal colonization of the TE prosthesis can cause accelerated deterioration and can increase the frequency of replacement. Therefore, consideration for transition to a yeast-resistant prosthesis may be indicated. There are patient-changeable and clinician-placed (i.e., indwelling) prostheses. Patient-changeable prostheses can last from less than 1 month to 3 months on average, whereas clinician-placed prosthetics can last 3 to 6 months on average. The goal is for the patient to be as independent as possible with their care. This includes daily cleaning and maintenance. The advantages of the patient-changeable prosthesis is that it is less expensive than the clinician-placed prosthesis. In addition, in the event of prosthesis failure, the patient can replace the prosthesis independently. The clinician-placed prosthesis comes with added options (e.g., antifungal, large tracheal or esophageal flanges, dual valves, weighted valves). However, the indwelling prosthesis can cost two to three times more than a patient-changeable prosthesis. Additionally, if the prosthesis fails, the time for prosthesis replacement can range from 1 to 3 days. The voice prosthesis that is selected will be based on each individual's need. In addition, social and financial factors need to be considered. Some patients have to pay for their own prosthesis out of pocket or need to travel long distances to visit the speech pathologist for replacement. Therefore, cost in combination with replacement interval and travel time has to be considered along with the clinical indication for prosthesis selection.

Voice production can be difficult for some patients even when there is a properly fitting TE prosthesis. There are several causes of aphonia following the placement of a voice prosthesis. These include posttreatment edema, spasm of the cricopharyngeus, and pharyngeal stenosis. A VFSS is utilized for the evaluation of spasm versus stenosis. If a stenosis is present, then dilation is appropriate. If there is hypertonicity of the pharyngoesophageal segment or cricopharyngeal spasm, this can be treated with botulinum toxin injection in a clinic setting or administered under fluoroscopy.

Sound production with a TE voice prosthesis requires adequate occlusion of the tracheostoma. The tracheostoma can be occluded directly with a digit, an object, a stoma filter with application of digital pressure (Fig. 39.6), or with a mechanical valve that fits over

Figure 39.6 A patient with an adhesive tracheostoma baseplate heat and moisture exchange system with the cassette in position. The patient will push on the cassette for tracheoesophageal (TE) voice production.

the stoma. A mechanical valve is considered to be *hands free* and fits into a tracheostomal housing that can be adhered to the skin adjacent to the stoma or inserted into a self-retaining tracheal button that is placed in the stoma. The hands-free devices most closely duplicate an intact larynx because the patient does not have to use a digit to occlude the stoma. Use of forced exhalation closes off the valve, shunting air through the TE prosthesis. The challenges with these devices are retention while speaking, avoiding obstruction due to secretions, and maintaining optimal respiratory support for valve closure. For effective long-term use of a tracheostomal housing used with a hands-free device, the peristomal skin must be able to withstand wound breakdown. An alternative to the adhesive tracheostomal housing is a stoma button. The button fits in the tracheostoma, and retention is facilitated by a slightly stenotic stoma and a small retention collar on the distal end of the button. For those patients who are not able to use a stoma button but who require use of a tube to maintain stoma patency, another option is a combination of the adhesive housing and the laryngectomy tube. If the retention and secretion issues can be overcome, the hands-free device is a major step forward in the rehabilitation of the head and neck cancer patient (Fig. 39.7).

Every stoma is different and, as a result, there is an endless variety of devices that assist in the retention of heat moisture exchange (HME) cassettes and hands-free devices. There are two categories of devices: peristomal, which are retained around the stoma, and intrastomal devices, which are fit into the stoma. For most patients, a peristomal base plate is fit first until adequate healing allows for an evaluation for the use of a stoma button. The tracheal stoma (TS) base plate is an adhesive-backed attachment that adheres to the peristomal skin. These can be worn daily and up to 3 days as tolerated. They come in different shapes (i.e., oval, round, oblong), types (i.e., XtraBase, Stabilibar), and varying strengths of adhesive to facilitate effective retention for the wide range of peristomal shapes. We prefer to place intrastomal devices once the patient has healed. These are frequently uncomfortable when initially fitted. These devices are called stoma buttons and can be used if there is an adequate lip at the cutaneous mucosal junction to facilitate retention. Interestingly, this creates a situation where there is a benefit to a small stoma because the stoma button can be retained effectively

Figure 39.7 A patient with modified tracheostoma housing with hands-free speaking valve.

and will improve the patient's overall level of comfort. Of course, this is only an option in highly supported health-care environments. The use of a stoma button will affect the placement location of the TEP. To effectively use a stoma button, the TEP needs to be placed more inferiorly so the tracheal retention collar of the stoma button does not obstruct the TE voice prosthesis. The stoma button is re-used with replacement once or twice per year as needed.

There are many products available to raise the humidity level in the lungs after a laryngectomy. Generically, these items are referred to as HME systems. HME cassettes/cartridges are used to assist, in part, in the restoration of respiration lost as a result of surgery. The design varies slightly by manufacturer. Patients should be fitted as soon as the stoma is healed because these devices help to heat and increase the humidity of the air entering lungs. The result is a more comfortable patient who experiences less tracheal dryness, crusting, and less time in maintaining their stoma. As is the case with hands-free devices, they can be used with both peristomal and intrastomal devices. TE sound is generated when the HME is digitally occluded.

RESOURCES FOR REHABILITATION OF HEAD AND NECK CANCER PATIENTS

For the clinician, there are a number of useful references for the rehabilitation of head and neck cancer patients.

- Doyle PC, Keith RL. *Contemporary Considerations in the Treatment and Rehabilitation of Head and Neck Cancer*. Austin, TX: PRO-ED; 2005.
- Fried MP. *The Larynx—A Multidisciplinary Approach*. Vol. 15. Boston: Little, Brown; 1988.
- Logemann JA. *Evaluation and Treatment of Swallowing Disorders*. 2nd ed. Vol. 13. Austin, TX: PRO-ED; 1998.

Many larger communities and head and neck oncology programs have or are associated with support groups. However, there are few, if any, in small rural areas. It may be helpful for a newly diagnosed head and neck cancer patient to have the opportunity to speak with a member of the support group prior to, during, and after treatment. The following include additional information about support groups:

- Support for People with Oral and Head and Neck Cancer (SPOHNC) has a listing of support groups in the United States. In addition, it has a useful list of Web links for the head and neck cancer patient. SPOHNC can be located at www.spoync.org, PO Box 53, Locust Valley, NY, 11560-0053, 1-800-377-0928.
- Web Whispers is a laryngectomy online support group that provides information, has a monthly online newsletter, conducts an annual meeting, and provides loaner artificial electric larynx for members. It is located at www.webwhispers.org
- The International Association of Laryngectomees (IAL) is an international association with educational materials, meetings, and links to medical equipment companies. IAL can be located at www.theial.com/ial.
- CancerCare provides educational programs, counseling, information, and financial assistance. There are useful links and documents on recent cancer-related research. Patients can call

and obtain a free counseling from a social worker. It is located at www.cancer.org. To contact telephone counseling, call 1-800-813-4673.

- The Head and Neck Cancer Alliance has a link to a blog where patients can ask other patients about their experiences. The site is located at www.inspire.com/groups/head-and-neck-cancer-alliance/

For the patient, there is an “official” Web site for information as well as additional resources.

- Medline Plus is a patient health information site supported by the National Library of Medicine and the National Institutes of Health. It is located at www.nlm.nih.gov/medlineplus/head-and-neckcancer.html. This site is also available in Spanish.
- Cancer.Net offers information on a variety of topics for the head and neck cancer patient. The site is located at www.cancer.net.
- The National Cancer Institute offers information on head and neck cancer treatment, prevention, causes, and screening. The site can be accessed at www.cancer.gov/cancertopics/types/head-and-neck.
- Brook, I. *The Laryngectomy Guide*. Washington DC: Itzhak Brook, 2013. This is a guide aimed at providing practical information that can assist laryngectomees and their caregivers. Available in print and electronically.

Section 2 Cancer of the Thoracic Cavity

40 Molecular Biology of Lung Cancer

Leora Horn, Luiz Henrique de Lima Araujo, Patrick Nana-Sinkam, Gregory A. Otterson, Terence M. Williams, and David P. Carbone

INTRODUCTION

Lung cancer tumorigenesis is a multistep process of transformation from normal bronchial epithelium to overt lung cancer. Various molecular events resulting in gain or loss of function cause dysregulation of key genetic pathways involved in cellular proliferation, differentiation, apoptosis, migration, invasion, and other processes characteristic of the malignant phenotype. Mutations, including single nucleotide substitution or deletion, and translocation, deletion, or amplification of larger portions of genetic material may result from environmental factors, inherited susceptibility, or random events. Many genes are involved in tumorigenesis of both small cell lung cancer (SCLC) and non-small-cell lung cancer (NSCLC) (Table 40.1 and Fig. 40.1), but there are also unique genetic aberrations associated with each tumor type. The identification of the nature and frequency of these molecular abnormalities is necessary to determine their clinical implications (e.g., associations with smoking, histologic type, stage, survival, response to therapy), and define their clinical utility for the prevention and early diagnosis of lung cancer, and the development of therapeutic targets.

SUSCEPTIBILITY TO LUNG CANCER: GENETIC SUSCEPTIBILITY AND CARCINOGENS IN TOBACCO SMOKE

Tobacco use is the most important environmental factor associated with the development of lung cancer. Approximately 85% of lung cancer occurs in current or former smokers. Cigarette smoke contains more than 60 known carcinogens, 20 of which have been convincingly shown to cause lung tumors in laboratory animals or humans.¹ Of these, polycyclic aromatic hydrocarbons, such as benzo(a)pyrene, tobacco-specific nitrosamines, such as 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), and aromatic amines, such as 4-aminobiphenyl, appear to have an important role in cancer causation. Nitrosamines such as NNK induce lung tumors in mice independent of the route of administration. Among the polycyclic aromatic hydrocarbons, benzo(a)pyrene is the most extensively tested and the first to be detected in tobacco smoke. Its role in cancer tumorigenesis is well described, and its diol epoxide metabolite has been implicated as a cause of mutations in the TP53 gene.² One of the carcinogenic effects of tobacco smoke in the lung is the formation of DNA adducts, leading to errors in DNA replication and resulting in mutations. DNA adducts have been identified in the bronchial tissue of patients with lung cancer. In current smokers, adduct levels correlate with the amount of tobacco smoke exposure.^{3,4} In addition, in former smokers, the age at smoking initiation has been inversely associated with levels of DNA adducts, suggesting that the prevention of smoking in adolescence is of utmost importance in decreasing lung cancer risks.

Although tobacco use can account for the majority of lung cancers, most chronic smokers still do not develop lung cancer. Differences in inherent susceptibility may be related to variations in carcinogen-metabolizing enzymes, DNA repair mechanisms, chromosome fragility, and other homeostatic mechanisms. Among genes for carcinogen-metabolizing enzymes, polymorphisms in the cytochrome P-450 genes, CYP1A1, CYP2D6, and CYP2E1, and in mu-class glutathione S-transferase (GSTM1) have received the most attention. In addition to inherent susceptibility to the carcinogenic effects of tobacco smoke, large genomewide association studies have identified lung cancer susceptibility loci at 15q25, 5p15, and 6p21.^{5,6} In particular, polymorphisms in and around nicotinic cholinergic receptors at chromosome 15q25 appear to correlate with mRNA and protein expression of these receptors as well as functional changes in the calcium ion channel of the A5 nicotine receptor; these differences confer susceptibility to smoking behaviors.⁷

Researchers are optimistic that molecular epidemiology will help identify individuals at the highest risk of developing lung cancer. Such information, in addition to the smoking history, will be of great value in new lung cancer screening trials and in chemoprevention trials to identify persons at the highest risk of developing lung cancer.

MOLECULAR CHANGES IN PRENEOPLASIA

Before lung cancer is clinically recognizable, a series of morphologically distinct changes (hyperplasia, metaplasia, dysplasia, and carcinoma in situ) are thought to occur. It is believed that dysplasia and carcinoma in situ represent true preneoplastic changes. It is evident that preneoplastic cells contain several genetic abnormalities identical to some of the abnormalities found in overt lung cancer cells. For squamous cell carcinomas (SQCC), an immunohistochemical analysis has confirmed the abnormal expression of proto-oncogenes (cyclin D1) and TSGs (p53).⁸ Allelotyping of precisely microdissected, preneoplastic foci of cells shows that 3p allele loss is currently the earliest known change, suggesting that one or more 3p TSGs may act as gatekeepers for lung cancer pathogenesis.⁹ This is followed by 9p, 8p, and 17p allele loss and p53 mutation. Similarly, atypical alveolar hyperplasia, the potential precursor lesion of adenocarcinomas, can harbor KRAS mutations and allele losses of 3p, 9p, and 17p.¹⁰ Other genetic alterations, such as inactivation of LKB1, whose germline mutations cause Peutz-Jeghers syndrome, have also been implicated in the development of adenocarcinoma. These observations are consistent with the multistep model of carcinogenesis and a field cancerization process, whereby the whole tissue region is repeatedly exposed to carcinogenic damage and is at risk for the development of multiple, separate foci of neoplasia.¹¹ Although all types of lung cancers

TABLE 40.1

Most Frequently Acquired Molecular Abnormalities in Lung Cancer

Abnormalities	Small Cell Lung Cancer	Non-Small-Cell Lung Cancer
Microsatellite instabilities	~35%	~22%
Autocrine loops	GRP/GRP receptor; SCF/KIT	TGF- α /EGFR; heregulin/HER2/neu; HGF/MET
RAS point mutation	<1%	15%–20%
EGFR mutation	<1%	<10% (West), ~40% (Asia)
EML4-ALK	0%	3%–7%
ROS1	0%	1%
RET	0%	1%
ERBB2	0%	2%–4%
PIK3CA	0%	1%–3%
FGFR	0%	20%
MYC family overexpression	15%–30%	5%–10%
P53 inactivation	~90%	~50%
RB inactivation	~90%	15%–30%
p16 ^{INK4A} inactivation	0%–10%	30%–70%
LKB1 inactivation	~40%–60% (IHC)	20%–40%
Frequent allelic loss	3p, 4p, 4q, 5q, 8p, 10q, 13q, 17p, 22q	3p, 6q, 8p, 9p, 13p, 17p, 19q
Telomerase activity	~100%	80%–85%
BCL2 expression	75%–95%	10%–35%

GRP, gastrin-releasing peptide; SCF, stem cell factor; TGF- α , transforming growth factor- α ; EGFR, epidermal growth factor receptor; HER2, human epidermal growth factor receptor 2; HGF, hepatocyte growth factor; RB, retinoblastoma protein; IHC, immunohistochemistry.

have associated molecular abnormalities in their normal and preneoplastic lung epithelium, SCLC patients in particular appear to have multiple genetic alterations occurring in their histologically normal-appearing respiratory epithelium.

Molecular changes have been found not only in the lungs of patients with lung cancer, but also in the lungs of current and

former smokers without lung cancer. These molecular alterations are thus important targets for use in the early detection of lung cancer and for use as surrogate biomarkers in following the efficacy of lung cancer chemoprevention. The challenge is to identify not only the prevalence and temporal sequence of molecular lesions in lung preneoplasia, but also to determine which are rate

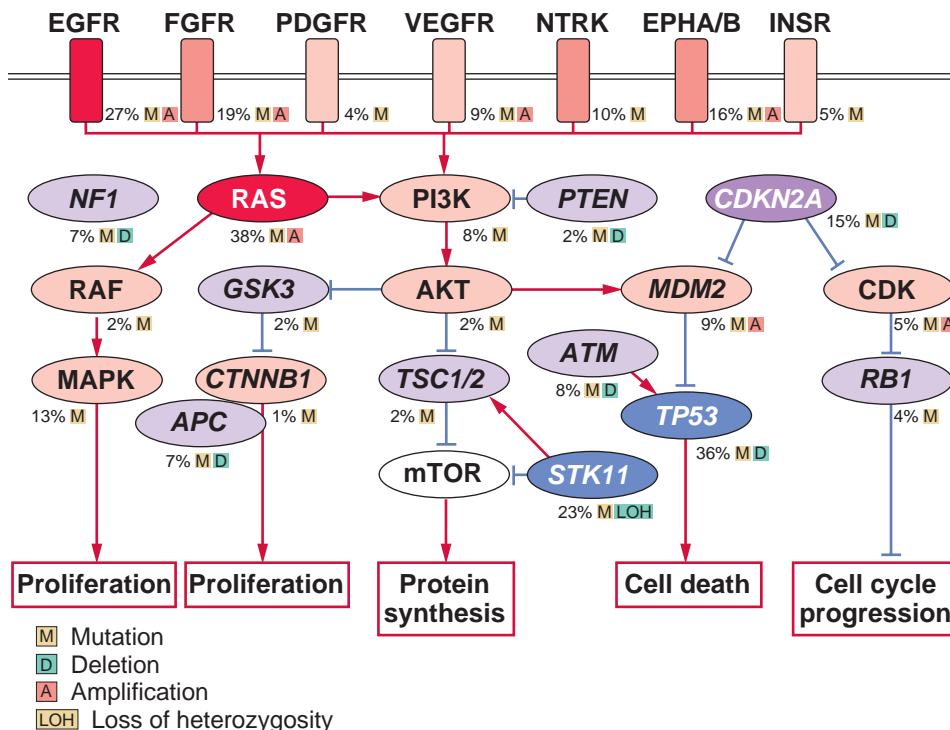

Figure 40.1 Significantly mutated pathways in lung adenocarcinomas. Genetic alterations in lung adenocarcinoma frequently occur in genes of the MAPK signaling, p53 signaling, Wnt signaling, cell cycle, and mammalian target of rapamycin (mTOR) pathways. Oncoproteins are indicated in pink to red and tumor suppressor proteins are shown in light to dark blue. The darkness of the colors is positively correlated to the percentage of tumors with genetic alterations. Frequency of genetic alterations for each of these pathway members in 188 tumors is indicated. (Reprinted by permission from Macmillan Publishers Ltd: Nature. Ding L, Getz G, Wheeler DA, et al. Somatic mutations affect key pathways in lung adenocarcinoma. *Nature* 2008;455:1069–1075. Copyright 2007.)

limiting and indispensable and thus represent potential candidates for intermediate biomarker monitoring and therapeutic efforts.

GENETIC AND EPIGENETIC ALTERATIONS IN LUNG CANCERS

Genomic Instability and DNA Repair Genes

Similar to other epithelial tumors, lung cancer cells typically display chromosomal instability—both numeric abnormalities (aneuploidy) of chromosomes and structural cytogenetic abnormalities.¹² Allele loss on chromosome 3p is thought to be among the earliest genetic change occurring in both NSCLC and SCLC.¹³ In addition, nonreciprocal translocations and recurrent losses involving 1p, 4p, 4q, 5q, 6p, 6q, 8p, 9p, 11p, 13q, 17p, 18q, and 22q may occur, representing changes in known and potential tumor suppressor genes (TSGs).¹⁴ Polysomes or regions of gene amplifications also occur and often involve proto-oncogenes, such as epidermal growth factor receptor (*EGFR*) and myelocytomatosis viral oncogene homolog (*MYC*).^{15,16} Simple reciprocal translocations are uncommonly observed in lung cancer, although translocations that give rise to *BRD4-NUT*, *CRCT1-MAML2*, *SLC34A2-ROS1*, and *EML4-ALK* fusion proteins have been recently reported.¹⁷⁻¹⁹ *ALK* and *ROS1* translocations have been shown to drive the development and proliferation of tumors, and targeted therapy has resulted in clinical responses in patients with these abnormalities (see the following). In addition, alterations in microsatellite polymorphic repeat sequences are found in 35% of SCLC and 22% of NSCLC.²⁰ Most recently, a comprehensive genomic analysis of lung squamous cell cancers has revealed a high-frequency selective amplification of chromosome 3q compared to lung adenocarcinomas.²¹ Furthermore, large-scale genomic profiling has established that there is a higher rate of copy number alterations, somatic rearrangements, and mutations found in squamous and adenocarcinoma lung cancers compared to other tumors.²² For example, squamous cell lung cancers exhibit 8.1 somatic mutations per megabase (Mb) compared to other cancers where the frequency ranges from 1.0 to 3.2 mutations per megabase. These studies highlight the increased genetic complexity, genomic instability, higher mutation rate, and thus more extensive molecular heterogeneity that typifies lung cancer compared to other tumor types.

Recurring mutations in DNA repair genes are becoming increasingly recognized in multiple solid tumor types, including lung cancer. Ataxia telangiectasia mutated (*ATM*) plays a central role in the DNA damage response pathway that is triggered after genomic insults, including errors during replication, exposure to genotoxic drugs, or ionizing radiation, and has been identified in lung adenocarcinomas.²²⁻²⁴ Alterations in other DNA repair genes have been identified, including *BRCA1* and *BRCA2*, proteins that are both involved in the repair process of homologous recombination especially for double-strand breaks, as well as *ATR*, which functions in sensing and activating DNA repair in response to single-stranded DNA breaks.²² Additionally, there is growing evidence that chromatin remodeling genes are highly mutated in lung cancer. Specifically, it has been recently shown that alterations in *MLL2*, *MLL3*, *MLL4* (a group of histone-modifying genes) cluster in lung cancers, along with mutations in *SMARCA4* and *ARID1A* (members of the *SWI/SNF* chromatin-remodeling complex).²¹⁻²⁴ Ongoing studies will serve to further evaluate the role of these putative TSGs in lung tumorigenesis.

The most powerful tumor surveillance mechanism is involved in DNA damage response and repair of errors in DNA replication.²⁵ The DNA glycosylase 8-oxo guanine (*OGG1*) specifically excises the oxidatively damaged mutagenic base 8-hydroxyguanine, which causes G:C→T:A transversions frequently found in lung cancer. Proof that *OGG1* is central to this DNA repair is the evidence that lung adenocarcinoma spontaneously develops in *OGG1* knockout

mice and 8-hydroxyguanine accumulates in their genomes.^{26,27} Individuals with low *OGG1* activity have a greatly increased risk of developing lung cancer. Polymorphisms in other DNA repair genes including *ERCC1*, *XRCC1*, *ERCC5/XPG*, and *MGMT/AGT* have been correlated with a reduction of polyaromatic hydrocarbon DNA adduct formation as well as with lower lung cancer risks in case-control studies. Furthermore, high expression of *ERCC1* is associated with decreased response to platinum-based chemotherapy, and overexpression of *ERCC1* correlates with better overall prognosis in NSCLC,²⁸ reflecting improved repair of lethal DNA damage by platinum on the one hand, and greater DNA stability with less aggressive disease course on the other. More recent studies, however, have called into question the predictive ability of *ERCC1* expression alone to predict cisplatin response, at least by immunohistochemical detection.²⁹ Similarly, ribonucleotide reductase M1 (*RRM1*) overexpression correlates with better de novo prognosis but resistance to gemcitabine.^{30,31} High levels of the mismatch repair protein *MSH2* have also been shown to be associated with poor survival with cisplatin, and may enhance the predictive significance of *ERCC1* expression.³² Prospective clinical trials investigating *ERCC1* and *RRM1* biomarker-guided therapy are currently underway.

PROTOONCOGENES, GROWTH FACTOR SIGNALING, AND GROWTH FACTOR-TARGETED THERAPIES

Advances in the understanding of lung carcinogenesis have yielded to a rapid discovery of novel driver oncogenes activated by mutations, translocations, or gene amplification. These alterations occur in genes that encode receptors or intracellular proteins crucial for cellular growth, proliferation, and survival, driving tumor formation and maintenance.

Receptor Tyrosine Kinases

EGFR is one of the most commonly mutated proto-oncogenes in lung adenocarcinoma. It is a transmembrane receptor-tyrosine kinase that is normally activated by binding with one of its ligands, members of the EGF family. *EGFR*-sensitizing mutations lead to constitutive activation of the tyrosine kinase and phosphorylation of downstream pathways ultimately resulting in uncontrolled proliferation, invasion, and metastasis. In 2004, investigators first noted mutations within the tyrosine-kinase domain of *EGFR* in patients who had sustained dramatic responses to the *EGFR* tyrosine-kinase inhibitors (TKIs), erlotinib and gefitinib.³³⁻³⁵ The frequency of such mutations varies from approximately 10% of lung adenocarcinomas in North American and European populations to as high as 50% in Asia.³⁶⁻³⁹ The leucine to arginine substitution at position 858 (L858R) in exon 21 and short in-frame deletions in exon 19 are the most common sensitizing mutations, comprising approximately 90% of cases. Sensitizing *EGFR* mutations are both prognostic for longer survival irrespective of therapy and predictive of response to *EGFR* TKIs.^{35,39-47} Other mutations have been described within the *EGFR* gene, and for some, the responsiveness to *EGFR* TKI-directed therapy is similar to the deletion 19 and L858R, including the L861Q and the G719X mutations. An *EGFR* sequencing analysis of more than 1,000 patients with adenocarcinoma showed that 27 patients (2.5%) carried exon 20 insertions, representing approximately 9% of all *EGFR* mutations.⁴⁸ These mutations are found in patients who share the same phenotype as the canonical sensitivity mutations within exon 19 and 21; however, treatment with *EGFR* TKIs does not result in dramatic responses, and the prognosis is more analogous to that of patients with wild-type *EGFR*. A major area of investigation has been the mechanisms of acquired resistance to *EGFR* TKIs. Both in vitro as well as rebiopsy studies from patients who have been

treated and subsequently progressed on treatment have shown two broad resistance mechanisms, secondary *EGFR* alterations and non-*EGFR* bypass mechanisms.⁴⁹ Approximately 50% of *EGFR* TKI resistance is due to a second site mutation, the T790M mutation occurring within exon 20.^{50,51} Other, non-*EGFR* mechanisms of TKI resistance include *MET* amplification, *PIK3CA* mutations, and change in histology to a small cell appearance.⁴⁹ The T790M mutation is also found to be present at a very low prevalence in the germ line and appears to increase lung cancer risk independent of smoking.⁵²

ERBB2 (formerly human epidermal growth factor receptor 2 [HER2]/neu) is a member of the *erbB* receptor family, along with *EGFR*. It is overexpressed in about 20% of NSCLCs, and amplified in 2% to 4% of cases.⁵³ *ERBB2* mutations have been identified in approximately 2% of NSCLCs, comprising in-frame insertions of 3 to 12 base pairs into exon 20, usually around the codon 776.^{34,38,54} A meta-analysis suggested that *ERBB2* overexpression is an indicator of poor survival in lung adenocarcinoma,⁵⁵ but amplification or mutations do not seem to be prognostic.^{55,56} Early trials examining targeted therapies selected patients on the basis of *ERBB2* overexpression and were mostly unsuccessful.⁵⁷ However, recent data suggest that trastuzumab, a recombinant humanized monoclonal antibody against *ERBB2*, may be active in *ERBB2*-mutant lung adenocarcinomas.³⁴ In addition, irreversible TKIs targeting *ERBB2* are in early clinical trials.

Hepatocyte growth factor receptor (HGFR) is a receptor tyrosine kinase encoded by *MET*. *MET* amplification has been reported in about 2% of NSCLCs, and has been implicated in up to 20% of cases with acquired resistance to *EGFR* TKIs.⁵⁸ Several therapeutic strategies, including antibodies that target HGFR and anti-HGFR TKIs are under clinical evaluation in NSCLC patients, mostly aiming to prevent or overcome *EGFR* TKI resistance.^{59–61}

Three other receptors have been nominated as potential drugable targets, especially in lung SQCC.^{62,63} Insulin-like growth factor receptor 1 (IGFR1) is a tyrosine kinase receptor that activates the MAPK and PI3K/AKT/mTOR pathways, playing an important role in cancer growth and progression.⁶⁴ IGFR1 expression is higher in lung SQCC, and gene copy number has been associated with survival.⁶⁵ Despite an initial promise, phase III studies of some anti-IGFR1 agents has halted due to excess toxicities, including treatment-related deaths in the experimental arm. Fibroblast growth factor receptor 1 (FGFR1) is a member of the family of fibroblast growth factor (FGF) receptors that are dysregulated in a variety of cancers. *FGFR1* amplification has been described in approximately 20% of lung SQCCs and has been associated with cigarette smoking and worse survival.^{66,67} In vitro studies showed activity with anti-FGFR inhibitors in cell lines harboring this feature, and pan-FGFR and multikinase inhibitors are in early phases of clinical investigation. Discoidin death receptor 2 (*DDR2*) is a member of the *DDR* family of transmembrane receptors that signals through SRC and STAT pathways. Mutations in the kinase domain have been reported in nearly 4% of lung SQCCs and were shown to yield malignant transformation in vitro.⁶⁸ Interestingly, some FDA-approved agents for chronic myelogenous leukemia seem to be active against the *DDR* family, including dasatinib, nilotinib, and imatinib.⁶⁹

Translocated Genes in Lung Cancer

The anaplastic lymphoma kinase (ALK) fusion protein is an activating oncogenic driver of lung adenocarcinomas occurring in 3% to 7% of all NSCLCs.^{70,71} Multiple ALK variants have been identified in lung cancer, and different ALK partners like kinesin family member 5B (*KIF5B*) have been described.^{70,72,73} Similar to *EGFR* mutations, ALK fusions occur almost exclusively in adenocarcinomas, specifically with acinar histology, in never or former light smokers.^{70,74–76} ALK fusions are not found in tumors with mutations in *EGFR* or *KRAS*, and patients appear to be of younger age com-

pared to those with *EGFR* mutant tumors.⁷⁶ The gold standard test for ALK translocations is fluorescence in situ hybridization (FISH), but a variety of methods have been proposed, including immunohistochemistry, reverse transcription polymerase chain reaction (RT-PCR), and next-generation sequencing (NGS). The clinical activity of crizotinib—an oral inhibitor against c-MET, ALK, and ROS1—was impressive in early trials involving patients with the *EML4-ALK* translocation.⁷¹ In a randomized phase III trial, crizotinib significantly improved progression-free survival (PFS), response rate (RR), and quality of life in comparison to second-line chemotherapy among patients with metastatic NSCLC harboring ALK translocations.⁷⁷ In a fashion analogous to that seen with *EGFR* TKI resistance, initial reports of resistance mechanisms include both ALK dependent (e.g., secondary mutations within ALK or amplification of the mutant ALK allele) and bypass tracks (e.g., the development of secondary *KRAS* and *EGFR* mutations have been described).^{78–81} Importantly, several second-generation inhibitors are under clinical investigation and have shown promising activity in patients with acquired resistance to crizotinib.^{82,83}

More recently, fusions involving the receptor tyrosine kinases ROS1 and RET have been described in NSCLC, each with oncogenic activity and potential utility as clinical biomarkers. ROS1 belongs to the insulin receptor family and is not normally expressed in the human lung tissue.⁸⁴ It has been demonstrated that ROS1 fusions induce autophosphorylation and downstream activation of common growth and survival pathways like mitogen-activated protein kinase (MAPK), STAT3, and PI3K/AKT. *ROS1* rearrangements occur in approximately 1% to 2% of NSCLC patients, mostly in adenocarcinoma histology, younger patients, and never smokers.⁸⁵ It has been shown that selective ALK inhibitors are also active in tumors harboring *ROS1* translocations, both in vitro and in vivo.⁸⁶ *RET* rearrangements were only described in NSCLC in 2011, involving *KIF5B* as a partner.^{87,88} Subsequently, *CCD6*, *NCOA4*, and *TRIM33* have been described as alternative *RET* fusion partners.^{89,90} Similar to ALK translocations, *RET* partners contain a coiled-coil domain that functions as a dimerization unit, leading to ligand-independent homodimerization of the fused protein and constitutive activation of the *RET* kinase activity mediated by autophosphorylation. Like ALK and ROS1, *RET* fusions are associated with a lack of smoking history and adenocarcinoma histology, with a frequency slightly higher than 1% in all comers.⁹¹ Agents including cabozantinib,⁹⁰ sorafenib, sunitinib, vandetanib, and ponatinib are being evaluated in this patient population.

Intracellular Signaling

Because downstream effectors are required for intracellular transduction of incoming growth factors or receptor signals, it is not surprising that proteins important in cytoplasmic signal transduction cascades are also implicated in carcinogenesis. The *RAS* gene family—in particular, *KRAS*—can be activated by point mutations at codons 12 or 13 in exon 2 in approximately 20% to 30% of NSCLCs. *KRAS* mutations more commonly occur in patients with significant smoking history and adenocarcinoma histology.⁹² Approximately 70% are G→T transversions, with the substitution of glycine by either cysteine or valine. Similar G→T transversions are observed in the mutated p53 gene, representing similar DNA damage as a result of bulky DNA adducts caused by the polycyclic hydrocarbons and nitrosamines in tobacco smoke. In a meta-analysis of 3,779 lung cancer patients, mutant *KRAS* was correlated to a worse prognosis in adenocarcinoma histology, but this link was not confirmed in a prospective study.⁹³ The poor prognosis has been proposed to be related to the fact that *KRAS* mutations rarely occur with *EGFR* mutations, and *EGFR* mutant tumors have a better prognosis than *EGFR* wild type. Thus, if *KRAS* mutations are evaluated only in *EGFR* wild-type tumors, the adverse prognostic effect of *KRAS* disappears.⁹⁴ Although the oncogenicity of aberrant *KRAS* is well established, effective agents that inhibit *KRAS* have not

reached the clinic. Another strategy has been to target downstream effectors of RAS, like the RAF family proteins and MEK. For instance, sorafenib—a broad-spectrum kinase inhibitor including the RAF family—led to a disease control rate of 79% in the BATTLE trial⁹⁵ among patients with either *KRAS* or *BRAF* mutations. However, these findings were not confirmed in a large phase III trial.⁹⁶ The addition of selumetinib (AZD6244), a MEK1/2 inhibitor, to docetaxel significantly improved RR and PFS in a randomized, phase II trial.⁹⁷ A phase III study evaluating this combination in patients with *KRAS*-mutant NSCLC is ongoing. Another MEK inhibitor, trametinib (GSK1120212), also showed promising results in combination with chemotherapy in early phase I/II studies.^{98,99} However, it is not clear whether these agents have a differential effectiveness according to the *KRAS* status, because similar responses have been observed in *KRAS* wild-type tumors.

The RAF proteins are serine/threonine kinases downstream of RAS, represented by three isoforms in mammals (ARAF, BRAF, and RAF1 [also known as CRAF]). BRAF is a known oncogene in lung adenocarcinoma, being mutated in approximately 3% of cases.¹⁰⁰ In contrast to melanoma, where the majority of BRAF mutations occur at valine 600 (V600E) within exon 15, V600E comprises only half of cases in lung adenocarcinoma. Interestingly, BRAF mutations are more likely to occur in former/current smokers. Dabrafenib (BRF113928)—a specific V600E BRAF inhibitor—demonstrated a promising RR of 40% in a phase II trial involving patients with lung adenocarcinoma harboring this mutation.¹⁰¹ Dramatic responses have also been reported with vemurafenib, another specific inhibitor that is U.S. Food and Drug Administration (FDA)-approved for the treatment of melanoma.¹⁰² Apart from BRAF, recurrent mutations at ARAF and RAF1 inhibitory sites were recently described in lung adenocarcinoma. Importantly, these mutations seem to be oncogenic in vitro, and may predict a response to targeted therapies, including sorafenib and MEK inhibitors.¹⁰³

MAP2K1 (also known as MEK1) is a serine/threonine kinase downstream of RAF. In NSCLC, point mutations have been identified in 1% of cases, comprising three major nucleotide substitutions (Q56P, K57N, and D67N).¹⁰⁴ These mutations tend to be nonoverlapping with other drivers and induce constitutive extracellular signal-regulated kinase (ERK) phosphorylation and cell proliferation in vitro. It is still unknown if these mutations will predict clinical benefit from anti-MEK therapies.

Another frequently altered intracellular pathway in lung cancer is PI3K-AKT-mammalian target of rapamycin (mTOR). Phosphatidylinositol 3-kinases (PI3Ks) are lipid kinases that participate in regulating cell growth, proliferation, and survival. They comprise heterodimers formed by an 85-kDa regulatory subunit and a 110-kDa catalytic subunit, the latter being encoded by *PIK3CA*. *PIK3CA* mutations have been reported in several cancer types, including a frequency of 1% to 4% in lung adenocarcinoma.^{105,106} However, a higher frequency of 16% was reported in the lung squamous section of The Cancer Genome Atlas (TCGA),¹⁰⁷ suggesting a predominance in this histologic subtype. The most common hotspots are at codons E542 and E545 in exon 9 (helical domain) and at codon H1047 in exon 20 (kinase domain). As opposed to other drivers, *PIK3CA* mutations often coexist with other oncogenic mutations in the case of lung adenocarcinoma and are not associated with smoking status.¹⁰⁸ *PIK3CA* mutations were shown to induce constitutive pathway activation and cell transformation in vitro¹⁰⁹ and have been associated with poor clinical prognosis.¹¹⁰ The best strategy to target PI3K and the population to be selected is still a matter of debate.

AKT1 is downstream of PI3K and is a member of a family of serine-threonine kinases. Recurrent mutations within the pleckstrin homology/lipid binding domain of AKT1 at E17K have been described in up to 1% of patients with lung adenocarcinoma.¹¹¹ This mutation causes constitutive activation of AKT and leads to cellular transformation in vitro and in vivo.¹¹²

Phosphatase and tensin homolog (PTEN) is a lipid/protein phosphatase that is integral to cellular processes and acts as a TSG gene by inhibiting the activity of the PI3K pathway. While germ-

line mutations in *PTEN* lead to Cowden syndrome, somatic mutations have been found in patients with lung cancer, as well as epigenetic inactivation. *PTEN* mutations may be more common in smokers and those with squamous cancer, and are also seen in patients with SCLC.¹¹³

THE TECHNOLOGY OF GENOMIC ANALYSES OF LUNG CANCER

In recent years, technologic advances have enabled the comprehensive analyses of gene expression, copy number alterations, mutations, and other genetic perturbations across a large number of tumors.¹¹⁴ In the lung cancer setting, such global approaches have led to the understanding of cancer biology and the molecular mechanisms underlying key cancer phenotypes at an unprecedented scope. More importantly, this knowledge has leveraged the identification of subsets of tumors whose biology may be affected by interventions targeted against key dysregulated genes or pathways.¹¹⁵ These efforts have been increasingly applied in individual institutions or collaborative groups as will be described.

Although direct dideoxynucleotide (ddNTP) sequencing (or Sanger sequencing) has traditionally been the gold standard for the detection of recurrent point mutations in NSCLC (like EGFR), newer methodologies have been developed that are not only less dependent on the tumor fraction in the sample, but also simultaneously determine the mutational status of many genes in a single reaction. Multiplex genotyping comprises methods such as Sequenom (Sequenom, San Diego, CA) and SNaPshot (Applied Biosystems, Foster City, CA).^{116,117} In an early report using these techniques from the Massachusetts General Hospital in 2009, at least one alteration was evident in 51% of 552 cases, and no overlap was observed among the main driver oncogenes.¹¹⁸ More recently, the Lung Cancer Mutation Consortium (LCMC)—a collaborative group that genotyped 1,000 lung adenocarcinomas in the United States—detected genetic alterations in 54% of cases, and 97% were mutually exclusive.¹¹⁹

NGS platforms, also known as massively parallel sequencing, offer a wide range of opportunities to characterize the cancer genome for DNA, mRNA, transcription factor binding sites, microRNA (miRNA), and DNA methylation patterns.^{120,121} In TCGA, 230 lung adenocarcinomas and adjacent samples were analyzed using various NGS platforms.¹²² A whole-exome approach was used in all cases, whereas whole-genome sequencing was performed in 34 samples. The authors found a very high mutation rate (median 4.56 mutations per megabase), consistent with a median of 159 mutations per tumor (range, 13 to 1,339). As demonstrated in prior experiences, this was among the highest rates in TCGA projects, only behind lung SQCC and melanoma. Somatic mutations were found in known oncogenes, like *KRAS*, *EGFR*, and *BRAF*, as well as chromatin modifiers as *ARID1A*, *SMARCA4*, and *SETD2*. A number of recurrent noncanonical mutations were documented, including a *MET* Y1003* mutation. Lung SQCC was also explored in TCGA, including 178 pairs of tumor/normal samples from patients with stages I through IV disease.¹⁰⁷ A total of 48,690 nonsilent mutations were identified through whole-exome sequencing, with a mean of 360 total exonic mutations per tumor (median, 8.4 per megabase). Ten genes were considered to harbor significant mutations, including *TP53*, *CDKN2A*, *PTEN*, *PIK3CA*, *KEAP1*, *MLL2*, *HLA-A*, *NFE2L2*, *NOTCH1*, and *RBI*. Frequent alterations were present in the following pathways: *CDKN2A/RB1* (cell cycle control), *NFE2L2/KEAP1/CUL3* (response to oxidative stress), *PI3K/AKT* (apoptotic signaling), and *SOX2/TP63/NOTCH1* (squamous differentiation). In addition, whole-transcriptome sequencing and microarray expression was carried out. The mRNA expression data clustered in four distinct subtypes named classical, basal, secretory, and primitive, which correlate with miRNA, methylation, somatic copy number alterations, and mutation spectrum.

As a more comprehensive insight into the lung cancer genome emerges, it becomes clear that its complex biology will require continuous efforts and more integrative analyses. For instance, it is

somewhat disappointing that approximately half of lung adenocarcinomas still lack a plausible target for drug development. It comes without saying that many alterations are detected in TSGs, for which no targeted therapies are available. These observations may also serve to argue that a fraction of driver mechanisms may be mediated by epigenetic or other regulatory mechanisms, as opposed to structural genomic alterations. One approach to fill this gap is the coordinated analysis of multiple types of data from large cohorts like TCGA. For example, integrating mutational data to gene expression, miRNA, or methylation profiling could potentially determine associations with particular sets of genes. Such gene sets could be subjected to computational analyses and biochemical studies to discover the biologic and clinical significance, as well as proposing alternative therapeutic strategies. The Clinical Proteomic Tumor Analysis Consortium (CPTAC) is an ongoing program that exemplifies the integration of high-throughput cancer genomics and proteomics using samples from TCGA, as well as cell lines and xenograft models.¹²³

It is also intriguing that current genomic studies rely primarily on computational approaches to identify *driver* events and distinguish them from the background of *passenger* mutations. Such analyses may be flawed not only by the relatively low sample size, but also by the filtering method on its own.^{124,125} Indeed, most comprehensive genomic studies (as previously described) included a few more than a hundred samples and are not empowered to detect rare mutations. Larger efforts will be essential to achieve a larger number of cases per cancer type, as exemplified by TCGA and the International Cancer Genome Consortium. In addition, continuously improving the accuracy of analytical methods will be key to avoid false discoveries and to avoid overlooking potential targetable alterations.

EPIGENETICS/EPIGENOME

Over the last 20 years, it has become apparent that epigenetics dysregulation is nearly universal in cancers, and specifically in lung cancer. Indeed, a recent study showed that the determination of the methylation status of a four gene panel (CDKN2A, CDH13, RASSF1A, and APC) is predictive of lymph node recurrence in stage I cancers.¹²⁶ A separate study confirmed the prognostic impact of a separate panel of methylated genes.¹²⁷ Unfortunately, despite the near universal finding of hypermethylation of tumor-relevant genes and the prognostic impact of transcriptional silencing of these genes, attempts at interfering with this epigenetic program by using hypomethylating agents (usually in conjunction with histone deacetylase inhibitors) has failed to have a dramatic impact on typical tumor response criteria, although each of these trials showed tantalizing evidence of biologic effect.^{128–130}

More recently, mutations within epigenetic modifying genes have been discovered in a variety of thoracic tumors. These include mutations within the SWI/SNF complex proteins SMARCA4/BRG1 and ARID1A.²⁴ The SWI/SNF complex is an important chromatin modeling complex that is essential in yeast and is thought to function as a tumor suppressor in many human tumors, including lung cancers. Other mutations or overexpression of other epigenetic modifiers, including histone methyltransferases, histone acetyltransferase coactivators and the histone lysine demethylase KDM2A, have been described as well.^{21,131,132} Whether these mutations or overexpression of genes act as *drivers* of oncogenesis or act as passenger mutations/alterations has not yet been clarified. Furthermore, if these findings will serve as useful predictors of response to epigenetic therapy will depend on the development of well-designed prospective biomarker-driven and/or stratified trials.

TUMOR SUPPRESSOR GENES AND GROWTH SUPPRESSION

A number of TSGs have been identified that inhibit lung tumorigenesis or suppress key phenotypes in developed lung carcinomas.

Many classical tumor suppressors have been identified by decades of work examining genes involved in human-inherited cancer syndromes and elucidating their role in sporadic cancers. Germ-line mutations in some TSGs, such as LKB1/STK11, *p53*, and *RB1*, give rise to inherited tumor syndromes; however, a somatic loss of TSGs within sporadic cancers is more commonly seen, including *p53*, *PTEN*, *CDKN2A* (encoding both *p16^{INK4A}* and *p14^{ARF}*), *ATM*, *NF1*, *RB1*, and *APC*. These have all been found to be mutated or lost in lung cancer through multiple mechanisms, such as inactivating mutations, chromosomal loss, methylation, or overexpression of other proteins that inhibit the suppressive gene's expression or activity.^{23,24} We discuss several of the most frequently lost TSGs in the following paragraphs.

p53 Pathway

The *p53* gene, located at chromosome 17p13, is crucial for maintaining genomic integrity in the face of cellular stress from DNA damage through gamma and ultraviolet irradiation, carcinogens, and chemotherapy. It is the most frequently mutated TSG in human malignancies, and mutations affect approximately 90% of SCLCs and >50% of NSCLCs. In NSCLCs, *p53* alterations occur more frequently in SQCC (81%) than adenocarcinomas (~50%).^{21,22,24} *p53* mutations have been linked to poorer prognosis retrospectively and in the TCGA Pan-Cancer analysis; however, they have not been shown to correlate with survival in a prospective randomized clinical trial.^{133,134} Most *p53* mutations are G→T transversions, which correlate with cigarette smoking.² The Li-Fraumeni syndrome of inherited germline *p53* mutation may also lead to increased susceptibility to lung cancer in adults; this risk is magnified by tobacco smoking, because carriers who smoked had a 3.16-fold higher risk for lung cancer than nonsmokers.¹³⁵ The majority of missense mutations occur in the DNA-binding domain of the protein, and five of the six most prevalently mutated sites are arginine residues that are involved with electrostatic interactions with DNA strands.¹³⁶ Missense mutations prolong the half-life of the *p53* protein, leading to increased protein levels detectable with immunohistochemistry. Also, because *p53* exerts its cellular actions as a tetramer, mutant forms of the protein appear to exert dominant negative effects on wild-type *p53* and have also been shown to inhibit the function of *p63* and *p73* family members.¹³⁷

In addition to mutational or deletional loss of *p53*, other regulatory components of the *p53* pathway are altered in lung cancer, including the *ATM* gene, the *p53* binding protein MDM2, and the *p14^{ARF}* tumor suppressor. *ATM* and the related protein *ATR* are tumor-suppressive serine/threonine kinases that activate cell cycle checkpoints in response to DNA damage and, ultimately, activate and stabilize *p53*.¹³⁸ Although *ATR* and the downstream checkpoint kinases (*CHEK*) are mutated in less than 1% of lung adenocarcinomas, *ATM* has been found to have deleterious mutations in 7% of lung adenocarcinomas. These mutations were largely mutually exclusive with *p53* mutations, likely indicating that mutations in both genes would have redundant effects, especially because it has been shown that gain-of-function mutations in *p53* can inactivate *ATM*.^{139,140} Conversely, the MDM2 E3 ubiquitin ligase negatively regulates *p53* by binding its transcriptional activation domain, inducing its nuclear export, and by polyubiquitinating *p53*, marking it for proteasomal degradation.¹⁴¹ Abnormal overexpression of MDM2 is found in NSCLC, where it is amplified in a significant number of tumors. MDM2 activity is inhibited by other tumor suppressor genes in the *p53* pathway, including *ATM* and also the *p14^{ARF}* tumor suppressor gene.¹⁴²

When *p53* is functional, it is activated by phosphorylation in response to cellular stress (e.g., DNA damage). Once activated, *p53* strongly induces the expression of other tumor suppressor genes that control cell cycle checkpoints (e.g., *p21^{WAF1/CIP1}*), apoptosis (*BAX*), DNA repair (*GADD45*), and angiogenesis (thrombospondin).¹⁴³ *p53* activation has also been found to alter miRNA expression and maturation.^{144,145} The high frequency of *p53* loss across

the entire spectrum of human tumors is a strong testament to its importance in inhibiting tumor development and growth. Restoring p53 activity in tumors is effective at halting their growth and could represent an effective therapy, although development of this strategy is challenging.¹⁴⁶ Several gene therapy clinical trials have been reported in which lung cancers are treated by an intratumoral injection introducing a wild-type p53 gene using retroviral or adenoviral vectors.¹⁴⁷ Other strategies have been developed to restore p53 activity without attempting to reintroduce the entire gene into tumor cells.^{148,149} The vaccination of patients with advanced cancer with a custom vaccine corresponding to their tumor's mutation in p53 or RAS has demonstrated the generation of mutant oncogene-specific immune responses associated with prolonged survival.¹⁵⁰ A trial of p53 vaccination in SCLCs produced measurable increases in tumor-specific immune response that was associated with improved outcome and response to therapy in some patients.^{151,152}

CYCLINS AND CELL CYCLE REGULATORY PATHWAYS

p16^{INK4A} is a cyclin-dependent kinase (CDK) inhibitor important for the integrity of the G1 checkpoint. Loss of p16^{INK4A} frees CDKs from inhibition, permitting constitutive phosphorylation of retinoblastoma (RB) protein and inactivation of its growth suppressive function. Approximately 40% of primary NSCLCs lose p16^{INK4A}, located on chromosome 9p21, making it the most common component of the p16^{INK4A}-cyclin D1-CDK4-RB pathway to be inactivated in NSCLC. Other CDK inhibitors are also lost at a lower prevalence in NSCLC, and the RB gene is mutated or lost in a significant minority of cases.¹⁵³ In contrast, a strikingly different pattern of pathway dysregulation is observed in SCLCs, in which abnormalities in p16 are rarely observed, but RB itself is nearly always abnormal. Although p16^{INK4A} point mutations in NSCLCs were observed in only 14% of tumors, homozygous deletions or aberrant promoter methylation are common mechanisms for p16^{INK4A} inactivation.²⁰ Indeed, aberrant p16^{INK4A} methylation is a frequent, early preneoplastic event in the pathogenesis of SQCC.¹⁵⁴ Furthermore, p16^{INK4A} and p14^{ARF} are alternative splice forms of RNA transcripts from the same DNA locus. p14^{ARF} is also a tumor suppressor gene and functions to stabilize p53. Thus, alteration at the p16^{INK4A} locus may not only abrogate p16^{INK4A} function but also disrupt p53 pathway through p14^{ARF}.¹⁵⁵

In the absence of inhibitory regulation by the CDK inhibitors, cyclins, and their catalytic partners, the CDKs phosphorylate the retinoblastoma protein, a growth-suppressive nuclear phosphoprotein located on chromosomal region 13q14. When in its active, unphosphorylated form, RB binds and inactivates proteins such as transcription factor E2F-1, preventing G1/S transition. The RB protein is absent or structurally abnormal in more than 90% of SCLCs and 15% to 30% of NSCLCs. Lung-targeted, conditional deletion of RB and p53 in mice leads to the development of SCLC that recapitulate that observed in humans.¹⁵⁶ Although the p16 and RB tumor-suppressive components of this pathway are frequently lost in lung cancer, the growth promoting cyclin and CDK components of the pathway are often overexpressed, and cyclin D1, cyclin E1, and CDK4 have each been shown to be amplified in a subset of lung cancers¹⁵⁷ and are overexpressed by immunohistochemical evaluation.

LKB1, AMPK, AND MTOR PATHWAY

LKB1 is a serine/threonine kinase that serves as a *master regulator* of several key intracellular pathways through phosphorylation of downstream regulatory kinases. Its tumor-suppressive role became apparent when it was discovered that inherited mutations in LKB1 gave rise to a rare autosomal-dominant polyposis/cancer susceptibility disease, Peutz-Jeghers syndrome.^{158,159} Subsequent to this

discovery it was found that LKB1 is somatically mutated and deleted in a range of other carcinomas, most prevalently in NSCLC, where approximately 20% to 30% of adenocarcinomas exhibit LKB1 loss.¹⁶⁰⁻¹⁶² SQCCs and large cell lung carcinomas also exhibit LKB1 loss but at a lower frequency, and an immunohistochemical analysis revealed absent LKB1 expression in two-thirds of SCLCs.¹⁶³ In a mouse model, tumors rapidly develop when conditional LKB1 knockout was combined with conditional expression of oncogenic KRAS using inhaled adenovirus-expressing Cre recombinase. Additionally, whereas most other mouse models of lung tumorigenesis (e.g., oncogenic KRAS with conditional p53 deletion) cause only lung adenocarcinomas, more than half of the tumors resulting from KRAS with conditional LKB1 deletion showed squamous or mixed histology, and large cell histology was also observed.¹⁶¹ LKB1 regulates a key metabolic checkpoint through its phosphorylation of the AMP-activated protein kinase AMPK. Phosphorylation of AMPK results in the suppression of tumor growth and metabolic activity by direct phosphorylation of metabolic enzymes and by activation of the tuberous sclerosis complex tumor suppressors, which block activation of the mTOR pathway.¹⁶⁴ In tumors that have lost LKB1, this growth-suppressive checkpoint is inactivated.^{165,166} Metformin, an oral hypoglycemic drug commonly used in diabetics, activates AMPK and has been found to inhibit proliferation and colony formation in vitro.¹⁶⁷ Retrospective analyses demonstrate reduced incidence of cancer among diabetics treated with metformin.¹⁶⁸⁻¹⁷⁰ In addition, metformin treatment of diabetics is associated with higher rates of complete response among neoadjuvantly treated breast cancer patients.¹⁷¹ Although metformin appears to require functional LKB1 in order to effect AMPK activation, other compounds have been identified that circumvent this requirement. Thus, direct pharmacologic reactivation of the downstream tumor-suppressive functions of AMPK may be a viable therapeutic strategy for LKB1-deficient tumors. In addition to its role in regulating the AMPK metabolic checkpoint, LKB1 has many other distinct roles dependent on other downstream effector kinases, such as salt-inducible kinase, NUA1, and microtubule-affinity regulating kinase. These actions play a role in regulating a variety of cellular phenotypes important to cancer, such as cellular motility and transcriptional regulation, and LKB1 has been shown to exert profound effects in maintaining cellular polarity.^{172,173} However, the relative importance of these various phenotypes in the biology of LKB1-deficient lung cancers is poorly understood.

OTHER PUTATIVE TUMOR SUPPRESSORS

Several other genes that are less well characterized than the tumor suppressor genes detailed previously have been identified as targets of recurrent mutational inactivation, chromosomal loss, and epigenetic repression in lung cancer. These candidate suppressor genes are often identified as regions of copy number loss or loss of heterozygosity (LOH) that occur in multiple tumors in large, genomewide studies of chromosomal architecture in lung cancer. Further experimentation is required to elucidate which molecular pathways and cellular phenotypes are affected and to define the functional importance of these candidates. Common regions of genomic loss surround the chromosomal regions of classical tumor suppressors CDKN2A, CDKN2B, LKB1, and RB1 (in small cell lung cancer). Other areas of recurrent loss in NSCLC occur at 9p23, 3p14.2, 3p21.3, 16q23.1, 2q21.2, 4q35, 5q12.1, and 13q12.11.¹⁵⁷ Many of these regions are also altered in SCLC, although there are fewer data available for this tumor type. Determining the functional roles of each individual gene can be challenging. Of genes included in the regions listed previously, missense mutations have been identified in PTPRD (9p23), LRP1B (2q21.2), BLU (3p21.3), and WWOX (16q23.1).^{174,175} Experimental reexpression of candidate genes has been shown to inhibit proliferation in tumor cell lines for many of these putative tumor suppressors,

including PTPRD, LRP1B, WWOX (16q23.1), FHIT (3p14.2), SMARCA4 (19p13.2), PTEN (10q23), and RASSF1, FUS1, BLU, and SEMA3B (3p21.3).^{176,177} However, for most of these candidates, the biologic implications of gene loss in a tumor is uncertain.

Immune Checkpoint Inhibitors

Immune checkpoint inhibitors have recently demonstrated promising results in lung cancer patients. In particular, inhibitors to cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) and programmed death 1 (PD-1) and programmed death receptor ligand 1 (PD-L1) are currently in clinical trials in both small cell and non-small-cell lung cancer patients. CTLA-4 is expressed on T cells and suppresses T-cell signaling.¹⁷⁸ Ipilimumab is a monoclonal antibody that inhibits CTLA-4 and is FDA approved for the treatment of melanoma. Randomized phase II trials in small cell and non-small-cell lung cancer patients demonstrated promising results when ipilimumab was combined with chemotherapy.^{179,180} Randomized phase III trials in SCLCs and NSCLCs are ongoing. Antibodies that block PD-1 include nivolumab (BMS-936558) and MK3475. These agents inhibit binding of PD-1 to both its ligands, PD-L1 and PD-L2. Antibodies that block PD-L1 include MPDL3280A and MEDI-4736. These agents inhibit binding of the ligand to its receptor PD-1 and B7.1. A large phase I trial of nivolumab included 129 NSCLC patients and reported a 17.1% response rate, 1-year survival of 42%, and 2-year survival of 24%.^{181,182} Based on this promising data, two randomized phase III trials in squamous and nonsquamous NSCLC patients and a single-arm phase II trial in squamous NSCLC patients have been completed with results anticipated. In patients with tumor samples available for assessment, PD-L1 expression by immunohistochemistry was associated with a response to therapy, whereas no response was observed in patients with tumors that were PD-L1 negative.¹⁸¹ A phase I trial that included 85 NSCLC patients treated with MPDL3280A reported a response rate of 23%.¹⁸³ Preliminary data reported that the response rate was higher in tumors that were IHC3 positive (83%), defined as 10% of tumors staining positive for the expression of PD-L1, and in smokers. Although anti-CTLA-4 antibodies are being employed with chemotherapy in lung cancer patients, single agent data with anti-PD-1 and PD-L1 antibodies appears promising, and it is unclear if these agents should be used alone or in combination with chemotherapy or targeted therapy in lung cancer patients.

OTHER BIOLOGIC ABNORMALITIES IN LUNG CANCER

Cellular Immortality Resulting from Increased Telomerase Activity

Cellular senescence is mainly regulated by telomerase, a ribonucleoprotein enzyme responsible for maintaining telomere length by de novo synthesis of telomeres and elongation of existing telomeres. The human telomerase reverse transcriptase (hTERT) catalytic subunit is the major determinant of telomerase activity in vitro and in vivo. During normal cell division, telomere shortening leads to cell senescence and thus governs normal cell mortality. TERT maintains telomere ends via the synthesis of TTAGG nucleotide repeats. Telomerase activation is considered mandatory for tumor cells to escape senescence and contributes to immortalization and cancer pathogenesis. For example, immortalization of primary human airway epithelial cells can be achieved by the successive introduction of the simian virus SV40 early region and hTERT.¹⁸⁴ Malignant transformation is seen when these immortalized cells are transfected by an activated RAS oncogene. Approximately 100% of SCLCs and 80% to 85% of NSCLCs have been demonstrated to express high levels of telomerase activity.

Furthermore, hTERT gene amplification occurs in 57% of NSCLCs, suggesting that this pathway is commonly targeted in lung cancer.¹⁸⁵ The prognostic significance of hTERT expression or activity remains controversial, although a recent study demonstrated that the copy number of serum hTERT mRNA was independently correlated with tumor size, tumor number, presence of metastasis, likelihood of recurrence, and smoking.¹⁸⁶ Furthermore, elevated telomerase activity and hTERT levels have been associated with worse DFS and overall survival in patients with stage I NSCLC.¹⁸⁷ In preneoplastic lesions, telomerase activity or expression of its RNA component, or both, are observed in situ in lesions with the expression proportional to the severity of histology grade, supporting a temporal role for telomerase activation during lung preneoplasia.¹⁸⁸ Thus, telomerase activity or expression can be used as a potential biomarker to detect premalignant as well as tumor cells. For these reasons, there is much interest in developing antitelomerase drugs as new therapeutics.^{189,190}

Deregulation of Apoptosis

Loss of normal apoptosis commonly occurs in many cancer types and is associated with the expansion of viable cells and the development of resistance to chemotherapy and radiation therapy. Many members of both the mitochondrial (intrinsic) and the death receptor (extrinsic) apoptotic signaling pathways are found to be abnormal in lung cancer. A member of the intrinsic pathway, the antiapoptotic gene BCL2 originally described in follicular lymphomas, is abnormally overexpressed in SCLCs (75% to 95%) and some NSCLCs (25% of SQCC and approximately 10% of adenocarcinoma) and is the prototypical member of the antiapoptotic Bcl2 family proteins.¹⁹¹⁻¹⁹³ BCL-2 expression is associated with good prognosis in NSCLCs.¹⁹⁴ Cytotoxicity of many chemotherapeutic agents is induced through the Bcl-2 apoptotic pathway; overexpression of Bcl-2 is associated with increased resistance to these agents.^{195,196} Other prosurvival Bcl-2 family members include Bcl-xL, Bcl-w, and Mcl-1. Conversely, a number of Bcl-2 family members have proapoptotic functions, including Bim, Bak, Bax, Bad, and Puma. Given the role of Bcl-2 and other members of this family in suppressing apoptosis and in reducing the efficacy of chemotherapy and radiotherapy, considerable effort is being made to develop Bcl-2 family targeted therapeutics in combination with chemotherapy.

In the extrinsic apoptotic pathway, death receptors are members of the tumor necrosis factor (TNF)/TRAIL receptor gene superfamily that consists of more than 20 proteins with a broad range of biologic functions, including regulation of cell death and survival, differentiation, or immune regulation. The best-characterized death receptor, Fas (CD95), and its ligand, FasL, have also been implicated in lung cancer. In general, lung cancers express FasL but not the receptor. However, as T cells express Fas, one model that may help explain the resistance of lung cancer cells to immune surveillance involves the clonal deletion of immune T cells that would otherwise be directed against lung cancer antigens by this Fas-FasL interaction. Both caspase-8 and caspase-10 expression appears to be decreased in lung cancer. Homozygous deletion or methylation of the CASP8 gene has been observed in SCLC cell lines, with 79% demonstrating loss of expression, suggesting that therapies that utilize the TNF/TRAIL receptor pathway of apoptotic activation may not achieve success in SCLC due to the impaired formation of the death-inducing signaling complex (DISC).¹⁹⁷ Of note, TRAIL-induced apoptosis is independent of p53 gene status. Conversely, because NSCLC has high rates of p53 inactivation (but predominantly intact caspase 8 pathways) and high levels of TRAIL receptor expression, this mode of therapy may prove beneficial. Polymorphisms in the promoter region of caspase-9 have been shown to contribute to risk of lung cancer development.¹⁹⁸

Another family of proteins that promote tumor survival are the inhibitors of apoptosis (IAP), which bind to and block caspase

function, especially caspase-3 and -7. IAPs also inhibit apoptosis via the modulation of the transcription of nuclear factor κ B (NF- κ B). In addition to X-linked inhibitor of apoptosis protein (XIAP), one of the best-known members of this class of protein is survivin. Its expression is high in the tumor but nearly nonexistent in adult normal tissue, and higher expression has been correlated with poor outcomes in NSCLCs.^{199,200} The suppression of survivin has been shown to sensitize lung cancer cells to radiation, suggesting that it can be a potential target for intervention.²⁰¹ During the activation of apoptosis, another class of proteins called Smac proteins are released from the mitochondria and neutralize IAPs, by competing with caspases for the binding of IAPs. Bcl-2 family inhibitors, TRAIL receptor agonists, Smac mimetics, and IAP inhibitors are currently undergoing clinical testing as agents that sensitize lung tumor cells to chemotherapy and radiation in order to promote apoptosis.²⁰²

microRNAS IN LUNG CANCER DIAGNOSTICS AND THERAPY

Approximately 2 decades ago, investigators made the startling discovery that components of the human genome, previously considered to be nonfunctional, actually harbored noncoding RNAs (ncRNAs) with gene regulatory properties.^{203,204} Termed microRNAs (miRNAs or miRs), these 22 nucleotide ncRNAs are now known to be highly conserved, are often localized within fragile chromosomal regions and have the capacity for gene regulation through either mRNA degradation or the inhibition of translation.²⁰⁵ Given their relative short length and redundancy, it is estimated that miRNAs may regulate up to 60% of the human genome. miRNAs have been implicated as regulators of biologic processes fundamental to both the initiation and progression of cancer (differentiation, proliferation, angiogenesis).^{206,207} The mechanisms of change in miRNA expression in

cancers are multifactorial. First, miRNAs tend to be localized to fragile chromosomal regions. Such chromosomal regions harbor amplifications, deletions, and translocations, many of which have been described in lung cancers.²⁰⁸ Thus, in some cases, patterns of miRNA deregulation may be linked to chromosomal aberrations. Changes in miRNA expression and function may also be driven by epigenetic changes, miRNA or target polymorphisms, environmental stimuli (e.g., cigarette smoke), and either tumor suppressors or oncogenes (e.g., p53).^{209,210} Although the function of many miRNAs remains largely unknown, research suggests that miRNA function is both disease and cell specific.

microRNA Biogenesis

The process of miRNA biogenesis is a complex one and investigators continue to explore the mechanisms that drive miRNA production (Fig. 40.2). Initially, a long primary transcript (pri)-miRNA transcript undergoes transcription by RNA polymerase II.²¹¹ The pri-miRNAs are then bound to the double-stranded RNA-binding domain (dsRBD) protein known as DiGeorge syndrome critical region gene 8 (DGCR8) for vertebrates.²¹² Subsequently, the RNase III endonuclease termed RNASEN/Drosha converts the pri-miRNA to a smaller stem-loop ~70 nucleotide (nt) precursor miRNA (pre-miRNA). These pre-miRNAs are then transported from the nucleus to the cytoplasm using the dsRBD, Exportin 5.²¹³ Once in the cytoplasm, the pre-miRNA is cleaved to a mature 18 to 25 nucleotide miRNA using Dicer. The mature miRNA sequence is then loaded into the RNA-induced silencing complex (RISC) complex after which it may then form complementarity to either the 3' or 5' untranslated region (UTR) of a target gene to induce either RNA degradation or the inhibition of translation. It is important to recognize that investigators have now identified

Figure 40.2 microRNA (miRNA) biogenesis.

additional mechanisms for miRNA biogenesis, suggesting that we are just beginning to understand the complexities of this process.

miRNA PROFILING IN LUNG CANCER

Early investigations in lung cancer have focused on applying high throughput platforms as a means for linking patterns of miRNA deregulation to clinical parameters. Of note, targeted the disruption of miRNA processing through the targeting of Dicer can promote lung tumorigenesis and has been associated with clinical outcome.²¹⁴ Yanaihara and colleagues²¹⁵ conducted high throughput profiling of cases of stage I adenocarcinoma of the lung. They identified over 40 miRNAs that distinguished lung tumors from adjacent uninvolved lung.²¹⁵ Of these miRNAs, decreased Let-7a-2 and increased miR-155 appeared to correlate with patient outcome. Because of that initial study, investigators have conducted multiple similar studies with the primary goals of identifying a prognostic miRNA signature^{216–218} and potentially actionable miRNAs.²¹⁸

Despite the multitude of miRNA profiling studies, investigators have yet to reach a consensus on which miRNAs confer the most accurate prognostic information. A primary reason for the lack of reproducibility is that, similar to other high throughput platforms, miRNA profiling studies are susceptible certain biases including small cohort sizes, varying platforms (array, sequencing, RT-PCR), and variability in data interpretation. In addition, most platforms are based on previously identified miRNAs. A recent study by Keller and colleagues²¹⁹ sought to use NGS to identify both previously unknown and novel mature forms of miRNAs. The authors conducted NGS on peripheral whole blood obtained from 10 patients with NSCLCs (stages IA through IIIA) and 10 healthy control patients. They identified 32 known and 7 novel miRNAs that were significantly altered in patients with lung cancer. In addition, they identified 41 novel mature forms of previously identified precursors and 76 novel miRNAs, thus suggesting that we have yet to identify all miRNAs that may be of potential clinical and biologic relevance.

miRNAs and Mutational Status in Lung Cancer

The identification of actionable somatic mutations such as EGFR and ALK has markedly altered clinical practice in lung cancer. Few studies have correlated lung tumor mutational status with miRNA deregulation. Dacic and colleagues²²⁰ examined EGFR-mutated, KRAS-mutated, and double-negative lung tumors for miRNA expression and identified few mutation-specific miRNAs. miR-155 was upregulated in double negative lung tumors, whereas miR-495 was upregulated only in KRAS-positive tumors and miR-25 was upregulated only in EGFR-mutated tumors. miRNAs have been implicated as drivers of both EGFR sensitivity and resistance. For example, Garofalo and colleagues²²¹ demonstrated that deregulation of select miRNAs miR-30b, miR-30c, miR-221/222, miR103, and miR-203 contributed to both *in vitro* and *in vivo* sensitivity of NSCLC to gefitinib.²²¹ Several miRNAs, including miR-128b, miR-7, and miR-145, have been validated as directly targeting EGFR.^{222–224} In the case of miR-7, investigators determined both *in vitro* and *in vivo* that EGFR signaling was mediated in part by miR-7 induction in a Ras/ERK/Myc dependent manner.²²⁵ Conversely, liposomal-mediated delivery of miR-7 has been shown to overcome EGFR resistance in T790M-mutated lung cancer cell lines.²²⁶

Integrating miRNAs into Clinical Decision Making in Lung Cancer

Although significant progress has been made in miRNA discovery, few miRNAs have reached clinical application in human disease; however, two recent discoveries have led to the application

of miRNAs as directed therapeutics. The first involves the directed targeting of miR-122 as a therapeutic in hepatitis C, whereas the other study, which is much earlier in development, involves supplemental replacement of the tumor suppressor miRNA miR-34 in the setting of hepatocellular carcinoma or solid malignancies that have metastasized to the liver.^{227,228} No such studies have reached clinical application in lung cancer; however, ongoing investigation suggests that miRNA signatures may be of value in both diagnostic and therapeutic decision making. In particular, investigators are exploring the potential for miRNA signatures in the settings of indeterminate lung nodules and early detection, histologic classification, and chemotherapeutic response, each of which can present clinical challenges. Schembri and colleagues²²⁹ demonstrated that the human airway epithelium was susceptible to changes in miRNA expression following cigarette smoke exposure. They identified 28 miRNAs that were differentially expressed in airway epithelium from current and never smokers. One particular miRNA was miR-218, which was downregulated in smokers. Since that initial finding, studies have demonstrated downregulation of miR-218 in SQCC of the lung.²³⁰ Few studies to date have identified a miRNA signature for solitary lung nodules.²³¹ The concept of integrating miRNA profiling in lung cancer early detection is an intriguing one. Using cohorts drawn from a longitudinal lung cancer screening trial, Boeri and colleagues²³² tested and identified plasma-based miRNA signatures that could predict the risk for the development of lung cancer, diagnosis, and prognosis.

Another potential area for integration for miRNA biology into the clinic is in the setting of determining chemotherapeutic response. Several studies have been conducted using miRNAs to distinguish chemosensitive from chemoresistant tumors.^{34,221,233,234}

Noninvasive miRNA Detection

There have been numerous studies exploring potential noninvasive biomarkers in lung cancer. These biomarkers have included circulating DNA, transcripts, select proteins, cytokines, and angiogenic factors. Despite such exciting studies, a lack of reproducibility and a lack absence of mechanistic insight have limited the clinical impact. Recently, investigators demonstrated the utility of sputum miRNA in the early detection of lung cancer. Using a training set of 154 patients (66 with lung cancer and 68 controls) and a test set of 64 lung cancer patients and 73 smoking controls, Shen and colleagues²³⁵ showed that sputum levels of miR-31 and miR-210 had a sensitivity of 65.2% and a specificity of 89.7% in diagnosing lung cancer. Interestingly, when combined with a computed tomography (CT) scan, the resultant specificity was higher than with a CT scan alone.²³⁵ An independent study identified sputum miR-205, miR-210, and miR-708 as potential diagnostic biomarkers in early stage lung cancer.²³⁶

Investigators recognize that components of the lung tumor microenvironment, including endothelial cells, macrophages, and fibroblasts to name a few, each harbor distinct biologic programs that drive cross-talk with the primary tumor, thus fostering tumor progression. Although several mechanisms that underlie this exchange of information have been proposed and explored, there are likely to be many others. Although multiple gain of function and silencing studies have shed light on the multitude of intracellular physiologic functions of miRNAs, few have truly explored the manner by which miRNAs may carry genetic information and programming between cells and their environment. Recently, investigators have demonstrated that miRNAs may circulate both freely attached to select proteins (e.g., Ago) or lipids and packaged within extracellular vesicles (EV), including exosomes, apoptotic bodies, and microvesicles (Fig. 40.3). The concept of *packaged* miRNAs is particularly intriguing as a mechanism for the intercellular transfer of genetic material.²³⁷ These paradigm-shifting discoveries have led to an intense investigation for novel mechanisms by which circulating miRNA may serve as mediators of intercellular communication. However, several unanswered questions remain, including defining the distribution and mechanism by which miRNAs are processed

Figure 40.3 Extracellular vesicles.

for cellular release, how they are packaged into EVs versus being bound to molecules, and ultimately, their biologic function in circulation. To date, some studies suggest that the majority of circulating miRNAs are not associated with exosomes but rather are bound to select proteins.²³⁸ Surprisingly, very few studies have examined the clinical and biologic role for extracellular miRNAs in lung cancer. Although the majority of studies to date have focused on linking global expression patterns of miRNAs in blood or other bodily fluids to clinical parameters, the reproducibility of signatures has been limited by variability in the compartment analyzed (whole blood, peripheral blood mononuclear cells [PBMC], serum, or plasma) and low cohort numbers. Identifying the *lung cancer signature* within these compartments is a major challenge.

Very few studies to date have examined for the presence of miRNAs in the circulation as either diagnostic or prognostic biomarkers in lung cancer. The earliest studies to examine miRNAs in the circulation were focused on merely providing scientific feasibility for the presence of miRNAs in the circulation. Studies have targeted whole blood, peripheral mononuclear cells, and plasma with no clearly reproducible signature.^{147,148,150}

INVASION, METASTASIS, AND ANGIOGENESIS

An investigation of the molecular mechanisms of invasion and metastasis has yielded a variety of candidate genes, including cell adhesion molecules such as the cadherins, integrins, and CD44. The E-cadherin–catenin complex is critical for intercellular adhesiveness and the maintenance of normal and malignant tissue

architecture. Epigenetically reduced expression of this complex in malignant disease is associated with tumor invasion, metastasis, and unfavorable prognosis in lung cancer. Another family of adhesion molecules are the integrins. α_3 Integrin has been shown to be important for normal lung development, and diminished expression correlated with a poor prognosis for patients with lung adenocarcinoma. Specific isoforms of CD44 may also be associated with lung cancer metastasis. Matrix metalloproteinases (MMP) are zinc-dependent proteases that belong to a family of endopeptidases, which degrade the extracellular matrix and basement membrane, necessary first steps in angiogenesis. The increased expression of MMPs has been strongly implicated in tumor growth, invasion, and metastasis. MMP2 and MMP9 have been associated with poorer prognosis. However, despite its established role in invasion and metastasis, many randomized phase III trials of MMP inhibitors have failed to demonstrate a survival benefit in patients with advanced lung cancer.²³⁹ This is perhaps related to the lack of specificity of these inhibitors and recent findings that some MMPs actually inhibit tumor growth.²⁴⁰ The stimuli that regulate tumor cell invasiveness are often generated or influenced by surrounding stromal or inflammatory cells and, as such, the invasive phenotype seems to be quite plastic, complex, and highly dependent on the context of the tumor microenvironment.²⁴¹

Angiogenesis, the formation of new blood capillaries, is necessary for a tumor mass to grow beyond a few millimeters in size. The angiogenic switch results from perturbation in the balance between inducers and inhibitors, both of which are produced by tumor and host cells. Vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and angiogenic cytokines, such as interleukin-8, have all been implicated in lung cancer.²⁴²

Furthermore, high microvessel density (MVD) and VEGF overexpression are predictive of poor outcome. Thus, tumor angiogenesis has become a major new therapeutic target for lung cancer.²⁴³ Clinical trials in NSCLC with bevacizumab, the humanized monoclonal antibody to VEGF, to chemotherapy prolongs PFS in phase III clinical trials, although improvements in overall survival were not always observed.^{244–246}

CANCER STEM CELL HYPOTHESIS

The cancer stem cell hypothesis proposes that a self-renewing undifferentiated stem cell population comprising a small fraction of the total tumor burden gives rise to more numerous and more differentiated progeny that populate the tumor.²⁴⁷ Among the characteristics reported to distinguish stemlike cells from cells constituting the bulk of tumors include the potential for supporting the continued growth of the local tumor mass, for seeding metastases throughout the body, and a resistance to cytotoxic therapies allowing the residual viable stem cells to repopulate the tumor after treatment. Because of their resistance to treatment and the potential for seeding distant metastatic disease, the study of cancer stem cells and the development of strategies effectively to eradicate all residual stem cells is of critical importance in cancer treatment.

Cancer stemlike cells can be isolated from a variety of tumor types using antibodies to unique cell surface proteins. They are capable of forming xenograft tumors at a high frequency after injection into immunocompromised mice. Empirically selected surface markers have been used to isolate putative stem cells from human breast cancer, glioblastoma multiforme, colon cancer, and other carcinomas, and these cells have a demonstrably greater potential for xenograft formation than do unselected tumor cells. The resulting tumors recapitulate the histologic appearance of the primary tumor as well as the heterogeneous expression of various surface and intracellular molecular markers.²⁴⁷

Putative lung progenitor cells have been described as cells residing at the bronchoalveolar duct junction that express both clara cell and pneumocyte markers or as lung resident cells of hematopoietic origin that express CD133.^{248,249} These cells have not been conclusively shown to be lung adult stem cell populations but are intriguing and have been shown to be involved in the repair of lung tissue after injury and may be involved in cancer development. In lung tumors, CD133^{250–253} and other commonly used markers of stemlike tumor cells (Hoechst dye efflux and aldehyde dehydrogenase activity)²⁵⁴ have been shown to identify subsets of tumor cells that display characteristics consistent with the cancer stem cell hypothesis. CD133 has been shown to segregate with template DNA in lung cells undergoing asymmetric cell division.²⁵⁵ However, conflicting reports suggest that CD133 may not define a specific subset of cells, because interconversion between CD133+ and CD133– populations is observed and CD133 expression may be associated with specific stages of cell cycle progression²⁵⁶; furthermore, some studies show no association between CD133 expression and propensity to initiate tumors.²⁵⁷ The cancer stem cell hypothesis has other important grey areas as well. It is not yet certain whether a consistent developmental hierarchy would exist for every individual tumor or only in certain cases, whether lineage differentiation in a tumor can be reversible, and which basic properties should be required to define a stemlike phenotype in a given population of cells. A highly increased propensity for xenograft formation is one of the most convincing features that can be demonstrated experimentally for proposed cancer stemlike cells. However, even the reliability of this evidence is called into question by the observation that a much higher rate of tumor formation is observed when mouse tumor lines are propagated in isogenic immunocompetent mice, which raises the possibility that the xenograft initiation phenotype may be related to the ability to adapt to the tissue environment of an immunocompromised mouse, rather than a general property of enhanced tumor formation.²⁵⁸

Nevertheless, the balance of evidence from diverse tumor types favors the hypothesis that stemlike cells are present within tumors and may play a key role in certain aspects of tumor biology. Furthermore, developmental pathways that are proposed to be important in governing cancer stem cell biology may be important oncogenic drivers of proliferation and invasion for unselected tumor cell populations in certain subsets of tumors, and are important avenues of research in their own right. For instance, the activity of particular genes—achaete-scute complex homolog 1²⁵³ and OCT4 transcription factors²⁵¹—have been implicated in regulating this subset of lung tumor cells.

Recent studies have defined aldehyde dehydrogenase (ALDH) activity as a robust marker for lung adenocarcinoma stemlike cells.²⁵⁹ ALDH-positive cells are highly tumorigenic and clonogenic as well as capable of self-renewal compared to the ALDH subpopulation. This subset and its behavior was shown to be dependent on Notch activity, specifically NOTCH3. The expression of ALDH7A1 was associated with increased risk of recurrence after surgical resection.²⁶⁰

Given the far-reaching implications of the cancer stem cell hypothesis and especially the concept that targeting developmental pathways cancer stem cells or, in particular, subsets of cancer could represent an important therapeutic strategy, these complex and exciting areas warrant further study in lung cancer.

MOLECULAR TOOLS IN THE LUNG CANCER CLINIC

Our understanding of the molecular genetic changes in lung cancer pathogenesis is advancing rapidly. Many genetic abnormalities identified in lung cancer are common to other human cancers, whereas others appear more specific to lung cancer, perhaps because of characteristics of the cells of origin and the unique nature of carcinogen exposure. Where their biochemical function is known, the proteins rendered abnormal appear to fall into several growth regulatory pathways.²⁶¹ Thus, our understanding of the fundamental workings and diverse molecular drivers of lung cancer is becoming clearer. A substantial effort has been made to translate the current scientific knowledge of these abnormalities from the bench to the bedside in order to improve patient outcomes. These approaches fall into three general categories:

- Development of early detection tools to identify primary and recurrent disease to enable effective early treatment. Because lung cancer eventually develops in only 1 of 10 cigarette smokers, the identification of persons with a genetic susceptibility to lung cancer should allow for targeting and the intensification of smoking cessation, early detection, and chemoprevention efforts. The National Lung Cancer Screening Trial (NLST)²⁶² randomized patients at high risk for developing lung cancer, defined as individuals between 55 and 74 years of age with a =30 pack-years history of cigarette smoking; former smokers must have quit within the previous 15 years. There was a 20% reduction in lung cancer mortality in the LDCT screened population (95% confidence interval [CI], 6.8% to 26.7%; $p = 0.004$). Based on this data, the U.S. Preventive Services Task Force has recommended annual CT screening for these high-risk patients. The high false-positive rate and the fact that many lung cancers arise in patients who do not meet these eligibility criteria stress the need for developing diagnostic biomarkers to aid in defining an appropriate management of CT-detected nodules and biomarkers of risk for better defining the population who would benefit from screening, including, potentially, germ line T790M.
- Development of new cancer-specific therapies based on knowledge of genetic abnormalities. These may include replacing or pharmacologically reactivating mutant tumor suppressor genes, developing new drugs targeting activated proto-oncogenes,

interfering with autocrine or paracrine growth stimulatory loops, and inhibiting angiogenesis, metastasis, and antiapoptosis. Some new therapies may be highly effective as single agents in some patients. However, it is likely that for many patients, combinations of two or more targeted or cytotoxic agents will be required to maximize clinical benefit, and determining the optimal combination of therapy for a given patient will be an additional challenge in the field.

- Identification of prognostic and predictive biomarkers, such as the EGFR mutation and ALK-EML4, ROS1, and RET fusion

previously described that are both direct targets and predict the response and outcomes to specific therapies. Such tools will play an increasingly important role in selecting optimal treatment strategies as the number of molecularly targeted therapies expands.

These are exciting times in the molecular biology field of lung cancer, in which the science directly informs patient care and vice versa. Improved outcomes are surely to be the result, and patients can be given a degree of hope never before possible.

41 Non-Small Cell Lung Cancer

Frank C. Detterbeck, Roy H. Decker, Lynn Tanoue, and Rogerio C. Lilenbaum

INCIDENCE AND ETIOLOGY

Lung cancer is the most common cause of cancer death worldwide. The World Health Organization International Agency for Research on Cancer reported the global incidence of lung cancer at approximately 1.8 million new cases in 2012.¹ The overall ratio of mortality to incidence is high, with the 5-year survival rate in the United States still only 17%.² Consequently, the mortality burden is staggering, with lung cancer causing an estimated 1.59 million deaths per year around the world. Lung cancer accounts for nearly one-third of all cancer deaths in the United States and causes as many cancer deaths as the next four leading causes of cancer deaths combined (breast, colon, prostate, and pancreas).²

A relatively unique aspect of lung cancer is the strong association with a potentially avoidable risk factor, namely smoking. This has far-reaching psychological, social, political, and societal implications. An attitude of blame has contributed to low prioritization of lung cancer research and a lack of activism among people affected by the disease. Furthermore, this attitude and the relatively poor outcomes have promoted nihilism in both the medical and patient community about both treatment of the disease and attempts to make advances.

It is important to look beyond the simple association of lung cancer and smoking. Over half of those diagnosed with lung cancer in the United States are either never-smokers or people who quit smoking many years earlier.³⁻⁵ Furthermore, lung cancer occurring in never-smokers is relatively common, occurring in about 20,000 individuals in the United States; this puts deaths from lung cancer in never-smokers among the top 10 causes of cancer deaths in the United States (e.g., more than cancer of the ovaries, uterus, or lymphomas).² This underscores that the etiology of lung cancer is complex and not well understood.

Major advances have been made in all aspects of lung cancer, from screening, to surgical, chemotherapy and radiotherapy (RT) treatment, methods of palliation, as well as the understanding of fundamental aspects of the biology of the disease. Lung cancer has become a vibrant and dynamic field, with a vast and growing literature describing advances in every facet of this disease. This makes it an impossible task to summarize the state of the art in one short chapter; it is inevitable that some areas will be missed or covered superficially, and new advances will have emerged during the course of publication. Nevertheless, this chapter is an attempt to cover the most important clinical aspects of lung cancer, which represents a major source of suffering and mortality throughout the world.

The highest incidence and mortality rates from lung cancer are observed in men in Central and Eastern Europe, Southern Europe, Eastern Asia, Micronesia, and Northern America, and in women in Northern America, Northern Europe, Australia/New Zealand, and Micronesia (Fig. 41.1). The highest estimated age-standardized lung cancer incidence rates occur in more developed regions of the world, where smoking is more prevalent (Fig. 41.2). Globally, lung cancer is still more common in men than in women, reflecting different historical and temporal exposure to tobacco smoking. The evidence does not suggest that

women are either more or less susceptible than men to the carcinogenic effects of tobacco. On a hopeful note, the incidence rates in men appear to be falling or at least stabilizing in all regions, likely reflecting the impact of successful national initiatives focused on tobacco control (Fig. 41.3). In contrast, incidence rates in women appear to be increasing in most regions or at best stabilizing in a few.

Smoking

At the turn of the 20th century, lung cancer was a rare malignancy. In an extensive autopsy review in the United States and Western Europe in 1916, Adler found that lung cancers represented <0.5% of all cancer cases.⁶ Over the next several decades, a substantive increase in the incidence of lung cancer was noted; at the same time, observations of the adverse health effects of smoking were made. In 1941, Ochsner and DeBaKey stated, "it is our definite conviction that the increase in the incidence of pulmonary carcinoma is due largely to the increase in smoking, particularly cigaret (sic) smoking."⁷ Two landmark case-control studies published in 1950 by Doll and Hill⁸ in the United Kingdom and Wynder and Graham⁹ in the United States established a causal link between cigarette smoking and bronchogenic carcinoma. The Royal College of Physicians in the United Kingdom in 1962¹⁰ and the Surgeon General of the United States in 1964¹¹ endorsed the conclusion that cigarette smoking is the major cause of lung cancer. Population trends of lung cancer incidence mirror smoking behavior, with a typical lag time of approximately 20 years (see Figs. 41.1 and 41.2). Both the number of cigarettes smoked per day and the duration of smoking correlate with lung cancer risk, with longer duration in particular being associated with a much higher risk.¹²

Cigarette smoke is a complex aerosol, with nicotine being the primary determinant of addiction and tar being the particulate residue left when nicotine and water are removed from tobacco smoke. More than 50 carcinogens in tobacco smoke have been identified, including N-nitrosoamines formed by nitrosation of nicotine during smoking, and polycyclic aromatic hydrocarbons.¹³⁻¹⁵ The N-nitrosoamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone is associated with DNA adduct formation and DNA mutations that result in the activation of KRAS oncogenes.^{16,17} Both N-nitrosoamines and polycyclic aromatic hydrocarbons may be metabolically activated to become carcinogenic, or alternatively may be metabolically detoxified; the balance of these processes will determine exposure. Other carcinogens in tobacco smoke carcinogens do not require activation (e.g., benzene, vinyl chloride, or radon). The dose of carcinogen(s) received from smoking will vary with the composition of the cigarette itself, including whether a filter is present, and the intensity of inhalation. Because of regulatory mandates, cigarettes contain less nicotine and tar than in years past. However, smokers may compensate by smoking more intensively (more puffs per minute and deeper, longer inhalations) to satisfy nicotine addiction. Mentholation of cigarettes may also facilitate

Figure 41.1 Estimated age-standardized rates of lung cancer per 100,000 population by region of the world. (Reproduced from GLOBOCAN 2012, International Agency for Research on Cancer, World Health Organization.)

more intense smoking, as it changes the aroma of the smoke and decreases the irritant effect of the smoke, thereby facilitating more intense inhalation.^{18,19}

Genetic Predisposition

The cumulative lifetime risk for lifelong smokers in their eighth decade of life is approximately 16%.²⁰ The host factors that confer “protection” from lung cancer in the majority of individuals who smoke and never develop lung cancer, or determine increased susceptibility in those individuals who do, are not clear. An estimated 300,000 lung cancer deaths occur in nonsmokers annually in the world; in many of these cases, no specific risk or exposure can be identified.^{21,22} It is widely accepted that genetic (inherited) factors as well as epigenetic (acquired) DNA changes contribute to the development of malignancy. The association of lung cancer with rare Mendelian cancer syndromes or in family aggregates supports the contribution of high-penetrance, low-frequency genes.^{23,24}

Mutations in low-penetrance, high-frequency genes that encode enzymes involved in activation or detoxification of carcinogens, or enzymes involved in DNA repair, also influence lung cancer susceptibility.^{25–27}

A large European case control study and meta-analysis of 41 studies demonstrated that the risk of lung cancer increased if there was a first-degree family member with lung cancer (odds ratio = 1.63) and increased further if two or more family members had lung cancer (odds ratio = 3.6).²⁸ The Liverpool Lung Project reported that a family history of early onset lung cancer (age <60 years) was associated with an odds ratio for lung cancer of 2.02.²⁹ While some polymorphisms in a few candidate genes have been identified, the broad field of host genetic factors determining lung cancer susceptibility is still poorly understood and is an area of intense investigation. We do not yet have the tools to identify which individuals might be intrinsically more likely to develop lung cancer or more vulnerable to the carcinogenic effects of cigarettes. Such knowledge eventually may help define specific populations who should be targeted for lung cancer screening.

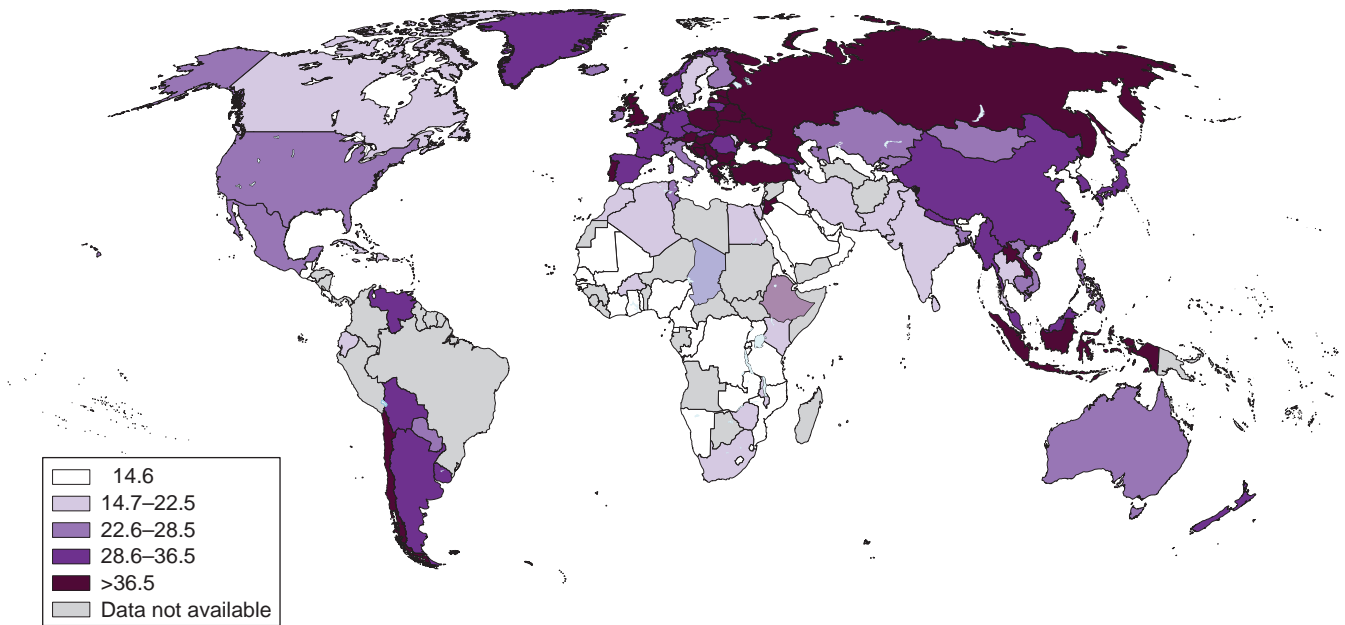

Figure 41.2 Percentage of tobacco use among adults by country in 2005. (Reproduced from GLOBOCAN 2012, International Agency for Research on Cancer, World Health Organization.)

Occupational/Environmental

Though smoking is clearly the most important modifiable risk factor, many other factors influence the development of lung cancer. It is estimated that approximately 10% of lung cancer cases are at least in part related to occupational exposures.³⁰ Many workplace materials have been identified as carcinogens, including, among others, arsenic, asbestos, beryllium, cadmium, chromium, nickel, radon, and vinyl chloride. Of these, asbestos is the most common, having been used widely for its insulating properties and recognized as a lung carcinogen as early as the 1940s.³¹ There has been controversy as to whether asbestos exposure per se confers lung cancer risk or whether asbestosis, the associated interstitial lung disease, is required. A recent long-term follow-up of a large group of North American insulators originally studied in the early 1980s provided further data on asbestos exposure, asbestosis, and cigarette smoking.³² In the non-smoking cohort, lung cancer risk was increased with asbestos exposure alone, and further increased if asbestosis was also present. In the smoking cohort, there was an additive risk of smoking and asbestos exposure, with a supra-additive increase in risk if both smoking and asbestosis were present. Thus it appears that while asbestosis clearly increases lung cancer risk, particularly in smokers, asbestos exposure alone also increases risk, albeit to a lesser degree.

Radon gas was first implicated as increasing lung cancer risk in workers in underground uranium mines. The awareness of radon as a carcinogen has focused attention on domestic radon gas as a common indoor pollutant.^{33–36} Radon is felt to contribute to an estimated 15,000 to 20,000 lung cancer deaths in the United States annually.³⁶ Other indoor air pollutant carcinogens include environmental tobacco smoke and byproducts of biomass fuels used for heating and cooking. Outdoor air pollution contains carcinogens generated by fossil fuel combustion and diesel exhaust, which can be adsorbed to fine particulates small enough to be inhaled into the airways. These exposures are of particular concern in countries such as China, where indoor domestic use of coal and wood, intense urban outdoor pollution, and an epidemic of tobacco smoking are likely all contributing to an alarming rise in lung cancer incidence.

Cancer risk related to medical imaging has been an area of increasing public health concern, particularly with the escalation of

use of high technology studies such as computed tomography (CT) and positron emission tomography (PET). Radiation exposure acquired in this way is cumulative, with risk extrapolated on a linear model based on known cancer risk in survivors of the atomic bomb in Japan, and after therapeutic radiation given in the past for medical diseases including tuberculosis and ankylosing spondylitis.^{37–40} Based on this model, even lower cumulative doses incur some risk. Recognition of the potential harms of radiation from medical imaging makes more urgent the need to utilize these tests judiciously, develop methods to track cumulative radiation exposure to specific organs, and improve technologies that will minimize patient exposure. This need is particularly cogent anticipating implementation of lung cancer screening with low-dose chest CT scanning.

Lung cancer is typically a disease of older individuals; ironically, as overall health status improves in developing countries and those populations acquire longer life expectancy, their lung cancer risk may increase. Whether gender is a factor has been a topic of considerable debate. At present, the body of evidence does not support any significant sex-related difference in susceptibility to smoking-associated lung cancer.⁴¹ African Americans have consistently been observed to have higher lung cancer rates as well as worse 5-year survival than Caucasian Americans.² In developed nations, socioeconomic factors including education and income are inversely associated with risk. Lifestyle factors, including diet and physical activity, likely influence risk. An inverse association of diets higher in fruit and vegetable (cruciferous and carotenoid-rich) consumption with lung cancer risk has been consistently described.^{42,43} The evidence for physical activity is less clear, though higher levels of activity have been described as associated with lower cancer risk.⁴⁴

The presence of underlying pulmonary disease is increasingly recognized to influence lung cancer risk. Cigarette smoking is the major etiologic factor in both lung cancer and chronic obstructive pulmonary disease (COPD). COPD per se is an independent risk factor after controlling for smoking.^{45,46} The mechanism(s) by which fixed airways disease may etiologically be implicated in carcinogenesis are not defined, but potentially include mutagenesis through activation of the NF-kappaB inflammatory pathway, protease-antiprotease imbalance, or chronic inflammation itself.^{47–49} The presence of interstitial lung disease has also been associated

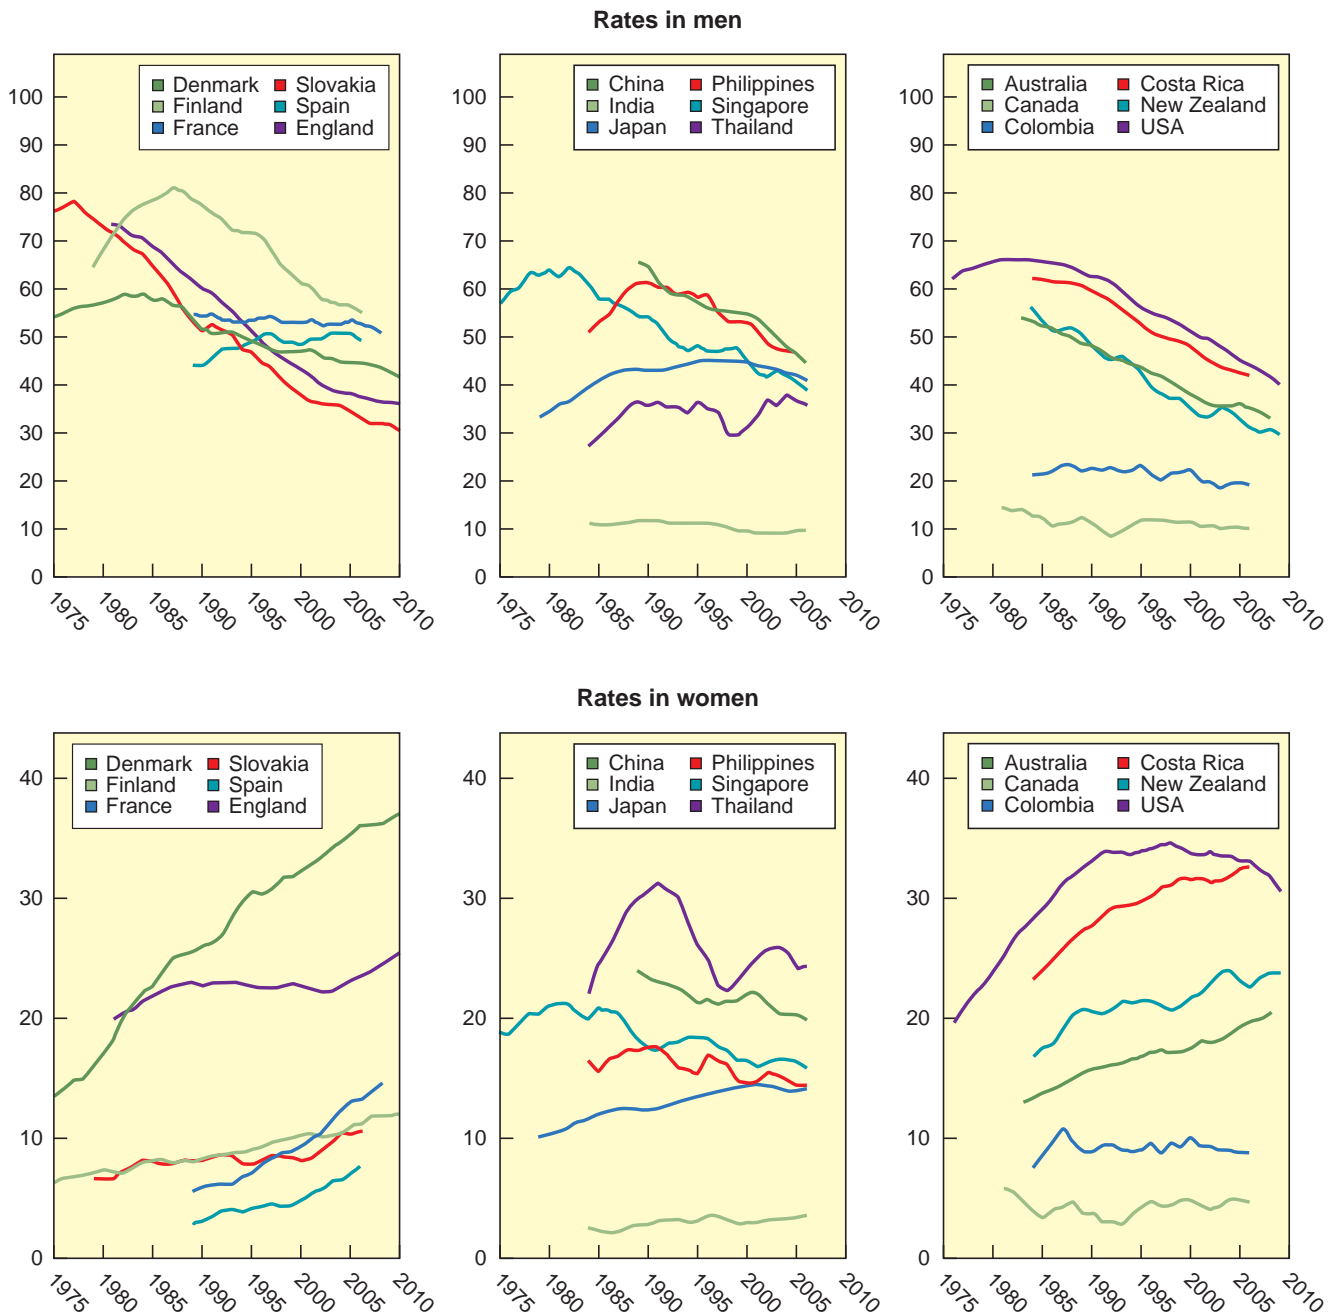

Figure 41.3 Trends in mortality from lung cancer showing the age-standardized mortality rate from lung cancer per 100,000 men (top row) and women (bottom row) in selected countries. (Reproduced from GLOBOCAN 2012. International Agency for Research on Cancer, World Health Organization.)

with an increase in lung cancer risk. In particular, patients with idiopathic pulmonary fibrosis have been reported to have an odds ratio for lung cancer of 8.25 compared to controls.^{50,51} In contrast to COPD, cigarette smoking is usually not etiologically implicated in interstitial diseases, although chronic inflammation typically is felt to contribute to the pathologic process.

ANATOMY AND PATHOLOGY

Stage Classification

The stage classification for non-small-cell lung cancer (NSCLC) follows the tumor, node, metastasis (TNM) paradigm used for most solid tumors. Staging ensures a uniform standardized nomenclature to describe the anatomic extent of disease, namely

the primary tumor site (T component) as well as cancer spread to nodes (N component) or distant metastatic sites (M component). The most recent (seventh edition) of the lung cancer stage classification is based on an unprecedented effort directed by the International Association for the Study of Lung Cancer (IASLC).⁵²⁻⁵⁵ This involved an international database of over 100,000 patients, identified over the period 1990 to 2000 from 46 sources in 19 countries in North America, Asia, Australia, and Europe, and a sophisticated statistical analysis with extensive internal and external validation.⁵⁶ This stage classification applies to small cell and NSCLCs as well as carcinoid tumors.^{57,58}

Several characteristics of the IASLC database are important to recognize in order to appropriately interpret some of the results. This was a retrospective database, with limitations in the level of details available. For example, some of the definitions of the TNM descriptors contained too few patients to allow statistical analysis

of the impact of that tumor characteristic. Because the database consisted of patients diagnosed between 1990 and 2000, advances in technology (e.g., PET imaging) and treatment modalities that are routine today are not reflected. The analysis did not account for what treatment (if any) was given. In fact, there was a great deal of variation in outcomes depending on the type of source data and the geographic region. Thus, while the outcomes created a phenomenal tool to define where to draw distinctions between TNM categories and groupings, the outcomes themselves represent a global cross-section from the past with less clear relevance to specific patients today.

The definitions of the T, N, and M categories for both NSCLC and small-cell lung cancer (SCLC) are outlined in detail in Table 41.1.⁵⁹ The T, N, and M categories are then grouped to define particular stages of lung cancer (both NSCLC and SCLC), as outlined in Fig. 41.4. While ideally each stage would represent a homogeneous group of patients, this is not necessarily the case, as is evident in the range of T, N, and M combinations that comprise stage IIB or IIIA, for example. Nevertheless, the system provides a practical way of managing the complexity of a large number of T, N and M categories into a more limited number of stage groups.

TABLE 41.1

Stage Classification: T, N, M Descriptors

Category	Descriptor Definition	Subgroup ^a
T (Primary Tumor)		
T0	No primary tumor	
T1	Tumor ≤ 3 cm, ^b surrounded by lung or visceral pleura, not more proximal than the lobar bronchus	
T1a	Tumor ≤ 2 cm ^b	T1a
T1b	Tumor > 2 but ≤ 3 cm ^b	T1b
T2	Tumor > 3 but ≤ 7 cm ^b or tumor with any of the following ^c : Invades visceral pleura, involves main bronchus ≥ 2 cm distal to the carina, atelectasis/obstructive pneumonia extending to hilum but not involving the entire lung	
T2a	Tumor > 3 but ≤ 5 cm ^b	T2a
T2b	Tumor > 5 but ≤ 7 cm ^b	T2b
T3	Tumor > 7 cm ^a or directly invading chest wall, diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium, or tumor in the main bronchus < 2 cm distal to the carina, ^d or atelectasis/obstructive pneumonitis of entire lung, or separate tumor nodule(s) in the same lobe	T3 _{>7} T3 _{Inv} T3 _{Centr} T3 _{Satell}
T4	Tumor of any size with invasion of heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina; or separate tumor nodule(s) in a different ipsilateral lobe	T4 _{Inv} T4 _{Ipsi Nod}
N (Regional Lymph Nodes)		
N0	No regional node metastasis	
N1	Metastasis in ipsilateral peribronchial and/or perihilar lymph nodes and intrapulmonary nodes, including involvement by direct extension	
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)	
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral, or contralateral scalene or supraclavicular lymph node(s)	
M (Distant Metastasis)		
M0	No distant metastasis	
M1a	Separate tumor nodule(s) in a contralateral lobe; or tumor with pleural nodules or malignant pleural dissemination ^e	M1a _{Contr Nod} M1a _{PI Dissem}
M1b	Distant metastasis	M1b
Special Situations		
TX, NX, MX	T, N, or M status not able to be assessed	
T _{is}	Focus of in situ cancer	T _{is}
T _{1^d}	Superficial spreading tumor of any size but confined to the wall of the trachea or mainstem bronchus	T _{1SS}

^aThese subgroup labels are not defined in the International Association for the Study of Lung Cancer publications (see Goldstraw P, Crowley J, Chansky K, et al. The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming [seventh] edition of the TNM Classification of malignant tumours. *J Thorac Oncol* 2007;2:706–714; Rami-Porta R, Ball D, Crowley J, et al. The IASLC Lung Cancer Staging Project: proposals for the revision of the T descriptors in the forthcoming (seventh) edition of the TNM classification for lung cancer. *J Thorac Oncol* 2007;2:593–602; Rusch VW, Crowley J, Giroux DJ, et al. The IASLC Lung Cancer Staging Project: proposals for the revision of the N descriptors in the forthcoming seventh edition of the TNM classification for lung cancer. *J Thorac Oncol* 2007;2:603–612; Postmus PE, Brambilla E, Chansky K, et al. The IASLC Lung Cancer Staging Project: proposals for revision of the M descriptors in the forthcoming [seventh] edition of the TNM classification of lung cancer. *J Thorac Oncol* 2007;2:686–693) but are added here to facilitate a clear discussion.

^bIn greatest dimension.

^cT2 tumors with these features are classified as T2a if ≤ 5 cm.

^dThe uncommon superficial spreading tumor in central airways is classified as T1.

^ePleural effusions are excluded that are cytologically negative, nonbloody, transudative, and clinically judged not to be due to cancer.

(Reproduced with permission from Detterbeck F, Tanoue L, Boffa DJ. The new lung cancer staging system. *Chest* 2009;136:262.)

It is worth emphasizing what the stage classification system does and cannot accomplish. It is designed to be a consistent, stable nomenclature for the anatomic extent of disease. Although this is a major component in a patient's prognosis, the prognosis depends on many other factors, including age, comorbidities, environmental factors, and treatment factors. Particular tumor or patient factors (e.g., genetic mutations, central/peripheral lung location) may have a major impact in certain settings (e.g., a particular treatment strategy) but not in others, and at certain times during the course of the disease. Therefore, stage classification is not sufficient to capture the complexity of prognostic prediction for specific patients in specific clinical settings. Furthermore, although the anatomic extent of disease is an important component of selecting a treatment approach, this is also determined by other factors (e.g., histologic type, molecular information, patient-specific factors such as comorbidities). In addition, stage classification must remain relatively static and consistent to be useful, while treatment should continually evolve and improve. Thus, treatment must be determined by the results of clinical trials and cannot be determined merely by a stage classification nomenclature.

Histologic Classification

The histologic spectrum of lung cancer has clearly changed over the past several decades. SCLC has decreased from about 25% to <15% of all lung cancers.⁶⁰ Adenocarcinoma is now the most dominant histologic type, replacing squamous carcinoma. With the advent of more frequent CT imaging, an increased proportion of more indolent small tumors is being recognized.⁶¹

The histologic classification of lung cancer has become much more nuanced. In the past, the major NSCLC histologic types (adenocarcinoma, squamous cell carcinoma, and large cell carcinoma) were simply lumped together. It is critical to differentiate these because they respond differently to certain chemotherapeutic agents. Immunohistochemical stains and genetic characterization can facilitate the distinction between subtypes.^{62,63} It is recognized that the vast majority of adenocarcinomas are mixed subtypes; these are now classified according to the predominant subtype with the percent of each noted in 10% increments.⁶³ Furthermore, the adenocarcinoma subtypes have been defined according to preinvasive, minimally invasive, and invasive groups (Table 41.2),⁶³ reflecting the increasingly recognized spectrum of aggressiveness of lung cancers encountered in the Western world today. Finally, bronchopulmonary carcinoid

and salivary gland tumors are less common types that are also included among lung cancers.⁶⁴

Genetic Characterization

A fairly detailed understanding of cellular and genetic characteristics of cancer has emerged. A way to organize this is the concept of "hallmarks of cancer." Initially 6 hallmarks were defined; by 2011, this had increased to 10 (resisting cell death, sustaining proliferative signaling, evading growth suppressors, enabling replicative immortality, activating invasion and metastasis, inducing angiogenesis, deregulating cellular energetics, avoiding immune destruction, genome instability and mutation, tumor-promoting inflammation).^{65,66} A potential 11th hallmark has recently been suggested (epigenetic or RNA deregulation).⁶⁷ The ability to identify mutations in genes that play a role in various of these mechanisms has substantiated the importance of these hallmarks as being fundamental to malignant behavior.

Genetic characterization allows better classification of lung cancers. A systematic characterization of genetic alterations in 1,255 patients with lung cancer reveals that most histologic types have a characteristic pattern of genetic alteration.⁶² Large-cell lung cancer is the exception, exhibiting alterations associated with each of the other major histologic types. Using genetic characterization, the vast majority of cases initially classified simply as large-cell lung cancer could be assigned to another histologic group (e.g., adenocarcinoma, squamous carcinoma, SCLC), which was corroborated by prognostic and other similarities among the genetically grouped cohorts.⁶²

Particular mutations have sparked a great deal of attention, primarily because they have led to dramatic therapeutic breakthroughs (Table 41.3). Mostly these involve driver mutations for sustained proliferative signaling. Mutations in the epidermal growth factor receptor (EGFR) gene are the best-known examples. Such driver mutations have received much attention because targeted treatment can yield dramatic results, although the overall proportion of patients with these mutations may be quite small. Particularly because identification of these genetic alterations drives the choice of treatment, some have suggested that classification based on targetable mutations may be a better way to classify lung cancers than by histologic features.

Classification by genetic alterations is thwarted by the complexity of these changes. Whole genome and whole exome sequencing of 183 lung adenocarcinomas revealed greater complexity in genetic alterations than what is seen in most other cancers.⁶⁷ Although many mutated genes were found, 15% did not have a single hallmark alteration, and almost 40% have fewer than four hallmark alterations.⁶⁷ Focusing on mutations in which a targeted therapy is available or being developed may be practical, but belies the complexity of cancer biology. Even in those instances where dramatic responses have been achieved, in most cases resistance eventually develops. Furthermore, while driver mutations can sometimes clearly play a major role in cancer growth, alterations in many of the other hallmarks of cancer are less amenable to treatment, at least at this time. Finally, the well-documented finding that some EGFR-mutated adenocarcinomas that have become resistant to treatment with a tyrosine kinase inhibitor (TKI) have been transformed into a SCLC underscores that our understanding of the fundamental nature of lung cancer is still rudimentary.

Prognostic Factors

Prediction of prognosis is fervently desired, but remains an elusive goal. Developing a system to do this is complex and must solve a

number of inherent conflicts. Hence the state of affairs is that we have identified a few factors that have prognostic value (at least in some clinical settings), but it is spotty and explains only a small amount of the actual observed outcomes.

Prediction of prognosis is inherently complex.⁶⁸ There are many factors that contribute; these can be grouped roughly into environmental factors, tumor-related factors, and patient-related factors (Fig. 41.5). The prognosis is inherently linked to a specific clinical scenario and to the outcome of interest. The scenario includes treatment-related factors and timing (e.g., the prognostic significance of an EGFR mutation is different if the patient is to undergo treatment with an EGFR inhibitor, regular chemotherapy, or neither, and different prior to treatment than upon developing resistance).

There are inherent conflicts in prognostication.^{68,69} We derive our knowledge from studying groups of patients with a particular characteristic, but we seek individualized prognostic prediction, tailored to a particular person. The ability to individualize is limited because we do not have sufficient detail of all of the other factors of the group to assess how well the group fits with the individual. Even if we had more and more detail, the more specific we get, the more limited the dataset available to derive the prediction becomes, and thus the greater the uncertainty about the prediction. Finally, the data we base the prediction on is inherently based on past observation, yet the prediction is for the future, and thus cannot take into account new developments that inevitably occur.

Prognostic prediction is inherently different than stage classification.⁶⁹ Stage classification is a nomenclature to describe the anatomic extent of disease. It must remain relatively static and be used in a consistent uniform manner; the classification we assign to a particular extent of tumor today must be the same as what we assign to the same extent next year or else it is a useless nomenclature. However, prognostication is inherently fluid and constantly changing as advances occur and the setting changes. Stage classification must be consistent and definitive while prognostic prediction is inherently speculative and uncertain.

TABLE 41.3

Genetic Alterations in Non-Small-Cell Lung Cancer

Genetic Alteration	Frequency	Test	Targeted Agents ^a
Nonsquamous			
KRAS mutation	25%	Sequence	None
EGFR mutation	15%	Sequence	Gefitinib, erlotinib, afatinib
ALK rearrangement	5%–7%	FISH	Crizotinib, ceritinib
ROS1 rearrangement	1%–2%	FISH	Crizotinib
HER2 (mutation only)	2%–4%	Sequence	Trastuzumab, pertuzumab, lapatinib, afatinib
BRAF mutation	2%–3%	Sequence	Vemurafenib, dabrafenib
RET rearrangement	1%–2%	FISH	Carbozantinib
MET (mutation only)	1%–2%	Sequence	None
MEK1 mutation	<1%	Sequence	None
PIK3CA mutation	1%–2%	Sequence	None
Squamous			
FGFR1 amplification	20%–25%	FISH	None
FGFR1 mutation	5%	Sequence	None
PIK3CA mutation	5%–10%	Sequence	None
DDR2 mutation	3%–5%	Sequence	Dasatinib
PTEN mutation/deletion	15%–20%	Sequence	None

FISH, fluorescence in situ hybridization.

Prognostic Prediction System

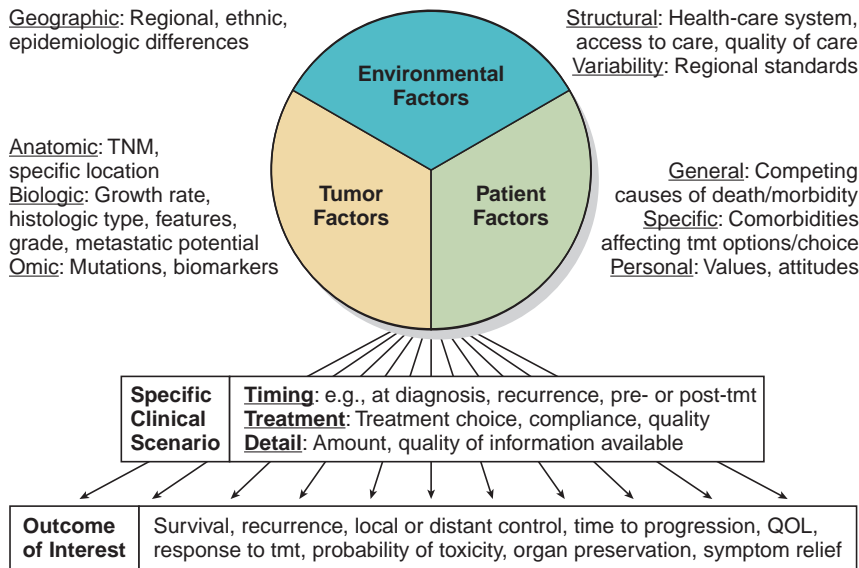

Figure 41.5 Schematic of a prognostic prediction system, taking into account environmental, patient-related, and tumor-related factors. The prediction must be specific to the clinical scenario and the outcome of interest. TNM, tumor, node, metastases; QOL, quality of life; tmt, treatment.

As part of the stage classification project, the international staging committee undertook a review of data on prognostic factors in lung cancer among surgically treated patients in the worldwide IASLC database.⁷⁰ Pathologic TNM class was most important, but age and gender also had independent prognostic significance. Histologic cell type (particularly bronchioloalveolar carcinoma [BAC]) may have some prognostic value; however, this is linked to other variables and is probably best understood when we can take into account the newer subclassification of adenocarcinoma, which was not available at the time of the analysis.⁶³ Many other potential factors, such as genetic features or PET intensity, were also not available for analysis. In sum, development of a prognostic model is very complex, situation specific, and constantly changing. We have only a rudimentary understanding at this point, and no overarching system of how to develop a universal prognostic prediction model.

PREVENTION AND SCREENING

Prevention

Tobacco Control

The global epidemic of lung cancer is linked most strongly to population engagement in cigarette smoking. While other modifiable risk factors (e.g., exposure to occupational or domestic carcinogens) are clearly identifiable, it is tobacco smoking that has driven the steep rises in lung cancer incidence and mortality witnessed over the last century in developed and developing nations. Primary prevention has the greatest overall potential to minimize lung cancer risk, and smoking cessation is still the most powerful intervention to diminish lung cancer risk in persons who smoke. Smoking cessation even into the seventh decade of life results in a decrease in lung cancer incidence, and so it is never too late to quit.^{20,71} While smoking rates have decreased dramatically since the publication of the first surgeon general's report on the health consequences of smoking in 1964, approximately 20% of adult Americans still habitually smoke.

Important public health interventions have included stricter control of tobacco products by government regulatory agencies, limitations on cigarette advertising, particularly those geared toward children, the use of text and graphic warnings on cigarette

packaging, and global initiatives to inform the public of the health hazards of smoking.⁷²⁻⁷⁵

Smoking Cessation

There are many physiologic and psychological factors that contribute to make smoking a difficult addiction to overcome. However, there have been major advances in understanding these, and solid scientific data regarding which interventions work best and in which individuals. Nicotine acts in an area of the brain associated with a sense of "safety" and "survival functions."⁷⁶ This appears to explain the paradox of difficulty in giving up smoking even when faced with a life-threatening disease that is a consequence of smoking. This struggle and the illogical nature of it, combined with the stigmatism associated with smoking, lead to feelings of shame, helplessness, and depression that further aggravate the problem.⁷⁶ It is easy to succumb to a fatalistic defense that "it is too late anyhow." However, data clearly shows that patients with lung cancer who continue to smoke approximately double their risk of dying.⁷⁶ Quitting smoking is associated with better response to treatment, better quality of life (QOL), better long-term survival, and a lower risk of second primary cancers.⁷⁶⁻⁷⁹ Furthermore, data shows that a diagnosis of lung cancer represents a particularly opportune moment to intervene.⁷⁶

Smoking cessation intervention should be included in the health care of any individual smoking cigarettes. It is important to use a sophisticated, evidence-based approach and an organized smoking cessation program to achieve the best results.⁷⁶ A simple recommendation to stop smoking or provision of self-help materials is largely ineffective. Several points are important. Tobacco dependence is best managed in a chronic disease model with repeated intervention over time. Intensive behavioral therapy and counseling (e.g., weekly) is of significant benefit in several randomized controlled trials (RCT). In addition, seven first-line medications reliably increase long-term smoking abstinence rates (bupropion, varenicline, nicotine patch, gum, lozenges, inhaler, and nasal spray).⁷⁶ These increase effectiveness two- or three-fold and result in abstinence rates of ~25%. Often, combinations of these may be more effective than a single intervention. These medications have been shown to be safe in most patients, including those who are about to undergo either surgery, RT, or chemotherapy. It is best to initiate the cessation interventions at the outset. Specifically, it is safe (and beneficial) for patients to stop smoking even a short time (e.g., 1 to

2 weeks) before undergoing surgery; pharmacologic interventions are safe to continue in the perioperative period as well.⁷⁶ A well-organized thoracic oncology program, therefore, should include an evidence-based smoking cessation program that is fully integrated with the diagnostic and treatment components of patient care.

Chemoprevention

The concept of chemoprevention is based on the data that lung cancer is the end result of a multistep accumulation of carcinogen-driven genetic and epigenetic changes. In theory, chemical agents might prevent these changes by a variety of proposed mechanisms, such as detoxifying carcinogens and modifying pathways that influence cell growth and behavior. Epidemiologic and animal studies had suggested that derivatives of the antioxidant vitamins A and E might be protective against lung cancer. However, large clinical trials of alpha-tocopherol and beta carotene in subjects at risk of developing lung cancer failed to demonstrate any benefit, and two studies suggested that beta carotene was actually associated with an increased incidence of lung cancer as well as cardiovascular disease.⁸⁰⁻⁸³ To date, no chemopreventative intervention has been demonstrated to be of benefit for lung cancer. The focus has shifted from large RCTs to studies to better define the underlying biology and appropriate surrogate end points.⁸⁴

Screening

At present, the majority of patients with lung cancer have advanced disease at the time of diagnosis. This preponderance of advanced disease, where prognosis is poor even with treatment, is a major contributor to the dismal overall 5-year survival rate of 18%; this contrasts starkly with breast, colon, and prostate cancers, the next three leading causes of cancer death, whose 5-year survival rates over the past several decades have increased to 90%, 65%, and nearly 100%, respectively.² These improved survival rates are arguably attributable at least in part to early detection resulting from widely available and broadly accepted, albeit still controversial, screening interventions.

An effective screening tool for early detection of lung cancer has been an elusive goal for decades. Several large randomized trials performed during the 1960s and 1970s evaluating lung cancer screening with chest radiography with or without sputum analysis at varying time intervals failed to demonstrate any mortality benefit,⁸⁵⁻⁸⁹ and a Cochrane meta-analysis⁹⁰ concluded that there was no evidence to support the use of chest radiography or sputum cytology as a lung cancer screening modality. More recently, chest radiography was re-examined as a lung cancer screening tool in

the Prostate, Lung, Colorectal and Ovarian trial, which enrolled 154,901 participants aged 55 to 74 years from 1993 to 2001.⁹¹ No difference in lung cancer mortality was seen between those randomized to screening with annual chest radiography versus no screening, regardless of the degree of smoking. Together, these studies clearly demonstrate that there is no mortality benefit associated with serial chest radiography as a screening tool.

In the 1990s, intense interest was generated by the results of a number of observational studies evaluating low-dose CT (LDCT) as a lung cancer screening modality. Eventually, a number of RCTs were performed in various sites around the world. The largest of the RCTs was the National Lung Screening Trial (NLST), which included 53,454 subjects, ages 55 to 74 with at least 30 pack-years of cigarette smoking, who were either currently smoking or had quit smoking within the prior 15 years.⁹² NLST subjects underwent three rounds of annual screening, randomized to either chest radiograph or LDCT. Approximately 1% of subjects had lung cancer over the duration of the trials. At a median follow-up of 6.5 years, there was a 20% relative reduction in lung cancer mortality observed in the LDCT arm (Fig. 41.6).⁹² None of the other RCTs evaluating lung cancer screening with LDCT is of the scale of the NLST; in the trials in which the data has become available, the mortality benefit has been nonsignificant, and without a trend toward a benefit.⁹³⁻⁹⁵ The subjects in all of these studies had smoked and were of middle to older age. A multisociety systematic review of lung cancer screening with LDCT analyzed the evidence from 8 RCTs and 13 prospective cohort studies.⁹⁶ This review found a composite significant benefit for LSCT screening, with few ensuing harms, when LDCT screening was conducted in the setting of an organized, structured program. Consistent with this, many organizations (American College of Chest Physicians [ACCP], American Cancer Society, Society of Thoracic Surgeons, American Association of Thoracic Surgery, National Comprehensive Cancer Network [NCCN], US Preventative Services Task Force) have recommended that healthy smokers or former smokers (quit <15 years ago, ≥ 30 pack years of smoking) age 55 to 74 years or 80 years be considered for LDCT screening.⁹⁶⁻¹⁰¹

Teasing out further details on who to consider for screening will rely heavily on modeling studies as the effort needed for further RCTs is too great. To explore this, the Cancer Intervention and Surveillance Modeling Network developed five independent models based on a US cohort born in 1950.¹⁰² All five models included dose-response information relating to cigarette exposure; 26 scenarios varying in age, screening frequency, and smoking exposure were modeled with respect to the percentage of cancers detected at an early stage, the number of lung cancer deaths prevented, and life-years gained were balanced against outcome measurements of harm, including the number of CT screenings

Figure 41.6 Lung cancer mortality and overall mortality reduction by computed tomography (CT) screening in the National Lung Screening Trial. CXR, chest X-ray. Data taken from Aberle D, Adams A, Berg C, et al. Reduced lung-cancer mortality with low-dose computed tomographic screening. *N Eng J Med* 2011;365:395-409.

required, the number of follow-up imaging exams, the number of overdiagnosed lung cancers, and radiation-related lung cancer deaths. Based on the models, a range of different screening scenarios are arguably valid, with different balances of benefits and harms, with the most efficient screening projected in a population similar to the NLST. On the basis of the Cancer Intervention and Surveillance Modeling Network analysis, the US Preventative Services Task Force now recommends "annual screening for lung cancer with low-dose computed tomography in adults ages 55 to 80 years who have a 30 pack-year smoking history and currently smoke or have quit within the past 15 years."¹⁰¹

There are potential downsides to screening with LDCT that must be considered in the decision to pursue screening for any population or for a given patient. The most obvious of these is the high rate (20% to 50%) of finding small nodules, which are benign and inconsequential in about 97%.⁹⁶ These findings can create unnecessary anxiety, lead to further more intense imaging with significant radiation exposure, and sometimes invasive biopsies with potential complications. In the highly organized LDCT screening studies, only 1.2% to 5.6% of subjects underwent a surgical biopsy or procedure, about 25% of these were for what turned out to be benign nodules.⁹⁷ Finally, it is clear that screening detects a higher proportion of slow-growing, less aggressive cancer, some of which may even be inconsequential.^{103,104} Appropriate management of these issues that are inextricably linked to screening is essential in order to minimize harms and achieve the greatest benefits.

The complexities of the identification of the "right" population or individuals to screen, combined with the potential harms associated with LDCT screening, argue strongly that screening for lung cancer is a multifaceted process, involving much more than the simple ordering of a scan. The process for most individuals should include an individualized risk assessment for lung cancer^{29,105-108}; a discussion about the potential harms of screening, including false-positive results; the potential for cumulative diagnostic radiation; and the possibility of invasive evaluation to diagnose nonmalignant disease. Smoking cessation intervention should be an integral part of this process for individuals still smoking or at risk for relapse. This process should be performed in a multidisciplinary setting. There is data to suggest that if lung cancer screening is done in an unstructured way, the ratio of benefits to harms may be significantly altered. Because implementation of lung screening is just beginning, careful consideration and monitoring is needed to see if the benefit seen in the NLST can be achieved with broader application.

DIAGNOSIS

Clinical Presentation

Approximately a quarter of patients with lung cancer are diagnosed at early stage. These patients are typically free of symptoms; their cancers are identified incidentally during evaluation of unrelated issues. While the proportion of asymptomatic early stage lung cancers may increase with the implementation of screening, at present more than half of patients have advanced lung cancer at the time of diagnosis. These patients typically come to attention because of symptoms related to the primary tumor, metastasis to distant sites, or paraneoplastic syndromes.¹⁰⁹

The most common pulmonary symptoms are cough, hemoptysis, and dyspnea.¹⁰⁹ Cough may represent the effects of the primary tumor on the airways, with endobronchial or extrinsic airway obstruction, postobstructive atelectasis or infection, or airway inflammation with secretions. Hemoptysis may also result from airway inflammation or necrosis, but may also be related to parenchymal tumor necrosis and cavitation. Dyspnea may arise from a wide variety of tumor-related issues, including mechanical compromise of the airways, lymphangitic spread, pleural effusion, hypercoagulability with pulmonary thromboembolism, or even pericardial

effusion. Direct extension of the primary tumor to adjacent structures may cause pain from invasion of the chest wall or brachial plexus, hoarseness from impingement of the recurrent laryngeal nerve, superior vena cava (SVC) syndrome, Horner syndrome (ptosis, miosis, anhidrosis) from invasion of the sympathetic chain and stellate ganglion, or pericardial tamponade.¹⁰⁹

Symptoms related to metastatic disease may be constitutional or organ related. The most common sites of NSCLC metastases are the brain, bone, liver, adrenals, and lung, though any organ can be affected. Focal neurologic symptoms, persistent headache, bony pain, or unexplained weight loss, anorexia, or fatigue should raise the suspicion for metastatic disease. Likewise, laboratory abnormalities such as anemia, liver function test abnormalities, or hypercalcemia should raise concern for distant spread.¹⁰⁹

Paraneoplastic syndromes are well described with lung cancer; it is important to recognize that these syndromes are unrelated to metastatic disease and do not preclude curative intent therapy. Hyponatremia related to syndrome of inappropriate secretion of antidiuretic hormone is seen most commonly with SCLC but can occur with other malignant or benign lung processes. Hypercalcemia related to ectopic production of parathyroid hormone-related peptide is more common than hypercalcemia related to bony metastases and is most commonly associated with squamous cell carcinomas. Ectopic corticotrophin (Cushing syndrome) is usually associated with SCLC or early stage carcinoid tumors. Hypertrophic pulmonary osteoarthropathy typically manifests as symmetric and painful arthropathy of the limbs associated with characteristic findings of new periosteal bone formation of the long bones. Neurologic syndromes are less common but include the Lambert-Eaton myasthenic syndrome and encephalomyelitis-subacute sensory neuropathy, both of which are typically associated with SCLC.¹⁰⁹

Diagnostic Approach

In most patients, an experienced clinician can make a clinical diagnosis of lung cancer with a high degree of reliability (>95%).¹¹⁰ The main factors that contribute to this are the risk factors for development of lung cancer (e.g., age, smoking history, family history, presence of significant COPD), the clinical presentation, and the radiographic appearance of the lesion on CT (e.g., spiculated, upper lobe, node enlargement). If needed, algorithms are available that can predict the likelihood of lung cancer,^{108,112-115} but the judgment of experienced clinicians is just as good.¹¹²

If the probability of lung cancer is high (e.g., >80%), it is generally more efficient to proceed with evaluation of the stage than confirmation of the diagnosis.^{110,116,117} Frequently, this will identify a necessary procedure that will serve both to confirm the stage as well as the diagnosis. For example, biopsy of a potential solitary metastasis or of a suspicious mediastinal node can confirm both the stage and diagnosis. Those situations that require tissue confirmation of the stage are discussed in the next section. In other situations, the stage is reliably defined by imaging alone; in this case, confirmation of the diagnosis is achieved from whatever site is easiest. Nevertheless, establishing a presumptive clinical stage is an important step that defines how best to proceed to confirm the diagnosis.

There are also situations in which the reliability of the clinical diagnosis is less certain; this occurs most frequently in the case of a localized, solitary pulmonary nodule (SPN). An SPN is defined as a solitary lesion <3 cm in diameter, surrounded by normal lung, and not associated with other abnormalities in the thorax, such as lymphadenopathy or pleural effusion. These nodules are usually found as incidental findings on imaging studies done for other reasons. When the probability of cancer is intermediate (i.e., about 5% to 65%), PET imaging can be helpful in defining a management algorithm.^{118,119} PET does not definitively establish the diagnosis; therefore, it is only helpful when it alters the probability of lung cancer sufficiently to justify either proceeding with a

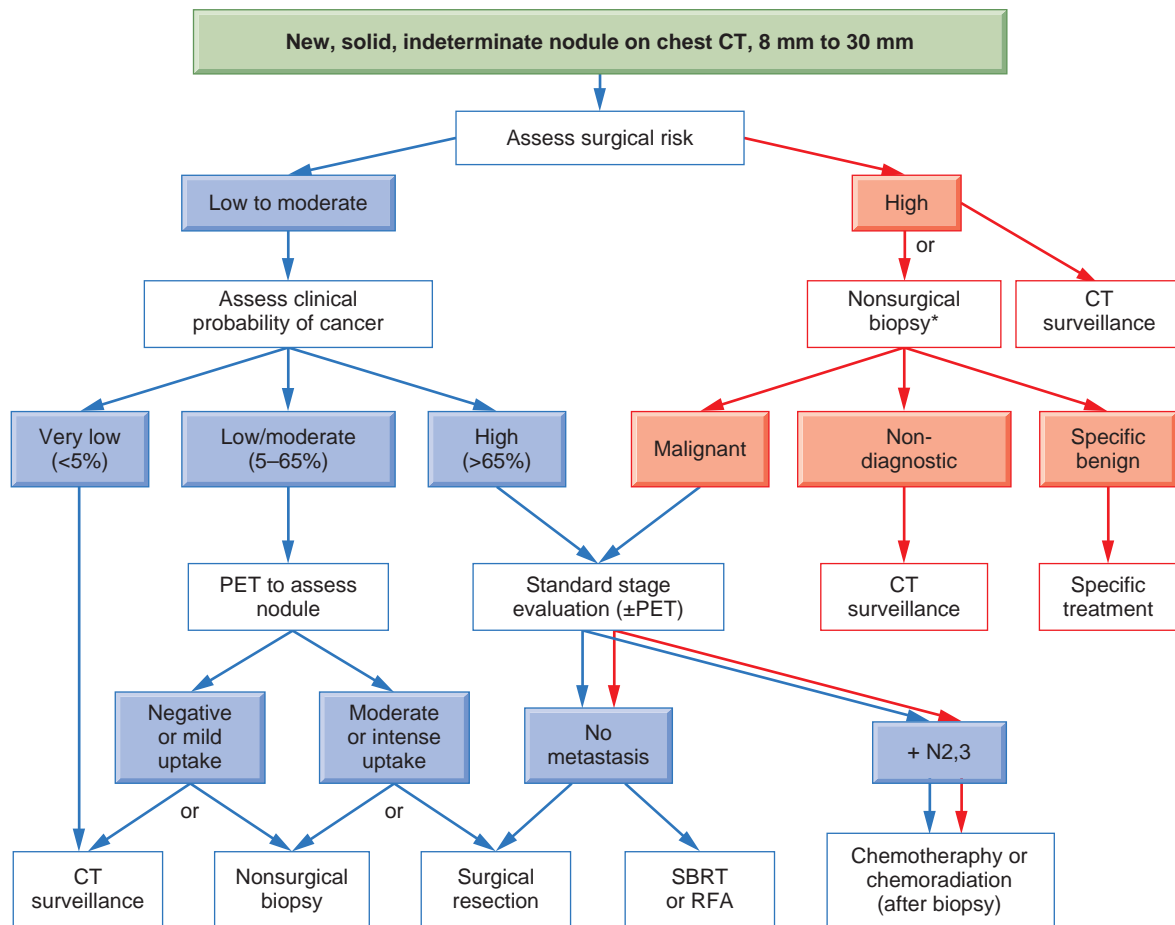

Figure 41.7 Management algorithm for individuals with solid pulmonary nodules 8 to 30 mm in diameter. Branches indicate steps in the algorithm following nonsurgical biopsy. *Among individuals at high risk for surgical complications, we recommend either computed tomography (CT) scan surveillance (when the clinical probability of malignancy is low to moderate) or nonsurgical biopsy (when the clinical probability of malignancy is moderate to high). PET, positron emission tomography; SBRT, stereotactic body radiotherapy; RFA, radiofrequency ablation. (Reproduced with permission from the American College of Chest Physicians Lung Cancer Guidelines, Gould MK, Donington J, Lynch W, et al. Evaluation of individuals with pulmonary nodules: when is it lung cancer? *Chest* 2013;143:e93S–120S.)

biopsy or observation. False-positive PET results may occur with any inflammatory or infectious process: tuberculosis, fungal infections, rheumatoid nodules, and sarcoidosis—when such a process is suspected, PET is generally not helpful (it does not differentiate between such a process and cancer). PET also carries a high false-negative rate with ground glass opacities (GGO), carcinoid tumors, or small lesions; in these situations, PET should also generally be avoided. Specifically, the false-negative rate of PET in a GGO is approximately 90%.¹¹⁸ The false-negative rate in solid lesions <1.5 cm is ~15% and in lesions <1 cm ~30% to 50%.¹¹⁸ Although the “resolution” of modern PET scanners is ~6 mm, this is a technical and not a clinical term—a lesion must have a diameter of *four times the resolution* in order to detect >90% of the 18-fluorodeoxyglucose activity that is present. This fact also explains why the detected standard uptake value of a lesion falls linearly for lesions smaller than ~2 cm, even if the actual amount of 18-fluorodeoxyglucose activity remains the same.^{118,120}

A nonsurgical biopsy can be accomplished by transthoracic needle aspiration (usually guided by CT) or via bronchoscopy. This is most useful when a benign diagnosis is suspected, but this is rather uncommon.¹²¹ In patients with a high suspicion of lung cancer, a biopsy can confirm the diagnosis, but in this situation the false-negative rate of a nonspecific diagnosis is ~20%¹¹⁶; therefore, a surgical biopsy should be pursued unless the patient is too high

risk.¹¹⁹ When doing a tissue biopsy, it is crucial to obtain enough tissue for histologic and molecular characterization.¹¹⁶

To summarize, PET is most useful when there is an intermediate probability of lung cancer; PET should not be used for lesions that are <1 cm or for a GGO. A biopsy can be important in certain instances when there is doubt about the diagnosis. With a high probability of cancer, it is best to complete the stage evaluation and obtain tissue in a manner that is suited to confirm the stage as well. A detailed management approach for SPN is available for the ACCP lung cancer guidelines, as summarized in Fig. 41.7.¹¹⁹

STAGE EVALUATION

General Approach

Staging is a critical aspect of the evaluation of all patients known or suspected of having lung cancer. Clinical stage (identified by a “c” prior to the stage group) is determined by all information available before any definitive treatment. This may involve merely a simple history and physical examination, may include imaging studies, or may involve invasive biopsies or surgical procedures with sampling the primary tumor, intrathoracic lymph nodes, pleural fluid, or

extrathoracic sites. Pathologic staging (identified by a “p” prior to the stage group) is determined only if surgical resection with intent to cure is performed. All patients undergo clinical staging; the subset of patients who have pathologic staging all first had a clinical stage defined that determined that a surgical resection was indicated. Pathologic staging is inherently more accurate than clinical staging; comparison of survival typically demonstrates better survival for pathologically as compared to clinically staged patients.⁵² Nonetheless, it is the clinical stage that drives the initial treatment decisions, and thus it is imperative that the process of defining the clinical stage be performed rigorously.

The process of stage evaluation should begin as soon as there is a strong suspicion of lung cancer, and the data and recommendations in the rest of this section apply to such patients. As noted in the previous section, in most patients a review of the CT and the patient’s symptoms and risk factors for lung cancer will establish a clinical diagnosis of lung cancer with a high degree of accuracy.¹¹⁰ A thoughtful approach will often establish stage and diagnosis simultaneously and efficiently (Table 41.4). The approach to confirming the clinical diagnosis and stage is different for patients with a negative clinical evaluation and clinical stage I lesion on CT, a positive clinical evaluation suggestive of distant metastases, or those with a negative clinical evaluation but a CT suggestive of hilar or mediastinal node involvement.¹¹⁰

Extrathoracic Staging

As noted, the initial comprehensive clinical evaluation is an important first step in determining whether a primary tumor has spread. The clinical evaluation consists of a comprehensive history, physical examination, and simple laboratory testing. Constitutional symptoms, focal symptoms, abnormalities on the physical examination, or unexplained liver function abnormalities, anemia, or hypercalcemia may suggest distant metastases. Because the false-positive rate of this evaluation is around 50%, this suspicion must be confirmed. If the clinical evaluation points strongly to a particular site, further imaging or biopsy should be targeted to the observed abnormalities. For example, needle aspiration of enlarged supraclavicular nodes identified on physical examination may efficiently

establish both diagnosis and stage. If the clinical evaluation is positive but less focal, imaging for distant metastases is needed (PET and brain magnetic resonance imaging [MRI] or CT).¹²²

If the patient has a typical presentation with multiple sites identified on imaging that are typical of metastases, there is no need to confirm the stage (stage IVb) histologically (although there is still a need to get tissue to document the type of cancer, which should be obtained from whatever site is easiest). However, if there is a solitary site that is typical of metastatic disease, in general this should be confirmed by biopsy (see Table 41.4). Several studies have found in such scenarios that the suspected solitary metastasis is actually benign in 10% to 50%.^{123,124} Confirmation should also be obtained if the presentation is unusual or the appearance of the possible metastases is unusual.

If the clinical evaluation is negative, the incidence of finding occult distant metastases detectable by imaging varies according to the clinical intrathoracic stage. For cI by CT with a negative clinical evaluation, the incidence of finding true distant metastases is approximately 5%,^{110,124–132} and the incidence of detecting a false-positive finding of a distant metastasis is actually higher. In patients with cIII (N2) the incidence of finding occult disease is 25% to 30%.^{110,125,127,128,130,133–136} For stage cII, there is much less data but the incidence appears to be 15% to 20%.^{110,128} Therefore, there is good reason in cII or cIII patients to pursue imaging for distant metastases: PET and brain MRI with and without contrast are optimal, although an abdominal/pelvic CT, bone scan, and brain CT with contrast is reasonable if PET is not available or brain MRI is not possible.

The value of PET imaging for the detection of distant metastases in larger cI tumors is controversial. There no clear data specifically for this group. RCTs of the value of PET in general have shown varying results depending on the clinical setting and the likelihood of metastases in the patient population included.^{131,137–140} Those studies showing a benefit have included patients selected by minimal criteria (i.e., a general practitioner’s suspicion of lung cancer based on a chest X-ray alone) or patients with clinical findings suggestive of metastases and little conventional imaging,^{138,139} whereas those that have found no difference involved patients that had a low suspicion of metastases based on the clinical evaluation by a lung cancer specialist and who had already undergone

TABLE 41.4

Approach Diagnosis and Staging of Patients with Probable Lung Cancer

Clinical Scenario	Result of Clinical Evaluation	Confirmation of Extrathoracic Stage	Confirmation of Intrathoracic Stage	Confirmation of Diagnosis
NSCLC				
Peripheral cI	Neg (FN 5%)	Not needed	CT alone (FN <10%)	Surgical resection
cII, central cI	Neg (FN 5%–15%) ^a	PET	Mediastinoscopy vs. EBUS ^b	Surgical resection
cIII, discrete N2,3 enlargement	Neg (FN 30%)	PET, brain MRI	EBUS vs. mediastinoscopy ^b	Mediastinal node biopsy
cIII, diffuse infiltration	Neg (FN 30%)	PET, brain MRI	CT alone is sufficient	Easiest site ^c
cIV	Pos (FP 50%)	PET, brain MRI	not needed	Easiest site if multiple typical metastases ^c Biopsy of suspected site if solitary potential metastasis
SCLC				
Any	Any	PET, brain MRI	CT	Easiest site ^c

NSCLC Non-small cell lung cancer; cI, clinical stage I; Neg, negative; FN, false negative; CT, computed tomography; cII, clinical stage II; PET, positron emission tomography; EBUS, endobronchial ultrasound; cIII, clinical stage III; MRI, magnetic resonance imaging; cIV, clinical stage IV; Pos, positive; FP, false positive; SCLC, small-cell lung cancer;

^a Rate not specifically defined for stage II (defined for stage I and II combined). FN rate may be up to 15%.

^b Fine needle aspiration carries FN rate of about 30% in most series.

^c For example, sputum, bronchoscopy, fine needle aspiration of supraclavicular node, transthoracic needle aspiration.

conventional imaging.^{131,137} The ACCP and NCCN guidelines are relatively generic in recommending PET in essentially all patients with a suspected or diagnosed lung cancer, without accounting for details of the clinical stage before PET or the clinical setting (only c1a and GGO lesions are excluded from the PET recommendation by the ACCP).^{110,141}

Mediastinal Staging

If there are no distant metastases, the status of the mediastinal nodes becomes critical in determining the right treatment strategy. Much information is already available from the CT scan. However, while there are situations in which it is reliable, there are also many in which it is notoriously unreliable. One can distinguish four groups of patients based on the CT findings: (A) tumors with mediastinal infiltration, meaning that discrete lymph nodes can no longer be distinguished or measured; (B) tumors with enlargement of discrete mediastinal node(s) (≥ 1 cm in short axis diameter on an axial image); (C) normal mediastinal nodes but either N1 node enlargement or a central (hilar) tumor; and (D) peripheral tumors with no evidence of N1 or N2,3 node enlargement.¹¹⁰

In group A, clinical experience shows the false-positive rate is essentially 0; thus, invasive biopsy is not needed to confirm mediastinal involvement (Fig. 41.8). The rate of a false positive of discrete node enlargement in category B is $\sim 40\%$, making invasive staging necessary. For central tumors (category C), the false-negative rate of the lack of N2,3 enlargement is $\sim 25\%$, again making invasive biopsy important. In category D (peripheral tumor with no N1-3 enlargement), the false-negative rate of CT is $\sim 10\%$ ($< 10\%$ for T1 and $\sim 12\%$ for T2); thus, many feel that invasive confirmation of a lack of N2,3 involvement is not needed (especially if PET is also negative; see the following), whereas some feel this rate is high enough to justify invasive biopsy.¹¹⁰

PET scanning adds information, but does not alter the indications for invasive staging significantly.¹¹⁰ A positive PET in an enlarged node (group B) carries a 15% to 20% false-positive rate,

whereas a negative PET in an enlarged node carries a 20% false-negative rate, making invasive biopsy necessary either way.¹¹⁰ For central tumors (group C), a negative PET still has a 20% false-negative rate, and a positive PET in the mediastinum has a 20% chance of being a false positive. For a peripheral tumor with no node enlargement, a negative PET has a false-negative rate of $\sim 3\%$ (but a positive PET may be false positive). This data makes it clear that in groups A and D imaging can generally be considered adequate, but in groups B and C invasive biopsy is needed regardless of the PET results (unless compelling data for distant metastases is present).¹¹⁰

There are multiple techniques to invasively confirm the presence or absence of N2,3 involvement. These include traditional mediastinoscopy, video-mediastinoscopy, so-called super mediastinoscopies that involve a complete mediastinal lymphadenectomy performed as an outpatient via a cervical incision, endobronchial ultrasound (EBUS) and needle aspiration, esophageal ultrasound and needle aspiration, simple “blind” transbronchial needle aspiration, video-assisted thoracic surgery (VATS), and rarely CT-guided transthoracic needle aspiration. There are differences in which nodes are accessible, whether these procedures are applicable to multiple node sampling, and how feasible they are for sampling normal sized versus enlarged nodes (Table 41.5). The technique and thoroughness of how the procedure is done probably has a major impact on the reliability of the results.^{110,142}

The choice of which invasive staging technique to use is probably best tailored to specifics of the institution and the patient. In trained hands, all can be performed with low morbidity and mortality. There is RCT data to suggest that if good quality EBUS is available, this may be the best first step in most patients.^{110,143} However, the institutional availability of expertise is an important factor. In many reports, the false-negative rate of EBUS has been $\sim 20\%$, although in expert hands this appears to be lower (particularly if lymphocytes are obtained). Similarly, a video-assisted lymphadenectomy via mediastinoscopy has a false-negative rate of $\sim 2\%$, but is not available in most institutions. What is critical is an interest in thorough staging and experience with at least some of the various techniques available.

Confirmation of Intrathoracic Stage

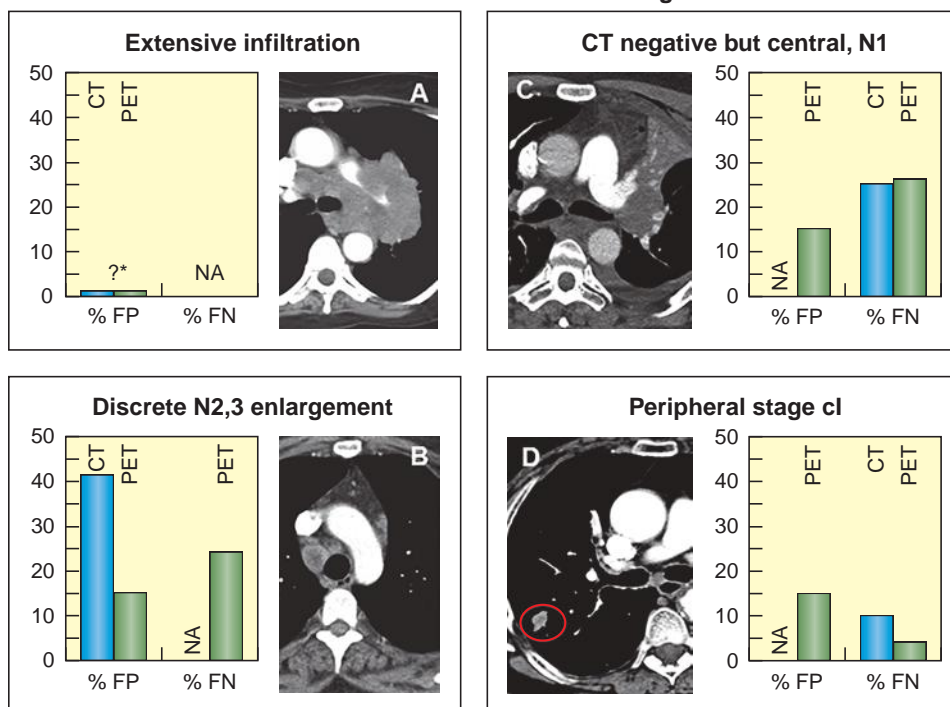

Figure 41.8 False-positive and false-negative rates for computed tomography (CT) and positron emission tomography (PET) assessment of mediastinal nodes by the American College of Chest Physicians intrathoracic radiographic (CT) classification categories. ?*, estimated, no actual data available; NA, not applicable; % FP, percent of positive test results that are false positive ($= 100 - \text{positive predictive value}\%$); % FN, percent of negative test results that are false negative ($= 100 - \text{negative predictive value}\%$). TABLE 41.5

Accessibility of Node Stations to Various Invasive Mediastinal Staging Techniques

Invasive Mediastinal Staging Technique	Accessible Lymph Node Stations
Traditional Mediastinoscopy	1, 2R, 2L, 3, 4R, 4L, anterior 7
Videomediastinoscopy	1, 2R, 2L, 3, 4R, 4L, 5, 7, 8, 10R
Anterior mediastinotomy (Chamberlain)	5, 6
Video-assisted thoracic surgery	Right-sided: R2, R4, 7, 10, 11
	Left-sided: L2, L4, 5, 6, 7, 10, 11
Transthoracic needle aspiration or biopsy	Variable; restricted to enlarged nodes
Transbronchial needle aspiration	2R, 2L, 3, 4R, 4L, 7, 10, 11
Endoscopic ultrasound with needle aspiration	4L, 5, 7, 8, 9
Endobronchial ultrasound with needle aspiration	2R, 2L, 3, 4R, 4L, 7, 10, 11, 12

MANAGEMENT BY STAGE

Overview of Lung Cancer Treatment Modalities

Structural Aspects of Patient Care

The field of lung cancer has grown to encompass a huge body of knowledge, more than what any one person can stay abreast of. Furthermore, it has become complex, with many different specialties that contribute to the evaluation and management of the patient. This makes it important to provide care in a multidisciplinary manner. The key aspect is to have a system of care delivery that is developed together with all relevant disciplines, and to have a forum for discussion so that major patient management decisions can be made with involvement of relevant specialties. It is important to provide an opportunity for different specialties to bring up points that one is unaware of, not merely to involve another specialty when one knows that they have something to offer. Unfortunately, many people think that simply having patients referred to another specialty from time to time constitutes multidisciplinary care; however, it is the system of care developed by the entire team, the ability to introduce salient points that are not being considered, and the collaborative decision making that really defines multidisciplinary care.

It is recommended and even mandated in many countries that patients with lung cancer receive care in a multidisciplinary fashion.^{109,144} This is recommended by the ACCP lung cancer guidelines, based on a review of literature; specifically, the staging evaluation, the physiologic evaluation of the ability to undergo treatment, and the treatment planning should be done in a multidisciplinary setting.¹⁴⁴ Multidisciplinary evaluation is also recommended by the NCCN guidelines.¹⁴¹ It has been difficult, however, to quantitate the impact of multidisciplinary care, because it is difficult to separate this aspect from other structural, thoroughness, and quality of care issues. A growing body of literature is showing benefits in terms of timeliness of care, more frequent use of various treatment modalities, and survival.^{109,144} In the end, it may not be important to disentangle the impact of multidisciplinary care from other quality of care issues. The key point is to recognize that organization of care, which involves multiple disciplines, has a major impact on outcomes of patients with NSCLC.

There is extensive data that the care for a large proportion of patients with lung cancer is suboptimal. A study of the US National Cancer Database revealed that the proportion of patients with NSCLC and *no comorbidities* that received suboptimal care (defined as deviating from guidelines that were in place at the time) was approximately 33% for stage I, 40% for stage II, 46% for stage III, and 47% for stage IV.¹⁴⁵ Other studies show that there are major regional differences (more than three-fold) in the United States in the frequency of use of different treatment modalities, implying that these are not related to patient factors or what is appropriate, but likely related to regional differences in the quality of care delivery.^{146,147} Several studies have shown that despite the existence of clinical guidelines for many years recommending careful mediastinal staging with biopsy confirmation, the large majority of patients are staged using CT alone (which is notoriously inaccurate).^{148–150} Furthermore, such limited clinical staging was associated with dramatically worse outcomes, stage for stage (adjusted hazard ratio [HR] for death of ~1.7 to 2.3 for overall and cancer-specific survival).¹⁴⁸

There is extensive evidence that structural aspects of care (e.g., case volume, specialization) have a marked effect on outcomes.^{151,152} A comprehensive literature review on effect of volume/specialization in quality of cancer care concluded that “An extensive, consistent literature that supports a volume-outcome relationship was found for cancers treated with technologically-complex surgical procedures. . . . Across studies, the benefit from care at high-volume centers exceeds the benefits from breakthrough treatments.”¹⁵³ In lung cancer, most of these studies have focused on surgical treatment. With very few exceptions, these studies have found lower perioperative mortality and better long-term survival in high-volume versus low-volume centers, teaching versus nonteaching facilities, and when treatment is delivered by thoracic versus general surgeons (Fig. 41.9).^{151,152}

However, the relationship between volume and outcomes is not consistent on an individual institution level; there are low-volume institutions with excellent outcomes and vice versa. This suggests that volume is only a marker for other aspects of care. It is possible that low-volume centers have less availability of expertise or cutting-edge treatment interventions. However, it is much more likely that it is a marker for how organized the care delivery is. In most high-volume institutions, care will become more organized simply out of necessity. Although it has not been directly studied, there is indirect data to support that the organization of care is the critical component.¹⁵⁴ At any rate, developing a locally appropriate, organized, multidisciplinary process of care together with tracking of outcomes certainly represents an opportunity for many institutions, and appears likely to have a significant impact on outcomes. The impact of such organized care appears to be much greater than many treatment modality advances that are heralded as major breakthroughs.^{148,155,156}

In constructing a review of lung cancer for international use, one must recognize there are regional differences (e.g., the proportion of specific cell types, use of specific treatment modalities, penetration of screening). Although some of these have been identified, their impact on the management of patients has not received much study. Nevertheless, a recognition that they exist is important. Furthermore, general conclusions and recommendations must always be tailored to the local setting. Policies may sometimes not apply because of differences in the patient population, the availability of particular interventions, and what is easily accepted in the local culture.

There are major regional differences in outcomes, perhaps best highlighted by the IASLC database results. There was a more than two-fold difference in survival rates between regions (e.g., median survival cNO 29 months versus 70 months; cN2 12 months versus 20 months for Asia versus Europe; cT1a 74 months versus 64 months, cT1b 67 months versus 46 months for Asia versus Europe, respectively).¹⁵⁷ The results were inconsistent, with different regions being better or worse depending on the TNM subgroup in question, although there was a slight trend toward better outcomes

Figure 41.9 Surgical outcomes according to case volume. Perioperative mortality and long-term survival according to institutional case volume of patients undergoing surgical resection for lung cancer. (Data taken from Howington J, Blum M, Chang A, et al. Treatment of stage I and II non-small cell lung cancer: Diagnosis and management of lung cancer, 3rd ed: American College of Chest Physicians evidence-based clinical practice guidelines. *Chest* 2013;143:e278S–313S.)

in Asia.¹⁵⁸ It is not clear what the reasons for these differences are. It is well known that the incidence of EGFR mutation is higher in the Asian lung cancer population. There are differences in the proportion of subtypes of NSCLC. There are societal differences regarding how aggressive and which treatment modalities are generally accepted. There are differences in the availability of various technologies and treatment methods (e.g., EBUS, PET, VATS, four-dimensional RT, stereotactic body RT [SBRT], genetic testing). The impact of these differences is not clear, but it does emphasize that general recommendations need to be thoughtfully considered in light of differences as compared with the population and setting in which the data was derived.

Surgery

There have been major advances in surgical treatment of lung cancer in the past two decades, just as there have been in RT and chemotherapy. Most prominent is perhaps the use of minimally invasive resection (VATS), which makes a lung cancer resection a very different experience for the patient. The perioperative morbidity is cut in half, the hospital stay reduced to 3 to 4 days in the United States, and the return to normal functioning is dramatically quicker. This is well documented in several meta-analyses,^{159–165} large-scale outcomes studies,^{166–170} propensity matched studies,^{168,171–182} and small randomized studies.^{183–185}

While the data makes VATS the recommended treatment in the ACCP lung cancer guidelines,¹⁵¹ it is used variably in different centers. Those that have embraced it perform about 80% of resections by VATS, but there remain many institutions that are not comfortable and use VATS relatively sparingly. It is likely this will change, given the amount of data supporting the VATS approach. Furthermore, robotic-assisted thoracic surgery is now being practiced at some centers. It is clear this is also a safe and effective approach. Whether there are benefits for the patient with respect to perioperative or long-term outcomes for robotic versus VATS resections is unclear.

Even open thoracotomy has changed. Smaller, muscle-sparing incisions are now commonly used. There are many newer ways of pain management that allow greater patient mobility and avoidance of complications. The management of postoperative air leaks has changed; quantitation using digital devices allows earlier chest tube removal and earlier hospital discharge.¹⁸⁶ Such postoperative management approaches have changed the experience for patients undergoing thoracotomy from what it typically was 20 years ago.

The value of care delivered by dedicated thoracic surgeons, who have a focused interest in noncardiac thoracic surgery and lung cancer in particular, is increasingly recognized. The ACCP lung cancer guidelines recommend that surgical care be delivered by such an individual, on the basis of a review of the literature that demonstrates better outcomes.¹⁵¹ Intraoperative lymph node staging was previously often spotty; there is now a much better appreciation for the necessity to do this for both the surgeon and pathologist, and acceptance of substandard intraoperative staging is diminishing.¹⁵¹

There has also been a major advance in the ability to safely carry out extensive resections, for example involving cancers invading the thoracic inlet, vertebral column, and SVC. This makes it feasible to consider surgery as part of the treatment approach for tumors that appear to be only locally invasive. In the past, many of these tumors were simply considered unresectable; however, the modern techniques and ways of reducing morbidity make surgery a reasonable option.

The advances in surgical therapy have changed patient selection for surgery. The improved perioperative outcomes allow older and more frail patients to undergo surgery (e.g., a VATS resection or a segmentectomy).^{151,166,187} Patient selection is also altered by the recognition that previous criteria had been very conservative. These had primarily defined thresholds above which there was little concern; however, they ignored the fact that risk is a continuous variable and that many patients below previous thresholds could undergo resection with quite acceptable low risk of perioperative mortality. Other previous contraindications for surgery such as a

history of myocardial infarction are rendered moot if a successful intervention for the coronary artery disease has been accomplished and overall cardiac function has been preserved. Thus, evaluation of which patients can safely undergo surgery, including VATS and sublobar resection, has become much more nuanced and is best approached in a multidisciplinary fashion, which should include a dedicated thoracic surgeon, a pulmonologist with knowledge about lung cancer treatment options, and a radiation oncologist as well.

Radiation Therapy

Advances in Radiation Technique

Three-Dimensional Conformal Radiation Therapy. Before the widespread use of three-dimensional conformal RT (3DCRT) in the 1990s, the predominant RT technique for treating locally advanced lung cancer was two-dimensional. Radiation beams would be designed using bony anatomic landmarks visible on fluoroscopic imaging. 3DCRT uses CT datasets, using beams from multiple angles to conform to contoured target volumes and similarly avoid contoured normal tissue. Inherent in 3DCRT is the use of dose-volume histograms to compare the normal tissue dose among different beam arrangements. 3DCRT provides a significant advantage over two-dimensional radiation: conformal beam design and the ability to manipulate beam geometry and weighting through the planning process improves coverage of the tumor target, and decreases the dose to normal tissue. The use of CT datasets in RT planning also enables the fusion of complementary imaging modalities, such as PET or MRI.

Intensity-Modulated Radiation Therapy. The use of intensity-modulated RT (IMRT) has been increasing in frequency over the past two decades. In contrast to 3DCRT, IMRT is inverse planned. The radiation oncologist specifies the dose to tumor targets, dose limits to organs at risk, and assigns their relative priority. Beam geometry is selected, and a computer algorithm is used to determine the optimal beam intensity and fluence pattern to meet the planning constraints. While 3DCRT beams are static, in IMRT the beam intensity is not constant—the use of a dynamic multileaf collimator varies the intensity across the beam aperture during treatment. The use of IMRT results in a more conformal plan than 3DCRT, thus reducing the exposure of surrounding normal tissue to high doses of radiation.^{188,189} In patients with bulky NSCLC, the use of IMRT decreased the volume of lung receiving >20 Gy by 10%, corresponding to a decrease of >10% in the calculated risk of radiation pneumonitis (RP). An example of 3DCRT and IMRT plans for a patient with locally advanced NSCLC is shown in Fig. 41.10.

Image-Guided Radiotherapy and Tumor Motion Considerations. Image-guided RT implies the presence of radiographic imaging incorporated into the radiation treatment device. Commonly used imaging devices include kilovoltage orthogonal planar imaging or cone-beam CT scanning. This allows direct visualization of the tumor target and/or critical organs immediately before treatment is delivered, while the patient is immobilized, as frequently as every treatment fraction. The use of image-guided RT allows the reduction of the expansion margin around the clinical target volume, since interfraction variations in patient positioning are reduced.¹⁹⁰ This can, in turn, reduce the exposure of the surrounding normal lung tissue.

Figure 41.10. Radiation treatment plans: Comparison of two methods. A 64-year-old former smoker presented with stage IIIA non-small-cell lung cancer, with disease in the right lower lobe, hilum, and mediastinal station R4. Concurrent chemoradiation was recommended. Radiation plans were generated using three-dimensional conformal radiotherapy (3DCRT) and intensity-modulated radiotherapy (IMRT). Representative axial slices from the two plans are shown: the *top panels* compare 3DCRT (*left*) to IMRT (*right*) at the level of the aortic arch, the *bottom panels* are similarly presented for an axial level below the carina. The planning target volume is shown in *red*, isodose lines are demonstrated for 60 Gy (*dark blue*), 40 Gy (*yellow*), 20 Gy (*green*) and 5 Gy (*white*). The use of IMRT decreased the mean lung dose (16 Gy versus 13 Gy) and V20 (32% versus 23%), but increased the volume of lung receiving 5 Gy. The esophageal dose was also lower with IMRT; V30 was reduced from 41% to 23%.

A large component of the expansion margin for lung cancer is designed to allow for positional uncertainty of the tumor that corresponds with the respiratory excursion of the diaphragm. Allowing for intrafraction respiratory motion is a required part of radiation treatment planning for lung cancer, and can be accomplished in several ways. The use of four-dimensional CT scans in treatment planning allows the accurate measurement of tumor motion for an individual patient,¹⁹¹ and the correlation of tumor position with an external fiducial. After the acquisition of a four-dimensional CT scan, various motion management techniques can be employed: expansion of the intended treatment volume based on the measured motion, gated treatment in which the patient is only treated during a portion of the respiratory cycle, or abdominal compression where the diaphragmatic motion is damped using external compression devices. Tumor tracking, where the radiation aperture follows tumor while it moves, is an area of growing interest.

Proton Therapy. The use of charged particle therapy such as protons is an area of active investigation in lung cancer. Protons have distinct physical characteristics that suggest they can be used to deliver thoracic radiation with a lower risk of side effects, when compared to standard photon therapy. The deposition of proton energy in tissue can be modulated by changing the beam energy, leading to much lower entry doses than photons, and an even more significant in the drop-off of the exit dose. Proton radiation beam arrangements do not need to enter and exit through lung tissue to avoid critical structures such as the spinal cord, which should decrease the risk of RP and radiation fibrosis.¹⁹² Phase 2 trials of fractionated proton therapy with concurrent chemotherapy in locally advanced lung cancer have demonstrated excellent median survival, with relatively low toxicity.^{193,194} A large cooperative group randomized trial is ongoing.

Radiation Toxicity. The risk and severity of radiation toxicity are related to the dose and volume of normal tissue that are exposed, to the presence or absence of underlying comorbidities, as well as the functional organization of the particular organ at risk. Emami et al.¹⁹⁵ published a comprehensive review of partial-volume organ tolerances for normal tissue that served for more than a decade as the standard source for radiation dose limits, and risk of toxicity. These parameters were based predominantly on clinical data from older, two-dimensional RT planning. Recently, a large multidisciplinary effort was undertaken, the Quantitative Analysis of Normal Tissue Effects in the Clinic, to summarize the published three-dimensional dose-volume/toxicity data in the literature, review normal tissue complication probability modeling, and provide practical guidance for organ dose limits.¹⁹⁶

Radiation Pneumonitis and Pulmonary Fibrosis. Clinically significant pneumonitis occurs in somewhere between 5% and 50% of patients receiving definitive fractionated radiation for locally advanced lung cancer, and is often the dose-limiting factor in radiation planning. RP may occur during fractionated treatment or up to 18 months afterward, with a peak incidence at approximately 2 months. The most common clinical presentation is a persistent, nonproductive cough; dyspnea; low-grade fever; and fatigue. Chest X-ray or CT scan may be normal, or depending on the time course there may be GGO (within 2 to 6 months), patchy consolidation (4 to 12 months), or fibrosis (≥ 10 months). The earliest radiographic changes occur within the medium- to high-dose radiation volumes, though later changes may extend into unirradiated lung. Pulmonary function testing shows reduced lung volumes, tidal volumes, and diffusion capacity. A variety of dose-volume models have been evaluated as predictive metrics of RP, including threshold volumes (i.e., V_{dose}), mean lung dose (MLD), and normal tissue complication probability models. Accumulated data from the Quantitative Analysis of Normal Tissue Effects in the Clinic effort suggest that while there is gradually increasing risk with increasing

exposure, with no safe threshold dose below which the risk of RP is zero,¹⁹⁶ the risk of grade 2 or greater RP was $<20\%$ when the MLD was held to <20 Gy during conventional radiation fractionation. Commonly used thresholds include a $V_{20} <30\%$ to 35% , or $V_5 <60\%$, corresponding to a risk of RP of $<20\%$.

RP occurs less commonly after SBRT in comparison to conventionally fractionated radiation.¹⁹⁷ The risk of symptomatic RP does seem to follow a similar relationship to dose and volume irradiated as seen in conventionally fractionated treatment,¹⁹⁸ though specific dose thresholds are evolving as experience with SBRT grows. Takeda et al.¹⁹⁹ retrospectively examined 265 patients, and with a median follow-up of 19 months the incidence of grade 2 to 5 pneumonitis was 18.5%, 4.5%, 0%, and 0.4%, respectively. Predictors of grade 2 or higher RP on multivariate analysis included V_{20} . A large series from Indiana University examined dosimetric predictors of pneumonitis²⁰⁰ in a group of 143 patients treated with SBRT. RP (grade 2 to 4) occurred in 9.4% of cases. Pneumonitis was noted in 4.3% of patients with a MLD of ≤ 4 Gy, compared with 17.6% of patients with MLD of >4 Gy ($p = 0.02$), and in 4.3% of patients with a $V_{20} \leq 4\%$ compared with 16.4% of patients with V_{20} of $\geq 4\%$ ($p = 0.03$).

RT-induced dyspnea may have several contributing causes, including not only RP but also RT to other thoracic organs at risk. Emerging evidence suggests an interaction between cardiac dose and RP,²⁰¹ and there may be additive dyspnea due to pleural and pericardial effusions, cardiomyopathy, and bronchial stenosis or bronchiectasis. Bronchial fibrosis and stenosis has been reported with radiation dose escalation beyond 70 Gy.²⁰²

Several patient- and treatment-related factors also impact the risk of RP, independent of dose and volume. In a large dataset derived from patients treated on Radiation Therapy Oncology Group (RTOG) trials, the risk of RP was significantly higher for tumors in the lower lung fields.²⁰³ Older age may increase the risk of RP, and patients who continue to smoke through treatment may be at decreased risk.¹⁹⁶ Several chemotherapy agents that are commonly administered to patients with lung cancer concurrently are associated with an increased risk of RP, including docetaxel, gemcitabine, and particularly the commonly used carboplatin and paclitaxel combination.²⁰⁴

Glucocorticoids are commonly used to treat RP in patients who have moderate to severe symptoms, although the efficacy and appropriate starting dose and tapering schedule have not been defined in a prospective fashion. Prophylactic antibiotics or anticoagulants do not appear to effect the development of RP, although they are frequently given. Pulmonary parenchymal fibrosis is the underlying cause of long-term dyspnea after thoracic radiation, likely the result of chronic treatment-induced inflammation. No standard clinical approach has been definitively demonstrated to reverse or even slow the progression of pulmonary fibrosis, though several therapies have shown signs of activity, including pentoxifylline.²⁰⁵ Amifostine is a radioprotector that has been tested in several randomized trials, with mixed results.^{206,207} Captopril is an angiotensin-converting enzyme inhibitor that has been shown to reduce the development of radiation-induced fibrosis in animal models.²⁰⁸

Esophagitis and Esophageal Stenosis. Acute esophagitis is typically the dose-limiting side effect during fractionated RT for thoracic malignancies. Grade 3 or greater acute symptoms (i.e., severely altered eating/swallowing, tube feeding, parenteral nutrition, or hospitalization indicated) occurred 18% of the time, in a series of $>1,000$ patients undergoing chemoradiation.²⁰⁴ Acute esophagitis may coexist with, and be exacerbated by, comorbid conditions such as candidiasis or reflux disease. Other factors identified as increasing the risk or severity of acute esophagitis include the use of accelerated fractionation and older patient age.²⁰⁹ The use of concurrent chemotherapy is associated with an increased risk.²¹⁰ The use of concurrent bevacizumab with RT has led to case reports of fistulae.^{211,212} Clinically significant late toxicity, such as

stenosis or fistula formation, is less common after conventionally fractionated radiation, occurring in <5% of patients.^{213,214}

Treatment of acute esophagitis is primarily supportive, frequently requiring topical agents, dietary changes, and narcotic pain medication. It is often prudent to either evaluate or treat empirically for viral or candida esophagitis. Patients may benefit from proton pump inhibitors for comorbid reflux disease, and topical agents for mucosal irritation such as sucralfate or local anesthetic agents. The ability of the radioprotectant amifostine to reduce the risk and severity of acute esophagitis has been evaluated in several prospective trials, but no benefit was noted in a large randomized, cooperative group study.²⁰⁷

Heart. For thoracic malignancies, the dose and volume of radiation to the heart and great vessels varies considerably, depending upon the anatomic distribution of the target and the treatment technique. The overall excess risk of cardiac mortality after thoracic RT is low,²¹⁵ but moderate toxicities have been reported more commonly. Acutely, this can include pericarditis, which can develop during treatment or within several months afterward. Months after radiation, there can be pericardial effusion, and over years progressive fibrosis may rarely lead to constrictive pericarditis. Ischemic changes in the cardiac muscle can manifest with a long latency and may lead clinically to congestive heart failure or ultimately a higher cardiac mortality.²¹⁶ Valvular abnormalities have been reported, presumably due to late fibrotic changes. In the great vessels, there can accelerated atherosclerosis that worsens over years to decades, leading to an increased risk of structural damage such as aneurysm. Comorbid clinical conditions may increase the risk of RT-induced cardiac toxicity,²¹⁷ including hypertension, diabetes, obesity, and genetic predisposition. The risk of cardiac mortality from RT has been specifically demonstrated to be increased in patients over 60 years old, and by tobacco use.^{218,219} There are reports that concurrent paclitaxel may also increase this risk.^{220,221}

Brachial Plexus. Radiation brachial plexopathy is a rare but serious complication of fractionated radiation to conventional doses. There are case reports of early, transient neuropathy that may occur during or shortly after radiation, and may resolve spontaneously.²²² Late radiation plexopathy is more clinically significant; it manifests years after radiation to the supraclavicular area and may manifest as hypesthesia, paresthesia, and weakness of the affected arm and shoulder. It may progress to total paralysis of the affected arm, and severe pain. The dose tolerance of the brachial plexus is less defined than other thoracic organs, partly due to the difficulty in defining the plexus radiographically during radiation treatment planning. A contouring atlas has been adopted, so that more robust clinical data can be collected.²²³ Late plexopathy is rare in patients who receive conventional doses of fractionated radiation.²²⁴ For SBRT, brachial plexopathy is a more significant concern, because the biologically effective dose prescribed to the target exceeds the tolerance of the plexus.^{220,221}

Chemotherapy

There has been a long evolution in the treatment of NSCLC since the early editions of this textbook. It was not until the late 1980s that the benefits of chemotherapy with respect of overall survival (OS) and QOL versus supportive care were appreciated in patients with advanced disease.²²⁵⁻²²⁷ In the early 1990s, a new generation of chemotherapeutic agents, used in combination with platinum analogs, consolidated the benefits of treatment and established chemotherapy.

In the mid to late 1990s, the combination of chemotherapy and RT in patients with stage III disease showed superior outcomes compared to single modality and created a new paradigm of combined modality therapy, still considered the standard to this date.²²⁵ During the 2000s, chemotherapy was tested in the adjuvant setting

and became a new standard of care by improving the cure rates in selected patients with stage IB through IIIA disease.²²⁸ Remarkably, over the course of two decades, or five editions of this textbook, chemotherapy has become an established treatment modality for the majority of patients with NSCLC.

The discovery of somatic mutations in a subset of lung tumors is the most significant paradigm shift in the treatment of lung cancer in the last decade. Since the initial report on EGFR,²²⁹ the understanding that specific molecular alterations serve as oncogenic drivers, and that blockade of these pathways by specific agents can lead to robust and prolonged responses, has revolutionized the approach to patients with lung cancer. This discovery has launched the era of personalized medicine, in which patients are managed based on specific characteristics of their tumors.

The evolution of chemotherapeutic management of NSCLC has ushered in many more fundamental changes in how we think about stage IV NSCLC. At one time, it was questionable whether the treatment was worse than the disease, now this is a vibrant, successful, fast-paced field with new discoveries that challenge the ability to keep pace. There are many effective cytotoxic agents, targeted therapy, and immunotherapy, and which are used in first-, second-, and third-line settings. The treatments can be dramatically effective, and it is no longer surprising when a patient with incurable NSCLC can be successfully managed over many years. We are clearly moving toward management of stage IV NSCLC as a chronic disease.

The management of stage IV NSCLC is complex. It is not merely a question of which drug to use, but which sequence, how to plan the first course of therapy taking into account later options, and when to initiate a new treatment. Treatment is viewed less as a defined course of therapy and more as a continuum over time. The lines between treatment courses are blurred: when does a course of therapy become maintenance, when is maintenance therapy early institution of second-line treatment? More aggressive palliation of specific symptoms or conditions (brain, spine, bone metastases, airway obstruction, etc.) has far-reaching effects, including a better QOL and a more positive attitude, but also a better ability to tolerate active treatment.

The evolution of chemotherapy treatment of NSCLC has led to different end points in clinical trials. OS, once considered a hard end point, has become problematic. Because OS reflects the entire continuum of management and a combination of interventions, it is often difficult to discern what effect a particular portion of the treatment strategy has on OS. Progression-free survival (PFS) has become more prominent as it can assess a specific portion of the continuum of treatment. However, it is controversial whether and under what circumstances it is an appropriate measure.²³⁰ More subtle measures such as toxicity and QOL are also used as primary end points. Thus, end points of clinical research have become more difficult to measure and attribute to a particular intervention. At the same time, the standards of what is considered clinically relevant and sufficient to call a trial positive has decreased.²³¹ The combination of these trends raises issues for clinical research moving forward.

The treatment has become much more specific; having evolved from a one-size-fits-all NSCLC approach to being histology based, and even more specifically directed to small cohorts identified by particular genetic mutations. These markers have an impact not only on response but also on susceptibility to toxicity in some cases. This radically changes the economics of treatment, research, and drug development. The specific cohorts are smaller and more difficult to identify. The need to screen a larger population to identify a few individuals can be costly and inefficient. Cost is determined not just by the cost of therapy but also cost of and ability to find the right cohort.²³²⁻²³⁴ The dramatic response that can be seen with such targeted therapy can lead to approval of a therapy based on nonrandomized data alone, reducing the costs of drug development. However, the more limited cohort for whom it is applicable also limits the potential return. The pace of new discoveries in

specific tumor subgroups creates challenges in how to conduct appropriate clinical research in a timely enough manner. New approaches to trial design, such as an adaptive Bayesian structure, may offer innovative, more flexible options than the traditional phase 1, 2, and 3 research schema.²³⁵ There are many forces in play in the dynamic, rapidly changing field.

Preinvasive and Minimally Invasive Disease (Bronchial Intraepithelial Neoplasia, Adenocarcinoma in Situ, Ground Glass Nodules)

Bronchial intraepithelial neoplasia appears to be a precursor to central airway squamous cell carcinomas. These lesions are infrequently encountered, usually in patients with abnormal sputum cytology or during surveillance of the central airways. Although techniques have been developed (autofluorescence bronchoscopy, narrow-band imaging) that are more sensitive in detecting such lesions, it is unclear how these should be implemented.²³⁶ Among high-risk patients who participated in a screening program, about 30% of high-grade dysplasia and 50% of carcinoma in situ lesions were observed to progress; however, the rates were highly variable among studies (with follow-up periods of ~1 to 10 years).²³⁶ A substantial proportion of lesions regress during follow-up. One of the problems is that there is moderate interobserver variability in the classification of such biopsies. Photodynamic therapy seems to be fairly effective at treating lesions deemed worthy of intervention, but it is not well established which lesions need intervention, as many do not progress.²³⁶

In 2011, a new subclassification of adenocarcinoma was introduced, covering a spectrum from atypical adenomatous hyperplasia (AAH), adenocarcinoma in situ (AIS), minimally invasive adenocarcinoma (MIA), lepidic predominant adenocarcinoma, and various types of invasive adenocarcinoma (acinar, papillary, micropapillary, etc.).⁶³ Although not conclusively established, this carries the implication that the earlier lesions (e.g., AAH, AIS) may be precursors to invasive adenocarcinoma. It must be emphasized that these entities can only be classified after resection (not on the basis of a limited biopsy).⁶³ However, there is a strong correlation between the histologic classification and the radiographic appearance, although this has not been quantitatively defined. AAH and AIS lesions generally appear as pure ground glass nodules (GGN) on CT, and MIA and lepidic predominant adenocarcinoma are often part-solid GGNs, while other types of adenocarcinoma are generally mostly solid-appearing lesions on CT. The increased use of CT has led to more frequent recognition of these lesions and creates a need to define how to manage them.

Pure GGNs are focal lesions seen incidentally on a chest CT; this is distinct from more diffuse or patchy ground glass appearance of the lung, which generally signifies benign interstitial or inflammatory lung disease. A number of studies have reported outcomes of such lesions during a period of observation of 1 to 3 years.²³⁷ It is difficult to be precise because of slight differences in definitions and inclusion criteria and duration of follow-up. Approximately 10% to 20% of pure GGNs disappear, usually within 3 months. About 10% decrease in size, but it should be noted that approximately 20% of adenocarcinomas that were eventually resected after a period of observation were observed to have decreased in size.²³⁷ Most remain stable, around 20% increase in size, and ~10% (range, 0% to 30%) develop a solid component.²³⁷

Other papers have focused on diagnoses made during observation of a GGN, which may skew the data toward the more suspicious lesions that motivated intervention. These studies have found that approximately 75% of pure GGNs are benign (and still followed), ~10% are AAH, 10% to 20% are BAC, and ~5% are adenocarcinoma.²³⁷ It is hard to translate the older terms BAC and adenocarcinoma used in these studies into the new subclassification

of adenocarcinoma. Among studies that focused on lesions that were actually resected, ~30% of pure GGNs were benign (including AAH), the majority was BAC, and ~10% were diagnosed as adenocarcinoma. The incidence of adenocarcinoma was <5% in pure GGNs <10 mm in size, and ~25% if >10 mm.²³⁷

The rate of invasive cancer is substantially higher in part-solid GGNs (although these are by definition still >50% ground glass). A diagnosis of adenocarcinoma is made in ~10% during a period of observation. Of those coming to actual resection, ~30% are adenocarcinoma and most of the rest were classified as BAC; ~10% were adenocarcinoma among part-solid GGN <10 mm versus ~40% if >10 mm.²³⁷

Triggers for intervention are still evolving. There is a growing impression that pure GGNs may be simply observed, while a part-solid GGN usually warrants intervention, especially if the solid component has recently developed. The rate of growth should also be factored in—a lesion that has grown 2 mm in 5 years may not warrant intervention. Significant growth over the course of a year or development of a solid component should generally trigger resection.^{119,237,238} Exact definition of recommendations and specific documentation of results is hampered by the short periods of follow-up in studies so far, the loose correlation between radiographic appearance and histologic results, the inability to establish a diagnosis of a preinvasive lesion before resection, and the uncertainty about the malignant potential of AAH, AIS, MIA, and even lepidic predominant adenocarcinoma.

Multiple studies suggest that a limited resection of a pure or >50% GGN results in excellent outcomes (5-year survival >95% with no recurrences).²³⁷ One can question whether all of these lesions actually need to be resected in the first place. Nevertheless, one prospective carefully done study of limited resection found no recurrence at 5 years, but by 10 years 13% developed a staple line recurrence of a genetically apparently identical tumor, despite a reasonably wide negative margin originally.²³⁹ The ACCP lung cancer guidelines suggest a sublobar resection for a pure GGN <2 cm with careful attention to achieving an adequate margin.¹⁵¹

Patients with GGNs often have several lesions. These lesions should be approached conceptually as independent lesions. Each lesion should be managed individually, intervening when necessary and observing other when there is no change and a low suspicion of invasive cancer.^{119,237,238} There is no reason to give chemotherapy to these patients if these are independent early cancers or preinvasive lesions; chemotherapy has no role as a chemopreventative agent.

Stage I (T1,2 N0)

The standard of care for healthy patients with a clinical stage I NSCLC is surgical resection.^{14f,151} This is based on decades of experience showing good long-term survival rates with few recurrences after resection. Examination of the 2010-11 US National Cancer Database shows that surgery was the dominant treatment strategy (surgery in 66%, RT in 23%, and no treatment in 9%). In the US Surveillance Epidemiology and End Results (SEER)-Medicare database (i.e., patients age >65 years), the treatment given to stage cI patients in 2007 was surgery in 67%, RT in 16%, and no treatment in 18%.²⁴⁰ The ACCP Lung Cancer Guideline recommends that patients with stage I NSCLC being considered for curative therapy be evaluated by a thoracic surgeon or a multidisciplinary team (even if nonsurgical therapy is being considered). Those undergoing surgery should be treated by a thoracic surgeon with a demonstrated focus on lung cancer (grade 1B).¹⁵¹ There is a growing body of literature that demonstrates that outcomes are demonstrably better with specialty training and at higher volume centers (HR = 0.7 for perioperative mortality and 0.9 for long-term outcome in high-volume centers in a recent meta-analysis).¹⁵²

Across the world, for NSCLC cases diagnosed between 1990 and 2000, staged and treated according to the local routines at the

time the survival as reported by the huge IASLC database is 50% for cIa and 43% for cIb, and 73% for pIa and 58% for pIb.⁵² More recent Japanese national cancer statistics demonstrate 5-year survival rates of 77% and 60% for cIa and cIb, and 84% and 66% for pIa and pIb.²⁴¹ It is important to note that only about half of the deaths within 5 years in stage I NSCLC are due to recurrences; the 5-year recurrence rate is only about 20%.²⁴²⁻²⁴⁴ The majority (60%) of recurrences are identified within the first 2 years.^{244,245} Late recurrences beyond 5 years are seen in 10% to 20% of patients, but it is unclear how many of these "recurrences" are actually new primary cancers.^{246,247}

The ACCP Lung Cancer Guideline suggests that a minimally invasive (e.g., thoracoscopic [VATS] or robotically assisted) resection is preferred over an open thoracotomy for stage I NSCLC (grade 2C).¹⁵¹ This is based on consistent data from small RCTs, matched case-control studies, propensity matched cohort studies, meta-analyses, and large outcomes studies, which demonstrate lower perioperative mortality, fewer complications, and shorter hospitalization as well as at least equivalent long-term stage-matched survival.^{151,159,160,168,171,176,248-250} The penetration of VATS for major lung resection has been growing annually at US academic medical centers, but is performed almost exclusively by thoracic surgeons (not cardiac, general, or oncology surgeons).²⁵¹ RCTs and large database outcome studies show no difference in the ability to biopsy or resect mediastinal nodes by VATS,^{159,176,183,184,252,255} although there may be a less thorough assessment of N1 nodes.²⁵² The ability of patients to receive adjuvant chemotherapy is improved following VATS lobectomy.^{254,255}

A lobectomy remains the treatment of choice for good-risk patients with stage I NSCLC in general (ACCP Lung Cancer Guideline grade 1B).¹⁵¹ This is a general conclusion, which is a different issue than asking whether an alternative resection is acceptable in patients that cannot tolerate a lobectomy, or whether there are particular cohorts for which the general statement does not apply. The recommendation for lobectomy over a more limited resection is based on better survival and lower local recurrence rates after lobectomy. Unfortunately, the data is not of high quality. This result is demonstrated by a RCT with only minor flaws,^{256,257} but because it stems from the late 1980s, the relevance to the current era can be questioned. Other uncontrolled comparative studies corroborate these results, but the patients undergoing sublobar resection were clearly not the same (often not able to tolerate lobectomy or with smaller tumors). Furthermore, the sublobar resections often involved a mixture of segmentectomy and wedge resection, although segmentectomy generally results in better survival and less local recurrence than a wedge.

Specific groups that have been considered to be potentially suitable for a sublobar resection include patients with tumors <2 cm, <1 cm, pure GGO lesions, and elderly patients. For solid smaller lesions and older patients, the data is unclear; comparisons have yielded conflicting results, probably because of the inability to account for selection and confounding factors. Comparisons involving primarily wedge resection tend to show worse results, whereas those involving segmentectomy are more similar to lobectomy.¹⁵¹ Two RCTs are under way to address the value of segmentectomy for solid tumors <2 cm. Increased perioperative mortality or competing causes of death such as might be present in older patients are reasonable to consider; however, clear guidance on when this tips the balance away from lobectomy is not possible from the currently available data.¹⁵¹ On the other hand, there is fairly extensive data that patients with predominantly GGO lesions <2 cm consistently experience excellent 5-year outcomes after sublobar resection (predominantly segmentectomy), with the implication that it would be difficult for lobectomy to yield even better results. This led the ACCP guideline committee to recommend sublobar resection for predominantly GGO lesions <2 cm (grade 2C).¹⁵¹ However, it is important to have an adequate margin, and there is data from a carefully done prospective study that segmentectomy may be associated with late recurrences (between 5 and 10 years).²³⁹

At the time of surgical resection, at least a systematic lymph node sampling should be performed. This involves systematically looking for and sampling a representative node from N1 and ipsilateral mediastinal node stations. Data supports that this results in more accurate staging than selective sampling.²⁵⁸⁻²⁶¹ However, there appears to be no survival benefit to a complete lymph node dissection in RCTs, at least not in clinical stage I patients.^{151,260-262}

Adjuvant chemotherapy or RT is not indicated after complete resection of stage I NSCLC. Although the majority of recurrences after resection of stage I NSCLC are distant, multiple RCTs that have included stage I patients have suggested that there is no benefit to adjuvant chemotherapy.²⁶³⁻²⁶⁵ A meta-analysis that addressed stage-specific subgroups did not find a benefit for either stage Ia or Ib.¹⁵⁵ An unplanned subgroup analysis in one study suggested that there may be a benefit for tumors ≥ 4 cm,²⁶⁶ but this has not been borne out by further follow-up or other analyses. Other negative prognostic factors have been suggested (i.e., tumor differentiation, vascular invasion, histologic features), but the argument that chemotherapy will have an impact is purely speculative. The ACCP NSCLC guideline, which is more evidence based, takes the position that adjuvant chemotherapy should not be given for stage Ia or Ib with the stance that speculative arguments should not overpower RCT data.¹⁵¹ The NCCN guideline, however, which is primarily consensus based, suggests considering adjuvant chemotherapy for high-risk stage Ib patients, by taking into account potential negative prognostic factors.¹⁴¹ On the other hand, tegafur (an oral 5-fluorouracil agent available in Japan) has been found to improve survival in two RCTs when given orally for 2 years.^{267,268}

Adjuvant RT is also not indicated after complete resection of a stage I NSCLC; in fact, the RCT data suggest it is likely to be harmful.^{151,269} A more recent RCT and an outcomes analysis of the SEER database confirm this result.^{270,271}

While lobectomy remains the standard of care for stage I NSCLC, there are patients who are considered poor candidates for this approach. However, poor risk for lobectomy is difficult to define. VATS resection has decreased the perioperative mortality,^{272,273} data shows that lung function is reduced much less or even improved in patients with severe COPD,^{272,274-276} and the majority of data mixes lobectomy and various forms of sublobar resection together (often including good-risk patients with low-risk tumors together with poor-risk patients with high-risk tumors). Furthermore, data suggest that limited pulmonary reserve correlates primarily with perioperative mortality, whereas long-term functional limitations are often due to random unpredictable events. The ACCP guideline recommends caution about undertaking lobectomy if the predicted postoperative FEV1 or predicted postoperative DLCO is <30% or <22 mL on a stairclimbing test.²⁷² Such patients should undergo a formal exercise test and a careful multidisciplinary evaluation. While lobectomy may still be found to be appropriate, other options such as a segmentectomy, wedge, SBRT, or radiofrequency ablation (RFA) should also be considered.²⁷² The multidisciplinary decision making is crucial, because there are many aspects that must be taken into account (e.g., how functional the portion of lung is that contains the cancer, technical issues with doing either surgery, SBRT or RFA, and issues related to confirming the stage of the patient).

Sublobar resection undertaken as a compromise due to poor pulmonary reserve cannot be compared to sublobar resection undertaken electively because of favorable tumor characteristics. Furthermore, the outcomes for a segmentectomy cannot be compared to a wedge resection, although frequently these are combined. The available studies show that the perioperative mortality for a sublobar resection in compromised patients is around 5%, even when the resection involves a thoracotomy (not VATS).¹⁵¹ The issue is one of long-term results. In the ACCP guideline review, 5-year survival after segmentectomy/wedge for stage I NSCLC in compromised patients ranged from 40% to 70%; there was a trend to worse outcomes than for lobectomy in case-matched comparisons, although the differences were not statistically significant in most studies.

The recurrence rate after sublobar resection was 0% to 18%.¹⁵¹ In one of the few series to specifically compare (retrospectively) compromised patients undergoing segmentectomy versus wedge, the 5-year survival was better for segmentectomy (80% versus 48%; $p = 0.005$) and the recurrence rate was lower (16% versus 55%; $p = 0.001$).²⁷⁷ In conclusion, when surgery (usually open thoracotomy) was judged to be reasonable in compromised patients, a sublobar resection could be accomplished quite safely (mortality ~5%) and the long-term outcomes were encouraging, especially for segmentectomy, which appears to be better than a wedge resection.

Nonsurgical treatment options have also emerged for compromised patients. SBRT has received the most attention. In contrast to conventionally fractionated radiation therapy, which uses small daily fractions over the course of 6 or more weeks, an SBRT treatment plan typically delivers a much higher biologically effective dose over three to five treatment visits. This requires a high degree of precision to avoid delivering the increased dose to the surrounding tissue. For lung cancer, this means highly reproducible immobilization, management of respiratory motion, and accurate localization during treatment delivery. The result is markedly higher rate of local control and survival and markedly lower toxicity when compared to conventional RT.

Because SBRT is well tolerated, does not require general anesthesia, and results in minimal damage to surrounding lung, it has been used primarily in the management of early stage lung cancers in patients who could not tolerate surgical resection of any type. In general, these appear to have been rather severely compromised patients in reported studies. The diagnosis of lung cancer was confirmed in about 75% of patients (range, 30% to 100%). In many of the studies, the cases not confirmed by biopsy were clinically diagnosed as lung cancer by a multidisciplinary tumor board on the basis of growth and/or PET activity. The lesions treated appear to have been primarily solid typical lung cancers, not indolent, ground glass tumors or screening detected cancers. The median tumor size has generally been 2 to 3 cm.

Many of the studies involving SBRT for NSCLC have reported 2-year outcomes. Survival is approximately 60% at 2 years (45% to 79%) and 40% at 5 years (24% to 50%).¹⁵¹ Cancer-specific survival is approximately 75% at 2 years (50% to 90%) and 60% at 5 years (34% to 73%).¹⁵¹ Disease control at the primary tumor site is approximately 90% at 2 years (83% to 100%).

Early prospective trials suggested that SBRT is associated with a higher risk of moderate to severe adverse events in a central or perihilar tumors. However, there are several published examples of safe SBRT schedules for such patients, all delivering a somewhat lower biologically effective radiation dose than that described in the RTOG 0236.^{278–281} Taken together, the cumulative experience in SBRT for central lung tumors suggests that the use of more protracted fractionation, lower dose, and prioritizing normal tissue dose constraints over target volume coverage appear to reduce the risk, but there is a suggestion that this comes at the cost of somewhat lower local control. The RTOG 0813 was a phase 1/2 dose escalation study of SBRT in central tumors that has completed accrual, and the results will inform treatment of these tumors.

There is much less data for RFA, but reported OS is approximately 80% at 2 years and 30% at 5 years (20% to 61%), with a control at the primary tumor site being achieved in approximately 60% (58% to 92%). It is very difficult to compare outcomes of patients treated surgically to those treated with SBRT or RFA—the degree of comorbidity is different, the confirmation of stage and diagnosis is different, and the definition of local control outcomes are different. Randomized studies have not been able to be conducted.

In summary, it can be said that surgical resection remains the standard for stage cI NSCLC. This should involve a lobectomy with at least a systematic mediastinal node sampling and should be performed by VATS in an experienced center. Tumors that are amenable to a sublobar resection (with attention to adequate margins!) are primarily GGO lesions <2 cm; the data for small solid tumors or in elderly patients is not clear. In patients with

limited pulmonary reserve who are considered poor risk for lobectomy, segmentectomy can be accomplished safely in selected patients with good long-term outcomes. A wedge resection is probably oncologically similar to nonsurgical treatment. Although survival results appear slightly better for wedge resection than SBRT, any comparison is confounded because the patients, tumors, and workup are quite different. However, the results of such interventions appear to be good enough to justify their use and appear to be better than that of completely untreated, conventionally detected stage I NSCLC.

Stage II (T1,2 N1)

The recommended treatment for clinical stage II NSCLC without major comorbidities is surgical resection followed by adjuvant chemotherapy.^{141,151} Surgery has been the mainstay of treatment for many decades; an additional benefit to adjuvant chemotherapy has been demonstrated more recently (discussed subsequently). The ACCP recommends that patients be evaluated by a thoracic surgeon with a focus on lung cancer and be discussed in a multidisciplinary forum (grade Ib).¹⁵¹ This is the standard in many European countries as well.

In the IASLC database, the 5-year survival was 36% for cIIa and 25% for cIIb (representing frequent stage misclassification). Survival was 46% for pIIa and 36% for pIIb.⁵² These patients were diagnosed and treated between 1990 and 2000, mostly without the availability of PET scanning and likely mostly by surgery alone. In the Japanese national database, the 5-year survival rates in 2004 were 54% and 44% for cIIa and cIIb, and 61% and 47% for pIIa and pIIb, respectively.²⁴¹ In the Lung Adjuvant Cisplatin Evaluation meta-analysis of patients receiving resection plus adjuvant chemotherapy, the 5-year survival was estimated to be 45% for stage II NSCLC.²⁸² In stage II NSCLC, approximately 75% of deaths are due to recurrence.^{283,284}

At the time of resection, the ACCP suggests that a formal mediastinal node dissection be performed (grade 2B), because there is some data suggesting that survival may be improved.¹⁵¹ Selective sampling of only abnormal-appearing nodes is clearly substandard, and does not accurately define the pathologic stage. There is no difference in the accuracy of stage definition between a systematic mediastinal node sampling and a complete mediastinal node dissection.^{151,258,260} However, there is a suggestion that survival and recurrence is better after a complete node dissection from randomized and nonrandomized studies.^{151,258,260,285,286} Although substandard node assessment at the time of resection has been common, it should no longer be accepted given the data and value of adjuvant chemotherapy.

Stage II NSCLC involves either hilar (N1) nodes or a central (hilar) primary tumor. Whenever possible, a sleeve resection should be performed as opposed to a pneumonectomy.¹⁵¹ A sleeve resection involves resection of a portion of the bronchus to that of the uninvolved lobes of the lung. The same can be done for the pulmonary artery. Although the data is retrospective and subject to potential confounding by other factors, several reviews have found lower operative mortality and complications for sleeve resection versus pneumonectomy, equivalent or better long-term survival, lower recurrence rates, and better QOL.^{151,287,288}

Adjuvant chemotherapy is clearly indicated after complete resection of stage IIa,b (N1) NSCLC, and adjuvant platinum-based chemotherapy is recommended by the ACCP and NCCN clinical guidelines.^{141,151} This is based on the results of several randomized trials and meta-analyses.¹⁵⁵ There is data suggesting that cisplatin-vinorelbine may offer the best efficacy compared with other doublets.^{155,289} While a few RCTs have not been positive, they have generally had significant flaws.¹⁵¹

The benefit of adjuvant therapy rests in the use of cisplatin-based combinations.¹⁵⁵ Carboplatin was used in one randomized

trial, exclusive to patients with stage IB disease, which did not show a statistically improvement in survival, save for a subset of patients, identified in a post hoc analysis, with tumors ≥ 4 cm in greatest diameter.²⁶⁶ Although carboplatin may be considered an alternative for patients with an absolute contraindication to cisplatin, the majority of candidates for adjuvant chemotherapy should receive cisplatin in combination with vinorelbine, docetaxel, gemcitabine, or with pemetrexed in patients with nonsquamous histology. While the bulk of the adjuvant data is based on cisplatin-vinorelbine, other regimens have been endorsed by the National Cancer Institute. It is assumed, though not yet demonstrated, that these regimens have comparable efficacy in this setting as in more advanced stages. Four cycles of adjuvant chemotherapy are typically recommended.

There are a number of nuances to mention. While the survival benefit of adjuvant therapy is sustained in late follow-up, it is diminished and there are late intracranial failures.^{263,290} The lack of benefit in some RCTs suggests that factors such as the quality of surgery, the choice of chemotherapy, and the use of RT may play an important role. Whether adjuvant chemotherapy should be used for larger primary tumors (> 5 cm) without local lymph node metastasis (T2bN0M0) is unclear. The ACCP guideline does not recommend this (based on equivalent survival in JBR10 and Cancer and Leukemia Group B [CALGB] 9633),¹⁵¹ but the NCCN guideline suggests this can be considered.¹⁴¹

Postoperative RT (PORT) is not recommended for completely resected NSCLC.^{141,151} The PORT meta-analysis found a nonsignificant survival detriment for PORT in N1 patients.²⁶⁹ However, techniques of RT have advanced from what was used in many studies included in the PORT meta-analysis, and there are nuances that may be important. A SEER analysis found slightly worse survival for stage II patients receiving adjuvant RT.²⁷¹ A subset analysis of stage II patients in the ANITA study demonstrated a 12% survival advantage of PORT in the no adjuvant chemotherapy arm, but a 16% survival disadvantage in the arm receiving adjuvant chemotherapy.²⁹¹ In the setting of a positive bronchial margin, PORT is recommended by the ACCP and NCCN, although there is very little available data addressing this.^{141,151} In summary, adjuvant RT should not be used after complete resection of stage II NSCLC; while modern techniques may change this recommendation in the future, it is also possible that better adjuvant chemotherapy obviates the benefit of RT.

Preoperative chemotherapy is not recommended. This has been addressed by one RCT involving stage I-II NSCLC, although about two-thirds of the patients were stage Ib; 624 patients were randomized to either surgery alone, preoperative chemotherapy, or surgery and adjuvant chemotherapy (three cycles of paclitaxel/carboplatin).²⁹² There was no difference in OS or disease-free survival between any of the arms. A subgroup analysis of stage II (T3 or N1) patients found a nonsignificant trend in disease-free survival favoring preoperative chemotherapy versus surgery alone (HR = 0.88; 95% confidence interval = 0.69 to 1.12; 5-year disease-free survival 41% versus 35%; $p = 0.31$). There was no benefit to adjuvant chemotherapy versus surgery alone in this subgroup analysis (HR = 1.01; 5-year disease-free survival 37% versus 35%; $p = 0.97$). However, given the limited number of patients, no suggestive conclusions can be drawn from this experience.²⁹²

Locally Invasive Tumors (T3,4 N0,1)

Certain tumors are characterized by local invasiveness (or size). Although they are classified as stage IIb, IIIa or IIIb, they may be biologically different than tumors distinguished primarily by nodal involvement.

T3N0,1

T3N0M0 tumors are classified as stage IIb, whereas T3N1M0 tumors are stage IIIa.^{293,294} Most commonly, this involves tumors

that are locally invasive into adjacent structures, with the chest wall being the most common site. The presence or absence of pain is probably the best indicator of chest wall involvement. In patients with cT3N0M0 tumors, the ACCP and NCCN guidelines suggest imaging for potential distant metastases and invasive mediastinal staging to detect possible occult N2,3 involvement, although data defining the incidence of such involvement is not available.^{141,295}

Surgical resection is the recommended therapy for T3N0,1M0 NSCLC involving the chest wall.^{141,295} The 5-year survival after an en bloc complete resection is consistently 50% to 60% for T3N0M0 tumors, whereas it is $< 5\%$ with no resection or an incomplete resection (even with adjuvant RT).²⁹⁵ Because a discontinuous (versus en bloc) resection is associated with worse outcomes, there should be a low threshold to chest wall resection whenever there is suspicion of involvement. Several retrospective studies of completely resected patients found no difference in OS or recurrence with or without PORT^{296,297} with one exception.²⁹⁸ Currently, postoperative chemotherapy or RT for completely resected T3 chest wall tumors is not recommended, although the data is limited.²⁹⁵

The 5-year survival for other resected T3N0 tumors (i.e., involving the mainstem bronchus or other central T3 structures) appears to be slightly lower at about 25% to 30%.^{299,300} Careful stage evaluation followed by resection is the recommended approach. There is no data that defines the role of adjuvant therapy after complete resection. Nevertheless, the NCCN guidelines recommend adjuvant chemotherapy for all T3N0,1 tumors after an R0 resection, without providing any data or details.¹⁴¹ The ACCP guidelines do not address this question.

The seventh edition of the stage classification classifies tumors ≥ 7 cm as T3, even without invasion into adjacent structures. A few studies of large cancer databases have investigated the impact of size.³⁰¹⁻³⁰³ Among T3 ≥ 7 N0 tumors, the use of preoperative therapy was not associated with significantly better survival; negative prognostic factors were age and a size of > 10 cm.³⁰² For T3 ≥ 7 N1 tumors, the best outcomes were seen after a combination of surgical resection and adjuvant chemotherapy; negative prognostic factors by multivariate analysis included a size of > 10 cm and the need for pneumonectomy.³⁰³

Pancoast Tumors

Pancoast tumors are lung cancers that invade the structures of the thoracic inlet (i.e., the first rib, brachial plexus, subclavian vessels, or upper thoracic spine).^{295,304} These tumors typically present with shoulder or arm pain; however, pain down the arm or a Horner syndrome is not required to classify a tumor as a Pancoast tumor. The key feature is the involvement of structures in a complex area that raises challenges for local treatment. There is no direct data, but given the treatment challenges it is recommended that imaging for distal metastases and invasive mediastinal staging be done routinely.²⁹⁵

The standard treatment is concurrent chemoradiation followed by resection for localized tumors.^{295,305} This is based on several phase II studies that have shown better complete resection rates and lower local recurrence when compared with historical series using preoperative RT alone.²⁹⁵ The chemotherapy regimen typically involves a platinum doublet (e.g., cisplatin, etoposide), and usually 45 Gy of RT is given although some recommend more.²⁹⁵

Surgical resection of Pancoast tumors has advanced, with a better understanding of the anatomy of the anterior, middle, and posterior portions of the thoracic inlet, and the advent of different surgical approaches addressing particular problems each situation presents.³⁰⁴ Furthermore, techniques allowing extended resections have developed. In specialized institutions, resection and reconstruction of subclavian vessels or vertebral bodies can be accomplished safely. The long-term survival of such resections is encouraging (20% to 40%); this is usually combined with pre- or postoperative additional chemotherapy or RT.³⁰⁶⁻³¹¹ Resection should involve a lobectomy and all involved structures; it is crucial

to achieve a complete resection, and surgery should only be undertaken in an institution with the ability to carry out resection of whatever is encountered.

The outcomes of neoadjuvant chemoradiotherapy followed by resection have found an R0 resection rate of ~90% and a pathologic complete response rate of ~50%.²⁹⁵ The average 5-year survival was approximately 55% (range, 37% to 84%), and the average local recurrence rate was 6%. However, it must be noted that approximately 20% of patients enrolled in these studies dropped out for various reasons, and are not included in the outcomes reported. Approximately one-third of the enrolled patients had T4 tumors, and only a few had N2,3 nodal involvement.²⁹⁵ In contrast, 5-year survival of patients treated with preoperative RT and resection is ~25%, with about one-third having an incomplete resection and about two-thirds experiencing a local recurrence.

If resection cannot be accomplished, curative intent treatment with chemoradiotherapy should be considered, as suggested by ACCP and NCCN guidelines.^{141,295} If palliation is the goal, RT is suggested, which is effective in relieving pain in about 75% of patients.²⁹⁵

T4N0,1

Most patients with involvement of T4 structures have involvement of N2,3 nodes; these patients should be treated with chemoradiotherapy just like patients with infiltrative stage IIIa,b (N2,3) NSCLC. However, there are a small number of patients with tumors that are locally invasive but without significant nodal involvement (T4N0,1M0). Surgical techniques have advanced significantly so that T4 structures such as the carina, SVC, aorta, and vertebral column can be resected and reconstructed relatively safely. Resection appears reasonable even when cardiopulmonary bypass is needed: in a review of all reported cases, the perioperative mortality rate was 0% and the 5-year survival was 37%.³¹² However, these remain major surgical interventions and should be reserved for specialized centers. Reports from such centers demonstrate perioperative mortality rates of ~10% (lower in more recent reports), with 5-year survival rates of approximately 30%.²⁹⁵ These long-term outcomes appear to be better than what is reported in series of T4 patients treated with definitive chemoradiotherapy, but this observation must be made with recognition that the resected patients are probably more highly selected.

In patients with cT4N0,1M0 tumors, a careful search for distant metastases and invasive mediastinal staging is suggested.²⁹⁵ The incidence of occult N2,3 node involvement is not well documented, but many series include a substantial proportion of patients who were found to be pN2. The presence of N2,3 disease is a negative prognostic factor in many (but not all) studies.²⁹⁵

The role of preoperative chemotherapy or chemoradiotherapy is not well defined, but limited data suggest it may be of benefit.³¹³⁻³¹⁵ The data generally demonstrate high rates of complete resection and good long-term survival rates after preoperative therapy. While this data cannot disentangle the effect of selection from that of treatment, it does suggest that preoperative therapy should be considered when combined with the more robust data for stage IIIa (N2) patients, demonstrating that preoperative therapy is better than primary surgical resection.³¹⁶

Stage III (N2,3)

Stage III encompasses a large group of patients; discussion of management of these patients is aided by division into several subgroups. Although there are many ways to divide this, we find that the method used by the ACCP is simple and practical, and lends itself to clinical application.³¹⁷ We distinguish patients with “incidental N2” disease, meaning there was no reason to suspect N2 involvement preoperatively but it is nevertheless found intra- or postoperatively. The next group is patients with discrete N2,3

node involvement. Such nodes can be individually distinguished and measured, and are suspicious either due to enlargement, PET activity, or because of a central primary tumor or N1 involvement (which correlates with a ~25% chance of occult N2,3 involvement).¹¹⁰ These patients are distinguished from those with infiltrative stage IIIa,b disease, in which matted nodes or tumor infiltration makes distinction/measurement of individual nodes difficult. This division can be reasonably easily defined clinically and provides a structure for discussion.

Incidental Stage IIIa (N2)

Patients in whom N2 disease is not suspected but nevertheless found post- or intraoperatively are classified as incidental N2.^{317,318} It is assumed that appropriate staging for distant or mediastinal nodes has been done. If N2 is discovered intraoperatively in a patient with clinical signs pointing to possible N2 involvement (enlarged or PET-positive N1-3 nodes)—in other words an inadequately preoperatively staged patient—the ACCP suggests it is better to abort the resection and proceed first with appropriate staging.³¹⁶ The data and recommendations in the following sections only apply to patients who are incidental N2 despite appropriate preoperative stage evaluation.

Postoperative Chemotherapy. The Non-Small Cell Lung Cancer Collaborative Group²²⁵ conducted a meta-analysis in 1995 evaluating the effect of adjuvant chemotherapy in stage I-IIIa NSCLC, including 14 trials and 4,357 patients. Five trials used alkylating agents, eight used cisplatin combinations, and three used tegafur or tegafur-uracil. There was a significant decrease in survival after treatment with alkylating agents ($p = 0.005$), no change in survival with 5-fluorouracil alone or in combination, and platinum-based chemotherapy produced an improvement in survival of 5% at 5 years ($p = 0.08$). A number of randomized trials conducted in Europe and North America since the 1995 meta-analysis have examined the efficacy of platinum-based chemotherapy after surgery. Three trials showed no significant benefit,^{265,319,320} but several others showed improvement in recurrence-free survival or OS.^{266,290,321-323} The Lung Adjuvant Cisplatin Evaluation meta-analysis¹⁵⁵ included 4,584 patients treated on the five largest platinum-based adjuvant trials (ALPI, ANITA, BLT, IALT, and JBR-10), and revealed an absolute 5-year OS benefit of 5.4%. Four of the studies included stage III disease; there were a total of 760 patients with N2 lymph nodes. Although there was no improvement in survival in stage I disease, there was a significant survival benefit in patients with stage II and III disease. There appeared to be no difference between vinorelbine, etoposide, vinca alkaloids, or other agents when combined with cisplatin.

Both the ACCP and NCCN guidelines recommend adjuvant chemotherapy for completely resected stage IIIa (N2) disease.^{141,316}

Postoperative Radiotherapy. Despite appropriate preoperative staging, at times a patient will undergo surgical resection as primary therapy for presumed stage I or II disease, and mediastinal sampling at the time of surgery will be positive. For select patients, there may be a role for PORT. While the role of adjuvant chemotherapy has been relatively well defined in multiple prospective randomized trials, the indications for and benefit of PORT are subject to debate. Considerations include both the T and N stage, the status of surgical margins, and consideration of the extent and type of surgery. The variability in the extent of both surgical resection and surgical staging, both independent indicators of outcome, presents a challenge to identifying patients who might benefit from adjuvant RT.

A large retrospective SEER analysis²⁷¹ included a subset analysis of resected stage III (N2) patients (data on the margin status was not available). In this group, PORT was associated with a significant improvement in OS (27% versus 20% at 5 years). Although this retrospective analysis suffers from a lack of information about

patient characteristics, how the treatment approach was selected, or details of the treatment given, it suggested lower toxicity associated with better radiation treatment techniques may have decrease the toxicity of PORT and allowed a survival benefit to emerge. A follow-up SEER study supported that treatment-related morbidity was declining as radiation techniques improved.³²⁴ Specifically, PORT was associated with increased cardiac mortality in patients with stage II or III NSCLC between 1983 and 1988 (HR = 1.49), but not in patients treated between 1989 and 1993 (HR = 1.08; p = not significant). Similarly, a recent work stratified the randomized PORT trials by the use or nonuse of linear accelerators.³²⁵ PORT decreased local recurrence, whether patients were treated with linear accelerators or cobalt machines. There was a survival benefit associated with PORT (an absolute increase of 13% at 5 years) when delivered with linear accelerators, but not when delivered with older cobalt units. These studies support the hypothesis that PORT delivered using modern radiation technology may be associated with a lower risk of treatment-related death than was noted in older, randomized studies, and therefore radiation-related morbidity and mortality is less likely to detract from a potential survival benefit in the modern era.

The ACCP suggests adjuvant RT when the concern about local recurrence is high.³¹⁶ The NCCN suggests that adjuvant RT sequentially after adjuvant chemotherapy may be an option, but does not specify further how to make this decision.¹⁴¹

Postoperative Chemoradiotherapy. The PORT meta-analysis and the majority of the retrospective and population-based studies of PORT examined patients that were treated before the benefit of adjuvant chemotherapy was established. In the modern era, most patients with N2 disease receive adjuvant cisplatin-based chemotherapy. The additional benefit of PORT in the setting of adjuvant chemotherapy was examined in a post hoc subset analysis of the Adjuvant Navelbine International Trialist Association (ANITA) study.²⁹¹ The trial randomized patients with stage IB to IIIA NSCLC to adjuvant cisplatin and vinorelbine, or observation. PORT was recommended, but not required or randomized, for patients with node-positive disease. Out of 840 patients, 232 received PORT. On multivariate analysis, PORT improved survival in patients with N2 disease, in both the chemotherapy and no-chemotherapy arms. Shen et al.³²⁶ conducted a trial in completely resected stage IIIA, N2 NSCLC randomized to paclitaxel and cisplatin with or without RT. There was an improvement in local and distant relapse in the RT group, and in the subgroup of patients with two or more lymph nodes positive, there was an improvement in OS.

Single-arm prospective studies have established the efficacy and safety of PORT with concurrent chemotherapy,^{327,328} and several randomized studies have evaluated PORT with or without chemotherapy. The addition of concurrent chemotherapy to PORT, compared to PORT alone, does not appear to improve local control, disease-free survival, or OS.³²⁹⁻³³¹ A comparison of sequential to concurrent chemotherapy with PORT showed increased toxicity, without an increase in OS, with concurrent therapy.³³² Together, the data suggest that when PORT and chemotherapy are recommended adjuvantly, sequential therapy provides the same benefit as concurrent with less toxicity. For patients at the highest risk of local/regional recurrence (e.g., a positive surgical margin), the value of concurrent therapy can only be extrapolated from studies demonstrating a benefit to concurrent chemoradiotherapy in patients with gross unresectable disease.

Adjuvant chemotherapy for completely resected stage IIIA (N2) disease is not recommended by either the ACCP or NCCN guidelines.^{141,316}

Discrete N2 Node Involvement

Discrete N2/N3 involvement defines patients in whom individual mediastinal nodes can be identified and measured on a CT. These nodes may be enlarged on CT or normal sized but suspected by

PET uptake or by other characteristics such as a central tumor or N1 node involvement.³¹⁶ The terms “resectable” and “unresectable” are specifically avoided because they are notoriously subjective and inaccurate; for example, it is consistently shown that 25% to 35% of stage IIIa (N2) patients who are selected for surgery end up with an incomplete resection.^{316,317}

Such patients should undergo invasive mediastinal staging to confirm N2 or N3 involvement (the false-positive rate for discrete node enlargement on CT is ~40%, and for PET positivity it is ~15% to 20%).¹¹⁰ Furthermore, such patients should undergo a careful evaluation for distant metastases, which are found in about 25% despite a negative clinical evaluation.¹¹⁰ The subsequent discussion assumes that appropriate staging evaluation has been carried out; it is not acceptable to proceed to resection without thorough invasive mediastinal staging or imaging for distant metastases in patients in whom there is reasonable suspicion of N2 node involvement.^{110,317} The results reported in this chapter do not apply to patients that are mismanaged (i.e., in whom clinical standards for stage evaluation prior to treatment have been ignored).

In evaluating treatment approaches for patients with discrete N2 involvement, it is best to focus on RCTs or on intent-to-treat analyses. However, the literature is replete with reported outcomes of particular cohorts of patients; these cohorts are often selected by characteristics that can only be defined in retrospect. While these studies provide data on these specific cohorts, it must be recognized that the outcomes represent not only a treatment effect but probably most predominantly the effect of selection. A common mistake is to attribute the outcomes entirely to the treatment and forget that the effect of treatment cannot be disentangled from that of selection. Another common mistake is to assume that the outcomes of patients who complete a treatment approach apply to all patients who start on this approach. The extent of attrition and its effect on outcomes is perhaps best illustrated in a comprehensive analysis of 402 preoperatively identified patients with N2 involvement who were selected for preoperative chemotherapy with planned subsequent surgery (Fig. 41.11).³³³ While the 5-year survival of the patients who completed the planned approach was ~50%, this represented only about one-quarter of the original group; the 5-year survival of all patients selected for the treatment plan was only 13%. Finally, it must be emphasized that selection of a treatment approach must be based on factors that can be identified as pretreatment; the outcomes of patients according to factors that are available only in retrospect are useless to identify how to select patients for treatment.

Several RCTs have compared initial surgical resection for proven N2 versus preoperative chemotherapy.³¹⁶ These have generally found better survival in patients given preoperative therapy (average 2-year survival 40% versus 29%, 5-year survival 24% versus 17%).³¹⁶ However, most of these studies were underpowered and did not show a statistically significant difference. A 2007 Cochrane meta-analysis of stage III patients found a trend to better survival for preoperative platinum-based chemotherapy versus surgery alone (HR = 0.73; 95% confidence interval = 0.51 to 1.07; p = 0.1).³³⁴

Some groups have advocated that initial surgical resection is appropriate for some patients with N2 involvement. This argument is generally made citing good outcomes for cN0,1 patients with incidental N2 after resection³³⁵—this is not applicable to patients with N2 disease confirmed or suspected preoperatively. A few centers have published their results of preoperatively confirmed N2 patients that were selected for primary surgery: the average 5-year survival for all patients selected was 13%.^{316,336-338}

In summary, the data suggests that selection of patients with good outcomes after primary surgery has not been demonstrated, and limited data suggests that outcomes are better after preoperative therapy. Neither the ACCP nor the NCCN guidelines recommend primary surgery for confirmed N2 involvement.^{141,316}

However, it must be recognized that some of the data is relatively old. Techniques of mediastinal evaluation have progressed, at least in some institutions. The results of a microscopic deposit of cancer in an N2 node identified via video-assisted mediastinal

Figure 41.11 Fate of stage IIIa(N2) patients selected for neoadjuvant therapy and resection. Analysis of the fate of 402 good-risk patients, identified as having histologically proven but limited N2 involvement, who were selected as good candidates for preoperative chemotherapy followed by planned subsequent surgery. **(A)** Fate of all patients selected for this treatment approach. **(B)** Five-year survival of subgroups of patients based on subsequent outcomes and events during the planned treatment. EBUS, endobronchial ultrasound. (Data taken from Cerfolio RJ, Maniscalco L, Bryant AS. The treatment of patients with stage IIIA non-small cell lung cancer from N2 disease: who returns to the surgical arena and who survives. *Ann Thorac Surg* 2008;86:912–920.)

lymphadenectomy may not be the same as that derived from older literature. Furthermore, there appear to be regional differences, with survival being better for cN2 patients in Asia than North America or Europe.¹⁵⁷ However, no studies have defined how these factors can lead to appropriate selection of patients for primary surgery.

Several RCTs have compared preoperative therapy followed by surgery versus chemoradiotherapy alone.^{316,339–342} These have

found no significant difference, even in adequately powered studies, between these approaches, although arguably one can interpret there might be a slight trend to better survival in the surgical arms. In one larger study, a suggestion of better outcomes after treatment was completed was offset by higher treatment-related mortality in the surgical arm, particularly after pneumonectomy (Fig. 41.12).³³⁹ However, the perioperative mortality in this study appears to have been significantly higher than in other studies.³⁴³

Figure 41.12 Trimodality versus bimodality treatment of stage IIIa(N2) lung cancer. Survival of patients with stage IIIA (N2) non-small-cell lung cancer treated with trimodality (CT/RT/S) versus bimodality (CT/RT) therapy from the North American Intergroup Study 0139. The initial steeper slope of the trimodality arm demonstrates the importance of the perioperative mortality rate on the overall results of trimodality therapy. **(A)** Progression-free survival. **(B)** Overall survival. CT/RT/S, chemotherapy and radiotherapy followed by surgery; CT/RT, chemotherapy and radiotherapy. (Reproduced with permission from Albain KS, Swann RS, Rusch VW, et al. Radiotherapy plus chemotherapy with or without surgical resection for stage III non-small-cell lung cancer: a phase III randomised controlled trial. *Lancet* 2009;374:379–386.)

Reflecting these results, both the ACCP and NCCN guidelines suggest that either definitive chemoradiotherapy or preoperative therapy followed by surgery are reasonable treatment options for patients with confirmed N2 disease.^{141,316} The NCCN does not suggest how one might choose between these; the ACCP suggests that, given similar outcomes, patient preferences should factor significantly in the decision.³¹⁶ Furthermore, the ACCP suggests that the treatment strategy should be decided collectively by the multidisciplinary team of providers, and the entire proposed treatment plan should be defined at the outset. Finally, because quality of care aspects appear to play a significant role (e.g., perioperative mortality), the ACCP suggests that multimodality treatment be done at experienced centers that track their outcomes and can keep treatment-related morbidity low.

Various subgroups of patients have been suggested as possibly benefiting from a multimodality approach that includes surgery, such as those with “minimal” N2 disease, single station N2, cN0,1, younger, good surgical risk patients, those in whom mediastinal downstaging is achieved, those with radiographic response, and those requiring a lobectomy. However, most of these arguments are flawed, based on evidence of prognostic value but not predictive value for a treatment regimen that includes surgery, or because they are based on factors that cannot be clearly defined pretreatment. The best data for selection of a cohort for preoperative therapy with surgery is patients needing a lobectomy (as opposed to a pneumonectomy), although this is based on an unplanned matched-subgroup analysis in the study with an unusually high perioperative mortality after pneumonectomy.³³⁹

Response to preoperative therapy is often cited as a way to select patients who will benefit from resection. While this is prognostic (responders do better), there is no data that demonstrates that the better prognosis is affected whether resection is undertaken or not.³¹⁶ Furthermore, arguments that outcomes are poor in those who are not downstaged are confounded because most of the nondownstaged patients are not resected. Those that are resected despite ypN2 involvement have a 5-year survival of about 15%.³¹⁶ Finally, radiographic response by CT is notoriously inaccurate to define downstaging, and invasive methods other than a first-time mediastinoscopy are associated with high false-negative rates.³⁴⁴ The data regarding survival of downstaged patients relates to the postoperative stage. Therefore, the ACCP concludes that identification of patients that are more likely to benefit from surgical resection is not possible at this time based on pretreatment characteristics.

There is also debate about the choice of preoperative therapy (chemotherapy versus chemoradiotherapy). The NCCN suggests either approach is acceptable; the ACCP does not address this issue.^{141,316} This has been addressed directly in one RCT that compared preoperative chemoradiotherapy (cisplatin/etoposide \times 3, then cisplatin/vindesine with concurrent RT of 45 Gy) versus chemotherapy (cisplatin/etoposide \times 3; in this arm, PORT was given).³⁴⁵ Chemoradiotherapy resulted in a higher rate of mediastinal downstaging ($p = 0.02$), a higher incidence of a “near pathologic complete response” ($p = 0.001$), and a trend to a lower rate of incomplete resection ($p = 0.08$) with no difference in mortality related to either chemotherapy, RT, or surgery. However, the survival of the two treatment arms was essentially identical. Hence, there is no data to support one preoperative approach over another.

In summary, patients with confirmed discrete N2 involvement should not undergo primary surgical resection; no specific subgroups of patients have been documented for whom this is appropriate. The treatment approach should involve either preoperative therapy and surgery or definitive chemoradiotherapy. The outcomes of these two strategies appear to be similar, and factors such as patient preferences as well as local expertise and minimization of morbidity and mortality should play a major role in deciding upon a treatment approach. Definition of subgroups that are more likely to benefit from the inclusion of surgery is not possible from the available data; there is also no difference between preoperative

chemotherapy versus chemoradiotherapy. The treatment approach should be planned collaboratively with involvement of all of the relevant disciplines.

Infiltrative Stage III a,b

Patients with involvement of contralateral or multistation mediastinal nodes, supraclavicular nodes, or multiple clinically visible nodes on CT or PET/CT are most commonly treated with chemotherapy and radiation. This reflects not only the challenges in approaching these surgically, but the inherently higher risk of subclinical involvement of surrounding regional sites. In patients with good performance status (PS), concurrent chemotherapy and radiation has become the standard of care approach. In patients with poor PS or limiting medical comorbidities, therapeutic options include sequential therapy, RT alone, or palliative systemic treatment.

Radiotherapy Alone. Before the widespread use of chemotherapy, RT alone was a standard treatment option for patients with unresectable, locally advanced NSCLC. The RTOG 7301 trial established the optimal dose and fractionation for single-modality treatment.³⁴⁶ This study of inoperable patients randomized 375 patients to 40 Gy in 4 weeks, a split course of 40 Gy in 6 weeks, 50 Gy in 5 weeks, or 60 Gy in 6 weeks. The response rate was significantly better in the 60 Gy arm (63%), and there was parallel trend in improved OS (22% at 3 years in the high-dose arm).

In patients getting fractionated RT alone, altered fractionation and radiation dose escalation have been investigated in an effort to improve the relatively poor response and survival that is seen after standard 60 Gy. A dose escalation study conducted at the University of Michigan included 106 patients with stage I to III NSCLC, using doses from 63 to 103 Gy in daily fractions.³⁴⁷ Patients were allocated to dose based on the tumor volume and risk of pneumonitis, so no optimal dose was identified, but higher dose was associated with improved control and survival. The RTOG 8311 included 840 patients in a dose escalation trial, from 60 Gy to 79.2 Gy delivered in twice-daily 1.2 Gy fractions.³⁴⁸ The best OS, 29% at 2 years, was associated with 69.6 Gy twice daily. Similarly, the European Organisation for Research and Treatment of Cancer conducted a randomized phase II/III study of standard RT (60 Gy in 6 weeks) versus continuous hyperfractionated accelerated RT (CHART).³⁴⁹ CHART is given in 1.5 Gy fractions, three times daily, 7 days per week, to a total dose of 54 Gy. The use of CHART was associated with improved OS (20% versus 13%), but also a higher rate of severe acute dysphagia (49% versus 19%).

Concurrent and Sequential Chemoradiotherapy. The addition of chemotherapy to thoracic radiation improves OS, and concurrent chemoradiotherapy appears to offer superior outcomes when compared to sequential therapy. The addition of chemotherapy to radiation has been the subject of many prospective trials and several meta-analyses. The NSCLC Collaborative Group included individual patient data from 3,033 patients with stage IIIa or IIIb disease, enrolled in 22 trials.²²⁵ There was a significant increase in OS with the addition of chemotherapy, an absolute increase of 2% at years. At total of 11 of the 22 studies included cisplatin-based chemotherapy, and the largest benefit was seen in these patients. A meta-analysis of stage IIIa,b NSCLC studies included 1,887 patients from 14 trials.³⁵⁰ In patients who received cisplatin-based chemotherapy with radiation, there was a 30% reduction in 2-year mortality compared to radiation alone. In patients who received other chemotherapy, there was an 18% reduction. The preference for cisplatin-based chemotherapy was confirmed in a more recent meta-analysis, which was limited to studies that combined radiation with either cisplatin- or carboplatin-based chemotherapy.³⁵¹ They analyzed 1,764 patients from nine trials, and found an absolute improvement in OS of 4% at 2 years.

The use of concurrent, rather than sequential, chemotherapy with thoracic RT appears to improve OS, at the cost of increased acute toxicity. The RTOG 9410 was a three-arm trial: cisplatin and vindesine followed by RT (63 Gy once daily), cisplatin and vindesine with concurrent RT (63 Gy once daily), or cisplatin and etoposide concurrently with RT (69.6 Gy twice daily).³⁵² The median OS was significantly better in the concurrent arm with daily radiation, compared to sequential therapy (17 months versus 14.6 months), as was local control (66% versus 59%). Acute grade ≥ 3 toxicity was similarly higher with concurrent therapy; 48% versus 30% nonhematologic. Serious late toxicity was significantly different. The survival in the concurrent chemotherapy and twice-daily RT arm was 15.6 months, not significantly better than the control arm. This was confirmed in a trial by the West Japan Lung Cancer Group, in which patients were randomized to receive either sequential or concurrent chemotherapy.³⁵³ The chemotherapy was cisplatin, mitomycin, and vindesine in both arms. Sequential RT was 56 Gy in 5.5 weeks; the concurrent RT was 56 Gy in 7.5 weeks with a 2-week break midcourse. The median survival was better in the concurrent arm (17 months versus 13 months). There was no difference in esophageal toxicity.

Cisplatin- and carboplatin-based are the most common chemotherapy combinations delivered concurrently with thoracic radiation, extrapolated from the superiority of such combinations in the meta-analyses of sequential treatment. The best specific combination has not yet been clearly defined. In a three-arm noninferiority trial conducted by the West Japan Lung Cancer Group, the use of concurrent weekly carboplatin (40 mg/m²) and paclitaxel (area under the curve = 2) (CP) had comparable survival to mitomycin, vindesine, and cisplatin, and to irinotecan and carboplatin, with lower toxicity.³⁵⁴ A small randomized study compared weekly carboplatin (45 mg/m² and area under the curve = 2, respectively) to cisplatin and etoposide (CE) delivered every 3 weeks (cisplatin 50 mg/m² on day 1, etoposide 50 mg/m² on days 1 to 5).³⁵⁵ Both arms received concurrent thoracic RT to 60 Gy. The survival was superior in the CE arm (33% versus 13%). Neutropenia was more common with CE, and RP more common with carboplatin. A larger, phase 2/3 randomized study from the Chinese Academy of Medical Sciences (NCT01494558) comparing carboplatin to CE has completed enrollment and may answer this question. The use of pemetrexed in combination with platinum compounds is equally effective, and less toxic, than other combinations in patients with nonsquamous histology. The use of this combination, carboplatin (area under the curve = 5) and pemetrexed (500 mg/m²) with thoracic RT (70 Gy), has been shown to be both safe and effective in a phase 2 study from the CALGB.³⁵⁶ A large international randomized study comparing pemetrexed and cisplatin to etoposide and cisplatin with RT has been conducted but not yet reported. Attempts have been made to add targeted agents to standard chemoradiotherapy platforms in the setting of stage III disease, in an effort to incorporate chemo- and radiosensitizing agents. The addition of antiangiogenics has not improved outcomes: a randomized trial adding antiangiogenic AE-941 to carboplatin and radiation failed to show an improvement in OS.³⁵⁷ Similarly, a randomized trial conducted by the Eastern Cooperative Oncology Group added thalidomide to concurrent or sequential chemoradiation did not show any benefit. Bevacizumab, the monoclonal antibody to the vascular endothelial growth factor receptor has been added to chemoradiation in a phase 2 study that also incorporated an EGFR TKI and escalated radiation dose.²¹² There was no improvement over standard therapy. Several phase 2 studies have incorporated the monoclonal EGFR antibody cetuximab. A randomized phase 2 study, the CALGB 30407,³⁵⁶ suggested no benefit. Consistent with this, a phase 3 trial, the RTOG 0617, randomized patients getting carboplatin and thoracic RT to the addition of cetuximab. The preliminary results suggest no incremental benefit. The addition of EGFR TKIs to chemoradiation in unselected patients has been similarly disappointing; the Southwest Oncology Group S0023 randomized patients with stage III NSCLC to gefitinib or

placebo after CE and RT.³⁵⁸ OS was worse with gefitinib. Effort to incorporate TKIs into the treatment of stage III patients, in selected patients based on molecular profiling, are ongoing.

Induction or Adjuvant Chemotherapy with Chemoradiation. The role of adjuvant chemotherapy after definitive concurrent chemoradiation is not entirely defined and is likely dependent on the choice of concurrent systemic therapy. There are no published, randomized trials that support this specific approach with high-level evidence. The phase 3 Hoosier Oncology Group study enrolled patients receiving concurrent radiation and CE randomized to three cycles of docetaxel versus no further therapy.³⁵⁹ Enrollment stopped when futility analysis determined that there would be no chance of observing a benefit; the median survival was 21.2 months after adjuvant chemotherapy and 23.3 months for observation. The continued interest in adjuvant therapy likely stems from the desire to administer more than two cycles of full-dose chemotherapy in the setting of stage III disease, consistent with that given adjuvantly after surgery. This is relevant for concurrent regimens that include two cycles of concurrent chemotherapy, but of particular interest when the concurrent regimen is weekly carboplatin, as opposed to combinations that can be delivered concurrently with radiation at full systemic dose, such as cisplatin and etoposide or cisplatin and vinorelbine.

In the induction setting, the CALGB 39081 randomized patients to two cycles of carboplatin followed by RT and weekly carboplatin, or immediate treatment with RT and weekly carboplatin.³⁶⁰ In 366 enrolled patients, survival was not improved by the addition of two cycles of carboplatin before concurrent therapy. Induction therapy is not routinely employed before definitive chemoradiation but instead reserved for those patients where circumstances or disease volume precludes immediate chemoradiation.

Radiation Dose and Fractionation for Concurrent Treatment. The RTOG 7301 established 60 Gy in 6 weeks as the standard radiation for single modality therapy, and this regimen was adopted as one possible standard when combined with sequential or concurrent chemoradiotherapy. But the risk of local, in-field relapse among patients receiving definitive chemoradiation is high, between 30% and 50% depending on the length and manner of follow-up. A number of radiation dose escalation trials suggest that increasing radiation dose may improve local control and can be accomplished in at least a subset of patients. The RTOG 9311 was the first large dose escalation trial conducted with three-dimensional conformal radiation techniques. In an effort to increase the dose to the gross tumor and involved nodes, nodal regions without confirmed macroscopic or microscopic disease were not electively included. Either radiation alone or sequential chemoradiation were allowed.³²⁷ For each patient, the lung V20 was calculated, and the maximum dose cohort was based on their predicted risk of pneumonitis. Patients were treated from 70.9 Gy to 90.3 Gy in daily 2.15-Gy fractions. Dose escalation was well tolerated up to 83.8 Gy in the lowest-risk group and 77.4 Gy in the intermediate-risk group. The follow-up study, the RTOG 0117, escalated dose in the setting of concurrent cisplatin and docetaxel.³⁶¹ The study started at 75.25 Gy in 2.15 Gy fractions and was designed to escalate by increasing the dose per fraction (and decreasing the overall treatment duration). After excess toxicity was observed at the starting dose, dose de-escalation was done, reducing to 74 Gy in 2-Gy fractions. A total of 55 patients were treated at this dose, with a median survival of 21.6 months for stage III patients. A similar, small dose escalation study in 15 stage III patients receiving weekly chemotherapy also concluded that the maximum tolerated dose was 74 Gy in two fractions³⁶²; the median survival was 37 months.

A series of prospective studies conducted at the University of North Carolina also evaluated escalating radiation dose from 60 Gy to 74 Gy in 2-Gy fractions, with an expansion at 74 Gy. Patients received induction and concurrent carboplatin.³⁶³ With a

median follow-up of 5 years for 62 patients, the OS at 5 years was 27%. A follow-up phase 2 study with chemoradiation to 74 Gy and erlotinib included 48 patients. The median survival was 18 months, with a 29% rate of grade 3 or 4 toxicity. The CALGB 30105 was a randomized phase 2 study that also incorporated 74 Gy into two different induction and concurrent chemotherapy schedules. The median survival was 24 months in 69 patients in the superior chemotherapy arm.³⁶⁴

Finally, the RTOG 0617 sought to determine the absolute benefit of 74 Gy, versus standard 60 Gy, with concurrent weekly carboplatin. This was a two-by-two factorial design, where patients were randomized to standard or high dose, and to standard chemotherapy or chemotherapy and cetuximab concurrently with radiation. The 74-Gy arm was closed early when futility analysis determined that there would be no benefit over 60 Gy. The result of this randomization was presented; high-dose radiation was associated with worse OS compared to standard radiation (median survival 19.5 months versus 28.7 months). There were more treatment-related deaths in the high dose arm, and a higher rate of grade 3 or greater esophagitis. Oddly, local control was worse in the high-dose arm.³⁶⁵

Altered Fractionation with Chemotherapy. The use of standard, daily radiation fractionation is designed to balance the delivery of definitive dose to the tumor, while allowing daily repair of the surrounding normal tissue. Altered fractionation schedules take advantage of radiobiologic principles: hyperfractionation (increased number of fractions) should result in increased opportunity for normal tissue repair and a lower risk of late side effects. Accelerated radiation (shorter treatment duration) should improve local control by allowing less tumor repopulation. Hypofractionation (higher dose per fraction) is one method to achieve acceleration, typically at the cost of increased acute toxicity. SBRT is extreme hypofractionation, combined with precision targeting to reduce exposure of normal tissue. Because both hypofractionation and accelerated hyperfractionation may increase the acute side effects of radiation therapy, combining these regimens with concurrent radiosensitizing chemotherapy remains investigational.

The RTOG 9410 was a three-arm randomized trial: sequential chemoradiotherapy with 60 Gy once daily, concurrent chemoradiotherapy with 60 Gy once daily, and concurrent chemotherapy with 69.6 Gy twice daily (hyperfractionation). While the addition of concurrent chemotherapy improved survival, the hyperfractionated radiation arm was no better than daily treatment.³⁵² Schild et al.³⁶⁶ conducted a similar phase 3 trial, comparing concurrent CE with either daily RT to 60 Gy, or twice daily RT to 60 Gy in 6 weeks. There was no difference in local control or OS.

The use of CHART improved OS when compared to daily treatment, when radiation was the sole modality, but the advantage of hyperfractionation with concurrent chemotherapy has not been similarly demonstrated. The Eastern Cooperative Oncology Group 2597 examined hyperfractionated accelerated radiation therapy with sequential chemotherapy. Patients were randomized after two cycles of carboplatin to daily radiation (64 Gy in 32 fractions) versus hyperfractionated accelerated radiation therapy (57.6 Gy three times daily over 2.5 weeks).³⁶⁷ The study was closed early, partially because of the difficult logistic of three times daily treatment. Overall, 141 patients were randomized, and there was no significant difference in median survival (20.3 months versus 14.9 months favoring hyperfractionated accelerated radiation therapy).

The European Organisation for Research and Treatment of Cancer tested the use of hypofractionated RT in inoperable NSCLC.³⁶⁸ Overall, 158 patients were randomized to either gemcitabine and cisplatin before RT, or low-dose daily cisplatin (6 mg/m²) concurrent with RT. The radiation was delivered in 24 fractions of 2.75 Gy in 32 days (total 66 Gy). The combination of sequential or concurrent chemotherapy with hypofractionated radiation was well tolerated, with grade 3 esophagitis in 14% of patients in the concurrent arm. Similarly, a phase 2 trial in

49 patients with stage III disease used 60 Gy in 5 weeks with carboplatin, with a median survival of 28 months³⁶⁹; 29 of 49 patients had grade 2 or greater toxicity, and two patients died of bleeding complications.

Choice of Chemotherapy. In the setting of stage III disease, either prior to surgical intervention (neoadjuvant therapy), or when used concurrently with RT (combined modality therapy), cisplatin-based combinations are preferred. Combinations with etoposide, vinorelbine, paclitaxel, docetaxel, and pemetrexed have all been tested in this setting. Gemcitabine is generally avoided in this context due to its potent radiosensitizing properties and potential severe complications.³⁷⁰ However, unlike in adjuvant therapy, the use of carboplatin in the context of combined modality therapy for stage III disease is better documented. In particular, the use of carboplatin, administered on a weekly schedule and administered concurrently with standard thoracic RT, yielded roughly the same survival results as trials using cisplatin-based combinations.³⁶⁵ In stage III disease, neither induction nor consolidation chemotherapy appears to add to concurrent treatment.^{359,371} However, practitioners in the United States have been reluctant to limit treatment to two cycles of chemotherapy and tend to recommend an additional two cycles for total of four cycles.

Stage IV

Selection for Treatment

Patients with advanced NSCLC are often symptomatic and require prompt intervention. A “watch and wait” approach is generally not recommended.³⁷² A few selected patients who are asymptomatic at the time of the diagnosis and wish to forgo immediate treatment must be followed closely by clinical and radiographic criteria. In some circumstances, it is appropriate to administer local therapy prior to systemic therapy, such as symptomatic central nervous system disease, cord compression, painful skeletal metastases, or uncontrolled hemoptysis (discussed in more detail in the section “Specific Symptom Management”). However, chemotherapy is also an effective palliative tool and individualized judgment is recommended.

Chemotherapy is the mainstay of treatment for patients who present with stage IV disease at diagnosis or who experience recurrent disease that is not amenable to local therapy. In the 1990s and early 2000s, multiple RCTs clearly established that treatment of patients with stage IV NSCLC and good PS prolongs survival compared with basic supportive care alone.^{373,374} Because this question is considered to have been clearly answered, further trials addressing this have not been conducted in the last decade.

Patients are frequently more focused on QOL and express concern that treatment with chemotherapy will negatively impact this. Multiple RCTs have evaluated this and consistently shown that treatment with chemotherapy improves QOL compared to best supportive care in good PS patients.^{373,374} Chemotherapy for stage IV NSCLC is given as an outpatient; significant toxicity (grade ≥ 3) is uncommon. Nevertheless, QOL continues to be an important end point in studies comparing one regimen to another.

Therefore, both the ACCP and NCCN guidelines recommend that patients with stage IV NSCLC and a PS of 0,1 be treated with chemotherapy (based on level 1 evidence or a unanimous consensus, respectively).^{141,374} Patients with a PS of 2 may also benefit from chemotherapy, and this is recommended by the ACCP and NCCN guidelines, but in a nuanced fashion. This patient population is addressed specifically in a subsequent section.

Recent studies have demonstrated a median survival of approximately 10 to 12 months for patients with nonsquamous histology, and 9 to 10 months for squamous carcinoma (Table 41.6).³⁷⁵ The respective 1-year survival rates are 20% to 25% and 15% to 20%. These estimates are lower for patients with PS 2, regardless

^a Results apply to patients with performance status 0-1 and wild-type tumors.

of histology.³⁷⁶ Patients with sensitizing mutations treated with targeted therapy have a more favorable outcome, as detailed in the following.

First-Line Therapy

The approach is based on the patient's histologic subtype and PS (Fig. 41.13). Patients with nonsquamous histology, regardless of PS, should have the tumor submitted for molecular analysis and, in the presence of an actionable mutation, be treated with the appropriate targeted agent. For patients with nonsquamous cancers without a mutation and for patients with squamous histology, combination chemotherapy is the standard of care for patients with PS 0-1.^{141,374} Platinum-based regimens are the standard. An extensive literature has attempted to determine the “optimal platinum

analog,” cisplatin or carboplatin, in advanced disease. There is a general consensus that while cisplatin may be slightly more active, particularly with respect to response rate, the impact on OS is minimal, if any, and toxicity, especially nonhematologic, is worse.³⁷⁷ Carboplatin tends to be widely used in the United States, while cisplatin is still frequently utilized in Europe and Latin America. Agents that are typically combined with a platinum analog include pemetrexed (except in squamous carcinoma), paclitaxel, docetaxel, nab-paclitaxel, gemcitabine, vinorelbine, irinotecan, and etoposide (see Table 41.6). Studies have failed to demonstrate superiority of one regimen over another, and decisions regarding which agent to use are based on the toxicity profile, ease and convenience of administration, and cost.³⁷⁸

The choice of regimens tends to differ between the histologic types. Pemetrexed has no efficacy in squamous cell carcinomas and should not be used in these patients.³⁷⁹ Bevacizumab, an antiangiogenesis inhibitor, has a high rate of bleeding complications in squamous cell carcinomas and should not be used in these patients.^{156,380} The addition of a third cytotoxic agent does not improve outcomes and is not recommended.³⁸¹ The use of non-platinum doublets in first-line therapy is not encouraged but may be an alternative to occasional patients who have contraindications to both platinum analogs.³⁸²

The general standard is to administer four to six cycles of chemotherapy unless progression or toxicity prevents this.^{141,374} This is administered either alone or in combination with a biologic agent (bevacizumab). The biologic agent is typically continued until disease progression (see subsequent section). In addition, administration of maintenance chemotherapy should be considered (also as discussed in a later section).

PS 2 patients have a poorer prognosis and tend to benefit less from chemotherapy.³⁸³ However, new data have demonstrated a survival benefit for combination chemotherapy over single agent in patients with PS 2 despite higher toxicity rates.³⁸⁴ This trial demonstrated a significant improvement in survival for carboplatin and pemetrexed compared to pemetrexed alone. Benefits with respect

to symptom reduction and QOL have also been reported in PS 2 patients.³⁸⁵ Patients with PS 3 or lower are typically not candidates for chemotherapy.

Age alone is not a restriction to chemotherapy. In the past, patients aged ≥ 70 years were felt to be at high risk for complications and many were treated with single-agent therapy or denied active treatment altogether.³⁸⁶ A robust literature published in the past decade has demonstrated that elderly patients benefit from standard combination chemotherapy compared to single agent, including a pivotal clinical trial in which the combination of carboplatin, administered weekly, was superior to single-agent therapy.³⁸⁷ Toxicity, as in PS 2 patients, tends to be more severe. Carboplatin is easier to tolerate, and the use of cisplatin is discouraged in these patients. Octogenarians have been poorly represented in clinical trials, and caution is advised when applying these data to this age subset.³⁸⁸

Monoclonal Antibodies

Guidelines recommend the addition of bevacizumab, a monoclonal antibody directed against the vascular endothelial growth factor ligand, in addition to combination chemotherapy.^{141,374} Bevacizumab should be continued until disease progression. This is based largely on a US RCT in which bevacizumab in combination with carboplatin led to a significant improvement in survival in patients with nonsquamous cell histology with PS 0-1.¹⁵⁶ However, toxicity in general and treatment-related deaths in particular were significantly higher in the bevacizumab arm, including rates of pulmonary hemorrhage, thromboembolic phenomena, and neutropenia and thrombocytopenia. A similar study conducted in Europe, using two different doses of bevacizumab in combination with cisplatin and gemcitabine, showed a significant improvement in PFS (the primary end point) but not in OS.³⁸⁹

A recent study (Pointbreak trial) compared the two most frequently used bevacizumab-containing regimens: the original carboplatin-paclitaxel-bevacizumab versus carboplatin-pemetrexed-bevacizumab developed by investigators in Chicago.³⁹⁰ Both combinations were administered for four cycles followed by maintenance bevacizumab alone in the paclitaxel arm, and both pemetrexed and bevacizumab in the other arm. There was no significant difference in survival. Toxicity, while slightly different between the arms, did not seem statistically different.

These data demonstrate that bevacizumab can be used in eligible patients with advanced NSCLC in combination with chemotherapy. The benefit is modest, and toxicity can be significant. Patients with squamous cell carcinoma and hemoptysis should not receive bevacizumab, while patients on anticoagulation and with

previously treated brain metastases are eligible.³⁹¹ Patients with PS 2 do not typically receive bevacizumab.

Cetuximab, a monoclonal antibody directed against the EGFR, also demonstrated a significant improvement in survival when added to cisplatin and vinorelbine in a single randomized trial.³⁹² However, the clinical significance of the results has been questioned and, along with other negative trials in the first- and second-line setting,^{393,394} has not led to the approval of cetuximab in NSCLC. The ACCP guidelines do not recommend the addition of cetuximab to standard chemotherapy, but the NCCN guidelines suggest this is an option.^{141,374} Preliminary results of a new monoclonal antibody, necitumumab, have been positive in patients with squamous cell histology, while negative in patients with adenocarcinoma.

First-Line Therapy with Targeted Agents

For patients whose tumors harbor an actionable molecular alteration, in particular EGFR-sensitizing mutations and anaplastic lymphoma kinase (ALK) rearrangement, first-line therapy with the corresponding targeted agent should be considered. Several trials have demonstrated that in patients with EGFR-mutated cancers, gefitinib, erlotinib, or afatinib yield superior response rates and longer PFS compared to standard chemotherapy, with a more favorable toxicity profile (Table 41.7).³⁹⁵⁻³⁹⁹ Similarly, in patients with ALK-rearranged tumors, RCTs have confirmed the superiority of crizotinib over conventional chemotherapy.⁴⁰⁰ However, none of the trials demonstrated a significant improvement in OS for the targeted agent compared to chemotherapy. Although this is often attributed to crossover upon progression, other explanations such as acquired resistance may also play a role.

Other trials have tested whether a combination of chemotherapy and a targeted agent is superior to either chemotherapy or the targeted agent alone in patients selected based on clinical characteristics without mutational testing.^{401,402} None of these trials has demonstrated an advantage over the targeted agent, and the concurrent administration of chemotherapy and a TKI in first-line therapy is not recommended.

Importantly, patients without a known molecular alteration should not be treated with targeted agents in the first-line setting.⁴⁰³ In patients who need immediate treatment and whose molecular profile is still pending, chemotherapy upfront is the best option until the results become available.

Patients treated with a targeted agent upfront are maintained until progression. At that point, depending on the nature and the tempo of the progression, options include local/ablative therapy to

site(s) of oligoprogression and continuation of the targeted agent; change to a second generation inhibitor; and institution of chemotherapy, which can be done with or without continuation of the targeted agent.^{404,405} Patients with EGFR-mutated tumors should be carefully monitored once the TKI is discontinued due to the risk of “flare,” which can be severe and at times fatal.⁴⁰⁶ It is recommended that once a change in therapy is decided, the washout period be limited to a minimum. Interestingly, patients later re-challenged with the same EGFR inhibitor often have prolonged periods of stabilization.

Maintenance Therapy

The continuation of the same combination chemotherapy regimen beyond four to six cycles yields no discernible benefit.^{407–409} Assuming no evidence of progression, options at that juncture include close observation with treatment at progression or maintenance therapy. Continuation maintenance means that the nonplatinum agent used in the initial regimen is continued until disease progression. Another strategy is switch maintenance in which a new agent, one not used in the initial regimen, is initiated after the initial regimen. Both maintenance strategies have been shown to improve survival.

Continuation pemetrexed has led to an improvement in OS after four cycles of cisplatin-pemetrexed (Table 41.8).⁴¹⁰ A French trial also demonstrated an improvement in progression-free survival when gemcitabine was continued after four cycles of cisplatin-gemcitabine.⁴¹¹ Continuation maintenance is also frequently used with bevacizumab based on the pivotal trial previously discussed,¹⁵⁶ despite the lack of randomized data demonstrating a benefit for maintenance versus no maintenance.

Switch maintenance therapy trials have shown a benefit for pemetrexed and erlotinib after four cycles of a platinum-based doublet (see Table 41.8).^{412,413} A prior trial with docetaxel showed a progression-free survival advantage but the difference in OS, while clinically meaningful, did not reach statistical significance.⁴¹⁴ One criticism of these trials is that a relatively small percentage of patients randomized to the nonmaintenance arm actually received the same agent upon relapse.⁴¹⁵ In fact, in the Fidas trial,⁴¹⁴ a post hoc analysis of the patients who received this agent at the time of progression showed similar survival to those who received it as switch maintenance. This has led many thought

leaders to interpret that switch maintenance is akin to early institution of second-line therapy.

Maintenance therapy must be discussed as an option rather than a universal recommendation. Several patients can be safely watched and benefit from a treatment break. On the other hand, a number of patients recur with devastating complications and miss the “window of opportunity” for second-line therapy. As of now, there are no clinical, radiographic, or biologic markers that predict outcome after first-line therapy. The ACCP and NCCN guidelines suggest maintenance pemetrexed in nonsquamous NSCLC, either as continuation maintenance if the patient is on a pemetrexed regimen, or switch maintenance if they are not.^{141,374} Consideration of switch maintenance erlotinib is also suggested by both guidelines. The NCCN suggests continuation maintenance gemcitabine (category 2b), but the ACCP guideline recommends against it. However, it is clear that many factors must be considered in the decision, and clinical judgment is needed.

Second-Line Therapy

Multiple randomized trials have demonstrated that second-line therapy, with a noncross-resistant agent, leads to an improvement in survival compared to supportive care.³⁷⁴ In addition, consistent improvement in QOL has been documented.^{416,417} Cytotoxic agents used in this setting include docetaxel and pemetrexed.^{379,418} Gemcitabine is also used in previously treated patients despite the lack of randomized data. Efficacy is similar among the chemotherapy agents, but toxicity profiles are somewhat different. EGFR TKIs have also shown benefit in this setting.⁴¹⁹ Erlotinib received its original approval for previously treated patients, unselected by molecular criteria, and still is used in this setting.

Recently trials have addressed whether conventional chemotherapy is preferable to erlotinib (or gefitinib where applicable) for EGFR wild-type patients in the second-line setting.^{420–422} While only one trial showed an advantage with respect to OS, all trials showed a consistent trend toward better outcomes with chemotherapy. Based on these data, second-line chemotherapy is preferred for EGFR wild-type patients; erlotinib or gefitinib is usually used in these patients only after two lines of chemotherapy.

For patients whose tumors carry an EGFR mutation and who are treated with an inhibitor in the first-line setting, options at progression depend on the mechanism of resistance. The majority

of these patients have a secondary mutation, T790M, in exon 20, which shifts the affinity of the receptor preferentially to adenosine triphosphate.⁴²³ Several new agents that target T790M are in development.⁴²⁴ Other known mechanisms include conversion to a small-cell histology (usually responsive to platinum-etoposide combinations) and Her2 amplification.⁴⁰⁵ A repeat biopsy at the time of progression is therefore advised to better guide the second-line therapy options. In addition, some patients with EGFR-mutated disease have an indolent or limited progression, including central nervous system involvement, which can be managed with local/ablative techniques, without discontinuation of the systemic therapy.⁴²⁵

Patients with ALK rearrangement also have multiple mechanisms of resistance, including de novo mutations.⁴²⁶ While the same management principles apply to these patients, particularly those with indolent progression, the emergence of more specific second-generation ALK inhibitors, such as LDK 378, has become an appealing option.⁴²⁷

Third-Line Therapy

Contrary to second-line therapy, no randomized trial has shown a survival benefit for third-line therapy compared to placebo. The only agent approved for third-line therapy in the United States is erlotinib based on the same trial that led to the approval in second-line.⁴¹⁹ Candidates for third-line therapy were randomized to erlotinib or placebo, and those treated with the former experienced a survival benefit as well as improvement in symptom control of the same magnitude seen in second-line patients. Although no standard chemotherapy agent is formally approved for this indication, patients who have progressed on two prior lines and still maintain an acceptable PS are often treated in clinical practice with additional chemotherapy. The ACCP and NCCN guidelines recommend third-line treatment with erlotinib over basic supportive care in good PS patients.^{141,374}

SPECIAL CLINICAL SITUATIONS

Oligometastases

In general, the presence of distant metastases indicates incurable disease that must be treated palliatively, usually by chemotherapy. However, a small subset of patients presents with a limited number (e.g., one to three) number of metastatic sites. This is called oligometastatic disease, and there is ample evidence that a curative intent treatment approach can be successful.

The greatest amount of data comes from patients with NSCLC and isolated brain metastases. Definitive treatment of brain metastases can be an important component of palliative-intent treatment, but in this section we focus on eradication of all known disease with intent to cure. The ACCP and NCCN guidelines recommend this be considered in NSCLC patients with isolated brain metastases.^{141,295} A careful search (PET, brain MRI/CT) should be conducted to find evidence of more diffuse metastases. The number of brain metastases is not crucial as long as they can each be treated definitively.²⁹⁵ Invasive mediastinal staging should be done; involvement of N2,3 nodes is considered a contraindication for curative-intent therapy.^{141,295}

Treatment of patients with isolated brain metastases (T1-3N0-1M1b) generally begins with stereotactic radiosurgery or surgical resection of the brain metastases because of the devastating consequences of untreated brain lesions. Stereotactic radiosurgery and surgery for the brain metastases are complementary approaches with equivalent effectiveness; surgery is generally used with larger lesions that produce more mass effect and if the morbidity of a surgical approach is low. Curative resection of the primary lung tumor should follow the same principles dictated by the primary tumor regardless of the brain metastasis. Adjuvant chemotherapy

is then recommended, although based only on indirect data of a benefit in earlier stage patients.^{141,295} There is no data regarding the sequence (i.e., after treatment of the brain metastasis, whether to resect the lung lesion followed by chemotherapy or to administer chemotherapy and then later resect the lung primary). However, given the rapid recovery in general from modern (usually VATS) lung resection, it is probably best to get this accomplished before chemotherapy in general. Both the ACCP and NCCN recommend adjuvant whole-brain RT (WBRT) as well to decrease the chance of a brain recurrence; however, the data for the benefit of WBRT (for either survival or the rate of brain recurrences) is conflicting and indirect (not specific to oligometastatic tumors and curative-intent treatment).

Outcomes of curative-intent treatment of NSCLC with isolated brain oligometastases are reasonable. The surgical mortality from both resection of the brain lesion and the lung primary is about 2% in a recent systematic review.²⁹⁵ The 5-year survival is about 15% on average.²⁹⁵ The outcomes are the same whether patients present with a synchronous brain metastases or a metachronous brain metastasis that is found after a previous resection of an early stage NSCLC. Prognostic factors are poorly defined; outcomes may be slightly better in patients that are younger, have good PS, and have a lower T stage of the primary tumor.

There is data supporting a similar treatment approach for patients with isolated adrenal metastases.^{141,295} The staging approach and treatment strategy is similar, although the urgency of treatment of the brain metastasis missing. Usually, the adrenal metastasis is treated by surgical resection (often laparoscopic) followed in about 2 weeks by lung resection (often by VATS). Both the ACCP and NCCN recommend adjuvant chemotherapy, but this is based on extrapolation from patients with other disease stages.^{141,295}

A systematic review of outcomes found an average 5-year survival of 27% with curative-intent treatment of patients with NSCLC and isolated adrenal metastases.²⁹⁵ Prognostic factors have not been defined. The outcomes appear to be similar for synchronous and metachronous presentations.

Limited data is available regarding curative-intent treatment of oligometastatic disease in other distant sites. However, reported outcomes are quite good (5-year survival of 32% to 86%).²⁹⁵ The observation that outcomes are better for adrenal and other sites compared with brain oligometastatic disease probably simply reflects that clinicians have been more selective in choosing patients for curative-intent treatment involving nonbrain oligometastases. A prospective trial of aggressive curative-intent treatment for nonbrain oligometastatic disease found a median survival of only 11 months; however, this trial was not very selective and included many patients with N2 disease.⁴²⁸

Second Primary Lung Cancers, Additional Nodules, and Multifocal Lung Cancer

Patients with a lung cancer and additional nodules or lesions are challenging to manage. The additional lesion may be benign, may be a synchronous second primary lung cancer, one manifestation of systemic metastases, an additional nodule of cancer, or multifocal lung cancer. Appropriate categorization is difficult because the terms and definitions are ambiguous and the usage varies over time and between centers. The ACCP lung cancer guidelines have proposed a definition of terms and a structure for classification.^{158,295} This structure is based on the clinical presentation rather than pathology, which makes it applicable at the time of clinical decision making. Table 41.9 provides a summary of the approach to patients with additional lesions according to the clinical presentation. The NCCN guidelines also address these patients, but without any clarity about how to classify them.¹⁴¹

A critical step for most of these patients is evaluation by a multidisciplinary team. One must be careful; often, there is tendency

TABLE 41.9

Approach to Patients with Additional Nodule(s)

Presentation	Data Summary	Initial Evaluation	Assessment	Categorization	Management
Typical solid cancer, additional nodule on CT, no clinical signs of distant disease ^a	Large majority are benign	Multidisciplinary team ^b discussion	Judged very likely benign	Benign lesion	Treatment of primary lung cancer, observation of nodule per Fleischner guidelines
Locally advanced NSCLC, nodule(s), and clinical signs of distant disease ^a	No formal data	PET and brain MRI/CT Multidisciplinary team ^b discussion	Judged very likely stage IV	Stage IV	Stage IV treatment (i.e., chemotherapy)
			Judged unclear	Suspicious for Stage IV	Biopsy of nodule and other potential sites (N2,3 or M1b)
Typical solid cancer ^c and additional typical solid cancer ^c	~1.5% incidence	Thorough workup to rule out N2,3 or M1b Multidisciplinary team ^b discussion	Meets criteria for synchronous primaries if evaluation negative	Synchronous primaries	Manage each primary accordingly, and as patient will tolerate physiologically
Typical solid cancer and additional solid nodule	IASLC DB, but patients poorly defined, survival after resection better than for solitary M1b	Thorough workup to rule out N2,3 or M1b Multidisciplinary team ^b discussion	Judged unlikely to be synchronous second primary, but lesion suspected (or proven) malignant with same histology	Lung cancer with additional cancer nodule	Manage aggressively if T3 or T4 (consider resection), unclear if M1a (contralateral lung)
Lung cancer with GGO component and additional GGO (or semisolid) lesions	Indirect data, patients poorly defined	Multidisciplinary team ^b discussion	Fits pattern of multifocal disease	Multifocal lung cancer	Manage primary accordingly, and manage additional lesions according to guidelines for GGO

CT, computed tomography; NSCLC, non-small cell lung cancer; PET, positron emission tomography; MRI, magnetic resonance imaging; IASLC DB, International Association for the Study of Lung Cancer database; GGO, ground glass opacity.

^a Fatigue, weight loss, anorexia, bone pain, neurologic symptoms.

^b Team should include a chest radiologist, pulmonologist, and thoracic surgeon.

^c Spiculated solid lesion.

Table modified from the Kozower B, Lerner JM, Detterbeck FC, et al. Special treatment issues in non-small cell lung cancer: diagnosis and management of lung cancer, 3rd ed: American College of Chest Physicians evidence-based clinical practice guidelines *Chest* 2013;143:e369S–e399S.

to be swayed by the stage classification of additional nodules (e.g., T3_{satell}, T4_{ipsi nod}, or M1a_{contra nod}) and forget that many if not most patients belong in other categories. The classification of T3_{satell}, T4_{ipsi nod}, or M1a_{contra nod} is explicitly contraindicated when dealing with a second primary lung cancer or patients with distant metastases from lung cancer.⁵⁵ It is particularly important to remember that, in patients with a clinical and radiographic presentation consistent with early stage lung cancer and an additional subcentimeter nodule on CT, the large majority of these nodules are benign.^{295,429–431} Furthermore, identification of second primary lung cancers on clinical grounds has been quite accurate (as evidenced by survival outcomes), and these have most often been of the *same* cell type. Thus, it is clinical recognition and not necessarily a biopsy result that is critical to define second primary lung cancers. Because of these and other factors, the judgment of a multidisciplinary team is important in the evaluation of patients found to have additional lesions by CT.

Second primary lung cancers occur in about 5% of resected cases (either synchronous or metachronous presentation) and at a rate of about 1.5% per patient per year after curative treatment of a NSCLC. Approximately two-thirds of second primary lung cancers have been of the same histologic type; quite consistently the outcomes of tumors classified as second primary lung cancer based on different histology versus based on other features have been the same.²⁹⁵ It is reasonable to consider the radiographic appearances

in making a clinical determination of a second primary lung cancer. It has also been suggested to use molecular markers or the percentage of different subtypes of adenocarcinoma in making this determination, but this has not been extensively evaluated. All of the data available should be considered (clinical, radiographic, and pathologic) in making the determination whether a second focus of cancer is a second primary lung cancer or not.

When a synchronous second primary lung cancer is suspected, a careful search should be made for distant or mediastinal metastases as recommended by the ACCP and NCCN.^{141,295} If this evaluation is negative, each primary cancer should be treated in the usual fashion for early stage cancer, provided the patient has adequate reserve. SBRT offers another treatment option. The vast majority of reported synchronous second primary lung cancers have been resected (often a limited resection); the 5-year survival after resection is approximately 25% for all and 40% if both tumors are stage pI (range, 0% to 79%).

A metachronous second primary lung cancer is best defined as a cancer with either a different histology or an interval of >4 years—in these situations, one can be fairly certain it is not a recurrence. A site of cancer of the same histologic type appearing within 2 years is most likely a metastasis, and between 2 and 4 years is a gray zone.²⁹⁵ Once ~2 years have evolved, the stage of the initial NSCLC does not appear to affect the likelihood of recurrence versus new primary cancer. The judgment of a multidisciplinary

team, taking all factors into account, is important in classifying the situation as a second primary lung cancer versus a recurrence.

The staging evaluation of a metachronous second primary lung cancer should generally proceed as dictated by the characteristics of the second primary tumor alone.²⁹⁵ Most metachronous second primary cancers that are reported have been resected (often a limited resection); the 5-year survival after resection is approximately 30% for all and 40% for stage pI (range, 20% to 70%). No data is available regarding outcomes of unresected patients.²⁹⁵

Attention has been drawn to additional nodules ($T_{3\text{satell}}$, $T_{4\text{ipsi nod}}$, or $M_{1\text{contra nod}}$) by the seventh edition of the lung cancer staging system.^{295,294} The patients with additional nodules in the IASLC database were poorly defined, but specifically excluded those with second primary lung cancers or with distant metastases.⁵⁵ The additional nodules were probably recognized clinically in most cases (either pre- or intraoperatively) and proven pathologically to be of the same histologic type. The ACCP suggests that the additional nodule designations should be used for patients with a dominant “classic” lung cancer (i.e., solid, spiculated) and an additional solid nodule identified clinically or on pathologic examination.¹⁵⁸ It should be noted that most reports of patients with additional nodules of cancer have specifically excluded BAC because BAC is recognized to often present as multifocal disease. The ACCP clinically based definition effectively also excludes what was formerly called BAC pathologically from the cohort of patients classified as having additional nodules.

No additional diagnostic workup is recommended by the ACCP in patients with a secondary lesion in the same lobe ($T_{3\text{satell}}$). The data does not suggest a higher rate of occult distant or mediastinal metastases from what is predicted based on the dominant cancer, and the treatment recommendation is the same with or without an additional nodule in the same lobe (i.e., lobectomy).²⁹⁵ The 5-year survival appears to be about 10% to 15% worse, stage for stage, with an additional nodule compared to the same dominant cancer without an additional nodule.^{295,432} There does not appear to be a difference in survival whether there is one or several additional nodules.²⁹⁵

For additional nodules of cancer in a different lobe, the ACCP suggests a thorough search for distant disease (i.e., PET, brain MRI/CT) and invasive mediastinal staging, although direct data to support this stance is not available.²⁹⁵ If there is no N2,3 or M1b disease, resection of both the dominant cancer and an ipsilateral, different lobe nodule is recommended. The reported 5-year survival for resection of such patients with ipsilateral, different lobe, additional nodules is ~20%.²⁹⁵ The outcomes do appear to be better than if resection was not done. Much of the reported data comes from Asia, although there is no evidence of a geographic difference in outcomes in this cohort in the IASLC database. The survival appears to be worse if there is more than one additional ipsilateral, different lobe nodule, or with lymph node involvement.²⁹⁵

The ACCP also suggests resection of a contralateral additional nodule if thorough staging reveals no N2,3 or M1b involvement.²⁹⁵ Very limited data is available on resected patients; in the IASLC database, 98% of patients were not resected, and survival was poor (5-year survival = 3%). This has been corroborated by other registry reports.²⁹⁵

Multifocal BAC was a well-recognized entity. The term BAC has been abandoned because it was used loosely in many different settings.⁶³ In the context of multifocal BAC, this was probably most often what would now be called a lepidic predominant invasive adenocarcinoma. The combination of abandonment of the term BAC and the seventh edition of the stage classification has left a void in how to classify multifocal lung cancer, which is still an entity that is regularly encountered. The ACCP has proposed a definition of multifocal lung cancer as multiple lesions arising from GGOs, which may develop a solid component.^{158,295} This is a clinically focused definition, rather than one focused on particular pathologic findings; some of these lesions may be AAH, AIS, or MIA, but most are lepidic predominant invasive adenocarcinoma. A diffuse infiltrative pattern of disease (also called “pneumonic

type” of adenocarcinoma) is also included in the ACCP definition. For stage classification, the ACCP recommends that the T(m) designation should be used for patients with multifocal lung cancer (a designation that has been used rarely in lung cancer although it has been part of the stage classification system for more than a decade).^{158,293,294}

Multifocal lung cancer appears to have a decreased propensity for nodal or systemic spread and an increased propensity for additional pulmonary foci. The ACCP lung cancer guidelines therefore suggest that for multifocal lung cancer a search for distant or mediastinal metastases (i.e., PET, invasive mediastinal staging) is not necessary unless there is clinical suspicion.²⁹⁵ Additionally, the rate of recurrence after resection, which has often been a limited resection, is low. Therefore, the ACCP guidelines suggest that a limited resection be performed of any multifocal lesions that are thought to be invasive cancer.²⁹⁵ Lesions that are thought not to be invasive cancer (i.e., pure GGO) should generally be followed, because most of these appear to remain stable, at least for many years.^{119,151,295} Adjuvant therapy for R0 resected patients without nodal involvement is not recommended.

The published outcomes for resected patients with multifocal disease have been quite good (5-year survival of approximately 90%; range, 64% to 100%).²⁹⁵

PALLIATIVE CARE

Role of Palliative Care

A large number of patients with lung cancer will develop symptoms related to their disease. Metastases to the brain and spinal column may threaten significant neurologic compromise; airway obstruction or SVC syndrome may present urgently or with milder symptoms that progress to become severe if left untreated. And more common, less acutely severe, symptoms such as pain, dyspnea, cough, anorexia, or fatigue can significantly impact QOL, and may preclude cancer-directed therapy.⁴³³ The importance of palliative efforts in lung cancer care was highlighted in an RCT involving 151 patients with metastatic NSCLC who received standard oncologic treatment and were randomized to receive early palliative care or not.⁴³⁴ In patients who received early palliative care, there was a significant improvement in QOL and fewer depressive symptoms. Because the care mode resulted in better documentation of end-of-life preferences, patients receiving early palliative care were less likely to have aggressive resuscitation efforts and less likely to receive chemotherapy in favor of hospice care. Despite this, the authors also observed significantly improved OS (median, 11.6 months versus 8.9 months). While unexpected, this finding is consistent with prior studies that demonstrated shorter survival in patients with more severe depressed mood and worse QOL.⁴³⁵ These results suggest a model for improving patient mood and QOL during cancer care, and validate the importance of the early initiation of such efforts.

Specific Symptom Management

Airway obstruction is common in patients with lung cancer, as a result of tumor mass effect, bleeding, or mucous production.⁴³³ Therapeutic bronchoscopy is appropriate for evaluation, with interventions including mechanical disimpaction, brachytherapy, ablation, or stenting. Hemoptysis responds well to ablation with laser or electrocautery, and brachytherapy or external beam radiation may also be considered. A cough can be the direct result of malignancy, or due to secondary infection, or chemotherapy- or RT-induced pneumonitis. Evaluation and treatment for the latter etiologies should be considered, and otherwise cough suppression with opioids is appropriate. Malignant effusions, if symptomatic, respond to tunneled pleural catheters when the lung can be

re-expanded. Pleurodesis can be pursued for recurrent effusions, via talc slurry or poudrage.⁴³³

Pain, whether due to bone or soft tissue disease, is one of the most common symptoms of lung cancer. Nonsteroidal anti-inflammatory drugs should be prescribed to all patients, unless contraindicated, and, for those who require chronic medication, appropriate gastrointestinal prophylaxis (i.e., misoprostol, H2 antagonists, or proton pump inhibitors) should be added. For those patients who have a neuropathic component to their pain, the addition of an anticonvulsant or tricyclic antidepressant improves pain control. For moderate to severe pain, morphine or an alternative narcotic is recommended.⁴³³

Bony metastases without pathologic fracture or significant structural weakness can be managed with short-course RT and bisphosphonates. Patients with pathologic fractures, or with focal lytic lesions that involve >50% of the cortex of weight-bearing bones, should undergo surgical fixation to prevent debilitating injury, followed by RT. Vertebral compression fractures with instability can be stabilized surgically or through augmentation procedures.

Epidural spinal cord compression (ESCC) is one of the most serious complications of metastatic cancer. The most common presenting symptom is local pain, with or without radicular component.^{437,437} A bony metastatic lesion arising in the vertebral body can extend directly into the epidural space, impinging upon the spinal cord or cauda equina, or an induced vertebral compression fracture may retropulse bony fragments into the same space. Progressive pressure on the cord or nerve roots can lead to edema, ischemia, and irreversible neurologic compromise. MRI is the primary diagnostic intervention, although CT myelography may also demonstrate the characteristic impingement on the thecal sac. Additional plain films or CT imaging may be required to differentiate soft tissue extension from bony retropulsion. Corticosteroids should be administered as early as feasible. A small, single-blind randomized study of corticosteroids showed that the addition of dexamethasone to RT improved ambulation, an effect that was durable to 6 months (59% versus 33% remained ambulatory), without an effect on survival.⁴³⁸ The doses administered were higher than are typically used in the modern era, 96 mg intravenously followed by 96 mg/day and tapered over 10 days. Lower doses are typically used in an effort to avoid steroid-related complications.

Surgical or augmentation procedures are indicated for ESCC when there is spinal instability or the cause of the cord impingement is bony in nature. For symptoms caused by direct tumor compression, either surgical intervention or local RT may be appropriate. Evidence suggests that neurologic compromise of short duration is more apt to be meaningfully reversed by surgery than symptoms that have been present for longer duration.⁴³⁹ Patchell et al.⁴³⁹ conducted a randomized trial of surgery versus RT (30 Gy in 10 fractions) in 101 patients with symptomatic ESCC, all with neurologic symptoms of <2 days duration. Patients who underwent surgery were more likely to have symptomatic relief (62% versus 19%), more likely to ambulate (84% versus 57%), and had better OS (median, 126 days versus 100 days), clearly indicating that surgery should be strongly considered in patients with ESCC, particularly those with neurologic signs and symptoms of relatively acute onset. RT as primary treatment offers reasonable palliation of pain, but is highly unlikely to restore ambulation or otherwise reverse neurologic compromise.

Lung cancer accounts for approximately half of all brain metastases. Historically, survival after diagnosis of brain metastases is poor; a median of 6 months in the most robust candidates (i.e., those of young age, good PS, and brain-only disease).⁴⁴⁰ In patients with NSCLC, significant prognostic factors for survival in patients with brain metastases include age, PS, the presence of extracranial metastases, and the number of brain metastases.⁴⁴¹ The increased availability of active systemic therapy and targeted agents options has resulted in a subset of patients with brain metastases whose survival is significantly longer, increasing the importance of selecting

the appropriate brain-directed therapy to maximize control and minimize potential long-term morbidity.

Brain metastases are often accompanied by significant surrounding cerebral edema, and the latter is the most common cause of symptoms such as headache, nausea, vomiting, and ataxia. Steroids with predominant glucocorticoid activity, such as dexamethasone, are commonly used to address symptomatic patients, and can partially or completely relieve symptoms in otherwise untreated patients for several weeks. There is no evidence to suggest that steroid treatment of asymptomatic patients confers any benefit. For patients with severe symptoms due to mass effect or edema that are not amenable to steroid treatment, consideration should be given to surgical decompression. Noninvasive therapies such as radiosurgery or WBRT are unlikely to acutely improve symptoms.

WBRT was the standard-of-care approach to most patients with brain metastases for several decades, since a randomized trial demonstrated a 40% improvement in OS when compared to steroid treatment and supportive care alone.⁴⁴² Because WBRT can lead to significant fatigue and somnolence in the short term, and permanent neurocognitive deficits in the late term, patients with less bulky disease or those with an expectation of more prolonged survival are frequently treated with surgery or radiosurgery in place of whole-brain treatment.

For patients with a single brain metastasis, surgery or radiosurgery, either with or without WBRT, has become the standard-of-care approach. A landmark pair of studies by Patchell et al.^{443,444} established the separate roles of resection and WBRT in this setting. In the first trial, 84 patients with a solitary brain metastasis were randomized to surgical resection followed by WBRT or WBRT alone.⁴⁴³ The OS was significantly longer in the surgical arm (45 weeks versus 40 weeks), reflecting the marked benefit of local therapy for patients with good PS. The use of radiosurgery in place of surgery in patients with a solitary lesion also improves OS when given in addition to WBRT in a parallel fashion.⁴⁴⁵ The companion study from Patchell et al addressed the role of WBRT.⁴⁴⁴ In this trial, 95 patients with a solitary metastatic lesion underwent surgery, and then were randomized to WBRT or no further therapy. The addition of WBRT significantly improved local control of the resected lesion, reduced “elsewhere” failures in the brain, but did not improve OS.⁴⁴⁴ The significant reduction in brain recurrence seen in this study has been cited to support the routine use of WBRT after surgery or radiosurgery to a solitary brain metastasis, but the lack of any survival benefit has also been cited to suggest that active surveillance after local therapy is a reasonable approach.

Patients with one to three brain metastases may be treated with radiosurgery alone, WBRT, or both in combination. The value of radiosurgery in this population was established in the RTOG 9508,⁴⁴⁵ in which 333 patients with one to three metastases were randomized to either WBRT alone or WBRT followed by radiosurgery. In the subset of patients with a single metastasis, the addition of radiosurgery improved OS, consistent with the Patchell trial of surgical resection in the setting of WBRT. Patients with two or three lesions who received radiosurgery in addition to WBRT had better PS at 6 months posttreatment, but no incremental survival benefit. Withholding WBRT in these patients and treating them with radiosurgery alone is predicated on avoiding the neurocognitive sequelae of WBRT. In a small randomized trial, Chang et al.⁴⁴⁶ answered the question of whether WBRT could be avoided, randomizing patients with one to three brain metastases to either radiosurgery alone or radiosurgery and WBRT. The trial was stopped early when an interim analysis demonstrated an OS benefit to withholding WBRT. This finding was not consistent with prior surgical data and could be due to the increased opportunity to deliver subsequent chemotherapy in patients who did not have WBRT, or could be simply an anomalous finding in a relatively small study population. The clear and consistent result was that neurocognitive function was significantly better when WBRT was withheld.

In patients with poor PS or extensive extracranial disease, WBRT is appropriately the treatment of choice. In patients with more than five brain metastases, good PS, and limited extracranial disease, the role of WBRT versus stereotactic radiosurgery is ill-defined.⁴⁴⁷ Several efforts are currently under way to determine the optimal treatment for this population.

SVC syndrome may have various neoplastic and nonneoplastic causes. Bronchogenic carcinoma is the most common cause of SVC syndrome, underlying approximately 80% of cases at diagnosis.⁴⁴⁸ When the SVC becomes obstructed, blood returns to the heart through collateral vessels via the azygous vein or inferior vena cava. Venous collaterals dilate over weeks, compensating for the loss of SVC patency. Upper body venous pressure and resulting edema of the arm and face decrease over time, so that symptoms with sudden onset, from acute obstruction, can diminish over several weeks even without intervention. The severity of the symptoms is due not only to the degree of SVC narrowing, but also to the rapidity with which it develops. The characteristic signs include cyanosis, plethora, distention of subcutaneous veins, and edema of the head, neck, and arm. Patients may develop dyspnea and cough. In rare cases, severe and acute obstruction can result in cerebral edema or laryngeal stridor. The specific cause of SVC syndrome in a patient with known malignancy may be extrinsic compression from tumor mass or due to thrombus in the setting of hypercoagulability. Even in the case of malignant, extrinsic compression, the clinical course may be complicated by the subsequent development of a thrombus in the SVC or brachiocephalic vein, or the simultaneous tumor mass effect on the bronchi or heart.

Traditionally, SVC syndrome was viewed as a medical emergency, but accumulating experience demonstrates that the course of SVC is rarely life-threatening. In a review of 107 patients in whom intervention was withheld during evaluation, there were no serious consequences to deferring treatment until diagnosis and staging was completed.⁴⁴⁹ The symptoms often improve without active intervention, as collateral vessels dilate.⁴⁵⁰ Immediate intervention is warranted when symptoms are life threatening (e.g., cerebral edema leading to altered mental status, stridor,

or clinically significant hemodynamic compromise). When urgent intervention is indicated, intravascular stenting provides the most immediate relief. In the absence of life-threatening symptoms, the patient should be appropriately staged, biopsied, and the underlying malignancy treated in a manner appropriate for its stage and presentation. Patients with metastatic SCLC and SVC syndrome will likely respond to systemic therapy, which may be more appropriate than the initiation of urgent radiation. Patients with limited-stage SCLC and SVC syndrome should respond rapidly to chemoradiotherapy, or induction chemotherapy if that can be started more promptly. Patients with NSCLC and SVC syndrome are less likely to respond quickly to either chemotherapy or radiation, and so the threshold for placing an endovascular stent is somewhat lower. SVC syndrome is a poor prognostic factor in NSCLC, with a median survival from presentation of 5 months.⁴⁵¹

CONCLUSION

Lung still remains by far the leading cause of cancer deaths. The blame, guilt, and nihilism that stems from the relationship of smoking to lung cancer continues to be an issue, despite a better understanding of smoking as an addiction and the fact that most patients diagnosed will have quit smoking many years earlier. However, lung cancer has become a dynamic and vibrant field. Screening is able to reduce the rate of lung cancer deaths by decreasing the proportion that is diagnosed with advanced disease. Major improvements have been made in all treatment modalities: minimally invasive surgery, better RT targeting and delivery, and a diverse array of chemotherapeutic agents and methods of palliation of many symptoms. There have also been advances in epidemiology (focusing on more than simply smoking), in imaging, in accurate definition of the stage, and on understanding some of the biologic and genetic alterations encountered. Many questions remain, but there is no question that lung cancer is a dynamic, challenging, and exciting area in which much progress is being made.

SMALL CELL LUNG CANCER

Incidence and Etiology

Although the incidence of small cell lung cancer (SCLC) is declining, it remains a worldwide public health problem. The Surveillance, Epidemiologic, and End Results (SEER) database reports the proportion of SCLC cases among all lung cancers in the United States decreased from 17% to 13% in the past 30 years (Fig. 42.1),¹ whereas the age-adjusted rates per 100,000 decreased from 10.65 in 1990 to 6.74 in 2010.² Among the predicted 228,190 lung cancer cases in the United States in 2013,³ an estimated 29,665 cases of SCLC were diagnosed.

Only 2% to 3% of patients with this malignancy are never smokers^{4,5}; thus, as tobacco exposure causes SCLC in over 97% of cases, its incidence rates mirror smoking patterns. Peak cigarette consumption occurred in the 1960s, but declined following the Surgeon General's report linking smoking to cancer and the subsequent ban on tobacco advertising on television.⁶ The percentage of men who smoke decreased from 50% in 1965 to 21.6% in 2011, which is a much greater proportional reduction than in women, who went from a rate of 32% to 16.5% during the same time period.^{6,7} Correspondingly, the incidence of SCLC in men peaked in 1984 and since has been trending steadily down, whereas in women, the incidence peaked later and only has declined slightly.⁸ The gender gap has narrowed such that currently about half of the patients diagnosed with SCLC are women (see Fig. 42.1).

Anatomy and Pathology

Neuroendocrine tumors of the lung encompass a spectrum of tumors, including low-grade typical carcinoid, intermediate-grade atypical carcinoid, high-grade large cell neuroendocrine carcinoma (LCNEC), and SCLC.⁹ Because of their shared neuroendocrine properties, these tumors have common morphologic, ultrastructural, immunohistochemical, and molecular features. Despite this, there are also important differences in clinical, epidemiologic, histologic, and molecular characteristics.

SCLC is readily diagnosed on small specimens such as bronchoscopic biopsies, fine-needle aspirates, core biopsies, and cytology. The diagnosis of SCLC is based primarily on light microscopy (Fig. 42.2A): dense sheets of small cells with scant cytoplasm, finely granular nuclear chromatin, inconspicuous or absent nucleoli, and frequent mitoses. Necrosis is common and frequently shows large areas. The tumor cells usually measure less than the diameter of three small resting lymphocytes. They are round to be fusiform in shape and have scant cytoplasm. The nuclear chromatin is finely granular and nucleoli are inconspicuous or absent.⁹⁻¹¹ The mitotic rate is characteristically high, averaging 60 to 80 per 2 mm². Crush artifact is a frequent finding in small transbronchial or mediastinal biopsy specimens and can make pathologic interpretation difficult. The tumor cells of SCLC also

have a tendency to show a streaming artifact. This can also occur with non-small-cell lung cancer (NSCLC), lymphoma, and chronic inflammation. In surgically resected specimens where the tumor cells achieve better fixation, the cells of SCLC appear larger than in small biopsies.^{10,12} When a component of NSCLC, including adenocarcinoma, squamous cell carcinoma, large cell carcinoma, spindle cell carcinoma, and giant cell carcinoma, is present, the term *combined SCLC* is used with mention of the specific histology of the non-small-cell component.^{9,10} In resected specimens, combined SCLC may occur in up to 28% of cases.¹⁰ To diagnose combined SCLC and large cell carcinoma, the large cell carcinoma component must comprise at least 10% of the overall tumor.^{9,10}

The following immunohistochemical stains are helpful in difficult cases. A pancytokeratin antibody such as AE1/AE3 is useful to confirm if the tumor is a carcinoma. Neuroendocrine differentiation can be demonstrated using a panel of markers such as CD56, chromogranin, and synaptophysin. However, up to 10% of SCLCs may be negative for all neuroendocrine markers.¹³ A high proliferation rate of 80% to 100% should be seen with Ki-67. Thyroid transcription factor-1 (TTF-1) is positive in 70% to 80% of small cell carcinomas.¹⁴⁻¹⁶ Notably, TTF-1 can be positive in extrapulmonary small cell carcinomas, so it is not useful in determining the primary site of small cell carcinomas.¹⁷

Genetics

SCLC has been characterized by frequent inactivating mutations in the critical tumor suppressor genes *TP53* (75% to 90%)¹⁸ and *RBI* (60% to 90%).^{19,20} A mouse model with conditional inactivation of these two tumor suppressors in the lung generates lung tumors histologically and biologically similar to human SCLC.²¹

Recent reports including exome, transcriptome, and limited whole genome sequencing have provided insights into the fuller landscape of genetic alterations in SCLC.^{22,23} In addition to confirming *TP53* and *RBI* inactivation, these studies define other alterations of interest in SCLC, with potential therapeutic implications. One consistent finding from both reports was an exceptionally high degree of genomic alteration in this tumor type, including mutations, insertions, deletions, large scale copy number alterations, and gross inter- and intrachromosomal rearrangements. *MYC* family member alterations, including gene amplification of *MYC*, *MYCN*, and *MYCL1*, as well as a recurrent gene fusion involving *MYCL1*, are frequent in SCLC and may represent important drivers of SCLC oncogenesis. The tumor suppressor phosphatase and tensin homolog (*PTEN*) appears to be inactivated in approximately 10% of SCLC, and mutations of other factors in the same signaling pathway were also identified. Other alterations implicated as potential drivers in subsets of SCLC include amplification of the tyrosine kinase *FGFR1* (in 6% of cases) and of the developmental regulator and transcription factor *SOX2* (in up to 27% of cases). The therapeutic implications of the large majority of

Figure 42.1 Patients diagnosed with small cell lung cancer as a percentage of all lung cancer cases and the breakdown by gender.

the genetic alterations documented to date in SCLC have not been defined.

Several reports have described the rare phenomenon of transformation to SCLC as a mechanism of acquired resistance to epidermal growth factor receptor (EGFR) tyrosine-kinase inhibitors (TKI) in patients initially treated for EGFR-mutant lung adenocarcinomas.⁴ Of those cases with acquired resistance to EGFR TKIs, 3% to 14% will undergo SCLC transformation. Importantly, pure SCLC lack EGFR mutations and ALK rearrangements, even in those patients with this malignancy who are never smokers.^{4,24} However, in the rare cases of SCLC transformation as a mechanism of acquired resistance to EGFR TKIs, there is persistence of the original EGFR mutation in the tumors confirmed on biopsy. In all cases where SCLC has been documented as a mechanism of

acquired resistance to EGFR TKIs, the original tumor was a pure adenocarcinoma prior to EGFR TKI treatment, and the transformation was validated by histologic examination and confirmed by expression of neuroendocrine markers.

Screening

Screening computed tomography (CT) scans detect NSCLCs at an earlier stage compared to chest x-ray (CXR), or no screening, and can decrease lung cancer-specific mortality in heavy smokers.²⁵ However, the natural history of SCLC is characterized by rapid tumor growth and early metastatic spread. As such, the diagnosis of SCLC in an asymptomatic patient is rare.

Figure 42.2 Histologic appearance of neuroendocrine carcinomas. (A) Small cell carcinoma. (B) Typical carcinoid. (C) Atypical carcinoid. (D) Large cell neuroendocrine carcinoma.

The National Lung Screening Trial (NLST) enrolled 53,454 Americans age 55 to 74 years with a history of at least 30 pack-years of cigarette smoking, and randomly assigned them to undergo three annual screenings with either low-dose CT scans (LDCT) or standard CXR. LDCT screening identified a preponderance of adenocarcinomas, including many with bronchioalveolar subtype. SCLCs were not detected at early stages by either LDCT or CXR in the NLST. Although the study demonstrated a reduction in lung-cancer specific mortality compared to CXR, the similar rates and patterns of detection of SCLC make it unlikely that LDCT screening will reduce mortality specific to SCLC. Therefore, screening for SCLC by any method is not recommended.²⁵

Diagnosis

Presenting symptoms in patients with SCLC can be constitutional, pulmonary, the result of extrathoracic spread, or due to paraneoplastic disorders.^{26,27} In one series in which patient-reported symptoms were recorded using the Lung Cancer Symptom Scale, fatigue was the most common, symptom with decreased physical activity, cough, dyspnea, decreased appetite, weight loss, and pain occurring sometime in the course of the illness in the majority of patients.²⁷ Hemoptysis was noted in 14% in the same series.²⁷ The primary tumor often presents as a large central mass invading or compressing the mediastinum. Superior vena cava obstruction is present at diagnosis in 10% of patients with SCLC (Fig. 42.3),²⁸ and in these cases, the symptoms are often worsened by associated thrombosis in the compromised blood vessel. Chest imaging typically shows hilar and mediastinal adenopathy. Rarely, SCLC presents as a solitary pulmonary nodule.^{29,30} No more than 2% of SCLC present as a superior sulcus tumor.³¹

Most patients with SCLC have metastases at diagnosis. Bone involvement is usually characterized by osteolytic lesions, often in the absence of bone pain, or elevations in the serum alkaline phosphatase.³² Osteoblastic bone metastases do occur in some patients. Hepatic and adrenal lesions are typically asymptomatic. Brain metastases can be detected in at least 18% of patients at diagnosis,³³ which are often asymptomatic.

Paraneoplastic syndromes are common in SCLC and differ from those observed with NSCLC. SCLC accounts for approximately 75% of the tumors associated with the syndrome of inappropriate antidiuretic hormone (SIADH). Although serum concentrations of antidiuretic hormone are elevated in the majority of those with SCLC, only approximately 10% of patients fulfill the criteria of SIADH, and symptoms are present in no more than

5%. In some cases, ectopic production of atrial natriuretic factor contributes to the disorder in sodium homeostasis. The primary treatment for hyponatremia in SCLC patients is chemotherapy aimed at treating the disease. Additional management strategies include fluid restriction in mild cases or intravenous hypertonic saline in severe, symptomatic cases. Older pharmacologic interventions that have been used in SIADH, include demeclocycline and lithium, both of which induce nephrogenic diabetes insipidus.³⁴ More recently, tolvaptan, an oral vasopressin V2-receptor antagonist, has been shown to significantly improve serum sodium in patients with SIADH over a 4- and 30-day period.³⁵ Tolvaptan therapy should be initiated while patients are in the hospital to allow monitoring of the therapeutic response. Increased serum levels of adrenocorticotropic hormone can be detected in up to 50% of patients with lung cancer, but Cushing syndrome develops in only 5% of patients with SCLC. Low serum sodium is an adverse prognostic factor,³⁶ and patients with Cushing syndrome have a very limited survival.³⁷ The primary treatment of Cushing syndrome in SCLC patients is chemotherapy, although agents such as ketoconazole and mitotane have been used.³⁸ Hypercalcemia is rare in SCLC.

Paraneoplastic neurologic disorders seen in patients with SCLC include sensory, sensorimotor, and autoimmune neuropathies and encephalomyelitis.³⁹ These syndromes are thought to occur through autoimmune mechanisms, and antinuclear antibodies that bind to SCLC and to neuronal tissues have been identified. Symptoms may precede the diagnosis by many months and are often the presenting complaint. They may also be the initial sign of relapse from remission. An aggressive search may be required to discover small tumor nodules causing profound neurologic syndromes. Subacute peripheral sensory neuropathy associated with the anti-Hu antibody may be the most frequent paraneoplastic neurologic disorder seen in those with SCLC. Less common is the Lambert-Eaton syndrome, characterized by proximal muscle weakness that improves with continued use, hyporeflexia, and dysautonomia. Classic electromyographic findings confirm the diagnosis. The cause is related to autoantibody impairment of voltage-gated calcium channels. Rarer neurologic disorders seen in patients with SCLC include cerebellar degeneration or retinopathy. Two studies conflicted when evaluating whether the presence of paraneoplastic antibodies have prognostic implications^{40,41}; the utilization of different techniques to measure antibody levels may account for the discrepant results.⁴²

In contrast to the endocrine syndromes, for which successful treatment of the tumor effectively controls the symptoms, the occurrence and severity of the neurologic symptoms is unrelated to tumor bulk and usually does not resolve with antineoplastic therapy. Various therapies such as plasma exchange and immunosuppressive therapy with agents such as corticosteroids, cyclophosphamide, and tacrolimus have been tried, but generally offer little benefit. In patients with Lambert-Eaton syndrome, two randomized placebo-controlled trials of 3,4 diaminopyridine, which blocks potassium channel efflux from nerve terminals, demonstrated that treatment with this agent increases compound muscle action potentials and significantly improves muscle strength.⁴³ In a randomized trial with a crossover design, intravenous immunoglobulin also improved limb strength as measured by myometry over placebo in 10 patients with Lambert-Eaton syndrome.⁴³ However, the benefit was short lived and began to dissipate after just 8 weeks.

Staging

A simple two-stage system, introduced by the Veterans' Administration Lung Study Group (VALSG), has historically been utilized instead of the tumor, node, metastasis (TNM) system employed for most other cancer types.⁴⁴ In the VALSG system, limited stage is defined as disease confined to one hemithorax

Figure 42.3 Computed tomography scan showing small cell lung cancer with an infiltrative mediastinal mass causing compression of the superior vena cava (arrow).

that can be “encompassed” in a “tolerable” radiation field. These patients currently are treated with a combined modality approach. All other patients are considered to have extensive-stage disease. At presentation, approximately two-thirds of patients with SCLC have extensive disease and one-third have limited-stage disease.¹

In the VALSG staging system, the appropriate classification of ipsilateral pleural effusion, supraclavicular lymphadenopathy (ipsilateral or contralateral), or contralateral mediastinal lymphadenopathy as either limited or extensive stage remains controversial. Some large series have not found a survival difference between patients with an isolated ipsilateral pleural effusion and other patients with limited SCLC.⁴⁵ However, analyses of two large cooperative group databases, which included over 4,000 patients, showed that the survival of individuals with an isolated effusion was similar to that of patients with extensive disease.^{46,47} In clinical practice, it is assumed that an effusion is malignant unless three criteria are met: the fluid is transudative, nonhemorrhagic, and cytologically negative on repeated examinations. Patients with a malignant effusion are appropriate to exclude from a combined modality treatment because hemithoracic radiotherapy to encompass the entirety of the pleura is impractical.

The presence of supraclavicular lymphadenopathy commonly is associated with extensive disease but, when encountered in patients with otherwise limited disease (5% of cases), carries a trend toward poorer survival.⁴⁷ Contralateral mediastinal involvement also is usually classified as limited-stage disease. However, two studies that evaluated twice-a-day radiation regimens excluded patients with contralateral hilar disease to reduce the normal lung volume irradiated and the risk for toxicity.^{48,49}

For patients who appear to have limited-stage SCLC, some additional tests may be appropriate to confirm this assessment. Unilateral iliac crest bone marrow aspiration and biopsy are still a routine part of staging for many oncologists and should be performed in limited-stage patients with elevations of serum lactate dehydrogenase (LDH)^{50,51} and evidence of myelophthisis (nucleated red blood cells, leukopenia, or thrombocytopenia) on the peripheral blood smear. If there is evidence of a pleural effusion, a thoracentesis or thoracoscopy may help confirm that the effusion is nonbloody, transudative, and cytologically negative. Effusions too small to permit image-guided sampling should not be considered in staging.⁵² Osseous abnormalities seen on positron-emission tomography (PET) or bone scan require confirmation with magnetic resonance imaging (MRI), CT scan, or biopsy if they represent the only disease site that makes a patient extensive stage.

For the American Joint Committee on Cancer (AJCC) seventh edition, the use of a TNM staging system for SCLC has been revisited. To establish the accuracy of outcomes based on stage, cases of completely resected SCLC were staged using the same definitions as used for NSCLC.⁵³ The use of pathologic stage was necessary to accurately stage the patients used for this analysis. More favorable outcomes of patients have been reported in patients previously classified as *very limited* disease (i.e., no evidence of mediastinal metastases by CT or mediastinoscopy) treated with chemotherapy and radiation, as compared with other patients with limited-stage disease.^{54–56} The use of the TNM system is best applied for cases of early stage disease and may have less relevance for the majority of patients presenting with metastatic disease.

Clinical and Serologic Predictive and Prognostic Factors

Multivariable analyses suggest that performance status is a strong and reproducible predictive and prognostic factor.^{47,57,58} Poorer performance status can additionally identify individuals at higher risk for treatment-related complications. Several other clinical

parameters have been proposed. Female gender has been associated with improved response and survival in patients with SCLC.^{47,57,58} Older age (variably defined) has not been identified as an adverse prognostic factor in patients with SCLC in most^{59–62} but not all^{36,46,47} series. Older age has been associated with decreased performance status and more comorbid illnesses and often results in compromised chemotherapy dose intensity,^{63,64} which may partially explain its prognostic implications. Certain metastatic sites, such as the liver,^{65–67} the brain,^{66,68} bone marrow,⁶⁷ and bone,⁶⁸ as well as the total number of metastatic sites involved,⁴⁷ have been found to be of prognostic significance for patients with extensive-stage disease. Paraneoplastic Cushing syndrome has been correlated with a poor response to therapy and short survival.³⁷ Continued use of tobacco during combined modality therapy was identified as an adverse prognostic factor in a group of 186 patients with limited disease.⁶⁹ Elevation of serum LDH is found in 33% to 57% of all patients with SCLC and up to 85% of patients with extensive-stage disease and is a strong prognostic and predictive factor.^{46,57,65,66,68,70–72} Serum LDH elevation is associated with the presence of bone marrow involvement.⁵⁰ Although many other serum markers have been proposed to have prognostic significance, including neuron-specific enolase,^{61,66} chromogranin, and precursors of gastrin-releasing peptide,^{73,74} none have been strong and reliable enough to warrant general use. Carcinoembryonic antigen (CEA) has been found to predict outcome in SCLC in multiple series.^{57,75,76}

Management by Stage

General Recommendations for Initial Management

Once the pathologic diagnosis of SCLC is confirmed, a complete history and physical examination is the next step. Special attention should be paid to the cigarette smoking history. If a patient is a current smoker, he or she should be advised to quit immediately in the strongest terms and offered the most aggressive smoking cessation intervention available.⁶⁹ If the patient is a never smoker, the pathologic diagnosis of SCLC should be reviewed as only 2% to 3% of never smokers develop SCLC.^{4,5} The National Comprehensive Cancer Network (NCCN) has compiled consensus guidelines for the initial evaluation of individuals with SCLC.⁵² A complete blood cell count (CBC) with platelet count, electrolytes, calcium, creatinine, blood urea nitrogen (BUN), liver function tests, and LDH are recommended. All patients should undergo a contrast-enhanced CT scan of the chest, a gadolinium-enhanced MRI of the head, and whole-body PET or a bone scan. A PET scan can identify sites of metastases undetected by other modalities^{77–79} and can replace the bone scan.⁸⁰

All fit patients (Karnofsky performance status greater than 60% or Eastern Cooperative Oncology Group [ECOG] performance status 0, 1, or 2) should initially receive combination chemotherapy with etoposide plus either cisplatin or carboplatin for four to six cycles (Fig. 42.4).⁵² Supportive data, specifics of chemotherapy regimens, duration of therapy, and alternatives for patients with contraindications or special needs are discussed in the sections that follow. Patients with limited-stage disease should receive the chemotherapy concurrently with twice-daily thoracic irradiation beginning with the first, second, or third cycle.^{49,81,82} Patients who achieve a response to chemotherapy should receive prophylactic whole-brain radiotherapy at the conclusion of chemotherapy or chemoradiotherapy.⁸³ There is no routine recommendation for the treatment of patients who have a Karnofsky performance status of 50% or less or ECOG performance status 3 or 4. Because the toxicity of all treatment worsens and effectiveness lessens in patients with a low performance status, clinicians must carefully evaluate the agent(s) used and the appropriateness and goals of therapy individually. For many patients in this low performance status group, supportive care only and referral to hospice are the best options.

Treatment Paradigm for Small Cell Lung Cancer

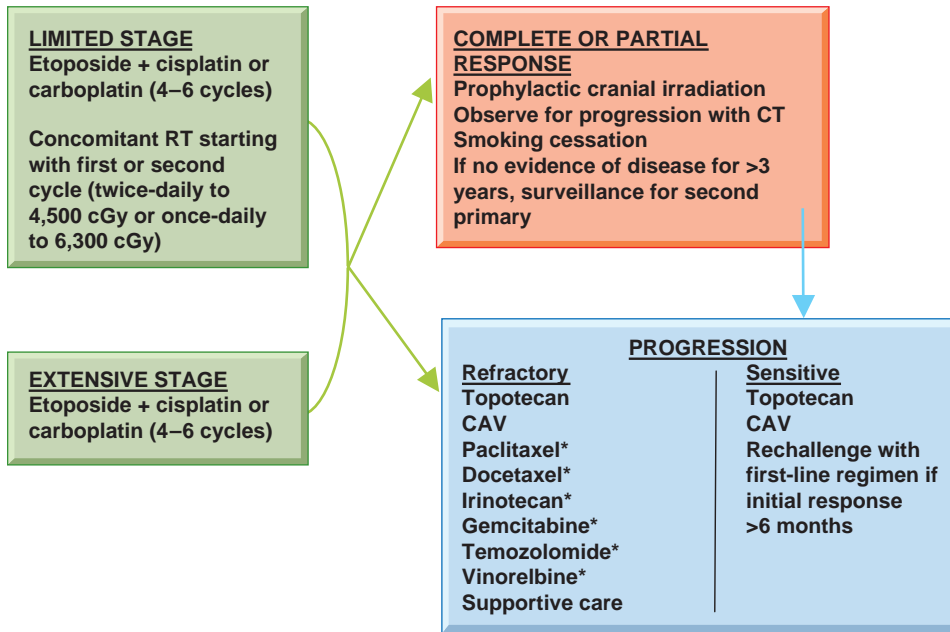

Figure 42.4 General treatment paradigm for small cell lung cancer.

*Single agents evaluated in phase II trials with activity in SCLC.

Chemotherapy

Evolution of Chemotherapy Regimens. The sensitivity of SCLC to chemotherapy agents was recognized about 50 years ago, and the primary role of systemic treatment in SCLC was established early on. Alkylating agents, anthracyclines, vinca alkaloids, and antifolates all showed single-agent efficacy. In the 1980s, the epipodophyllotoxin, etoposide, and the platinum analogs, cisplatin and carboplatin, were introduced, and their activity ranged from 40% to 60% in previously untreated patients.⁸⁴ Since then, numerous other chemotherapeutic agents have demonstrated activity in SCLC, but aside from the camptothecins, the drugs identified in the 1970s and 1980s remain the backbone of therapy. Ultimately, randomized trials of combinations demonstrated superior activity to single agents.^{85,86}

Livingston et al.⁸⁷ developed the cyclophosphamide, doxorubicin, vincristine (CAV) combination, and reported on 358 patients who received this combination followed sequentially by thoracic and brain irradiation. For patients with extensive disease, the complete response rate was 14%, the overall response rate was 57%, and the median survival was 26 weeks. For patients with limited disease, the rates were 41%, 75%, and 52 weeks, respectively. With these data, CAV became the standard chemotherapy regimen.

With the identification of etoposide as perhaps the most active agent, several modifications of the CAV regimen that included etoposide were tested. A randomized trial showed greater response duration and survival with cyclophosphamide, doxorubicin, and etoposide (CAE) compared with CAV.⁸⁸ Hong et al.⁸⁹ compared intensive cyclophosphamide and vincristine (CV) (with the dose of cyclophosphamide increased from 1,000 to 2,000 mg/m²) to CAV and to cyclophosphamide, etoposide, and vincristine (CEV) and reported that patients treated with CV had a shorter survival and experienced more myelosuppression than those treated on the other two arms. Five randomized trials have evaluated the addition of etoposide (CAVE) to the CAV regimen.^{90–94} In the three studies in which the doses of CAV were equivalent in each arm,^{90–92} a better response rate was evident in the arm that contained etoposide, in at least some patient subsets, with increased hematologic toxicity, although a nonstatistical improvement in survival was seen in only one study.⁹⁰ Two studies intensified components of this regimen in the CAV arm compared to the CAVE arm,⁹³ leading to equivalent myelotoxicity, response rates, and survival.

The etoposide/cisplatin (EP) regimen was tested in SCLC cases because this combination produced synergistic activity in preclinical systems. In addition, both agents could be given at full doses because of less myelosuppression with cisplatin. The first report by Sierocki et al.⁹⁵ at Memorial Sloan-Kettering Cancer Center in 1979 demonstrated the activity of this combination in SCLC. Subsequent studies by Evans et al.^{96,97} reported response rates of 55% in patients previously treated with CAV and 86% in newly diagnosed patients. Einhorn et al.⁹⁸ reported that two cycles of consolidation with EP, when added to the treatment of patients with limited disease who were responding to six cycles of CAV, produced longer survival than with CAV only. Three randomized trials have compared EP to cyclophosphamide, vincristine, and an anthracycline.^{99–101} Less myelosuppression occurred with EP, and, if given with radiation, patients experienced less esophagitis and interstitial pneumonitis. Furthermore, the largest trial showed that EP produced a better median (15 months versus 10 months) and 5-year (10% versus 3%) survival for patients with limited disease.¹⁰¹ Retrospective analyses and meta-analyses also support the superiority of cisplatin- or carboplatin-containing chemotherapy for SCLC.^{102–104} As a result, EP is now the standard first-line chemotherapy regimen for SCLC (Table 42.1).

Carboplatin has been substituted for cisplatin in SCLC chemotherapy regimens in an effort to decrease nonhematologic toxicities. Randomized trials comparing cisplatin and carboplatin suggest that they may have similar efficacy. The Hellenic Cooperative Oncology Group randomized 147 patients with either limited or extensive disease to receive etoposide 100 mg/m² days 1 to 3, and cisplatin 100 mg/m² or carboplatin 300 mg/m².¹⁰⁵ Concurrent radiation also was administered to responding patients starting with the third cycle. Response and survival were similar in the two arms. Nausea, vomiting, nephrotoxicity, and neurotoxicity were significantly lower in the patients who received carboplatin, as was grade 4 leukopenia. However, the sample size of this study is inadequate to confirm equivalent efficacy. A meta-analysis that evaluated individual subject data from four randomized trials with a total of 663 patients found that median overall survival (OS), median progression-free survival (PFS), and response rates were similar in the cisplatin and carboplatin arms. Although hematologic toxicities were higher in those patients that receive carboplatin, nonhematologic toxicities were increased in those that receive cisplatin.¹⁰⁶ Based on these data, etoposide and carboplatin can

be considered an appropriate first-line regimen, particularly in patients who cannot tolerate cisplatin.

More recently, platinum combinations with topotecan and irinotecan have emerged as potential regimens for initial therapy. Irinotecan was shown to have single-agent efficacy in Japanese studies.¹⁰⁷ The Japan Clinical Oncology Group compared cisplatin and irinotecan to EP as initial treatment in extensive disease.¹⁰⁸ The study was terminated after 154 of the planned 230 patients were enrolled because median (12.8 months versus 9.4 months) and 2-year (19.5% versus 5.2%) survival were significantly better in the group treated with cisplatin and irinotecan. Significant diarrhea occurred only in the irinotecan group, and myelosuppression was the most common toxicity in both groups and more frequent with EP. Two confirmatory studies were subsequently launched in the United States. In the first trial, the irinotecan/cisplatin schedule was modified in an effort to decrease toxicity, leading to equivalent response rates (48% for irinotecan/cisplatin versus 44% for EP), median time to progression (4 versus 5 months), and median OS (9 versus 10 months).⁴²⁵ The Southwest Oncology Group (SWOG) compared these two regimens with the same dose and schedule used in the Japanese trial and also showed, in a well-powered study, that outcomes are equivalent with the two regimens in Caucasian patients.¹⁰⁹ High response rates have been reported in several trials using irinotecan and carboplatin with varied dosing schedules.^{110,111} A phase III trial comparing that regimen with etoposide/cisplatin showed improved survival, but

the median survival of 7 months in the control arm, which used oral etoposide, was lower than expected.¹¹² Many hypothesize that population-based polymorphisms in uridine 5'-diphospho (UDP)-glucuronosyltransferase (UGT1A1), the enzyme responsible for detoxifying SN-38, the active metabolite of irinotecan, may account for differences in toxicity and efficacy between Japanese and Americans.¹¹³ The regimen of topotecan plus cisplatin also has undergone phase II and III testing.^{114,115} Eckardt et al.¹¹⁵ reported the results of a randomized trial including 784 patients in which patients received oral topotecan (1.7 mg/m² per day for 5 days) plus cisplatin, or standard etoposide and cisplatin. The response rates, median survival, and 1-year survival were identical. Severe neutropenia occurred more often with EP, but oral topotecan and cisplatin caused more anemia and thrombocytopenia.

Strategies to Improve Outcomes with Chemotherapy Regimens

Alternating Cycles of Combination Chemotherapy Regimens. The recognition of clonal heterogeneity within a tumor and the intolerance of treatment regimens that included more than four drugs due to overlapping toxicity led to trials of alternating chemotherapy combinations. The somatic mutation model developed by Goldie et al.¹¹⁶ predicted that the best probability of cure was achieved by the earliest possible introduction and the most rapid alternation of all active agents. If two equally effective non-cross-resistant

regimens were available, the model predicted that alternating between regimens every other cycle would be more effective than alternating after every three cycles or giving one regimen continuously for five cycles before switching to the second regimen.

Many randomized clinical trials have tested the concept of alternating multidrug combinations.^{100,117–121} The fact that the EP regimen was effective in patients who had progressed after cyclophosphamide-based chemotherapy suggested that these drug combinations were non-cross-resistant.¹²² With this in mind, the National Cancer Institute of Canada conducted a study in which 289 patients were randomized to CAV or CAV alternating with EP.¹¹⁹ Chemotherapy was given for a total of six cycles. The response rate (65% versus 47%), PFS, and median survival time (10 months versus 8 months) favored the patients who had received alternating therapy. The authors postulated that these findings could be the result of the inclusion of a more active regimen (i.e., EP) within the alternating arm, an advantage due to greater drug diversity with five effective drugs rather than three, or support of the Goldie et al. concept. A Japanese study compared CAV to EP to alternating CAV/EP in 288 patients with limited or extensive stage disease.⁹⁹ Patients with limited disease received four cycles of chemotherapy followed by thoracic irradiation and were found to have improved survival with the alternating regimen compared with CAV ($p = 0.058$) or EP ($p = 0.032$). No differences in survival were noted in the patients with extensive disease. Roth et al.¹⁰⁰ evaluated 437 patients with extensive disease in a randomized trial comparing EP for four cycles, CAV for six cycles, or CAV alternating with EP for a total of six cycles. Although a slight improvement occurred in PFS ($p = 0.052$) with the alternating regimen, there was no difference in response rate or OS among the treatment arms. The patients whose tumors did not respond to CAV and were crossed over to EP were twice as likely to benefit as individuals who initially received EP and were crossed over to CAV, although these differences were not significant (28% versus 14% for induction responders who relapsed and 15% versus 8% for patients with primary resistance). The modest activity seen when refractory patients were crossed over from one of these regimens to the other suggests that the CAV and EP combinations are not entirely cross-resistant, which works against a primary assumption of the Goldie et al. hypothesis. Taking all of these studies together, alternating regimens appears to have slight or no benefit over initial treatment with EP alone.

Additional studies have evaluated alternating chemotherapy introduced after achieving a response to an induction regimen.^{123–125} The National Cancer Institute of Canada designed a randomized trial in which 300 patients with limited disease received either CAV for three cycles followed by EP for three cycles or CAV alternating with EP for a total of six cycles.¹²⁶ Response rates, time to treatment failure, or survival did not differ. Wolf et al.¹²³ randomized 321 patients to treatment with ifosfamide plus etoposide given until a response plateau, followed by CAV or ifosfamide plus etoposide alternating with CAV. A total of six cycles of chemotherapy were delivered in each arm. No difference in outcome was noted.

Studies also have evaluated alternating more intensive regimens. For example, a German multicenter trial demonstrated that an alternating eight-drug regimen was superior to CAV.¹²⁷ Two other European trials testing three drugs regimens alternating with four drug regimens found no survival advantage to that approach.^{120,128} Again, the median survival times observed in these studies were no different from those that used EP alone.^{99,100}

Addition of a Third Chemotherapeutic Agent to Etoposide Plus Cisplatin. All efforts to add a third drug to the standard EP regimen have resulted in more toxicity with little or no improvement in survival. The three-drug regimen of etoposide, ifosfamide, and cisplatin (VIP), developed initially for refractory germ cell tumors, also has been evaluated in SCLC.¹²⁹ In randomized trials comparing VIP to EP, one study, which included patients with limited and extensive disease, found no difference in survival between the

two treatment groups,¹³⁰ whereas another, which was larger and enrolled only patients with extensive disease, identified a significant difference in median survival (9 months versus 7 months) and 2-year survival rates (13% versus 5%).¹³¹ In both studies, myelosuppression was more severe in the ifosfamide-containing arm. Single-arm studies substituting carboplatin for cisplatin in ifosfamide, carboplatin, and etoposide (ICE) have shown impressive response rates, yet cumulative myelosuppression.^{132,133} A large trial comparing ICE plus a midcycle dose of vincristine to other standard therapy demonstrated an improvement in the median and 1-year survival rates.¹³⁴ However, an increased rate of septicemia was noted with ifosfamide, carboplatin, and etoposide-vincristine (ICE-V) (15% versus 7% in the control arm).

Studies that added paclitaxel to EP reach the same conclusion: enhanced toxicity with similar efficacy. Two studies that compared EP to EP plus paclitaxel showed that the addition of the third drug increased toxicity, as well as treatment-related mortality, without improving survival.^{135,136} A German study that added paclitaxel to etoposide and carboplatin demonstrated a significantly better median survival (13 months versus 12 months) and 3-year survival (17% versus 9%) only in patients with limited disease as compared to treatment with etoposide, carboplatin, and vincristine.¹³⁷

Maintenance Therapy. A large number of randomized studies have examined whether maintenance chemotherapy prolongs survival in SCLC.^{117,138–148} Three studies that randomized patients in complete remission after induction therapy to maintenance treatment or observation identified improved survival with the prolonged treatment program in some patient groups.^{117,141,144} The Cancer and Leukemia Group B (CALGB) randomized 258 patients to one of four chemotherapy regimens, and 57 patients in complete remission underwent a second randomization to maintenance therapy or observation. Among the 46 patients with limited disease who proceeded to the second randomization, the median survival was improved with maintenance chemotherapy (17 months versus 7 months).¹⁴⁴ However, the initial regimens used in this study might be considered inferior to currently used treatments. In a second study, patients treated with six cycles of CAV and in complete remission were randomized to six additional cycles of the same chemotherapy or observation.¹⁴¹ For the patients with extensive disease, the median survival was improved by approximately 4 months with maintenance treatment. In an ECOG trial, patients were randomized to CAV alternating with another three-drug combination or CAV alone and, subsequently, those in complete remission after six to eight cycles of induction underwent a second randomization to maintenance treatment or observation.¹¹⁷ Patients assigned to CAV and maintenance therapy had a longer PFS and OS ($p = 0.09$) than patients who received only CAV with no maintenance. In contrast, for the patients who received the six-drug regimen, those who were given no maintenance survived longer than the patients who received maintenance treatment. These studies suggest that there may be patients—perhaps those with particularly chemotherapy-sensitive disease—who derive a benefit from maintenance. In unselected patients, however, clinical trials that have evaluated treatment programs that extend beyond six cycles of chemotherapy have not demonstrated an advantage in survival.

The Medical Research Council randomized 265 patients who had responded to six cycles of induction chemotherapy to an additional six cycles of maintenance or observation.¹³⁸ Overall, there was no difference in survival between patients treated with 6 or 12 cycles of chemotherapy, although for patients in complete remission at the time of randomization, a subset analysis suggested that maintenance provides a survival benefit. Three other large studies that randomized patients responding to 5 or 6 cycles of induction to a total of 12 cycles of chemotherapy or observation found no difference in outcome.^{142,143,146} Another study that randomized patients with limited disease from the start of chemotherapy to a total of 6 or 12 cycles identified inferior survival in the arm treated with the longer course of therapy.¹⁴⁰

Other studies have evaluated whether four cycles of chemotherapy are adequate.^{139,145,149} Spiro et al.¹⁴⁹ designed a study that included a double randomization at diagnosis. Patients received four or eight cycles of CEV and on relapse were given additional chemotherapy or supportive care. Of the four treatment arms, patients who received four cycles of chemotherapy and only supportive care at relapse had a significantly inferior median survival of 30 weeks. Four cycles of treatment were found to be adequate, provided that chemotherapy was offered to patients appropriate for additional therapy at relapse. Two additional studies evaluated four cycles of induction with longer treatment programs. A European trial randomized patients with limited and extensive disease who responded to four cycles of EP to CAV for up to 10 additional cycles or to observation with no survival differences, although the study had limited power due to small sample size.¹³⁹ ECOG enrolled 402 eligible patients with extensive-stage disease into a trial that delivered four cycles of EP followed by a randomization of patients with at least stable disease to four additional cycles of topotecan or to observation.¹⁴⁵ Although maintenance therapy increased the time before documentation of disease progression, there was no difference in OS.

Two recent meta-analyses have been conducted evaluating maintenance chemotherapy showing small improvements in survival and an increase in toxicity.^{150,151} Bozcuk and colleagues¹⁵⁰ reported an improved 1- and 2-year survival by 9% and 4%, respectively. Although Rossi et al.¹⁵¹ showed a significant OS benefit (hazard ratio [HR], 0.89, 95% confidence interval [CI], 0.81 to 0.92; $p = 0.02$) for maintenance treatment, this improvement was projected to an additional 2 weeks.¹⁵¹ Further, there was a high heterogeneity among the included trials.

In summary, four to six cycles of chemotherapy appear to be optimal in the management of limited and extensive SCLC. After the completion of this initial treatment, patients should be monitored closely and then offered further chemotherapy at the time of progression. Both the NCCN and the European Society of Medical Oncology Guidelines support this approach.^{52,152}

Dose Intensification. In experimental models, numerous chemotherapy drugs display log-linear or near linear dose-response curves,¹⁵³ and high-dose chemotherapy has proven effective at treating hematologic diseases. It seemed reasonable to test the hypothesis that more intensive chemotherapy could improve outcomes in SCLC. Methods used have included the use of higher chemotherapy doses without or with hematopoietic growth factor support, shortened cycle length, or extreme dose intensification with marrow or peripheral blood stem cell support.

Several investigators evaluated whether increasing the dose of drugs beyond the usual dose improves survival.¹⁵⁴⁻¹⁵⁹ Three randomized trials comparing standard versus high-dose CAV^{156,158} or EP¹⁵⁷ found no difference in response rates or median survival. No hematopoietic growth factors were used in these three trials, and, as such, myelosuppression and infections were significantly more severe in the high-dose arms. A randomized trial that did utilize granulocyte-macrophage colony-stimulating factor (GM-CSF) with dose escalation found that excess toxicity actually resulted in lower drug delivery and poorer response and survival rates in the dose-intense arm.¹⁵⁹ Only a French study with 105 limited-stage patients demonstrated improvements in PFS at 2 years (28% versus 8%) and OS (43% versus 26%) with the administration of higher drug doses.¹⁵⁴ Few oncologists have embraced this approach.

A number of studies have evaluated whether shortening the interval between chemotherapy cycles improves survival. A multicenter study randomized 300 patients, mostly with limited-stage disease, to six cycles of ICE-V delivered every 4 weeks or every 3 weeks.¹⁶⁰ In a second randomization, patients were given GM-CSF or placebo after each chemotherapy cycle. The delivered dose intensity was increased by 26% in the group receiving chemotherapy every 3 weeks compared to those treated every 4 weeks. The median survival (443 days versus 351 days) and the

2-year survival rate (33% versus 18%) were better in the intensified arm ($p = 0.0014$). GM-CSF did not reduce the incidence or the duration of febrile neutropenia, and there was no difference in survival between the patients who received GM-CSF or placebo. In a subsequent study, ICE given every 4 weeks was compared to ICE given every 2 weeks with support of GM-CSF, and autologous blood collected before the cycle was reinfused 24 hours after the chemotherapy.¹⁶¹ Although the median delivered dose intensity was increased by 82% without significant increased toxicity, no survival benefit was identified. Two studies compared treatment with cyclophosphamide, doxorubicin, and etoposide given either every 3 weeks, or every 2 weeks with GM-CSF support.^{162,163} The larger trial,¹⁶³ which also included a higher percentage of limited-stage patients, showed an improvement in complete response rate and OS, but the other trial did not. No fewer than four randomized trials have shown that intensive multidrug weekly regimens are no better, yet significantly more toxic than standard regimens.¹⁶⁴⁻¹⁶⁷

Numerous reports cite the use of high-dose chemotherapy with autologous bone marrow or stem cell rescue for treating SCLC.¹⁶⁸⁻¹⁸⁶ These studies have included small numbers of highly selected patients.^{161,182,183,187-189} Survival has not been shown to be better than conventional treatment. As in other chemosensitive solid tumors like breast cancer, high-dose chemotherapy with stem cell support does not appear to have a role in SCLC.

Treatment After Relapse Following Initial Therapy. The strongest predictor of outcome for patients with relapsed SCLC is the duration of remission. As such, patients are distinguished as having *sensitive* or *refractory* disease. The term *sensitive* implies an appropriate response to initial therapy that is maintained for 3 months or more. These patients have a higher likelihood of response to any additional chemotherapy; although, at best, it is approximately half that expected in the first-line setting. Survival from the start of a second regimen averages around 6 months. Patients with *refractory* disease either had no response to initial therapy or progressed within 3 months after completing treatment. Their chance of response to additional therapy is less than 10%, and their median survival from the start of a second regimen is 4 months.

The only approved agent in relapsed disease is topotecan. Ardizzoni et al.¹⁹⁰ reported a phase II trial in which topotecan, administered at a dose of 1.5 mg/m² daily for 5 days, yielded a response rate of 38% in sensitive patients and 6% in refractory patients. Median survival from the start of second-line therapy was 7 and 5 months, respectively. A randomized trial compared topotecan, administered at that same dose and schedule, to CAV in patients who relapsed at least 2 months after initial therapy.¹⁹¹ The response rates for topotecan (24%) and for CAV (18%) were similar. The median survival was 6 months in both arms. Symptom improvement was better with topotecan for four of the eight symptoms queried, and as such, the U.S. Food and Drug Administration approved intravenous topotecan for sensitive relapsed SCLC. Oral topotecan has also undergone extensive testing in patients with relapsed SCLC. In a randomized phase II study, oral topotecan at a dose of 2.3 mg/m² daily for 5 days was comparable to intravenous topotecan 1.5 mg/m² daily for 5 days with regard to response rate (23% versus 15%), median survival (32 weeks versus 25 weeks), and symptom control.¹⁹² Subsequently, the Medical Research Council showed that oral topotecan improved survival in relapsed sensitive and refractory SCLC over best supportive care alone (26 versus 14 weeks, respectively).¹⁹³ Oral topotecan led to a response rate of 7%, with a slower deterioration of quality of life and symptomatology. Another phase III study randomized 309 SCLC patients who had relapsed ≥ 90 days after first-line therapy to receive oral topotecan or intravenous topotecan.¹⁹⁴ The overall response rate and median survival time were 18.3% and 33 weeks, respectively, for patients who received oral topotecan compared to 21.9% and 35 weeks, respectively, for those who received intravenous topotecan. Although oral topotecan was associated with a lower

incidence of grade 4 neutropenia, diarrhea occurred more often in this group of patients. Oral topotecan also has received regulatory approval for second-line therapy of SCLC.

Amrubicin, a third-generation synthetic 9-amino-anthracycline with diverse molecular effects including DNA intercalation, inhibition of topoisomerase II, and stabilization of topoisomerase IIa cleavable complexes, has been studied extensively and has received approval in Japan for SCLC treatment.¹⁹⁵ A randomized phase II trial conducted there showed higher response rates and PFS compared with topotecan.¹⁹⁶ Two North American phase II trials of amrubicin showed encouraging results.^{197,198} In patients with refractory SCLC, the overall response rate for single-agent amrubicin was found to be 21%, with median PFS and OS of 3.2 and 6 months, respectively. Subsequently, 76 patients with sensitive SCLC were randomized in a 2:1 fashion to receive amrubicin or topotecan. Amrubicin treatment resulted in a significantly higher response rate than topotecan (44% versus 15%, $p = 0.021$), which led to improved PFS (4.5 versus 3.3 months) and OS (9.2 versus 7.6 months).¹⁹⁸ Despite phase II activity, preliminary results of the phase III study, which compared amrubicin to topotecan, were disappointing.¹⁹⁹ Although the activity of amrubicin was apparent, there was no statistically significant difference in OS observed between the two arms. The trend favored amrubicin (HR, 0.82; 95% CI, 0.68 to 0.99; $p = 0.036$), especially in the subgroup of patients with primary refractory disease (HR, 0.77; 95% CI, 0.59 to 1.0; $p = 0.047$). Although lower hematologic adverse events were noted in the amrubicin arm, these patients had a higher incidence of infections. The role of amrubicin for the treatment of patients with relapsed SCLC remains to be defined.

Temozolomide is an oral alkylating agent that crosses the blood-brain barrier. A phase II clinical trial of temozolomide in 64 patients with relapsed sensitive or refractory SCLC has been performed.²⁰⁰ Temozolomide therapy was well tolerated and associated with an overall response rate of 20% in this patient population, with a 23% response rate in the sensitive group ($n = 48$) and a 13% response rate in the refractory cohort ($n = 16$). Responses also were noted in patients receiving temozolomide as third-line treatment and in those with brain metastases.²⁰⁰ There is an ongoing multicenter phase II study comparing temozolomide and veliparib (a poly [ADP-ribose] polymerase [PARP] inhibitor) versus temozolomide and placebo in patients with relapsed sensitive and refractory SCLC (ClinicalTrials.gov identifier: NCT01638546).

Multiple trials have been conducted using other agents in this patient population. A list of single agents and their activity in relapsed SCLC is found in Table 42.2, many of which also have been tested in combination studies. In summary, the optimal drug or combination of drugs in relapsed SCLC has not been established. Single-agent topotecan or CAV are appropriate for patients with sensitive relapse. These regimens also could be used for patients with refractory SCLC, although the response rates are lower. Agents evaluated in phase II trials with activity in SCLC can be considered. For patients with relapse 6 months or more after initial therapy, rechallenging with the same regimen as used in first-line treatment is also a consideration.⁵²

Immunotherapy and Other Targeted Therapies

In light of the therapeutic plateau achieved with current chemotherapy, investigators have studied a wide range of novel therapies in the hopes of improving outcomes (Table 42.3).

Receptor Tyrosine Kinases and Growth Factors. Small molecule kinase inhibitors are now established therapies for several diseases, but as yet, have not proven efficacious in SCLC. c-Kit protein expression has been reported in 28% to 93% of SCLC tumors.²⁰¹ In vitro studies support the role of c-kit and its ligand, stem cell factor (SCF), on SCLC autocrine and paracrine growth stimulation,²⁰² and imatinib has demonstrated growth inhibition

of multiple SCLC cell lines.²⁰³ Nonetheless, three phase II studies in SCLC failed to demonstrate a single radiologic response to imatinib, even when enrollment was restricted to patients with tumors expressing c-kit protein by immunohistochemistry.^{201,204,205}

The PI3K/AKT/mammalian target of rapamycin (mTOR) signal pathway is defective in SCLC: SCLC cells possess a constitutively active PI3K²⁰⁶ and harbor PI3K and PTEN mutations^{22,23,207}; phosphorylated AKT is present in 70% of tumors in SCLC patients²⁰⁸; and protein expression of mTOR, S6K1, and phosphorylated 4EBP1 are elevated in SCLC cells compared to type II epithelial cells.²⁰⁹ Such alterations lead to growth, survival, and chemotherapy resistance in SCLC. Temsirolimus—the small molecule inhibitor of mTOR—was evaluated in an ECOG trial in which patients were randomized after initial chemotherapy to maintenance therapy with either high-dose or low-dose temsirolimus.²¹⁰ Although the PFS (1.8 months versus 2.5 months) and OS were better for the high dose arm (6.5 months versus 9.0 months), these results were no better than those observed in the previous ECOG trial of topotecan maintenance therapy,¹⁴⁵ suggesting no added benefit from temsirolimus. Similarly, a phase II trial of everolimus in relapsed SCLC did not demonstrate antitumor activity for this agent.²¹¹

The insulinlike growth factor receptor (IGF-1R), a member of the insulin receptor subclass of receptor tyrosine kinase, is activated by the ligands IGF-1 and IGF-2 and signals mitogenic and antiapoptotic signaling pathways contributing to cellular transformation and malignant growth.²⁰⁸ IGF-1R and its ligand, IGF-1, are expressed at increased levels in SCLC.²⁰⁸ The IGF-1R activates the PI3K-AKT pathway in SCLC, playing a role in the development and growth of the disease, as well as resistance to chemotherapy.²⁰⁸ Therefore, targeted inhibition of IGF-1R represents an attractive approach to enhancing chemotherapeutic efficacy and inhibiting tumor recurrence in patients with SCLC. Yet, the ECOG 1508 phase II study evaluating the monoclonal antibody, cixutumumab, together with cisplatin and etoposide in a randomized trial, failed to show an improvement in PFS with IGF-1R inhibition.²¹²

Developmental Pathways: The Hedgehog Pathway. The Hedgehog pathway is essential in early lung development and has a role in regulating stem cell maintenance and differentiation.²¹³ Hedgehog signaling may play a significant role in the development and proliferation of SCLC, which is a relatively undifferentiated airway epithelial tumor that may recapitulate aspects of early lung development.^{214,215} In vitro and in vivo studies have demonstrated that Hedgehog antagonists can inhibit SCLC and, when administered following chemotherapy, such inhibition may delay or prevent the recurrence of residual disease.²¹⁵ The ECOG 1508 phase II randomized trial in patients with extensive stage disease included an arm evaluating the addition of vismodegib, a Hedgehog inhibitor, to cisplatin and etoposide, which unfortunately, did not lead to an improvement in PFS.²¹²

Nonreceptor Oncogenes: Bcl-2 Genes. The antiapoptotic gene product, bcl-2 protein, is expressed in 80% to 90% of SCLC tumor samples and, as such, is a potential therapeutic target.^{216,217} Oblimersen (G3139) is an antisense oligonucleotide that suppresses bcl-2 expression. The CALGB conducted a series of studies with oblimersen in combination with chemotherapy for SCLC.^{218,219} In a randomized phase II study of etoposide/carboplatin with or without oblimersen, survival was inferior in the patients receiving oblimersen (HR for OS, 2.13; $p = 0.02$).²²⁰ Insufficient suppression of bcl-2 by this agent may explain its lack of efficacy. Navitoclax, a selective high-affinity small molecule inhibitor of bcl-2 and bcl-x_L (another antiapoptotic protein of the Bcl-2 family), resulted in dramatic tumor responses in SCLC cell line xenograft tumors as a single agent and enhanced the efficacy of standard cytotoxic agents against SCLC models.^{221–227} Yet, a recent phase II study of navitoclax demonstrated limited activity in patients

TABLE 42.2

Activity of Single Agent Chemotherapy in Relapsed Small Cell Lung Cancer

Drug (Ref.)	Dose/Schedule	N	Sensitive/Refractory	Response Rate (%)	Median Survival (mo)
Topotecan (IV) ¹⁹⁰	1.5 mg/m ² daily × 5 days	45	Sensitive	38	6.9
		47	Refractory	6	4.7
Topotecan (IV) ¹⁹¹	1.5 mg/m ² daily × 5 days	107	Sensitive (60 days)	24	6.0
Topotecan (IV) ¹⁹²	1.5 mg/m ² daily × 5 days	54	Sensitive	15	5.8
Topotecan (oral) ¹⁹²	2.3 mg/m ² daily × 5 days	52	Sensitive	23	7.5
Topotecan (oral) ¹⁹³	2.3 mg/m ² daily × 5 days	71	Sensitive + refractory	7	6.0
		30	Sensitive	3	
		41	Refractory	10	
Topotecan (IV) ¹⁹⁴	1.5mg/m ² daily × 5 days	151	Sensitive	22	8.8
Topotecan (oral) ¹⁹⁴	2.3 mg/m ² daily × 5 days	153	Sensitive	18	8.0
Irinotecan ¹⁰⁷	100 mg/m ² weekly	16	Sensitive ^a	47	6.2
Paclitaxel ⁴²⁶	175 mg/m ² every 3 wks	24	Refractory	29	3.0
Docetaxel ⁴²⁷	100 mg/m ² every 3 wks	34	Not specified ^b	25	NR
Gemcitabine ⁴²⁸	1,000 mg/m ² d1, 8, 15 every 4 wks	46	Both	12	7.1
Gemcitabine ⁴²⁹	1,250 mg/m ² d1, 8 every 3 wks	27	Both	0	6.4
Gemcitabine ⁴³⁰	1,000 mg/m ² d1, 8, 15 every 4 wks	38	Refractory	13	4.0
Vinorelbine ⁴³¹	25 mg/m ² weekly	24	Both	13	5.0
Vinorelbine ⁴³²	30 mg/m ² weekly	26	Sensitive	16	NR
Amrubicin ⁴³³	40 mg/m ² daily × 3 every 3 wks	44	Sensitive	52	10.3
		16	Refractory	50	11.6
Amrubicin ⁴³⁴	40 mg/m ² daily × 3 every 3 wks	75	Refractory	21	6.0
Amrubicin ¹⁹⁸	40 mg/m ² daily × 3 every 3 wks	50	Sensitive	44%	9.2
Amrubicin ¹⁹⁹	40 mg/m ² daily × 3 every 3 wks	225	Sensitive	31% (both sensitive & refractory)	9.2
		199	Refractory		6.2
Picoplatin ⁴³⁵	120–150 mg/m ² every 3 wks	24	Sensitive	8	8.1
		13	Refractory	15	6.2
Picoplatin ⁴³⁶	150 mg/m ² every 3 wks	6	Sensitive	4 (all three groups)	6.1 (all three groups)
		27	Resistant ^c		
		44	Refractory ^d		
Picoplatin ⁴³⁷	150 mg/m ² every 3 wks	268	Relapsed disease ^e	4	4.7
Temozolomide ²⁰⁰	75 mg/m ² daily for 21 out of 28 days	48	Sensitive	23	6.0
		16	Refractory	13	5.6

^a All but one patient had a chemotherapy-free interval of >90 days.

^b Previously untreated patients also included.

^c Defined as patients that relapsed within 90 days of the end of first-line platinum-containing chemotherapy.

^d Defined as patients that did not have a response to first-line platinum-containing chemotherapy.

^e Defined as those patients with relapse <6 months of completing first-line platinum-based chemotherapy.

IV, intravenous; NR, not reported; N, number of patients.

with recurrent and progressive SCLC.²²⁸ Results of a completed phase I trial of navitoclax with first-line combination chemotherapy for SCLC are not yet available (ClinicalTrials.gov identifier: NCT00878449). A third agent, obatoclax mesylate, which is a small-molecule BH3-mimetic that exhibits binding affinity for a range of bcl-2 family members, has been evaluated in various clinical scenarios. A phase II trial of obatoclax mesylate added to topotecan did not exceed the historic response rate seen in topotecan alone in patients with relapsed SCLC.²²⁹ The phase II randomized study of carboplatin and etoposide with or without obatoclax followed by maintenance obatoclax in patients with newly diagnosed extensive stage SCLC failed to meet its primary endpoint of improved response rate for those receiving obatoclax, although there was a trend for improved PFS (6 versus 5.4 months, $p = 0.084$) and OS (10.6 versus 9.9 months, $p = 0.052$).²³⁰

Angiogenesis Inhibitors. Angiogenesis inhibitors have entered into standard clinical practice for numerous malignancies, and they are being tested in SCLC as well. Two phase III trials that tested thalidomide as maintenance therapy after first-line chemotherapy showed no significant effect on OS.^{231,232} Likewise, vandetanib, an oral TKI of vascular endothelial growth factor receptor 2 (VEGFR-2) and EGFR, failed to improve PFS in a randomized phase II maintenance trial.²³³ In all of these cases, toxicity was significantly greater in the treatment arms. Similarly, sorafenib (inhibitor of RAF; VEGFR-2,-3; platelet-derived growth factor receptor alpha [PDGFR α]) and cediranib (inhibitor of VEGFR-1,-2,-3; PDGFR β ; c-KIT) showed minimal activity for relapsed disease when evaluated as single agents, although cediranib demonstrated a promising PFS of 8 months when administered with cisplatin and etoposide in a phase I study.²³⁴⁻²³⁶

TABLE 42.3

Immunotherapies and Other Targeted Agents That Have Undergone Testing in Small Cell Lung Cancer

Agent (Ref.)	Mechanism of Action	Study Design	Result
Interferon-alfa ⁴³⁸⁻⁴⁴¹	Immunomodulator	Phase III (multiple)	Two studies with improved survival in limited-stage patients, two studies with no survival benefit
Interferon-gamma ^{442, 443}	Immunomodulator	Phase III (multiple)	No improvement in survival
Interleukin-2 ⁴⁴⁴	Immunomodulator	Phase II	21% response rate but excessive toxicity
Warfarin ^{445,446}	Anticoagulant	Randomized phase II Randomized phase III	Significant improvement in PFS and OS Warfarin added to chemotherapy significantly improved response rates, and nonsignificant improvement in PFS and OS
Aspirin (1 g/d) ⁴⁴⁷	Anticoagulant	Randomized phase II	Aspirin added to chemotherapy did not improve survival
Subcutaneous unfractionated heparin ⁴⁴⁸	Anticoagulant	Randomized phase II	Heparin added to chemotherapy during first 5 weeks of treatment led to significantly improved response rates and PFS, as well as OS in limited stage disease
Ipilimumab ²⁴⁵	Humanized anti-CTLA4 antibody	Randomized phase II	Improved immune-related PFS when administered with carboplatin/paclitaxel in phased dosing schedule in chemo-naïve extensive stage SCLC
Marimastat ⁴⁴⁹	Matrix metalloproteinase inhibitor	Phase III	No improvement in PFS or OS
Tanomastat ⁴⁵⁰	Matrix metalloproteinase inhibitor	Phase III	No improvement in PFS or OS
Imatinib ^{201,204,205}	c-Kit tyrosine kinase inhibitor	Phase II (multiple)	No responses
Temsirolimus ²¹⁰	mTOR inhibitor	Randomized phase II	Improved survival at higher dose but no improvement in outcome compared with prior trials
Everolimus ²¹¹	mTOR inhibitor	Phase II	Limited antitumor activity in relapsed SCLC
Tipifarnib ⁴⁵¹	Farnesyl transferase inhibitor	Phase II	No responses
Cixutumumab ²¹²	Monoclonal IGF-1R antibody	Randomized phase II	No improvement in PFS when added to cisplatin/etoposide in chemo-naïve extensive stage SCLC
Vismodegib ²¹²	Hedgehog pathway inhibitor	Randomized phase II	No improvement in PFS when added to cisplatin/etoposide in chemo-naïve extensive stage SCLC
Oblimersen ²²⁰	Bcl-2 antisense	Randomized phase II	No improvement in response rate
Navitoclax ²²⁸	Bcl-2 and bcl-x _L inhibitor	Phase II	Limited activity in recurrent and progressive disease
Obatoclax mesylate ^{229,230}	BH3-mimetic exhibits binding affinity for bcl-2 family members, including bcl-2, bcl-XL, and mcl-1	Phase II Randomized phase II	No increased response rate when added to topotecan in relapsed SCLC Trend toward improved response rate, PFS and OS in chemo-naïve extensive stage SCLC
Bortezomib ⁴⁵²	Proteasome inhibitor	Phase II	One response in refractory patient (2% overall response rate)
BEC-2 + Bacille Calmette-Guerin (BCG) adjuvant ⁴⁵³	Ganglioside (GD3) anti-idiotype vaccine	Phase III	No improvement in PFS or OS
Thalidomide ^{231,232}	Multiple immunomodulatory effects, also inhibits VEGF	Phase III Phase III	Improved survival from 8.7 to 11.7 months but not significant (HR, 0.74; <i>p</i> = 0.16) No improvement in any parameters
Vandetanib ²³³	Tyrosine kinase inhibitor of VEGFR-2 and EGFR	Randomized phase II	No improvement in PFS
Sorafenib ²³⁴	RAF, VEGFR-2, VEGFR-3, PDGFR α inhibitor	Phase II	5% response rate in relapsed disease

TABLE 42.3

Immunotherapies and Other Targeted Agents That Have Undergone Testing in Small Cell Lung Cancer (continued)

Agent (Ref.)	Mechanism of Action	Study Design	Result
Cediranib ^{235,236}	VEGFR-1, VEGFR-2, VEGFR-3, PDGFR β , c-KIT inhibitor	Phase II Phase I	Minimal activity as a single agent in relapsed disease 8-month PFS with cisplatin and etoposide
Bevacizumab ²³⁸⁻²⁴¹	Monoclonal antibody to VEGF	Phase II (multiple) Randomized phase II	No increased risk of hemorrhage Favorable survival compared with historical control Improved PFS for bevacizumab, but not in OS

PFS, progression-free survival; OS, overall survival; mTOR, mammalian target of rapamycin; VEGF, vascular endothelial growth factor; PDGFR, platelet-derived growth factor receptor.

Sunitinib, which is known to inhibit VEGFR-1, -2, -3; PDGFR α ; PDGFR β ; c-KIT; and FLT3, was evaluated in a phase II trial as maintenance treatment after chemotherapy in patients with untreated extensive-stage SCLC (CALGB 30504).²³⁷ After receiving four to six cycles of etoposide with cisplatin or carboplatin, patients were randomized to sunitinib or placebo until progression of disease. Patients in the placebo arm could cross over to receive sunitinib at the time of progression. The study met its primary endpoint of PFS after chemotherapy from the time of randomization (3.77 versus 2.3 months for sunitinib and placebo, respectively; HR, 1.53; 90% CI, 1.03 to 2.27; $p = 0.037$). Further, there was evidence of single-agent activity for sunitinib as maintenance therapy and at crossover, as well as a trend toward improvement in survival.²³⁷

Multiple phase II studies adding the VEGF monoclonal antibody, bevacizumab, to chemotherapy have not shown any increased risk of pulmonary hemorrhage in this cohort of patients who commonly have central tumors and have yielded favorable survival rates when compared to historical controls.²³⁸⁻²⁴⁰ A randomized phase II study evaluated cisplatin or carboplatin plus etoposide with or without bevacizumab, for four cycles followed by single-agent bevacizumab or placebo until progression or unacceptable toxicity in patients with untreated extensive stage SCLC.²⁴¹ Median PFS was higher in the bevacizumab group than in the placebo group (5.5 versus 4.4 months; HR, 0.53; 95% CI, 0.32 to 0.86); however, there was no difference observed in OS, but a trend that favored placebo was noted (9.4 versus 10.9 months for bevacizumab and placebo groups, respectively; HR, 1.16; 95% CI, 0.66 to 2.04). Although no new or unexpected safety signals for bevacizumab were observed, the trend toward worse OS calls future prospects of bevacizumab into question unless a biomarker for benefit is discovered to select patients for this therapy.

Antigen-Independent Immunotherapy: Ipilimumab. Ipilimumab, a humanized immunoglobulin (Ig)G1 monoclonal antibody against cytotoxic T-lymphocyte antigen-4 (CTLA-4), has been approved for the treatment of patients with metastatic melanoma.²⁴² By blocking the inhibitory signal provided by CTLA-4, this class of antibodies can prolong the activation and proliferation of tumor-directed cytotoxic T cells, thus promoting an antitumor immune response.²⁴³ A randomized, double-blind, three arm phase II trial in patients with untreated stage IIIB/IV NSCLC or extensive stage SCLC was performed to evaluate the efficacy and safety of paclitaxel and carboplatin with or without ipilimumab given on two dosing schedules.²⁴⁴ Among the 130 patients with SCLC, the phased dosing schedule, in which ipilimumab was started in cycle three of paclitaxel and carboplatin, appeared to improve immune-related PFS (median 6.4 months for the phased ipilimumab arm versus 5.3 months for the control arm ($p = 0.03$)), immune-related best overall response rate (71% [95% CI, 55 to

84] versus 53% [95% CI, 38 to 68]) and OS (median 12.9 months versus 9.9 months [$p = 0.13$]), compared to paclitaxel and carboplatin, whereas the concurrent regimen did not lead to improved outcomes.²⁴⁵ Ipilimumab did not potentiate the toxicities of the chemotherapy, but was associated with moderate immune-related adverse events.²⁴⁵ Given these favorable results, a randomized, multicenter, double-blind phase III trial comparing the efficacy of platinum/etoposide with or without ipilimumab in patients with newly diagnosed extensive stage disease SCLC, with OS as the primary endpoint, has been conducted and the results are forthcoming. (ClinicalTrials.gov identifier: NCT01450761).

As seen previously, distinct pathways contribute to the pathogenesis of SCLC, leading to its unique biology and clinical features. The therapeutic strategies employed previously to target the basic molecular and cellular changes in SCLC have not led to significant changes in the management and outcomes of the disease, thus far. However, continued, rational, target-based approaches ultimately should lead to improved survival of patients with SCLC.

Radiation

Role of Radiotherapy in Limited Disease. Despite being exquisitely chemo- and radioresponsive, neither modality alone controls all aspects of disease. The CALGB trial of the late 1980s demonstrated that 90% of patients treated with chemotherapy alone failed locally.²⁴⁶ The meta-analysis of Pignon and Arriagada²⁴⁷ provided more data to mandate thoracic radiotherapy, but a number of treatment issues remained to be determined, including sequencing of radiation with chemotherapy, early versus late radiotherapy, altered fractionation, and prophylactic cranial irradiation.

Concurrent combined modality therapy is the standard treatment for SCLC patients with limited-stage disease.⁵² It requires close coordination between medical and radiation oncologists. A combined modality treatment approach requires patients with an excellent performance status. Single-modality therapy may be appropriate for those who are debilitated or have serious comorbidities. If the patient's condition improves sufficiently after the initial chemotherapy or radiotherapy, subsequent treatment with the other modality may be considered. Although gains in radiotherapy delivery and integration with PET imaging have been made, disease failure in local, distant, and sanctuary sites continue to be substantial clinical challenges.

Sequencing of Radiation with Chemotherapy. Concurrent therapy is the delivery of chemotherapy and radiation therapy throughout the same time period. Sequential therapy is the delivery of one modality only after the completion of the other, often requiring a delay to allow for adequate recovery from the initial modality. A 1992 meta-analysis evaluated trials in which

more than 2,100 patients with limited-stage SCLC were randomized to receive chemotherapy alone or with chest irradiation.²⁴⁸ Patients given combined modality therapy had a 14% reduction in death rate and an absolute 5.4% improvement in 3-year survival compared with those who received chemotherapy alone. Both differences were highly significant. A second and independent meta-analysis reached similar conclusions.²⁴⁹

The trials included in the meta-analysis used cyclophosphamide- and doxorubicin-based chemotherapy, which is excessively toxic when given with concurrent thoracic radiotherapy. Therefore, individual trials used strategies such as sequential or interdigitated chemoradiation and used different chemotherapy regimens during the concurrent phases. However, the current standard chemotherapy regimen of cisplatin and etoposide can be used safely with concurrent radiotherapy.

Thoracic Radiation Dose and Fractionation. Due to the radioresponsiveness of SCLC, modest doses of radiation from 45 to 50 Gy have been used. However, with modest-dose radiation therapy there is a high rate of local failure. For example, in the Intergroup trial, the control arm of 45 Gy given once daily had a 75% rate of intrathoracic relapse.²⁵⁰ Therefore, higher radiation doses or intensification (i.e., acceleration) appear necessary to improve local control. A retrospective review from Massachusetts General Hospital suggested that there may be continued dose response beyond 50 Gy.²⁵¹ The maximum tolerated dose of concurrent thoracic chemoradiation seems to be 45 to 51 Gy with a twice-daily approach and 70 Gy daily.²⁵² However, the advent of highly conformal radiotherapy techniques, such as intensity-modulated radiation therapy (IMRT) and the shift away from targeting clinically uninvolved nodal stations, may lead to tolerance of higher radiation doses, as discussed in the following paragraphs.

CALGB-39808 determined that 70 Gy delivered with daily fractions of 2 Gy with concurrent chemotherapy is feasible in the cooperative group setting and was associated with a median survival of 22.4 months and acceptable rates of esophagitis and pneumonitis.²⁵³ Other CALGB trials also have used 70 Gy of thoracic irradiation with concurrent chemotherapy.²⁵⁴ Once-daily fractionation is more familiar for radiation oncologists and typically is more convenient for patients, although it should be noted that some patients prefer the decreased overall treatment duration with a twice-daily schedule.

SCLC appears to be an ideal neoplasm for twice-daily treatment in that it has a high growth fraction, short cell cycle time, and small-to-absent shoulder on the *in vitro* cell survival curve, which may allow for a reduction in long-term pulmonary toxicity while maintaining antitumor efficacy.²⁵⁵ Pilot studies in the late 1980s combining etoposide and platinum with twice-daily chest radiation were promising, with median survivals greater than 2 years and, in most series, low rates of pneumonitis.^{250,256,257} An Intergroup study randomized 417 patients with limited-stage SCLC receiving 45 Gy in either daily fractions of 1.8 Gy or twice-daily fractions of 1.5 Gy, both given concurrently with the first of four cycles of EP.⁴⁹ Although fractionation is the obvious variable, the overall duration of radiotherapy varied as well (3 weeks versus 5 weeks), and longer treatment times may exert selective pressure on the emergence of resistant clones. The target volume included the primary tumor, bilateral mediastinal nodes, and the ipsilateral hilum, excluding uninvolved supraclavicular nodes. Local failure was reduced from 52% to 36% with the twice-daily schedule ($p = 0.06$). Of interest, only 6% of patients with twice-daily radiation failed in both local and distant sites, compared to 23% with daily treatment ($p = 0.01$). More importantly, although statistically significant differences in survival were not seen at 2 years,²⁵⁷ by 5 years the survival was 16% with once-daily treatment, compared to 26% with a twice-daily schedule ($p = 0.04$).⁴⁹ All patients who achieved less than complete response were scored as local failures, but some of those treated with the accelerated scheme who achieved only a partial response survived, as well as those with a complete response,

implying that the local failure rate was overestimated by imaging on that arm. There was a higher frequency of grade 3 esophagitis with twice-daily treatment, but overall long-term morbidities were not significantly different between the two arms.

A North Central Cancer Treatment Group trial attempted to reduce morbidity of twice-daily radiation by inserting a 2.5-week pause between two courses of 24 Gy each (therefore, the overall course was longer than the standard duration).^{48,258} After three cycles of induction chemotherapy, fit and responding patients were randomized to receive either the 48 Gy split-course regimen, or 54 Gy in a once daily regimen in 6 weeks.²⁵⁸ The 20% rate of 5-year survival was less than the benchmark 26% from the Intergroup trial. However, a follow-up trial used a higher dose of twice-daily radiation (total 60 Gy) with a 2-week treatment break and reported a favorable 5-year survival of 24%.²⁵⁹

A phase I trial conducted by the Radiation Therapy and Oncology Group (RTOG) and CALGB evaluated the use of 70 Gy delivered in daily fractionation or 45 Gy given in twice-a-day fractionation.²⁶⁰ Although it was intended to establish the maximum-tolerated doses (MTD) of irinotecan given with cisplatin and thoracic radiation, it also was the first trial to evaluate 70 Gy delivered at cycle one. Of the 15 patients treated to 70 Gy, 2 had dose-limiting toxicities (diarrhea, esophagitis, and cardiovascular complications).

RTOG-9712 was a phase I trial to establish the MTD of radiation therapy with delayed accelerated hyperfractionation.²⁶¹ With this technique, a large field encompassing the gross tumor and mediastinum was treated to 45 Gy. A smaller field that encompassed only the gross tumor was treated as a second daily 1.8 Gy treatment for the last 3 to 11 days. The MTD was found to be 61.2 Gy with this regimen, which subsequently was evaluated in RTOG-0239, a phase II trial.²⁶² It reported a 2-year OS of 37%, short of the predicted survival of 60%. However, the regimen demonstrated an excellent local control of 73%.

Currently, a randomized phase III trial is being conducted by the RTOG and CALGB to evaluate three fractionation schemes: 45 Gy in 1.5-Gy twice-daily fractions (standard), 70 Gy in 2-Gy fractions (Arm B), and 61.2 Gy with delayed accelerated hyperfractionation (Arm C). In the first part of this trial, toxicity was to be assessed and the less toxic of Arms B and C was to be compared head to head with the standard arm. Although no clear difference in toxicity was observed between Arms B and C, the delayed accelerated hyperfractionation arm has been dropped due to slow accrual, and the study is continuing as a two-arm trial. A separate Phase III randomized trial is also evaluating once versus twice-daily radiotherapy with concurrent chemoradiotherapy in Europe, comparing 66 Gy in daily 2-Gy fractions against the same control arm of 45 Gy in twice-daily 1.5-Gy fractions. Until results from these trials are available, twice-daily fractionation as established by the Intergroup trial remains the reference regimen for fit patients. However, it should be noted that the logistical and toxicity obstacles with twice-daily treatment apparently are substantial, because a recent survey of practice patterns indicated that fewer than a quarter of limited-stage SCLC patients receive twice-daily treatment in the United States.²⁶³

Early Versus Late Radiotherapy. Randomized trials have yielded conflicting results on whether concurrent irradiation is best given early or late in the chemotherapy program. There have been multiple meta-analyses of the timing of thoracic irradiation.²⁶⁴⁻²⁶⁸ One meta-analysis²⁶⁵ reviewed seven randomized trials with a total of 1,524 patients that addressed the timing of radiotherapy relative to chemotherapy. Early radiation therapy was defined as beginning before 9 weeks after the initiation of chemotherapy and before the third cycle of chemotherapy. Late radiation therapy began 9 weeks or more after the initiation of chemotherapy or after the beginning of the third cycle. They reported a small but statistically significant improvement in 2-year survival for patients receiving early radiation therapy. A greater benefit was observed in patients

receiving hyperfractionated radiation. Another meta-analysis²⁶⁹ evaluated four randomized trials consisting of 1,056 patients to determine whether the time from the start of chemotherapy until the end of radiotherapy (SER) was a predictor of survival. They found that there was a significantly higher 5-year survival rate in the treatment arms with a shorter SER. In addition, a low SER was associated with a higher incidence of severe esophagitis. This suggests that an important factor in the treatment of SCLC involves counteracting accelerated repopulation that occurs after treatment with chemotherapy. However, definitive evidence that early integration of radiotherapy leads to improved survival remains elusive. A recent randomized trial from Korea assigned patients to receive radiotherapy (albeit a nonstandard regimen of 52.5 Gy) with either the first or third cycle of chemotherapy with cisplatin or etoposide. There was no difference in survival or local control, but rather an increase in febrile neutropenia with early radiotherapy, suggesting that later integration of radiotherapy was preferable.⁸²

In clinical practice, it is often prudent to initiate chemotherapy immediately in these patients who are typically highly symptomatic and not delay treatment until radiation treatment planning is complete. Starting radiotherapy with the second cycle of chemotherapy is more readily achievable and should preserve the potential gains in efficacy obtained with early integration of radiotherapy with chemotherapy.

Radiation Therapy Treatment Volumes and Technique. An early randomized trial by SWOG showed no difference in recurrence rate whether pre- or postchemotherapy imaging was used to determine radiation therapy treatment fields.²⁷⁰ Of course, if early radiation therapy is used, then there is no postchemotherapy treatment volume. The Intergroup trial⁴⁹ included gross disease, the bilateral mediastinum, and the ipsilateral hilum in the treatment field. The uninvolved supraclavicular area was excluded. RTOG-9712²⁶¹ allowed for the treatment of the uninvolved supraclavicular area in the setting of apical tumors. A small phase II trial suggested that there may be increased elective nodal failure in the supraclavicular area if it is excluded from the treatment field.²⁷¹ Consultants from the International Atomic Energy Agency reviewed available literature in 2008 and found little evidence to guide the use of elective nodal irradiation.²⁷² However, a number of prospective and retrospective experiences have since been published and increasingly suggest that involved-field radiation therapy is not associated with an excessive rate of local–regional failure, particularly in an era of routine PET staging. A Dutch phase II trial of concurrent chemoradiation limited radiotherapy (RT) fields to the primary tumor and clinically involved lymph nodes and reported a relatively low local failure rate of 16%.²⁷³

Utilizing PET to guide the design of limited radiotherapy fields appears to reduce the probability of elective nodal failure due to the improved sensitivity of PET to detect nodal disease compared to CT alone. A follow-up trial from the same group that found a worrisome rate of elective nodal failure when utilizing involved-field RT in CT-staged patients showed that the rate of isolated nodal failure was only 3% with PET staging, compared to 11% without.²⁷⁴ A retrospective experience from the M.D. Anderson Cancer Center similarly showed a low rate of isolated elective nodal failure in a PET-staged cohort of patients who were treated with IMRT, a technique that gives lower incidental radiation doses to untargeted lymph node regions and, therefore, would theoretically increase the risk of elective nodal failure.²⁷⁵ Overall, these and other recent publications suggest that with modern staging and treatment techniques, the omission of elective nodal irradiation does not lead to an excessive rate of isolated nodal failure.^{276–278} Neither of the ongoing trials of daily versus twice-daily thoracic radiotherapy employ elective nodal irradiation in any of the trial arms (with the exception of mandatory coverage of hilar lymph nodes in the CALGB trial), indicating that the omission of elective nodal irradiation is increasingly considered within the standard of care for PET-staged patients.

In addition to the omission of elective nodal irradiation, another area of investigation in radiation technique is the implementation of more highly conformal delivery methods, such as IMRT or proton therapy. These techniques allow for significantly greater control of the location of radiation dose, particularly of incidental radiation dose outside of the target volume. Although this would seem to be an unequivocal advantage, theoretic concerns have persisted regarding the sensitivity of these techniques to respiratory organ motion, and the possibility that decreasing the incidental dose outside of the target volume might increase rates of regional or nodal failure. Investigators from the M.D. Anderson Cancer Center retrospectively compared outcomes with patients receiving standard three-dimensional (3D)-conformal radiation therapy and IMRT, and found no significant difference in OS or DFS.²⁷⁹ Proton therapy, which reduces the dose outside of the target volume more fully than is possible with any form of photon radiotherapy, has not yet been widely used in SCLC, with only one small report published so far.²⁸⁰ However, if the phase III trials demonstrate an advantage to higher dose radiotherapy, then IMRT and photon therapy are likely to gain in importance, because highly conformal techniques are often required to achieve high target doses while respecting dose limits to critical normal structures.

Toxicity of Radiation Therapy. The addition of chest irradiation has increased myelosuppressive, pulmonary, and esophageal complications of treatment, particularly with concurrent cyclophosphamide-based regimens.^{281–283} Esophagitis is a difficult toxicity to compare because trials often use unique grading systems. However, most trials with concurrent chemoradiation with a cisplatin-based regimen report a 10% to 25% rate of severe esophagitis.²⁸⁴ A retrospective review revealed that various radiation dosimetric parameters, such as mean esophageal dose and volume of esophagus receiving 15 Gy, were associated with a higher incidence of grade 3 or worse esophagitis in patients receiving twice-daily radiation.²⁸⁵ More recently, a large individual patient data meta-analysis of esophagitis after concurrent thoracic chemoradiotherapy indicated that the best predictor of esophagitis was the volume of esophagus receiving greater than or equal to 60 Gy, with the highest risk seen when 17% or more of the esophagus was exposed to such doses.²⁸⁶

Radiation pneumonitis (RP) has not been as well studied in SCLC as it has in NSCLC, most likely due to the fact that most trials have used a moderate dose of radiation therapy, below which high rates of RP rarely are seen. Recent trials report a RP rate of approximately 10%.^{253,287} This is lower than some of the trials reported in the 1980s and 1990s, probably due to improved radiation therapy techniques and better distinction between pneumonitis and other etiologies of respiratory distress, such as infection or tumor recurrence. The volume of lung receiving 20 Gy (V20) is a standard parameter used to predict lung toxicity in patients with NSCLC. A recent collaborative effort to define consensus dose limits for RP recommended that the V20 be kept below 30% to 35% in order to keep the risk of pneumonitis less than 20%.²⁸⁸ It has been shown to have value in patients receiving concurrent accelerated hyperfractionated treatment for SCLC as well, with a V20 less than 25% associated with a lower rate of RP.²⁸⁹

Role of Chest Irradiation in Extensive Disease. Reviews of the historical literature indicated that the addition of chest irradiation plus chemotherapy for patients who have extensive-stage SCLC may improve local control in the thorax, but without change in survival.^{290,291} Successive large studies by the SWOG also confirmed a benefit on local control but not survival.^{118,292} Because patients with extensive disease generally achieve complete response rates of only 20% to 25% with current chemotherapy regimens and frequently relapse in distant metastatic sites, it is unsurprising that the routine application of additional local therapy did not have a clear impact on survival. Several clinical trials have randomized patients with extensive disease to chemotherapy alone or in combination with irradiation to the chest disease, as well as to some or all

sites of overt distant metastases.²⁹²⁻²⁹⁵ Although most of these did not show survival advantages with the addition of radiotherapy, it is notable that the most recent trial did.²⁹³ In this trial, patients with at least a partial response to chemotherapy at the primary site and a complete response in distant sites were randomized to receive thoracic radiation with additional chemotherapy, or chemotherapy alone. Thoracic radiotherapy was associated with significantly better survival and a trend toward better local control. A recent, small phase II trial of consolidative thoracic radiation suggested that rates of symptomatic recurrence in the chest were low with this strategy and may, therefore, have an important quality of life benefit irrespective of any survival benefit.²⁹⁶ Preliminary results from the Dutch phase III trial randomizing extensive stage SCLC patients who have had a response to four to six cycles of chemotherapy to thoracic radiation therapy or no thoracic radiation therapy has found a survival benefit at two years but not at one year, which was the primary endpoint.²⁹⁷ The RTOG is conducting a randomized trial in which patients with extensive-stage disease and four or fewer metastatic lesions (excluding the central nervous system [CNS]) receive prophylactic cranial irradiation and consolidative RT to the thorax and all metastatic sites, or prophylactic cranial irradiation (PCI) alone. Although the routine use of consolidative thoracic radiation cannot yet be justified, the improved local control, attendant impact on symptomatic progression, and possible survival benefit make it a reasonable consideration in patients with significant responses to initial chemotherapy.

Prophylactic Cranial Irradiation. Brain metastases are detected in at least 18% of SCLC patients at diagnosis³³ and eventually are diagnosed in another 20% to 25%, with an increasing likelihood seen with lengthening survival.^{298,299} An actuarial analysis reveals a probability of brain metastases ranging from 50% to 80% in patients who survive 2 years.^{298,230} At postmortem examination, they are found in up to 65% of patients.³⁰¹ Because these metastases are sometimes the sole site of clinical relapse and are frequently clinically disabling, PCI has been recommended by many,³⁰² but not all,³⁰³ authorities. The rationale is essentially an extrapolation from original strategies used in acute lymphocytic leukemia of childhood.

A large number of early prospective randomized trials assessed the benefit of PCI given at or within a few months of diagnosis.^{144,304-307} When these trials were considered together, PCI reduced the frequency of clinically detectable brain metastases from 24% to 6%. However, no significant impact of PCI on survival was seen in any of those studies. Retrospective analyses suggested that virtually all benefit with PCI was confined to patients who achieved a complete remission from their initial treatment.³⁰⁰ In an actuarial analysis, partial responders or nonresponders have similar risks of recurrence in the brain regardless of whether PCI was administered. This is not surprising because persistent systemic cancer could readily metastasize to the CNS after the completion of PCI.

In a meta-analysis of almost 1,000 patients in seven trials between 1977 and 1995, patients were evaluated with and without PCI after initially obtaining a complete response.³⁰⁸ PCI doses ranged from 24 to 40 Gy in most patients. The meta-analysis suggested that a significant gain in survival with PCI, with 3-year survival figures increasing from 15% to almost 21%. PCI significantly decreased the probability of brain metastases and increased the likelihood of disease-free survival. Higher doses appeared to have no impact on survival, although seemed to have an increasing effect of preventing brain metastases. A trend also was seen toward a decreased risk of brain metastases when PCI was administered earlier. The meta-analysis was not able to assess the impact of PCI on cognitive function, because most of the studies did not include thorough neurocognitive assessments. Two studies that assessed baseline neuropsychological function before treatment demonstrated that many patients appear to have abnormalities of cognitive function as initial manifestations of their cancer, even when brain metastases were not detected and before any treatment.^{309,310}

An Intergroup trial evaluated standard-dose versus higher dose PCI after complete response for limited-stage disease.³¹¹ Seven hundred twenty patients were randomized to either 25 Gy in 10 fractions or 36 Gy delivered in 18 daily fractions of 2 Gy or 24 twice-daily fractions of 1.5 Gy. There was no significant difference in incidences of brain metastases between the standard-dose group and the high-dose group. The OS was significantly worse in the higher dose group, although this was due to extracranial disease progression rather than toxicity. The reason for this counterintuitive result remains unclear. This study further established 2,500 cGy in 10 fractions as the standard dose of PCI for limited-stage patients, although some practitioners use a regimen of 3,000 cGy in 15 fractions, which should have similar biologic efficacy.

A recent EORTC randomized trial demonstrated a survival benefit with PCI in patients with extensive-stage SCLC who had had a response to chemotherapy.⁸⁵ The use of PCI significantly improved the rate of 1-year freedom from symptomatic brain metastases from 14.6% to 40.4% and the 1-year survival from 13.3% to 27.1% in the 286 randomized patients. Various fractionation schemes were used, but the most common ones were 20 Gy in five fractions and 30 Gy in 10 fractions. A common criticism of this trial is its lack of mandatory pretreatment brain imaging to rule out clinically occult brain metastases, raising the question of whether the observed survival benefit was due to treatment of patients who already had detectable brain metastases. In an era of routine and regular imaging of the brain with sensitive MRI examinations, it has been suggested that the actual rate of developing brain metastases in thoroughly staged extensive-stage patients is relatively low, which may attenuate the potential benefit of routine PCI in this cohort. Nevertheless, the results of the EORTC trial established PCI as a standard consideration for all extensive-stage patients achieving a response to initial therapy.

A major concern with recommending PCI is the significant risk of toxicity associated with it. It is evident that some long-term survivors have neurologic and intellectual impairment as well as abnormalities on CT scan that may be related to PCI.^{312,313} In one study, CT scan and CNS abnormalities were significantly more frequent in patients who had received PCI or therapeutic brain irradiation than in those who had not.³¹⁴ These findings were especially disturbing because complete responders are at greater risk for possible complications. Many deficits on neuropsychological testing have been unsuspected on casual examination, but a few patients have obvious major impairments. CT scan abnormalities continue to worsen for several years after treatment has ended, although the abnormalities may eventually stabilize.³¹⁵ Neurologic abnormalities were most prominent in one series of patients who were given PCI concurrently with high-dose chemotherapy or in individual radiation fractions of 4 Gy.³¹² Some authorities suggest that PCI should be administered only in standard fractions of 2 Gy after the completion of chemotherapy.²⁵⁰

After PCI, neuropsychological and imaging abnormalities may or may not be due to PCI. Chemotherapy, paraneoplastic syndromes, micrometastases, and chronic cigarette and alcohol abuse may be important contributors. In one study that evaluated cognitive function in patients before and after chemoradiation but before PCI, deficits were discovered in verbal memory, frontal lobe function, and motor coordination within both groups of patients.¹¹⁸ A similar, more recent study indicated that 47% of SCLC patients had impaired cognitive function before PCI, and that PCI was not associated with persistent declines in cognitive function.³¹⁶ The administration of methotrexate, procarbazine, and lomustine has decreased over the past 15 years; these particular agents have been incriminated in neuropsychological dysfunction. One of the studies included in the meta-analysis had almost 300 patients who were randomized to receive PCI after having achieved a complete remission to initial treatment.³⁰⁴ There were no obvious differences in the neuropsychological function between the two groups, but only 33 patients underwent a complete reassessment at 18 months. Inasmuch as neuropsychological abnormalities possibly due to PCI progress over time, these data are insufficient to exclude radiation-associated cognitive damage, but they are nonetheless relevant.

A recent decision analysis suggests that for patients who have had a complete response to initial therapy, PCI offers a better quality-adjusted life expectancy, even if a mild to moderate neurotoxicity rate was assumed.³¹⁷ If PCI is not administered concurrently with chemotherapy, radiation-induced permeability alterations that allow more of the chemotherapeutic agent into the brain parenchyma should be obviated. The authors' guidelines for PCI, after a thorough discussion with the patient of potential risks and benefits, are as follows: (1) PCI is typically recommended as soon as a partial or complete response to induction therapy has been confirmed, and after acute toxicities have resolved, which is typically 2 to 4 weeks after completion of all chemotherapy. Note that in the EORTC trial of PCI for extensive-stage patients, PCI was given 4 to 6 weeks after chemotherapy. (2) The standard fractionation of 2500 cGy in 10 fractions is recommended for all patients in whom PCI is deemed appropriate, with a consideration of 2000 cGy in five fractions for extensive-stage patients for whom, due to borderline performance status or significant logistical impediments, shortening overall treatment time is felt to be important.

Role of Chemotherapy and Radiation Therapy to the Neuroaxis. For overt metastatic lesions within the CNS, doses of 3 Gy daily to a dose of 30 Gy typically is used. Overt intracranial metastases appear to be more difficult to sterilize than intrathoracic disease.³¹⁸ Due to the propensity for SCLC patients to develop multifocal brain metastases, stereotactic treatment for brain metastases is typically not appropriate because the risk of brain relapse beyond the treated lesion would be unacceptably high. However, in the context of prior whole brain radiation or prophylactic cranial irradiation, stereotactic treatment may be considered as a salvage option.³¹⁹

Chemotherapy also is a therapeutic option for brain metastases, perhaps because the blood-brain barrier is disrupted in the setting of macroscopic metastatic disease. Small series of patients in whom brain metastases were present at diagnosis have been treated with standard chemotherapy regimens without radiation, and the majority have demonstrated clinical and radiographic improvement.³²⁰ Chemotherapy also has been used at the time of relapse, and response rates of 33% to 43% have been reported.³²⁰⁻³²² In previously treated patients, the response to chemotherapy in the brain appears to be comparable to the response rates in other organs, and it is not dissimilar from the activity of irradiation, which in one series produced a partial response rate of 50%; the median survival was 4.7 months in a series of 22 patients.³²³ In the phase II trial evaluating temozolomide in patients with relapsed or refractory SCLC, patients with progressive brain metastases that had received prior cranial irradiation demonstrated an intracranial response to the agent.²⁰⁰ Thus, although brain irradiation remains the standard for patients who have not been previously irradiated, chemotherapy is a reasonable option for those in whom recurrent disease develops after prior brain radiation, particularly if active systemic disease is also present.

Surgery

Even before the advent of combination chemotherapy for SCLC, the poor outcomes in various case series clearly indicated that surgery is not advisable as a sole treatment modality in this disease.³²⁴⁻³²⁷

Given that SCLC patients generally present with bulky unresectable disease, studies evaluating surgery are limited. In some cases, patients who undergo thoracotomy for an abnormal pulmonary nodule are unexpectedly diagnosed with SCLC.⁵⁵ About 4% of solitary pulmonary nodules are diagnosed as SCLC.^{29,30} In these cases, a complete surgical resection should be performed and the patient should be referred for adjuvant therapy. Based on current recommendations, patients with N0 disease should then receive adjuvant chemotherapy, whereas patients with nodal involvement should receive chemotherapy and mediastinal radiation.⁵²

Nodal status and primary tumor (T) status have significant effects on the survival of patients who have undergone resection. Angeletti et al.³²⁸ and Shepherd et al.³²⁹ reported increased survival

of node-negative compared to N1 and N2 patients after surgical resection and postoperative chemotherapy, whereas Macchiarini et al.³³⁰ found a decrease in 5-year survival with increasing T category in surgically resected patients without nodal metastases. Rea et al.³³¹ reported that 51 stage I or II SCLC patients resected and given chemotherapy after resection had 5-year survival rates of 52% (stage I) and 30% (stage II). In the review by Lucchi et al.,³³² stage I or II resected SCLC patients who underwent postoperative chemotherapy had 5-year survival rates of 47% and 15%, respectively. Stage III patients from this series who underwent surgery followed by adjuvant therapy had a 5-year survival of 14%. The largest experience examining the role of surgery followed by adjuvant therapy in SCLC was a cooperative group trial conducted by the International Society of Chemotherapy Lung Cancer Study Group.⁵⁴ Four-year survival rates for completely resected, pathologically staged SCLC patients with N0 (n = 69), N1 (n = 58), and N2 (n = 36) who received postoperative therapy were 60%, 36%, and 33%, respectively. Based on these studies, most authorities believe that surgery may have a role as part of a multimodality approach, but only for patients with stage I disease.⁵² A mediastinoscopy should be performed in all patients who are being considered for resection of known SCLCs. In a large series from the University of Toronto, surgery followed by chemotherapy had the same outcome as treatment in the reverse order.³²⁹

Surgical resection also has been studied as a way of reducing the risk of local recurrence in patients with limited disease after the completion of chemoradiation. Although most patients with SCLC succumb to metastatic disease, local recurrence occurs in 35% to 50%.⁴⁹ Furthermore, tumors may have a mixed histology such that residual NSCLC remains after treatment of the more chemosensitive SCLC component. Of 38 cases resected after chemoradiation in a University of Toronto study, 29 had pure SCLC but 4 were pure NSCLC, 2 had a mixed histology, and 3 had no residual tumor.³³³ Several groups have reported the feasibility of this approach, although notably in these prospective studies, only about half of the cases were resectable and pneumonectomies were frequently required.³⁰⁵⁻³⁰⁷ One randomized trial attempted to address the question of whether surgical resection of persistent local disease adds any benefit to the usual approach of chemoradiation for limited-stage patients.³³⁴ The Lung Cancer Study Group enrolled 328 patients who were first treated with CAV for five cycles. Fit patients with at least a partial response were then randomized to surgical resection or not. All patients were then intended to receive thoracic and prophylactic cranial irradiation. As with the previously reported studies, only a fraction of the patients were eligible for surgery after induction therapy; only 146 patients were randomized, and this diminished the power of the statistical analysis. Nonetheless, no differences in OS or even in local control rates were noted between the two groups. NSCLC or mixed NSCLC/SCLC comprised 11% of the resected specimens. These data suggest that surgical resection of residual disease in limited-stage SCLC does not improve outcomes. The use of surgery for patients with SCLC should be restricted to patients with stage I tumors.

Palliative Care

Survivorship Issues

Although minor advances have transpired over the past 3 decades, there has been no dramatic change in outcomes for SCLC since the introduction of EP chemotherapy in the late 1970s, with median survival improving only by 2 months from 7 to 9 months between 1972 and 1990.³³⁵ Although this therapy significantly changes the natural history of SCLC, and the use of twice-daily concomitant radiotherapy and prophylactic cranial irradiation adds incremental benefit in patients with limited disease, the number of persons cured remains small. Few patients with extensive disease attain long-term survival. Patients are at greatest risk of dying from SCLC during the first 24 months after diagnosis. This risk declines

between years 2 and 3 and is further reduced beyond year 3. In the SEER program database, OS at 2, 3, and 5 years was 12%, 7%, and 5%, respectively.³³⁶

Excessive mortality in long-term survivors is due primarily to the development of second primary tumors, mainly NSCLC, and other illnesses associated with cigarette smoking.^{67,337–340} Late relapse can occur in approximately 10% of patients at 5 years.³⁴¹ Overall, the relative risk of a second primary tumor in patients who survive beyond 2 years is increased 3.5-fold. The second lung cancer risk is increased 13-fold among those who received chest irradiation.³³⁷ Because most of the second primary tumors are NSCLC or other malignancies of the upper aerodigestive tract, it is likely that field cancerization due to tobacco exposure has occurred.^{337,338} The risk of a second primary tumor increases significantly over time and with continued smoking. Treatment with alkylating agents further magnifies this risk.³³⁷ For example, the risk of a second lung cancer in patients who continue to smoke was approximately fourfold more than those who stopped before the diagnosis of SCLC and twofold greater in patients who received chest irradiation compared to nonirradiated patients. The cumulative risk of a second lung cancer was 32% at 12 years and continued to increase beyond that time point. Secondary leukemias have been seen as well.^{339,340} Patients successfully treated for SCLC constitute an extraordinarily high-risk group for second malignancies and require close surveillance. The cigarette smoking status of every long-term survivor of SCLC should be assessed at every visit. Aggressive smoking cessation efforts should be marshaled for any patient who expresses an interest in quitting. In addition, this population should be considered for studies evaluating new surveillance technologies and chemoprevention.

Long-term survivors are also at increased risk for non-cancer-related problems, including complications of treatment (e.g., pulmonary fibrosis in patients receiving thoracic irradiation, neurologic impairment both as a consequence of treatment with cranial irradiation and paraneoplastic effects of SCLC, and the acceleration of coronary artery disease following thoracic irradiation) as well as tobacco-related illnesses like heart disease, stroke, and chronic obstructive pulmonary disease. In a French study of patients surviving beyond 30 months, treatment-related sequelae included neurologic impairment in 13% of the patients, pulmonary fibrosis in 18%, and cardiac disorders in 10%.³⁴² A return to work was possible in 40% of these patients and was not influenced by the presence of late treatment-related complications. In a Danish analysis of patients surviving 5 years or more, there was a six-fold increased risk of death from noncancer causes, particularly cardiovascular and pulmonary diseases.³⁴³ Physicians who care for survivors of SCLC should aggressively implement all strategies to reduce cardiovascular disease. These patients should be considered high risk and managed like any other high-risk individual.

TYPICAL AND ATYPICAL CARCINOID TUMORS

Incidence and Etiology

Although over 60% of carcinoid tumors originate in the gastrointestinal system, about 25% of all carcinoids have a pulmonary origin, representing the second most common involved site.³⁴⁴ Pulmonary carcinoids comprise about 2% of all primary lung tumors.³⁴⁵ Over the past 30 years, the age-adjusted incidence rate in pulmonary carcinoids has significantly increased, which may represent the improvement in classification of these tumors, as well as the rise of imaging techniques.³⁴⁴ There is a higher incidence of pulmonary carcinoids in women compared to men and whites compared to blacks.^{346,347}

Atypical carcinoids, which have a higher likelihood of metastatic spread or relapse after surgery, are distinguished from the typical carcinoids, which have a more favorable prognosis. Ten percent

to 30% of pulmonary carcinoids are atypical.^{348–350} Patients with typical carcinoids are approximately 10 years younger than those with atypical carcinoids, which occur in the 6th decade of life.^{347,351} Carcinoids are not clearly caused by smoking like SCLC and LCNEC, although some series suggest that a higher percentage of patients with atypical carcinoid smoke as compared to patients with typical carcinoid tumors.^{347,348,352} Pulmonary carcinoids occur rarely in association with multiple endocrine neoplasia type 1 (MEN-1) syndrome. Some sporadic pulmonary carcinoid tumors demonstrate inactivation of the *MEN-1* gene located on chromosome 11q13.³⁵³

Anatomy and Pathology

All carcinoids are malignant. Typical carcinoids are low grade and atypical carcinoids are intermediate grade. Although carcinoid tumors can be diagnosed by small biopsies or cytology, it is difficult to separate a typical from an atypical carcinoid. This distinction usually requires a surgical biopsy or resection specimen. The histologic appearance of typical and atypical carcinoids is similar with a uniform population of tumor cells arranged in organoid nests with a moderate amount of cytoplasm with an eosinophilic hue (see Fig. 42.2B,C). The finely granular nuclear chromatin frequently has a salt-and-pepper appearance. There are a wide variety of histologic patterns in these tumors, including spindle cell, oncocyctic, glandular, follicular, clear cell, and melanocytic. Stromal ossification can occur as well. Atypical carcinoids show increased mitoses (see Fig. 42.2C) with 2 to 10 mitoses per 2 mm² or necrosis that is typically punctate.³⁵⁴ Mitotic activity is the most important way to distinguish typical from atypical carcinoid. The most useful immunohistochemical neuroendocrine markers are chromogranin, synaptophysin, and CD56. If the mitotic count is 11 or more mitoses per 2 mm² (10 high power fields), a diagnosis of LCNEC or SCLC is favored over atypical carcinoid.^{354,355} In small specimens where mitotic figures are difficult to demonstrate, it may be helpful to use Ki-67 staining because most typical carcinoids show less than 5% staining, atypical carcinoids are usually 10% to 30%, and most LCNECs or SCLCs usually have a very high proliferation index of 80% to 100%.³⁵⁶

Nodular neuroendocrine proliferations 0.5 cm or larger are called *carcinoid tumors*. Smaller proliferations are called *tumorlets*, which are separated from carcinoid tumors by size, but with identical morphology of cells. Tumorlets usually are incidental histologic findings of no clinical significance, although they can be seen in interstitial or airway inflammatory and fibrosing conditions. A very rare condition called *diffuse idiopathic pulmonary neuroendocrine cell hyperplasia* (DIPNECH) is regarded as a preinvasive condition for pulmonary carcinoids. Patients with DIPNECH have widespread neuroendocrine cell hyperplasia and tumorlets in their airways and can develop multiple carcinoid tumors.³⁵⁷

Screening

Screening for pulmonary carcinoids is not useful. They represent a very small percentage of all lung malignancies and have an indolent natural history. In one study, atypical carcinoid was diagnosed in only 2 of 31,567 (0.006%) asymptomatic patients undergoing baseline lung cancer screening CT scans.³⁵⁸

Diagnosis

Two-thirds of carcinoids develop in the major bronchi. As a result, the most common presenting symptoms include obstructive pneumonia, pleuritic pain, atelectasis, dyspnea, and cough.^{348,359} Hemoptysis may occur in 10% to 20% of patients. Up to 30% of patients with pulmonary carcinoid tumors are asymptomatic at presentation. In contrast to carcinoids of gastrointestinal origin, carcinoid syndrome (facial flushing, diarrhea, wheezing) is rare in pulmonary carcinoids, occurring in only about 2% of cases.^{348,359} Cushing syndrome due to ectopic corticotropin production has

been reported in approximately 2% of pulmonary carcinoids.³⁶⁰ A rare manifestation of pulmonary carcinoids is acromegaly due to the ectopic production of growth hormone–releasing hormone (GHRH), yet these tumors are the most common cause of extrapituitary secretion of GHRH.³⁶¹

The initial workup proceeds in a similar fashion as with other lung tumors, but once a diagnosis of carcinoid is confirmed, more specific radiologic and serologic evaluations for these neuroendocrine tumors may be employed. A biopsy of the central tumors can be easily obtained by bronchoscopy. A biopsy of peripheral lesions by fine needle can be performed, but a definitive diagnosis may be difficult to ascertain in small cytology samples. In addition to routine chest imaging with CT scans, nuclear medicine studies are helpful adjuncts for staging (Fig. 42.5). Due to the overexpression of somatostatin receptors, immunoscintigraphy by somatostatin analogs such as octreotide is widely used. In one series, the sensitivity and specificity was 90% and 83%, respectively.³⁶² In patients with somatostatin receptor–positive pulmonary carcinoids, octreotide scans have been found to be useful for follow-up and in the detection of recurrent disease, as well as for guiding treatment options.³⁶³ Fluorine-18 (18F) fluorodeoxyglucose (FDG)-PET scanning may be less accurate because these indolent tumors generally have a low standard uptake value (SUV),³⁶⁴ but some still advocate its potential

use.³⁶⁵ Recent series have shown that 18F-FDG–PET is useful for the assessment of intermediate- and high-grade neuroendocrine tumors and may have prognostic value.^{366,367} Elevated chromogranin A levels have been measured in serum or plasma, although they have been found to be lower in pulmonary carcinoids compared to gastroenteropancreatic endocrine tumors.^{368,369} In the setting of advanced or metastatic disease, chromogranin A levels can be useful to follow disease activity.³⁶⁹ Urinary 5-hydroxyindoleacetic acid (5-HIAA) may be elevated in patients with carcinoid syndrome.

Staging

Pulmonary carcinoid tumors are staged according to the TNM classification used for NSCLC in the AJCC seventh edition. The International Association for the Study of Lung Cancer (IASLC) proposed and approved this in 2009 when it was determined that the TNM staging system was helpful in predicting the prognosis for pulmonary carcinoids.³⁷⁰ Applying this staging system to cases in the National Cancer Institute SEER registry and cases submitted to the IASLC database, it was determined that 5-year OS for patients with stage I was 93%, stage II was 74% to 85%, stage III was 67% to 75%, and stage IV was 57%.³⁷⁰ Survival is significantly better for

Figure 42.5 (A) Computed tomography scan and (B) associated octreotide scan of a patient with bilateral typical carcinoid.

typical carcinoid than for atypical carcinoid. Five-year and 10-year survival rates have been reported at 87% and 87%, respectively, for typical carcinoids, whereas they were 56% and 35%, respectively, for atypical carcinoids.³⁵³ Predictors of survival include stage, tumor size, higher mitotic rates (i.e., atypical subtype), and age greater than 60.^{347,352,370} Importantly, patients with multiple nodules have a very favorable prognosis, likely reflected by the fact that these individuals tend to have the underlying preinvasive lesion, diffuse idiopathic pulmonary neuroendocrine cell hyperplasia.³⁷⁰

Management by Stage

Stages I, II, and III

Surgery is the primary treatment modality and the only curative option for patients with pulmonary carcinoids. Because carcinoids often present centrally, a pneumonectomy or bilobectomy is frequent, but most patients undergo a lobectomy.^{345,352} For patients with favorable prognostic features, such as typical histology and the absence of lymph node involvement, a more limited resection has been proposed.^{359,371} Patients with atypical carcinoids should be resected using the same principles guiding surgery for NSCLC.³⁷²

Because mediastinal lymph node metastases occur in patients with pulmonary carcinoids, complete mediastinal lymph node dissection is advocated, with surgical resection of nodal metastases when feasible.^{351,373–377} Multiple series have found decreased incidences of local recurrence^{351,375} and improved survival when a complete mediastinal lymph node dissection is performed.^{350,373}

Adjuvant chemotherapy after surgical resection for patients with typical carcinoid with or without regional lymph node metastases (stages I, II, and III) is not recommended,⁵⁷⁸ because the risk of recurrence has been shown to be low: In a series of 291 resected typical carcinoids, only 3% of patients suffered recurrence.^{351,379} Similarly, following surgical resection, patients with stage I atypical carcinoid are followed expectantly. However, because systemic recurrence occurs more frequently in patients with atypical carcinoid with N1 or N2 involvement (stages II and III), documented to be as high as 26% in a surgical series,³⁷⁹ adjuvant chemotherapy after surgical resection has been advocated by some,³⁷⁸ but it is unknown whether this is beneficial. There is no defined adjuvant regimen for atypical carcinoid, yet due to similarities with SCLC, etoposide with cisplatin or carboplatin is generally used.³⁷⁸

The use of radiation therapy for carcinoid tumors is most similar to its pattern of use in NSCLCs. For tumors that are resectable, adjuvant radiation therapy is typically recommended in situations of residual disease (R1 resection) and mediastinal lymphadenopathy (N2 disease). The use of adjuvant radiation therapy for nodal disease is probably of greater utility in the more aggressive atypical carcinoid.³⁷⁸ In patients with unresectable disease, radiation therapy can be used after induction chemotherapy or concurrently.³⁸⁰ Doses of 60 Gy are typical. Carcinoid tumors are less responsive to radiation therapy than SCLC.³⁸¹

Stage IV

Data regarding the efficacy of chemotherapy specifically in pulmonary carcinoid (as opposed to gastrointestinal carcinoids) are lacking, because this tumor type has not been studied independently of other neuroendocrine tumors and occasionally has been omitted from such trials. Many of the studies have used older classification systems for carcinoids and different criteria for response. Various chemotherapeutic agents have been used, including doxorubicin, 5-fluorouracil, dacarbazine, cisplatin, carboplatin, etoposide, streptozocin, and interferon-alpha.^{368,382} Yet, in general, carcinoid tumors have no significant therapies that consistently induce regression.

Octreotide has been used in the treatment of these tumors. Retrospective reviews, including small numbers of patients with pulmonary carcinoids, have reported on the use of somatostatin analogs with improvement in carcinoid syndrome symptoms, as well as

prolonged disease control and survival, with very few individuals achieving a tumor response.^{383,384,385} These results are similar to the experience with octreotide in gastrointestinal carcinoids.³⁸⁶ Notably, the recent PROMID study showed that long-acting-release octreotide acetate significantly prolonged time to tumor progression compared with placebo in patients with newly diagnosed functionally active or inactive well-differentiated midgut neuroendocrine tumors (14.3 versus 6 months; HR, 0.34; 95% CI, 0.20 to 0.59; $p = 0.000072$). However, there was no improvement in OS.³⁸⁷ Although some studies evaluating peptide receptor radionuclide therapy with radiolabeled somatostatin analogs in patients resistant to octreotide have included bronchial carcinoids, the number of patients with this histology is small thus far to generate any meaningful conclusions. However, such agents have been found to have reasonable response rates and outcomes in patients with pancreatic neuroendocrine tumors and gastrointestinal carcinoids.³⁸⁸

Regimens typically used for SCLC often are recommended.^{378,389} However, typical carcinoids and atypical carcinoids are clearly less chemosensitive than SCLCs. In two small series that included 26 patients in total treated with chemotherapy (mostly etoposide and cisplatin), the response rate was about 20%.^{368,380} EP was administered to 18 patients with foregut-origin carcinoids (lung and thymus) who had progressed after first- or second-line treatment in a prospective study. Radiographic response was noted in 2 of the 5 patients with atypical carcinoid (40%) and in 5 of the 13 with typical carcinoid (39%). The median response duration was 9 months (range, 6 to 30 months).³⁹⁰ Similarly, etoposide with cisplatin or carboplatin was administered to 17 pulmonary carcinoid patients, with a 23.5% radiologic response (2 patients each with atypical and typical carcinoid) and median PFS of 7 months.³⁸⁵

Newer agents are being studied actively in neuroendocrine carcinoma. Temozolomide, a nonclassical oral alkylating agent, has been evaluated either alone or in combination with other agents. Thirteen patients with pulmonary carcinoids (10 typical, 3 atypical) were included in a retrospective study using single-agent temozolomide. Four of these patients (31%) had a partial response to treatment (3 typical, 1 atypical), and 62% derived clinical benefit (response or stable disease) with temozolomide.³⁹¹ In a larger retrospective study of 31 patients that included both typical and atypical pulmonary carcinoids, a partial response to treatment was noted in 3 patients (14%), whereas stable disease was observed in 11 patients (52%); median PFS and OS were 5.3 months and 23.2 months, respectively.³⁹² Eighteen patients with carcinoid and pancreatic neuroendocrine tumors metastatic to the liver that received capecitabine and temozolomide, were evaluated for response and outcome.³⁹³ The overall response rate was 61%, and three of the four carcinoid patients attained clinical benefit (complete response, $n = 1$; partial response, $n = 1$; stable disease, $n = 1$). From the time of liver metastases, median PFS and OS were 14 months (range, 4 to 18 months) and 83 months (range, 18.5 to 140 months) for this combination, respectively. These results suggest that the regimen of capecitabine and temozolomide is active and may prolong survival in this malignancy.³⁹³ In contrast, in two prospective trials that included patients with carcinoid tumors, a 7% response rate was noted using temozolomide with thalidomide and no response was observed using temozolomide and bevacizumab.^{394,395} However, because some studies have shown promising results for temozolomide, either alone or in combination with other agents in metastatic pulmonary carcinoids, larger prospective studies should be developed.

The mTOR pathway, which regulates cell growth, proliferation, and metabolism, has been implicated in the pathogenesis of neuroendocrine tumors.³⁹⁶ To determine if the addition of everolimus improved PFS, the randomized, placebo-controlled phase III study of everolimus plus octreotide long-acting repeatable (LAR) (RADIANT-2) included 429 patients with low-grade or intermediate-grade carcinoids, of which 44 were of pulmonary histology.³⁹⁶ Median PFS was 16.4 months (95% CI, 13.7 to 21.2 months) for the group receiving the combination of everolimus and octreotide LAR compared to 11.3 months (95% CI, 8.4 to 14.6 months) in the

octreotide LAR-only group (HR, 0.77; 95% CI, 0.59 to 1.0, $p = 0.026$); thus achieving the primary endpoint of the study. For the 44 bronchial carcinoid patients, median PFS was 13.6 and 5.6 months in the everolimus plus octreotide LAR group versus octreotide LAR-only group, respectively.³⁹⁶ Currently, we are awaiting results from the randomized, double-blind, phase III study of everolimus versus placebo in patients with advanced neuroendocrine tumors of gastrointestinal (GI) or lung origin only (RADIANT-4) (ClinicalTrials.gov identifier: NCT01524783). Well-differentiated carcinoid tumors are highly vascularized and extensively express VEGF, Hypoxia inducible factor 1-alpha, and microvessel density.³⁹⁷ As such, angiogenesis inhibitors have been investigated in this disease. In a phase II study, in low- to intermediate-grade neuroendocrine tumors, patients were randomized to receive either bevacizumab or pegylated interferon- α -2b (IFN α -2b). Only four patients with pulmonary carcinoids were included in this trial, where an 18% partial response rate was observed in the bevacizumab group compared with no responses in the pegylated IFN α -2b arm.³⁹⁸ Fourteen patients with foregut carcinoids of the lung and stomach were included in a phase II study using sunitinib, a multitargeted oral TKI. The overall response rate for patients with carcinoid tumors was only 2.4% with a median time tumor progression of 10.2 months.³⁹⁹ In contrast, in pancreatic neuroendocrine carcinoma, the randomized phase III trial of sunitinib versus placebo, demonstrated a significant improvement in PFS (11.4 versus 5.5 months, respectively; HR, 0.42; 95% CI, 0.26 to 0.66; $p < 0.001$).⁴⁰⁰

In patients with liver metastases, hepatic artery embolization, with or without intra-arterial chemotherapy has been associated with responses and improved outcomes in carcinoid patients.⁴⁰¹ Nine patients with pulmonary carcinoids who developed liver metastases underwent hepatic artery chemoembolization in a recently reported single institution retrospective review. Prolonged stable disease lasting up to 19 months was noted in eight of these patients, with three achieving a partial response.³⁸⁵ A newer embolization method, utilizing injectable particles conjugated to yttrium-90, permits the delivery of internal radiation into hepatic arteries that supply carcinoid liver metastases.³⁹⁷ Because randomized trials in embolization methods are lacking and some do experience treatment-related toxicities, patients must be selected carefully for these procedures.

In the approach to metastatic carcinoid tumors, many advocate using somatostatin analogs as first-line treatment in patients with well-differentiated tumors with little tumor bulk in the setting of a positive octreotide scan^{363,383} and chemotherapy for those with more rapidly progressing tumors or those who have progressed on less toxic treatments.^{402,403} Additional prospective, randomized studies are needed for both traditional cytotoxic and molecularly targeted agents in this disease, because early results are promising. Palliative radiation therapy can be used for symptomatic lesions.³⁸¹

LARGE CELL NEUROENDOCRINE CARCINOMA

Incidence and Etiology

LCNEC of the lung was first described in 1991 as a form of high-grade non-small-cell neuroendocrine carcinoma.⁴⁰⁴ LCNEC accounts for about 3% of surgically resected lung cancers.⁴⁰⁵ In previously reported series, LCNEC patients have a median age of 62 years (range, 33 to 87 years) and the vast majority of patients are male cigarette smokers.^{347,405}

Anatomy and Pathology

In the 2004 World Health Organization (WHO) classification, LCNEC is classified as a variant of large cell carcinoma.^{9,405,406} There are four ways that neuroendocrine differentiation can be manifest within large cell carcinomas: (1) If both neuroendocrine

morphology by light microscopy as well as neuroendocrine differentiation by immunohistochemistry or electron microscopy are seen, the tumor is classified as LCNEC; (2) if there is no neuroendocrine morphology by light microscopy and neuroendocrine differentiation is seen by immunohistochemistry or electron microscopy, the tumor is classified as large cell carcinoma with neuroendocrine differentiation (LCC-NED); (3) if the tumor lacks both neuroendocrine morphology by light microscopy and neuroendocrine differentiation by immunohistochemistry or electron microscopy, it is classified as a classic large cell carcinoma; and (4) if the neuroendocrine morphology (LCNEM) has neuroendocrine morphology but lacks neuroendocrine differentiation by electron microscopy or immunohistochemistry, it is classified as large cell carcinoma.^{9,405,406} Little is known about the latter category.

LCNEC are diagnosed based on the following criteria (Fig. 42.2D): (1) neuroendocrine morphology with organoid nesting, palisading, or rosettelike structures; (2) high mitotic rate greater than 10 mitoses per 2 mm² (average 60 to 80 mitoses per 2 mm²); (3) non-small-cell cytologic features, including large cell size, low nuclear or cytoplasmic ratio, nucleoli, or vesicular chromatin; and (4) neuroendocrine differentiation by immunohistochemistry (chromogranin, CD56, or synaptophysin) or electron microscopy.^{9,354} The tumor grows in organoid nests with peripheral palisading and rosettelike structures. The tumor cells have abundant cytoplasm, prominent nucleoli, and frequent mitoses.

When LCNEC has components of adenocarcinoma, squamous cell carcinoma, giant cell carcinoma, or spindle cell carcinoma, it is called combined LCNEC and the specific components present should be mentioned.^{9,354} Adenocarcinoma is the histologic type found most often in combined LCNEC. When SCLC is combined with LCNEC, the tumor becomes a combined SCLC, and LCNEC and should be regarded as a SCLC.

LCNEC will be positive for pancytokeratin and at least one neuroendocrine marker such as chromogranin, CD56, or synaptophysin. TTF-1 will be positive in 60% to 80% of cases. There is a very high proliferation index with 80% to 100% positive tumor cells.^{405,407} When the differential diagnosis of basaloid carcinoma is a consideration, diffuse strong staining for p63 or p40 would favor this diagnosis over LCNEC.¹⁵

It is difficult to make the diagnosis of LCNEC on small biopsies or cytology because the characteristic neuroendocrine morphologic pattern and neuroendocrine differentiation by immunohistochemistry are difficult to demonstrate in minute pieces of tissue.^{405,407} Therefore, in the vast majority of cases, a definite diagnosis of LCNEC will require a surgical biopsy. Separation of LCNEC from SCLC requires consideration of multiple histologic features such as cell size, nucleoli, chromatin pattern, and nuclear to cytoplasmic ratio, rather than a single criterion. Artifacts such as those introduced by frozen sections or poor quality hematoxylin and eosin-stained sections, can distort cellular morphology, resulting in confusion with SCLC.^{11,405,407}

Screening

Clinically, LCNEC is characterized by similar behavior to SCLC, with rapid tumor growth and early metastatic spread.³⁴⁷ Further, LCNEC represents a small percentage of all lung malignancies. In one study, LCNEC was diagnosed in only 15 of 31,567 (0.05%) asymptomatic patients undergoing baseline lung cancer screening CT scans.³⁵⁸ Therefore, screening for LCNEC is not useful.

Diagnosis

In patients with LCNEC, presenting symptoms mimic those of SCLC and other NSCLC. For example, in one series of 83 patients, the main symptoms were hemoptysis (30%), chest pain (22%), dyspnea (16%), cough (16%), and weight loss (13%); only 4% of patients were asymptomatic.⁴⁰⁸ Ectopic hormone production and paraneoplastic syndromes are typically absent.³⁴⁷

LCNEC generally present as peripheral tumors. When centrally located, endobronchial growth and obstructive pneumonia can be found.⁴⁰⁹ On CT scan, these tumors are often well defined and lobulated, without air bronchograms or calcifications; spiculated margins are less commonly observed.^{409,410} Inhomogeneous enhancement is found in larger diameter (33 mm or larger) tumors secondary to necrosis.⁴⁰⁹ LCNEC typically have homogeneously high FDG uptake on PET scans, which is helpful in locating extrathoracic metastases.⁴¹⁰ A definitive diagnosis may be difficult to determine in small specimens or by cytology, as indicated previously.^{405,407}; thus, a surgical biopsy is often needed in LCNEC.

Staging

The TNM classification used for NSCLC in the AJCC seventh edition is used for the staging of LCNEC.

Survival for LCNEC is poor and appears to be significantly worse than that of nonneuroendocrine NSCLC.⁴¹¹ In a series of 335 pathologic stage IA NSCLCs comprising 259 adenocarcinomas, 65 squamous cell carcinomas, and 11 large cell neuroendocrine carcinomas, the histology of LCNEC was found to have a significant adverse prognostic impact and was predictive of poorer overall survival.⁴¹¹ Asamura et al.³⁴⁷ found that the survival curve of LCNEC can be superimposed on that for SCLC, with no difference in survival stage for stage between the two, confirming the findings of multiple other series. Reported overall 5-year survival after surgical resection of LCNEC ranges between 15% and 57%,⁴⁰⁵ indicating that the recurrence rate after surgery is high. Data from different series reveal that the 5-year survival rate ranges between 33% to 62% in stage I patients, 18% to 75% in stage II patients, 8% to 45% in stage III patients, and 0% in stage IV patients.^{347,408,411-413} Factors significantly related to survival among clinicopathologic parameters are tumor stage and size (less than 3 cm versus 3 cm or greater),⁴⁰⁶ as well as male gender.⁴¹⁴

Management by Stage

Patients with LCNEC are managed as if they have NSCLC with the same treatment algorithm stage for stage. The controversy in LCNEC centers on the choice of chemotherapy. Based on the neuroendocrine features, should LCNEC be treated with the same chemotherapy regimens used for SCLC? Certainly the aggressive natural history and propensity to metastasize are similar to SCLC, yet LCNEC clearly does not demonstrate the same chemosensitivity. Published reports about LCNEC are not instructive because essentially all are small, retrospective series with a focus on patients who underwent surgery. Details regarding chemotherapy treatment, such as the agents used or the response rates, are generally not provided.

Stages I, II, and III

For patients with early stage LCNECs, resection is recommended. The modalities of choice are either lobectomy or pneumonectomy, with systematic nodal dissection.⁴¹⁵ After careful mediastinal lymph node sampling, patients without lymph node metastases seem to experience improved survival.⁴¹⁵

Given the aggressive nature of LCNEC, surgery alone is not sufficient for its treatment. Several small, retrospective studies have attempted to discern the role of neoadjuvant or adjuvant chemotherapy in LCNEC. In this setting, the use of SCLC-based regimens is supported. A Japanese group compiled data on 16 patients who received postoperative chemotherapy and 57 who did not.⁴¹³ For all patients, the 5-year survival was 62% for stage I, 18% for stage II, and 17% for stage III. The authors noted that the 5-year survival for the five patients with stage I disease who received adjuvant chemotherapy was 100%, whereas it was 51% for the 23 patients who did not. Postoperative chemotherapy did not affect survival for other stages.⁴¹³ In a retrospective review of 100 patients

with resected LCNEC evaluating the use of perioperative chemotherapy,⁴¹⁴ there was no association observed between OS and receipt of neoadjuvant ($n = 22$) or adjuvant ($n = 20$) platinum-based regimens (OS at 5 years was 50% for no therapy versus 45% for those that received chemotherapy, p adjusted for propensity score = 0.18). However, when the analysis was restricted to patients with completely resected advanced stage IB-IIIa disease, the receipt of platinum-based chemotherapy in either the induction and/or the adjuvant setting was marginally associated with improved median OS: 2 years (95% CI, 1 to 5.3 years) in the no platinum chemotherapy group, compared to 7.4 years (95% CI, 2.5 to not reached) in the platinum chemotherapy group (p adjusted for propensity score = 0.052).⁴¹⁴ In a retrospective analysis of 144 surgical LCNEC cases, Veronesi et al.⁴¹² showed that although perioperative chemotherapy only led to a trend toward improved survival in stage I patients, a statistically significant survival benefit was found across all stages compared to surgery alone ($p = 0.04$). In a retrospective review of 45 surgically resected patients with LCNEC, patients who did not receive chemotherapy after surgery were more likely to die than patients who underwent surgery plus chemotherapy ($n = 23$) (HR, 9.472; 95% CI, 1.050 to 85.478; $p = 0.0457$).⁴¹⁶ An improvement in OS was found in 23 of 63 patients who received perioperative platinum-based chemotherapy compared to those who underwent surgery alone (74.4% versus 32.3%, respectively; $p = 0.042$).⁴¹⁷ A multivariate analysis utilizing age, gender, pathologic stage, surgical procedure, and perioperative chemotherapy revealed that those patients who underwent surgery with chemotherapy had a significantly better prognosis than those who underwent surgery alone (HR, 0.323; 95% CI, 0.112 to 0.934, $p = 0.0371$).⁴¹⁷

As stated, SCLC-based regimens in the adjuvant treatment of LCNEC is supported, in particular. Iyoda et al.⁴¹⁸ performed a prospective analysis on 15 LCNEC patients who received adjuvant chemotherapy with EP and compared outcomes to a historic cohort of LCNEC patients treated without platinum-based adjuvant therapy. Prolonged survival was noted for the patients that received at least two cycles of SCLC-based regimens; the 5-year overall survival rates were 88.9% and 47.4% in the adjuvant chemotherapy group and in the control group, respectively. Further, those receiving platinum-based adjuvant chemotherapy were noted to have a significantly lower rate of tumor recurrence when compared to patients receiving non-platinum-based adjuvant chemotherapy or no adjuvant chemotherapy.⁴¹⁹ Finally, in an Italian retrospective series of 83 LCNEC cases, the 13 patients who received SCLC-based regimens had significantly better survival than the 15 patients who received drug combinations used in NSCLC (median survival, 42 months versus 11 months, respectively; $p < 0.0001$). The best prognosis was noted in stage I LCNEC patients who received SCLC-based adjuvant chemotherapy. In univariate and multivariate analyses, the administration of adjuvant chemotherapy with cisplatin or carboplatin plus etoposide was the most important variable correlating with survival.⁴⁰⁸ The interpretation of these reports is limited by their retrospective nature and the small sample size. However, these data, along with the known poor natural history and the routine use of adjuvant chemotherapy for SCLC and NSCLC, suggest that postoperative treatment with etoposide and cisplatin is appropriate in patients with completely resected LCNEC, including patients with stage I disease.

Data regarding the use of radiation therapy in this disease are sparse, but its role in the adjuvant setting is likely similar to that in NSCLC. As per the NCCN guidelines, definitive radiation therapy is recommended for patients who are unable to undergo surgical resection.⁴²⁰

Stage IV

The optimal chemotherapeutic regimen in relapsed or stage IV disease is not defined, although treatment with platinum-based regimens is advocated. Several studies have shown that the response rate of LCNEC to cisplatin-based chemotherapy is

comparable to SCLC. A retrospective series of 20 patients with advanced LCNEC (stage IIIA, 3; stage IIIB, 6; stage IV, 6; postoperative recurrence, 5) treated with platinum-based therapy showed a response rate of 50% (complete response, 1; partial response, 9).⁴²¹ Interestingly, the response rate for chemotherapy-naïve patients (64%) was better than those patients who were previously treated (17%).⁴²¹ Rossi et al.⁴⁰⁸ showed that in metastatic disease, the 12 patients who received SCLC-based chemotherapy had a significantly better median survival than the 15 patients who received common NSCLC regimens (51 versus 21 months, respectively; $p < 0.001$). Only the patients who received SCLC-based chemotherapy had a complete or partial response. In another retrospective review of 45 patients with pathologically confirmed LCNEC receiving first-line chemotherapy, response rates and outcomes were compared between those that received SCLC ($n = 11$) and NSCLC ($n = 34$) regimens. Those treated with SCLC regimens had nonsignificant higher response rates and median PFS and OS compared to patients in the NSCLC chemotherapy group (73% versus 50%, $p = 0.19$; 6.1 versus 4.9 months, respectively, $p = 0.41$; 16.5 versus 9.2 months, respectively, $p = 0.10$).⁴²²

Two single arm, multicenter phase II studies have been performed in patients with newly diagnosed stage IV LCNEC, each

of which had the response rate as the primary endpoint.^{423,424} In Japan, 44 patients were enrolled to receive cisplatin and irinotecan every 4 weeks. After careful pathologic review, 30 patients had confirmed LCNEC, whereas 10 actually were reclassified as SCLC. Comparing the two groups, the response rate for this regimen was 47% and 80% for patients with LCNEC and SCLC, respectively ($p = 0.082$). The median PFS and OS were higher in the SCLC group compared to the LCNEC group, 6.2 months versus 5.8 months ($p = 0.382$), and 17.3 months versus 12.6 months ($p = 0.047$), respectively.⁴²³ In the multicenter French study, 42 patients were enrolled to receive EP every 21 days. Here, the LCNEC pathology was confirmed in 29 patients, the response rate of which was 34%. In the analysis confined to the patients with confirmed LCNEC, the median PFS was 5 months and the median OS was 8 months, which was not significantly different than the group with other confirmed diagnoses (SCLC, 9; NSCLC, 1; and atypical carcinoid, 1).⁴²⁴

As can be seen, information regarding the treatment of LCNEC has been derived from small studies and suggests that these cancers should be treated as SCLC, although the response rates are lower and outcomes are inferior. Larger, randomized prospective studies are needed to determine the optimal treatment regimen for this disease.

43 Neoplasms of the Mediastinum

Robert B. Cameron, Patrick J. Loehrer, and Percy P. Lee

THYMIC NEOPLASMS

Incidence and Etiology

Thymic neoplasms, predominantly thymomas, constitute 30% and 15% of anterior mediastinal masses in adults and children, respectively. Surveillance, Epidemiology, and End Results (SEER) data suggest that 15 thymomas occur in every 100,000 person-years, are more common in males and Pacific Islanders, and increase in frequency into the 8th decade of life.¹ Other studies document an incidence as low as 0.15 to 0.32 per 100,000 persons. No specific etiology or risk factors are known, but a well-known association with myasthenia gravis (MG) does exist. Thymic carcinoma is a rare, aggressive thymic neoplasm that has a particularly poor prognosis and infrequently is associated with MG or other paraneoplastic syndromes.² Like thymoma, it is an epithelial tumor, but unlike thymoma it exhibits malignant cytologic features. Although it is unclear if thymoma and thymic carcinoma share a common cell of origin because molecular markers are unique for each, both most often are located in the anterior mediastinum, although other sites have been reported.³ Suster and Rosai⁴ reported on 60 patients with thymic carcinoma ranging in age from 10 to 76 years and with a slight male predominance. Nearly 70% of patients had symptoms of cough, chest pain, or superior vena cava syndrome. Extensive local invasion and distant metastases are more common than in thymomas.

Anatomy and Pathology

The thymus is an incompletely understood lymphatic organ functioning in T-lymphocyte maturation. It is composed of thymocytes, lymphocytes, and an epithelial stroma. Although lymphomas, carcinoid tumors, and germ-cell tumors all may arise within the thymus, only thymomas, thymic carcinomas, and thymolipomas arise from true thymic elements.^{5,6} The thymus develops from a paired epithelial anlage in the ventral portion of the third pharyngeal pouch and is closely associated with the developing parathyroid glands.⁷ The thymic epithelial stromal cells are likely derived from both ectodermal and endodermal components.⁸ During weeks 7 and 8 of development, the thymus elongates and descends caudally and ventromedially into the anterior mediastinum. Lymphoid cells arrive during week 9 and are separated from the perivascular spaces by a flat epithelial cell layer that creates the blood–thymus barrier. Maturation and differentiation occurs in this antigen-free environment and, during the 4th fetal month, lymphocytes begin to circulate to peripheral lymphoid tissue.⁸ Six subtypes of epithelial cells have been identified in the mature thymus.⁸ Four exist primarily in the cortical region and two in the medullary region. Type 6 cells form Hassall corpuscles that are characteristic of the thymus. These cells have an ectodermal origin and are displaced into the thymic medulla, where they hypertrophy, form tonofilaments, and finally appear as concentric cells without nuclei.^{7,8}

At maturity, the thymus gland is an irregular, lobulated organ. It attains its greatest relative weight at birth, but its absolute weight

increases to 30 to 40 g by puberty. During adulthood, it slowly involutes and is replaced by adipose tissue. Ectopic thymic tissue has been found to be widely distributed throughout the mediastinum and neck, particularly the aortopulmonary window and retrocarinal area, and often is indistinguishable from mediastinal fat.⁹ This ectopic tissue is the likely explanation for thymomas outside the anterior mediastinum and possibly for failure in some cases of a simple thymectomy to improve MG.

THYMOMA

Ninety percent of thymomas occur in the anterior mediastinum and the remainder arise in the neck or other areas of the mediastinum, including, rarely, the heart.¹⁰ The normal contour of the thymus is biconcave or flat. The diseased thymus gland displays a more convex margin. Thymomas grossly are lobulated, firm, tan-pink to gray tumors that may contain cystic spaces, calcification, or hemorrhage. They may be encapsulated, adherent to surrounding structures, or frankly invasive. Microscopically, thymomas arise from thymic epithelial cells, although thymocytes or lymphocytes may predominate histologically. True thymomas contain cytologically bland cells and should be distinguished from thymic carcinomas, which have malignant cytologic characteristics. Originally, in 1976, Rosai and Levine¹¹ proposed that thymomas be divided into three types: lymphocytic, epithelial, or mixed (lymphoepithelial). In 1985, Marino and Muller-Hermelink¹² proposed a histologic classification system determined by the thymic site of origin—that is, cortical thymomas, medullary thymomas, and mixed thymomas—which were later subdivided further.^{13,14} To unify the pathology of thymic neoplasms^{15–17} the World Health Organization (WHO) adopted a new classification system for thymic neoplasms (Table 43.1).¹⁷ WHO type A and B2 tumors are more likely to present with locoregional disease, compared with WHO type B3 and C tumors.^{18,19}

Although Suster and Moran²⁰ have proposed a simpler classification schema that separates thymic tumors into three categories of thymic carcinoma: well-differentiated (WHO types A, AB, B1, and B2), moderately differentiated (WHO type B3), and poorly differentiated (WHO type C), the full WHO classification system remains more broadly accepted.

Currently, the terms *noninvasive* and *invasive* thymoma are preferred over *benign* and *malignant* designations. Noninvasive thymomas have an intact capsule, are mobile, and are easily resected, although they can be adherent to adjacent organs. In contrast, invasive thymomas invade surrounding structures and should be removed with en bloc resection of involved structures despite a benign cytologic appearance. Metastatic disease may occur in both noninvasive and invasive thymomas and is most commonly seen as pleural implants or pulmonary nodules. Metastases to extrathoracic sites, such as the liver, brain, bone, and kidney, rarely occur.²¹

In 1981, Masaoka et al.²² developed a surgical staging system, shown in Table 43.2. An update of this series of 273 patients confirmed that both WHO histology and clinical staging were independently predictive of 20-year survival.²³ The Groupe

TABLE 43.1

World Health Organization Classification System for Thymic Epithelial Tumors

Tumor Type	Cells	Clinicopathologic Classification	Histologic Terminology
A	Spindle or oval	Benign thymoma	Medullary
B B1 B2 B3	Epithelioid or dendritic	Category I malignant thymoma	Cortical; organoid Lymphocyte rich; predominately cortical Cortical Well-differentiated thymic carcinoma
AB		Benign thymoma	Mixed
C		Category II malignant thymoma	Nonorganotypic; thymic carcinoma, epidermoid keratinizing and nonkeratinizing carcinoma, lymphoepithelioma-like carcinoma, sarcomatoid carcinoma, clear-cell carcinoma, basaloid carcinoma, mucoepidermoid carcinoma, undifferentiated carcinoma

From Patterson GA. Thymomas. *Semin Thorac Cardiovasc Surg* 1992;4:39–44 with permission.

d'Etudes des Tumeurs Thymiques (GETT) has another surgically oriented staging system.²⁴ The Istituto Nazionale Tumori system combines the Masaoka classifications in three distinct stage groupings (locally restricted, locally advanced, and systemic disease) and may better encompass all WHO subtypes.²⁵ Although the Masaoka staging system²⁶ and a tumor-node-metastasis (TNM) classification system²⁷ (Table 43.3) also have been used in staging thymic carcinoma, their utility is largely unproven.

THYMIC CARCINOMA

The histologic classification of thymic carcinoma was proposed by Levine and Rosai²⁸ and revised by Suster and Rosai.⁴ Tumors are classified broadly as low or high grade. Low-grade tumors include squamous cell carcinoma, mucoepidermoid carcinoma, and basaloid carcinoma. High-grade neoplasms include lymphoepithelioma-like carcinoma and small-cell, undifferentiated, sarcomatoid, and clear-cell carcinomas.^{4,26,29,30} Although the histologic classification of thymic carcinomas was designed to be descriptive, correlations with prognosis have been made. For instance, low-grade tumors may have

a more favorable clinical course (median survival rates of 25.4 months to more than 6.6 years) when compared with higher grade malignancies (median survival of only 11.3 months to 15.0 months).^{4,26}

Molecular profiling of rare solid tumors, such as thymic neoplasms, has taken place over the past decade.³¹ Emerging analyses do suggest that mutations in genes of the epidermal growth factor receptor (EGFR) and KIT pathways have documented a progressive increase in observed genomic aberrations from WHO subtype A thymoma to WHO subtype C thymic carcinoma.³²

Diagnosis

A meticulous history and physical examination, along with serologic and imaging studies, usually suggests the diagnosis. Although most anterior mediastinal masses are thymic malignancies, other etiologies also exist (Table 43.4). An improved pathologic analysis of image-guided percutaneous core needle biopsy specimens makes surgical biopsy rarely necessary.

Symptoms and Signs

Approximately 40% of mediastinal masses are asymptomatic and discovered incidentally on routine chest imaging.¹ The remaining 60% have symptoms related to either compression or direct invasion of adjacent mediastinal structures or to paraneoplastic syndromes. Asymptomatic patients are more likely to have benign lesions, whereas symptomatic patients more often harbor malignancies. Davis et al.³³ found that 85% of patients with a malignancy were symptomatic, but only 46% of patients with benign neoplasms had identifiable complaints. The most common symptoms are chest pain, cough, and dyspnea. Superior vena cava syndrome, Horner syndrome, hoarseness, and neurologic deficits are less common and often signal a malignancy.³³ Systemic syndromes associated with mediastinal neoplasms are shown in Tables 43.4 and 43.5.

Associated Systemic Syndromes

A myriad of associated systemic disorders may be identified in 71% of patients with thymomas, including autoimmune diseases (MG, systemic lupus erythematosus, polymyositis, myocarditis, Sjögren syndrome, ulcerative colitis, Hashimoto thyroiditis, rheumatoid arthritis, sarcoidosis, and scleroderma), endocrine disorders (hyperthyroidism, hyperparathyroidism, stiff-person syndrome, Addison disease, and panhypopituitarism), blood disorders (red cell aplasia, hypogammaglobulinemia, T-cell deficiency syndrome, erythrocytosis, pancytopenia, megakaryocytopenia, T-cell lymphocytosis, and pernicious anemia), neuromuscular syndromes (myotonic dystrophy,

TABLE 43.2

Thymoma Staging System of Masaoka

Stage	Description	5-/10-year Survival (%)
I	Macroscopically completely encapsulated and microscopically no capsular invasion	96/67
II	1. Macroscopic invasion into surrounding fatty tissue or mediastinal pleura, or 2. Microscopic invasion into capsule	86/60
III	Macroscopic invasion into neighboring organs (pericardium, great vessels, lung)	69/58
IV	a. Pleural or pericardial dissemination, or b. Lymphogenous or hematogenous metastasis	50/0

TABLE 43.3

Istituto Nazionale Tumori Tumor-Node-Metastasis (TNM)-Based Staging System

TNM	Description
T1	No capsular invasion
T2	Microscopic invasion into the capsule, or extracapsular involvement limited to the surrounding fatty tissue or normal thymus
T3	Direct invasion into the mediastinal pleura and/or anterior pericardium
T4	Direct invasion into neighboring organs, such as the sternum, great vessels, and lungs; implants to the mediastinal pleura or pericardium, only if anterior to phrenic nerves
N0	No lymph nodes metastasis
N1	Metastasis to anterior mediastinal lymph nodes
N2	Metastasis to intrathoracic lymph nodes other than anterior mediastinal
N3	Metastasis to prescalene or supraclavicular nodes
M0	No hematogenous metastasis
M1a	Implants to the pericardium or mediastinal pleura beyond the sites defined in the T4 category
M1b	Hematogenous metastasis to other sites, or involvement of lymph nodal stations other than those described in the N categories
Stage Grouping	Description
I	Locally restricted disease T1–2 N0 M0
II	Locally advanced disease T3–4 N0 M0 Any T N1–2 M0
III	Systemic Any T N3 M0 Any T any N M1
Classification	Description of Residual Disease
R0	No residual tumor
R1	Microscopic residual tumor
R2a	Local macroscopic residual tumor after reductive resection (more than 80% of the tumor)
R2b	Other features of residual tumor

Adapted from Shimizu J, Hayashi Y, Monita K, et al. Primary thymic carcinoma: a clinicopathological and immunohistochemical study. *J Surg Oncol* 1994;56:159–164.

TABLE 43.4

Systemic Syndromes Associated with Mediastinal Neoplasms

Tumor	Syndrome
Thymoma	Acute pericarditis, Addison disease, agranulocytosis, alopecia areata, Cushing syndrome, hemolytic anemia, hypogammaglobulinemia, limbic encephalopathy, myasthenia gravis, myocarditis, nephrotic syndrome, panhypopituitarism, pernicious anemia, polymyositis, pure red cell aplasia, rheumatoid arthritis, sarcoidosis, scleroderma, sensorimotor radiculopathy, stiff-person syndrome, thyroiditis, ulcerative colitis
Hodgkin lymphoma	Alcohol-induced pain, Pel-Ebstein fever
Neurofibroma	von Recklinghausen disease, osteoarthritis
Thymic carcinoid	Multiple endocrine neoplasia
Neuroblastoma	Opsomyoclonus, erythrocyte abnormalities
Neurilemoma	Peptic ulcer

TABLE 43.5

Systemic Manifestations of Hormone Production by Mediastinal Neoplasms

Symptoms	Hormone	Tumor
Hypertension	Catecholamines	Pheochromocytoma, chemodectoma, neuroblastoma, ganglioneuroma
Hypercalcemia	Parathyroid hormone	Parathyroid adenoma
Thyrotoxicosis	Thyroxine	Thyroid
Cushing syndrome	ACTH	Carcinoid tumor
Gynecomastia	HCG	Germ cell tumor
Hypoglycemia	? Insulin	Mesenchymal tumors
Diarrhea	VIP	Ganglioneuroma, neuroblastoma, neurofibroma

ACTH, adrenocorticotropic hormone; HCG, human chorionic gonadotropin; VIP, vasoactive intestinal polypeptide.

myositis, and Eaton-Lambert syndrome), as well as other disorders (hypertrophic osteoarthropathy, nephrotic syndrome, minimal change nephropathy, pemphigus, and chronic mucocutaneous candidiasis).³⁴ Symptoms of one or more of these disorders may lead to the original discovery of the mediastinal tumor.

Myasthenia Gravis

MG is the most common autoimmune disorder associated with thymoma, occurring in 30% to 50% of patients.³⁵ Younger women and older men usually are affected, with a female-to-male ratio of 2:1. Myasthenia is a disorder of neuromuscular transmission. The temporal association is variable and a prolonged interval between the diagnosis of MG and the development of a visible thymic tumor can occur.³⁶ Symptoms (e.g., diplopia, ptosis, dysphagia, fatigue) begin insidiously and result from the production of antibodies to the postsynaptic nicotinic acetylcholine receptor at the myoneural junction. Ocular symptoms are the most frequent initial complaint, eventually progressing to generalized weakness in 80% of cases. The role of the thymus in MG remains unclear, but autosensitization of T lymphocytes to acetylcholine-receptor proteins or an unknown action of thymic hormones remains possible.³⁷ The altered microenvironment may adversely impact the output of T-regulatory (Treg) cells, thus altering autoimmune homeostasis.³⁸ Pathologic thymic changes are noted in 70% of MG patients, with lymphoid hyperplasia predominating and thymomas seen only in 15% of patients.³⁷

The treatment of MG involves the use of anticholinesterase mimetic agents (i.e., pyridostigmine bromide [Mestinon]). In severe cases, plasmapheresis may be required to remove high antibody titers. Thymectomy has become an increasingly accepted procedure in the treatment of MG, although the indications, timing, and surgical approach remain controversial.³⁹ Some improvement in MG symptoms frequently occurs after a thymectomy, but complete remission rates vary from 7% to 63%.³⁹ Patients with thymomas do not respond as well to a thymectomy as MG patients without thymomas. Age 54 years and older and a symptom duration of less than 1 year are associated with poor outcomes⁴⁰; however, MG does not necessarily portend a poor outcome.⁴¹

Red Cell Aplasia

Pure red cell aplasia, an autoimmune disorder, occurs in 5% of patients with thymomas.⁴² Of patients with red cell aplasia, 30% to 50% have associated thymomas. Affected patients are older than 40 years of age in 96% of cases. A bone marrow examination reveals an absence of erythroid precursors and, in 30% of cases, a poorly understood associated decrease in platelet and leukocyte numbers. A thymectomy has produced remission in up to 38% of

patients. For patients with recurrent disease, octreotide and prednisone were effective in case reports.^{42,43}

Hypogammaglobulinemia

Hypogammaglobulinemia is seen in 5% to 10% of patients with thymoma (Good syndrome), and 10% of patients with hypogammaglobulinemia have been shown to have thymoma. Recurrent sinusitis is a common associated symptom in such patients. Defects in both cellular and humoral immunity have been described, and many patients also have red cell hypoplasia.⁴⁴ Thymectomy has not proven beneficial in this disorder.

Radiographic Imaging Studies

Imaging studies initially localize mediastinal neoplasms.⁴⁵ The posteroanterior and lateral chest radiographs define the location, size, density, and calcification of a mass, which helps focus the initial diagnostic testing; however, an intravenous contrast-enhanced spiral computed tomography (CT) scan remains the best imaging modality to accurately assess the nature of the lesion (cystic versus solid), detect fat and calcium, determine the relationship to surrounding anatomic structures, and, in some instances, predict invasiveness of the tumors.^{46,47}

Recent advances in electrocardiogram-gating and real-time magnetic resonance imaging (MRI) and angiography have dramatically increased the usefulness of this modality in the evaluation of mediastinal masses. Not only is it superior to CT in defining vascular involvement, but an MRI scan can also detect subtle differences in tumor contour, capsule clarity, and intratumoral signal (low), which correlate with the WHO classification of thymomas.⁴⁸

Recently, the usefulness of positron emission tomography (PET) scans in the evaluation of thymic tumors has expanded significantly. In a study of 51 patients, Benveniste et al. suggested that 18-fluorodeoxyglucose (18F-FDG) uptake by PET/CT scans was higher in thymic carcinomas than thymomas. Additionally, higher focal 18F-FDG uptake correlated with B3 thymomas, and greater 18F-FDG avid tumor volume predicted higher stage tumors.⁴⁹ In a contemporary study of 47 patients, Lococo et al. demonstrated that maximum standardized uptake values (SUV_{max}) and SUV_{max}/tumor size index, as determined by PET/CT, not only distinguished thymomas from thymic carcinomas, but also both parameters correlated with WHO malignancy grade and SUV_{max} predicted Masaoka stage.⁵⁰ On serial PET/CT imaging, decreased 18F-FDG uptake in 56 patients with stage III/IV thymic epithelial malignancies treated after only 6 weeks of chemotherapy was shown by Thomas et al.⁵¹ to correlate with longer progression-free survival (11.5 versus 4.6 months; $p = 0.044$) and a trend toward longer overall survival (31.8 versus 18.4 months; $p = 0.14$).

Serology and Chemistry

Many germ-cell neoplasms release chemical markers into the serum that may be measured to confirm a diagnosis, evaluate the response to therapy, and monitor for tumor recurrence. Lactate dehydrogenase, α -fetoprotein (AFP), and human chorionic gonadotropin- β (β -hCG) are common tumor markers that should be obtained in male patients with anterior mediastinal masses. Also, adrenocorticotropic hormone, thyroid hormone, and parathormone may help differentiate certain mediastinal masses (see Table 43.4).

Invasive Diagnostic Tests

An accurate histologic diagnosis is essential for appropriate treatment of nearly all mediastinal neoplasms. Although some patients may still require open surgical biopsies, CT- or ultrasound-guided percutaneous needle biopsy is now standard in the initial evaluation of mediastinal masses.¹⁰ Although fine-needle specimens may distinguish carcinomas from benign pathology, core biopsies are necessary for most mediastinal neoplasms, especially lymphoma and thymoma. Recent series report diagnostic yields for percutaneous needle biopsy in excess of 90%.⁵² Complications include simple pneumothorax (25%), hemoptysis (7% to 15%), and pneumothorax, requiring chest tube placement (5%).⁵² In some circumstances, fine-needle aspiration of posterior and middle mediastinal tumors can be performed endoscopically using transesophageal ultrasonography.⁵³

Surgical procedures occasionally are still required in the diagnosis of mediastinal tumors. A mediastinoscopy is a relatively simple procedure with a diagnostic accuracy of more than 90% for biopsies of the upper middle and, in some surgeons' hands, the anterior and posterior mediastinum.⁵⁴ Anterior parasternal mediastinotomy (Chamberlain procedure) yields a diagnosis in 95% of anterior mediastinal masses and may be accomplished under local anesthesia.^{54,55} A thoracoscopy is a minimally invasive procedure that provides a diagnostic accuracy of nearly 100% in most areas of the mediastinum.⁵⁴ Currently, thoracotomy rarely is necessary solely as a diagnostic procedure.

Management by Stage

Thymomas, albeit slow growing, should be considered potentially malignant neoplasms. Surgery, radiation, and chemotherapy all may play a role in their management.^{41,56} Few prospective, well-designed clinical trials in the management of thymomas have been conducted, particularly evaluating the role of surgery and radiotherapy; however, the newly formed International Thymic Malignancy Interest Group is planning cohort studies to help guide diagnostic and therapeutic interventions.⁵⁷

Masaoka Stage I/II Thymoma

Complete surgical resection is the mainstay of therapy for stage I/II thymomas and is the most important predictor of long-term survival.⁵⁸⁻⁶¹ Although a median sternotomy with a vertical or submammary skin incision is most commonly used, bilateral anterolateral thoracotomies with transverse sternotomy, or the *clam-shell procedure*, is useful with advanced or laterally displaced large tumors. Recently, the use of minimally invasive surgery in stage I and II thymomas has expanded dramatically. One study comparing 76 thorascopic thymectomies to 44 transsternal resections reported a shorter hospital stay with the thorascopies.⁶² Similarly, two reports of robotic-assisted surgery, including a multicenter European study, were associated with less blood loss, fewer complications, and a shorter hospital stay, as well as similar operative times and short-term outcomes compared to sternotomies.^{63,64} Although randomized, prospective clinical trials are still lacking, it is highly likely that minimally invasive surgery in the hands of experienced

surgeons can produce identical oncologic outcomes with less morbidity than open surgery, as has been shown in other thoracic tumors, such as lung and esophageal cancers.

During any surgery, a careful assessment of areas of possible invasion and adherence should be made. Extended total thymectomy, including all tissue anterior to the pericardium from the diaphragm to the neck and laterally from one phrenic nerve to the other, including en bloc pericardium, phrenic nerve, chest wall, lung, and diaphragmatic resection (with reconstruction) in up to two-thirds of cases in order to achieve an R0 resection is recommended in all good performance status patients.^{41,58-60} Operative mortality is less than 3% in experienced centers.⁴¹

In the past, ionizing radiation has been used to treat various stages of thymomas. Furthermore, modern imaging, three-dimensional treatment planning, and delivery techniques have allowed thoracic radiotherapy to be prescribed in a safer fashion than noted in the past century. Radiation therapy is delivered in doses ranging from 30 to 60 Gy in 1.8- to 2.0-Gy fractions for 3 to 6 weeks.^{58,65,66} There are suggestions of a dose-response relationship with local control in some patients, albeit from retrospective data, although it is not clear that doses exceeding 60 Gy offer any consistent advantage^{67,68}; however, completely resected and microscopic residual disease can be well controlled with only 40 to 45 Gy.^{61,69} Emerging data suggest that certain histologic subtypes (WHO type B1 and B2) are more likely to respond to radiotherapy compared to others subtypes (WHO type B3), suggesting that the response is limited to the lymphocytic and not the epithelial cell component of the tumors.^{41,70-72} Gating techniques to minimize respiratory variation and intensity-modulated radiation therapy are new techniques that can minimize the dose heterogeneity, increase total dose and fraction size, and minimize toxicity.^{69,73,75}

Masaoka Stage III/IV Thymoma

The role of subtotal surgical resection, or *debulking surgery*, in stage III and IV disease remains highly controversial.⁷⁶ Several studies have documented improved 5-year survival rates after subtotal resection compared to a biopsy alone.^{58,61} Another study suggested no survival advantage to *debulking surgery* followed by radiation when compared with radiation alone, and a more recent report reached the opposite conclusion.⁷⁶ The use of surgery in recurrent disease remains to be defined.

Radiation therapy may be beneficial in selected patients with locally advanced disease.^{61,65,67,77} Large variations in the amount of tumor treated, radiation delivered, and tumor biology, however, make interpretation of these results difficult.^{61,67,78,79}

Cytotoxic chemotherapy has been used with increasing frequency in the treatment of invasive thymomas.⁸⁰ Both single-agent and combination therapy have demonstrated activity in the adjuvant and neoadjuvant settings. Doxorubicin, cisplatin, ifosfamide, corticosteroids, and cyclophosphamide all have been used as single-agent therapies.⁸¹ The most active agents are cisplatin, doxorubicin, ifosfamide, and corticosteroids; however, only a few single agents, such as cisplatin, ifosfamide, pemetrexed, gefitinib, and imatinib, have undergone formal phase II trials.

A number of molecular targets have been identified in thymic tissue.⁸³ Overexpression of the EGFR has been found in more than two thirds of patients, mostly WHO B2 and 3 subtypes.⁸⁴⁻⁸⁶ The overexpression of *c-kit* is common in thymic carcinoma, although *c-kit* mutations are less frequent.^{85,87,88}

Thymic Carcinoma

The optimal treatment of thymic carcinoma remains undefined, but currently, a multimodality approach, including surgical resection, postoperative radiation, and chemotherapy, is recommended.⁸⁹ Initial surgical resection followed by radiation has been used in most studies.^{4,26,27,29,90} Complete resection should be attempted, but often is not possible.^{26,91} One analysis noted a 9.5-month median survival after resection and postoperative photon-beam radiation therapy,⁹⁰

with a trend toward improved survival in other studies.^{4,26,29} Chemotherapy with cisplatin-based regimens similar to those used with thymomas have produced variable responses in a small number of patients.^{4,26,29} Combinations of doxorubicin, cyclophosphamide, and cisplatin also have generated partial responses, as has the combination of 5-fluorouracil and leucovorin in recurrent disease. Use of neoadjuvant chemotherapy has been reported in a small number of patients.^{89,92}

Results of Treatment

Thymoma

In nearly 700 patients in the SEER database treated between 1973 and 1998, advanced disease was associated with decreasing survival.⁴² According to various retrospective series, the 5- and 10-year survival rates for stage I, III, and IV tumors are reported to be 89% to 95% and 78% to 90%; 70% to 80% and 21% to 80%; and 50% to 60% and 30% to 40%, respectively.^{58,93} Ten-year disease-free survival rates of 74%, 71%, 50%, and 29% also have been reported for stage I, II, III, and IV disease, respectively.⁵⁸ Long-term results from an experienced Indiana University group has yielded a 66% 1-year overall survival.⁴¹ Although Maggi et al.⁵⁸ reported a 10% overall recurrence rate in 241 patients, less than 5% of noninvasive thymomas and 20% of invasive thymomas were noted to recur. A large Japanese multi-institutional experience with 1,320 patients reported 5-year survival rates of 100%, 98.4%, 88.7%, 70.6%, and 52.8% for Masaoka stages I, II, III, IVa, and IVb, respectively.⁵⁹ Although MG once was considered an adverse prognostic factor, this is no longer the case because of improved perioperative care, and in fact, MG actually may be associated with an improved survival owing to earlier tumor detection.^{41,94} Complete surgical resection of thymomas is associated with an 82% overall 7-year survival rate, whereas survival with incomplete resection is 71%, and with biopsy is only 26%.⁵⁸ Survival after a complete tumor resection has been similar in patients with noninvasive and invasive thymomas in several studies.^{59,60} Patients with MG and thymoma have a 56% to 78% 10-year survival rate and a 3% recurrence rate with 4.8% (1.7% since 1980) operative mortality after an extended thymectomy.^{61,95} Rarely, a syndrome of myasthenia crisis may occur following surgery and may lead to increased perioperative morbidity.⁹⁵

Although the data on whether outcomes are related to WHO subtype is inconclusive,^{41,71,72} it may be that when coupled with other factors such as completeness of resection, the WHO subtype may be prognostic in some patients.⁹⁶

For example, in stage I thymomas, adjuvant radiotherapy has been administered but has not improved on the excellent results with surgery alone (more than 80% 10-year survival rate).^{58,61} In stage II and III invasive disease, adjuvant radiation can decrease recurrence rates after complete surgical resection from 28% to 5%.⁶⁷ In addition, Pollack et al.⁶⁵ reported an increase in 5-year disease-free survival for stage II to IVa from 18% to 62% with the addition of adjuvant radiation, despite a 50% infield relapse rate in patients recurring with prior radiation. Stage II patients with cortical tumors^{97,98} and invasion of pleura or the pericardium are most likely to benefit from postoperative radiation.⁷⁷ Preoperative radiotherapy for extensive tumors has been reported in limited studies that suggest a decreased tumor burden and potential for tumor seeding at the time of surgery, although multivariate analyses suggested that chemotherapy may have played a role.^{58,61} Data suggest that not all Masaoka stage II patients may necessarily require postoperative radiotherapy (PORT).^{56,101} Indeed, a review of SEER registry data from 1975 to 2003 demonstrated a worse cancer-specific survival for patients with resected, localized thymoma who received PORT compared to those without (91% versus 98%; $p = 0.03$). For patients with regional disease, PORT had a slight but nonstatistically significant difference (91% versus 86%; $p = 0.12$).¹⁰² The absence of statistically significant therapeutic efficacy for PORT, despite

the suggestion of a lower local recurrence rate (i.e., 0% versus 8%) again has been confirmed in two recent studies.¹⁰²

Masaoka Stage III/IV Thymoma

The role of subtotal surgical resection or *debulking* surgery in stage III and IV disease remains highly controversial.⁷⁶ Several studies have documented 5-year survival rates from 60% to 75% after subtotal resection and 24% to 40% after biopsy alone.^{58,61} Although one study did suggest no survival advantage to debulking followed by radiation when compared with radiation alone, another more recent experience reached the opposite conclusion.⁷⁶ The use of surgery in recurrent disease remains to be defined. Maggi et al.⁵⁸ reported a 71% 5-year survival rate in 12 surgery patients and a 41% survival rate in 11 patients treated with radiation and chemotherapy alone. Prolonged tumor-free survival also was reported by Kirschner⁷⁴ in 23 patients. However, Urgesi et al.⁷⁸ noted a 74% 5-year survival rate in 11 patients undergoing surgery and radiation, compared with 65% in 10 patients treated with radiation alone (not statistically different). In 71 patients with thymoma (WHO types A and B3) with stage I to IVA disease, 53 (75.3%) patients are alive and free of disease, with 6 additional patients alive with disease with a mean follow-up of 66 months.⁴¹

Radiation therapy may be beneficial in selected patients with locally advanced disease.^{61,63,65,68,77} Radiotherapy after incomplete surgical resection produces local control rates of 35% to 74% and 5-year survival rates ranging from 50% to 70% for stage III and 20% to 50% for stage IVa tumors.^{61,66,67} In addition, Ciernik et al.⁶⁷ and others⁷⁸ have reported similar survival rates (87% 5-year and 70% 7-year) in patients treated with radiation alone compared with partial surgical resection and adjuvant radiation in small numbers of stage III and IV patients and patients with intrathoracic recurrences. Weksler et al.¹⁰⁵ reviewed SEER data on 322 patients with stage III thymoma who received postoperative adjuvant radiation and found that by multivariate analysis, disease-specific survival was improved ($p = 0.049$) but overall survival was not. However, large variations in the amount of tumor treated, radiation delivered, and tumor biology in particular make interpretation of these results difficult at best.^{61,67,78,79}

Cytotoxic chemotherapy has been used with increasing frequency in the treatment of invasive thymomas.⁸⁰ Both single-agent and combination therapy have demonstrated activity in the adjuvant and neoadjuvant settings. The most commonly used active agents are cisplatin and doxorubicin; however, only a few single agents, such as cisplatin, ifosfamide, pemetrexed, gefitinib, and imatinib, have undergone formal phase II trials.⁸⁰ Cisplatin at doses of 100 mg/m² has produced complete responses lasting up to 30 months, but lower doses (50 mg/m²) have associated response rates of only 10%.⁸¹ In 13 earlier patients, ifosfamide (with mesna) was given at a single dose of 7.5 g/m² or as a continuous infusion of 1.5 g/m² per day for 5 days every 3 weeks and resulted in five (38.7%) complete and one (7.7%) partial responses.¹⁰⁶ Varying regimens of corticosteroids have shown effectiveness in the treatment of all histologic subtypes of thymoma (with and without myasthenia), with a 77% overall response rate in limited numbers of patients.^{82,107,108} Corticosteroids also have been effective for patients unsuccessful with chemotherapy⁸²; however, the actual impact may only be on the lymphocytic and not the malignant epithelial component of the tumor.

Combination chemotherapy regimens have shown higher response rates and have been used in both neoadjuvant and metastatic settings in the treatment of advanced invasive, metastatic, and recurrent thymoma. Cisplatin plus doxorubicin-containing regimens appear to be the most active. Fornasiero et al.⁹³ reported a 43% complete and 91.8% overall response rate with a median survival of 15 months in 37 previously untreated patients with stage III or IV invasive thymoma treated with monthly (median, 5 months) cisplatin, 50 mg/m² on day 1; doxorubicin, 40 mg/m² on day 1; vincristine, 0.6 mg/m² on day 3; and cyclophosphamide, 700 mg/m² on day 4. Loehrer et al.¹⁰⁹ documented 10% complete and 50% overall response rates with a median survival of 37.7 months in 29 patients

with metastatic or locally progressive recurrent thymoma treated with cisplatin, 50 mg/m²; doxorubicin, 50 mg/m²; and cyclophosphamide, 500 mg/m², given every 3 weeks for a maximum of eight cycles after radiotherapy. Park et al.¹¹⁰ retrospectively described 35% complete and 64% overall response rates with a median survival of 67 months in responding and 17 months in nonresponding patients in 17 patients with invasive stage II and IV thymoma initially treated after relapse with cyclophosphamide, doxorubicin, and cisplatin, with or without prednisone. The European Organisation for Research and Treatment of Cancer noted 31% complete and 56% overall response rates with a median survival of 4.3 years in a small study of 16 patients with advanced thymoma treated with cisplatin and etoposide.¹¹¹ The addition of ifosfamide to cisplatin and etoposide had a lower than anticipated response rate (approximately 32%) in patients with thymoma and thymic carcinoma in a prospective Eastern Cooperative Oncology Group (ECOG) trial of 28 patients.⁹⁰

ECOG also conducted a prospective trial in patients with thymoma (n = 25) and thymic carcinoma (n = 21) who were treated with carboplatin plus paclitaxel, with a 33% objective response rate for the former group and 24% for the latter.¹¹² In total, these data suggest higher objective response rates achieved with anthracycline-based regimens.

Combined Modality Approaches

The use of neoadjuvant (induction or preoperative) chemotherapy has been evaluated as part of a multimodality approach to stage III and IV thymoma. Six combined reports document 31% complete and 89% overall response rates in 61 total patients treated with a variety of neoadjuvant chemotherapy regimens (80% cisplatin based).¹¹³ Twenty-two patients (36%) underwent surgery, with 11 (18%) achieving a complete resection (all treated with cisplatin). Nineteen patients were treated with radiotherapy, but only five patients had disease-free survivals exceeding 5 years. Rea et al.¹¹⁴ reported 43% complete and 100% overall response rates with median and 3-year survival rates of 66 months and 70%, respectively, in 16 stage III and IVa patients treated initially with cisplatin, doxorubicin, vincristine, and cyclophosphamide, followed by surgery. At surgery, 69% were completely resected and the other 31% received postoperative radiation. A recent report from the Amsterdam team noted a 50% objective response rate using the Response Evaluation Criteria in Solid Tumors (RECIST) criteria in 16 patients with locally advanced tumors.¹¹¹ Macchiarini et al.¹¹⁵ reported similar findings. Recently, the Japan Clinical Oncology Group reported a phase II trial (JCOG 9606) that treated 23 patients with unresectable stage III thymoma with 9 weeks of chemotherapy, including cisplatin 25 mg/m² on weeks 1 through 9; vincristine 1 mg/m² on weeks 1, 2, 4, 6, and 8; and doxorubicin 40 mg/m² and etoposide 80 mg/m² CODE on days 1 through 3 of weeks 1, 3, 5, 7, and 9.¹¹⁶ Twelve patients (57%) completed the planned 9-week therapy without mortality. Of 21 eligible patients, zero, 13 (62%), and 7 achieved a complete response, partial response, and stable disease, respectively. Subsequently, 13 (62%) underwent thoracotomies, with 9 (39%) undergoing complete R0 resection and postoperative radiotherapy (48 or 60 Gy in completely or incompletely resected disease, respectively). Progression-free survival at 2 and 5 years was 80% and 43%, respectively, and overall survival at 5 and 8 years was 85% and 69%, respectively. Survival was not improved by surgical resection. Finally, 25% complete (3 patients) and 92% overall response rates (11 patients) with an 83% 7-year disease-free survival rate (10 patients) were reported in only 12 patients at the M.D. Anderson Cancer Center who received cisplatin, doxorubicin, cyclophosphamide, and prednisone induction chemotherapy followed by surgical resection (80% complete) and adjuvant radiotherapy for locally advanced (unresectable) thymoma.¹¹⁷ The degree of chemotherapy-induced tumor necrosis correlated with Ki-67 expression.

Using two to four cycles of cisplatin, doxorubicin, and cyclophosphamide chemotherapy and sequential radiotherapy (54 Gy), a multi-institutional prospective trial demonstrated a 22% complete and 70% overall response rate. Also noted was a median survival of

93 months and a Kaplan-Meier 5-year failure-free survival rate of 54.3% in 23 patients with stage III (22/23) unresectable thymoma (GETT stage IIIA/IIIB), stage IV (1/23) thymoma, and thymic carcinoma (2/23).¹¹⁸ Approximately 25% of these patients also had MG. Although these results compare favorably with those obtained with neoadjuvant therapy followed by surgical resection and radiation, further data are required. In summary, postoperative (adjuvant) chemotherapy cannot be recommended based on these data.⁴¹

Molecularly Targeted Therapy

Molecular profiles of thymic epithelial malignancies have shown some differences between thymoma and thymic carcinoma, but overall, clinically relevant findings are inconsistent.¹¹⁹ For example, EGFR often is overexpressed in thymic epithelial malignancies, but activating mutations are rare.¹¹⁹⁻¹²⁵ However, with rare case reports of radiographic responses to cetuximab in advanced thymoma,^{122,123} a combined-modality phase II trial in locally advanced or recurrent but resectable stage II and IVA patients is now underway (NCT01025089). Other trials with gefitinib as a single agent and erlotinib plus bevacizumab in previously treated patients had minimal activity. Tyrosine-kinase inhibitors also have been investigated. Despite an initial reported brief thymic carcinoma response to imatinib, two subsequent trials in 20 thymic carcinoma patients failed to find any activity.¹²⁴ Some antitumor activity has been reported in thymic malignancies with dasatinib, an oral, multitargeted kinase inhibitor of *Bcr-Abl* and *src* kinases; ephrin receptor kinases; platelet-derived growth factor receptor; c-kit; and with sunitinib, another multikinase inhibitor.¹²⁵ A phase II sunitinib study in patients with previously treated thymic malignancies is underway (NCT01621568). The histone deacetylase inhibitor, belinostat, has demonstrated a promising 65% control rate (response rate = 5%) in a 41 patient phase II study and currently is being tested in combination with first-line chemotherapy (NCT01100944).¹²⁶ Thymus-specific targeted therapy, specifically with somatostatin analogs, has shown promise in small clinical trials.⁸⁴ Although the mechanism of action is unclear, inhibition of the insulinlike growth factor or EGFR pathways are possible. Response rates were seen in more than one third (37%) of patients with tumors that were resistant to cytotoxic chemotherapy with octreotide plus prednisone.⁸⁴ The median and progression-free survival of 15 months and 14 months, respectively, is encouraging. In thymoma patients with positive radionuclide octreotide scans, 12.5% of the patients demonstrated a partial response to octreotide alone, which increased to 32% with the addition of prednisone.⁸⁴

Thymic Carcinoma

The prognosis of thymic carcinoma is poor because of early metastatic involvement of mediastinal, cervical, and axillary lymph nodes; the pleura; the lungs; the brain; bone; and the liver.^{4,92,128} The overall survival rate at 5 years is approximately 35%.^{4,26} The recently reported Japanese experience noted a 88.2%, 51.7%, and 37.6% 5-year survival in patients with stages I/II, III, and IV, respectively.⁵⁹ Improved survival has been correlated with encapsulated tumors, lobular growth pattern, low mitotic activity, early-stage tumors, low histologic grade, lymphoepithelioma-like histology, and complete surgical resection.^{4,87,91,108} Furthermore, in multivariate analysis of SEER data, Masaoka stage and ethnicity emerge as significant determinants of survival in thymic carcinoma patients undergoing complete resection.¹⁰⁸ In addition, patients with stage IVa disease appear to benefit more from treatment than those with more disseminated disease (stage IVb).⁸⁸

THYMIC CARCINOID

Thymic carcinoid tumors are rare, male-predominant tumors that are associated with Cushing syndrome, multiple endocrine neoplasia, and, rarely, carcinoid syndrome.¹²⁹⁻¹³⁶ Thymic neuroendocrine

tumors may be differentiated from similar pulmonary tumors by their different PAX 8 (32% versus 8%) and thyroid transcription factor 1 (TTF-1) (8% versus 76%) staining characteristics.¹³⁶ Complete surgical resection with adjuvant radiotherapy for incompletely resected tumors is recommended.^{130–133} Chemotherapy rarely has been used.^{137,138} Although a 5-year survival rate of 60% has been reported with complete surgical resection,¹³¹ long-term survival is generally poor and is correlated with the extent of disease and the degree of tumor differentiation.¹³⁹

THYMOLIPOMA

Thymolipomas are rare soft, lobulated, and encapsulated benign neoplasms of the anterior mediastinum, which are composed of mature adipose and thymic tissue and account for 1% to 5% of thymic neoplasms.¹⁴⁰ They are also known as *lipothymomas*, *mediastinal lipomas with thymic remnants*, and *thymolipomatous hamartomas*.^{140,141} A review of 27 patients noted an equal gender distribution and a mean age of 27 years.¹⁴¹ Approximately 50% of patients presented with symptoms of vague chest pain, dyspnea, and tachypnea. Others have reported an association with MG, red cell aplasia, hypogammaglobulinemia, lichen planus, and Graves disease in adult patients, but less often than with thymoma.^{140,142–144} They often attain a large size before becoming symptomatic¹⁴⁵ and frequently are found in the anterior–inferior mediastinum “draped along the diaphragm” and connected to the thymus by a small pedicle, conforming to the shape of the cardiac and mediastinal structures.¹⁴¹ Microscopically, more than 50% consists of adipose tissue with the remainder being thymic tissue, often with calcified Hassall corpuscles.¹⁴¹ Malignant transformation does not occur. Treatment is a complete resection.¹⁴⁵

GERM CELL TUMORS

Incidence and Etiology

Mediastinal germ-cell (MGC) neoplasms account for only 2% to 5% of all germinal tumors but constitute 50% to 70% of all extragonadal tumors.¹⁴⁶ Most commonly seen in the anterior mediastinum, they account for 10% to 15% of all primary mediastinal tumors. MGC tumors are most commonly diagnosed in the third decade of life, but patients as old as 60 years of age have been reported. The incidence is equal in all ethnicities. Benign teratomas are the most common MGC tumor, accounting for 70% of the MGC tumors in children and 60% of those in adults. They can occur at any age, but most commonly occur between 20 and 40 years of age. Primary pure mediastinal seminomas account for roughly 35% of malignant MGC tumors and principally arise in men aged 20 to 40 years.¹⁴⁷ Although benign germ-cell tumors have no sex predilection, 90% of adult malignant germ-cell tumors occur in men, with a mean age of 29. Both benign and malignant extragonadal pediatric germ-cell tumors occur with equal sex distribution.

Anatomy and Pathology

Extragonadal germ-cell tumors arise along the body's midline from the cranium (pineal gland) to the presacral area, corresponding to the embryologic urogenital ridge, presumably from aberrantly migrated germ cells.¹⁴⁶ MGC tumors are broadly classified as benign or malignant. Benign tumors include mature teratomas and mixed teratomas with an immature component of less than 50%. Malignant germ-cell tumors are divided into seminomas (dysgerminomas) and nonseminomatous tumors. In addition, MGC tumors have a propensity to develop a component of non-germ-cell malignancy (e.g., rhabdomyosarcoma, adenocarcinoma, permeative neuroectodermal tumor), which can become the predominant histology.

Teratomas

Teratomas contain elements from all three germ-cell layers, with a predominance of the ectodermal component in most tumors, including the skin, hair, sweat glands, sebaceous glands, and teeth. The mesoderm is represented by fat, smooth muscle, bone, and cartilage. Respiratory and intestinal epithelium are often seen as the endodermal component. Teratomas may be solid or cystic in appearance and are often referred to as *dermoid cysts* if unilocular. The majority of mediastinal teratomas are composed of mature ectodermal, mesodermal, and endodermal elements and exhibit a benign course. Immature teratomas, which phenotypically appear as malignant ectodermal, mesodermal, or endodermal tumors, behave aggressively and generally are not responsive to therapy.

Seminomas

Seminomas uncommonly may exist in a pure form, but any elevation of serum AFP levels indicates the presence of at least a small element of nonseminomatous tumor.

Nonseminomatous Tumors

Mediastinal nonseminomatous germ-cell tumors are most commonly found in the anterior mediastinum and appear grossly as invasive, lobulated masses with a thin capsule. Nonseminomatous tumors include embryonal carcinomas, choriocarcinomas, yolk sac tumors, and immature teratomas.¹⁴⁸ They may occur in pure form, but in approximately one third of cases, multiple cell types are present. Other malignant components, including adenocarcinoma, squamous cell carcinoma, small cell undifferentiated carcinoma, neuroblastoma, rhabdomyosarcoma, or other sarcomas, may be present or even predominate, as usually occurs in immature teratomas.¹⁴⁶ Other synchronous hematologic malignancies, such as acute myeloid leukemia, acute nonlymphocytic leukemia, erythroleukemia, myelodysplastic syndrome, malignant histiocytosis, thrombocytosis, and most interestingly, acute megakaryocytic leukemia, also have been reported and may antedate the discovery of the germ-cell tumor. Karyotypic abnormalities, particularly the 47XXY pattern of Klinefelter syndrome, have been found in up to 20% of patients.¹⁴⁹ Of patients, 85% to 95% have systemic disease at the time of diagnosis. Common metastatic sites include the lungs, pleura, lymph nodes, the liver, and, less commonly, bone.¹⁴⁷

Diagnosis

Many patients with benign tumors, including 50% of teratomas, are asymptomatic; however, 90% to 100% of patients with malignant tumors have symptoms of chest pain, dyspnea, cough, fever, or complaints from compression or invasion of adjacent mediastinal structures.^{149,150} Seminomas typically grow slowly and metastasize later than their nonseminomatous counterparts, and they may reach a large size by the time of diagnosis with 20% to 30% remaining asymptomatic until discovered.¹⁴⁷ Symptoms are usually related to their effects on the surrounding mediastinal structures. Pulmonary and other intrathoracic metastases are present in 60% to 70% of patients, whereas extrathoracic metastases usually involve bone.¹⁴⁷

The determination of serum tumor markers is important in the diagnosis and follow-up of MGC tumors. Immunoassays for serum β -hCG and AFP should be obtained in all patients who have suspicious mediastinal masses. The elevation of β -hCG and AFP confirm a malignant tumor, and AFP (60% to 80%), β -hCG (30% to 50%), or both are elevated in 80% to 85% of nonseminomatous germ-cell tumors.¹⁵⁰ Patients with pure seminoma may have low levels of β -hCG, but AFP is not detected unless a nonseminomatous component also exists. Patients with benign teratomas have normal markers. Isochromosome 12p is diagnostic of undifferentiated germ-cell malignancies even in the absence of elevated serum markers.

MGC tumors typically are detected by standard chest radiographs, which are abnormal in 95% of cases. Most masses are noted in the anterior mediastinum, but 3% to 8% of tumors arise within the posterior mediastinum.¹⁴⁹ Chest CT scans demonstrate large inhomogeneous masses containing areas of hemorrhage and necrosis and also define the extent of disease, the relationship to surrounding structures, and the presence of cystic areas and calcification within the tumor. In teratomas, sonographic patterns may improve the diagnostic accuracy of CT scans alone.¹⁵¹ Abdominal imaging should be performed to assess for liver metastases. Careful examination of the testes, including a testicular ultrasound, should always be performed; however, a blind testicular biopsy or orchiectomy in patients with normal physical and ultrasound findings is not indicated because an isolated anterior mediastinal mass without retroperitoneal adenopathy is not consistent with a primary testicular tumor.¹⁴⁶ The diagnosis of nonseminomatous germ-cell tumors in young males with anterior mediastinal masses and elevated serum tumor markers (AFP and β -hCG) may be made without a tissue biopsy, and treatment may be initiated.¹⁵² If a tissue confirmation is necessary, a core needle biopsy with cytologic staining for tumor markers usually is adequate. Rarely, an open biopsy via an anterior mediastinotomy approach is necessary.¹⁵²

Management by Histology

MGC tumors are not formally staged according to the American Joint Committee on Cancer (AJCC) staging system but can be characterized as localized, locally advanced, and metastatic. Due to the lack of a staging system, these tumors will be discussed by histologic subtype.

Teratoma

Treatment of a mature mediastinal teratoma consists of complete surgical resection, which results in excellent long-term cure rates.¹⁴⁸ The tumor may be adherent to surrounding structures, necessitating resection of the pericardium, pleura, or the lung. Radiotherapy and chemotherapy play no role in the management of this tumor. For teratomas with a malignant component (immature) in patients over 15 years of age, adjuvant cisplatin-based combination chemotherapy (four cycles of cisplatin, etoposide, and bleomycin or vinblastine, ifosfamide, and cisplatin) is recommended. Neoadjuvant chemotherapy may be considered if the tumor is not completely resectable.¹⁴⁸

Seminoma

The treatment of mediastinal seminoma has evolved since the early 1970s. Seminomas are extremely radiosensitive tumors, and for many years, high-dose mediastinal radiation was used as the definitive therapy, resulting in long-term survival rates of 60% to 80%.¹⁵² Radiation therapy in the extragonadal seminoma, including recommendations for mediastinal and bilateral supraclavicular fields as well as for doses of 35 to 45 Gy was reviewed by Hainsworth.¹⁴⁷

Mediastinal seminoma, however, often presents as a bulky, extensive, and locally invasive disease, requiring large radiotherapy portals that would result in excessive irradiation of surrounding the normal lung, heart, and other structures. Additionally, 20% to 40% of irradiated patients fail at distant sites.¹⁴⁷ Currently, due to these limitations, only an isolated mediastinal seminoma with minimal disease is managed with radiotherapy alone. Instead, the use of cisplatin-based combination chemotherapy, which was previously used only in advanced gonadal seminoma, is now used as first-line therapy. Lemarie et al.¹⁵⁰ reported that 12 of 13 patients treated experienced complete remission, with only 2 subsequent recurrences. Bokemeyer et al.¹⁵³ reported an international analysis of 51 patients with mediastinal seminoma. Chemotherapy was primarily cisplatin based (45, 88%), but carboplatin was also used (3, 5.9%) and had a lower objective response rate (80% versus 93%). In this study, patients were treated with chemotherapy (38, 74.5%),

chemotherapy and radiation (10, 19.6%), or radiation alone (3, 5.9%). The progression-free survival and overall survival were 77% and 88%, respectively. Patients with extrathoracic metastases (6, 11.8%) had a worse prognosis. In a collective review of 52 patients by Hainsworth,¹⁴⁷ 14 patients had received prior radiation therapy, but all underwent chemotherapy with cisplatin and various combinations of cyclophosphamide, vinblastine, bleomycin, or etoposide. Complete responses to treatment were noted in 85% of patients, with 83% disease-free long-term survival.

Pure mediastinal seminoma, even with visceral metastases, falls into the intermediate-risk category of the new International Staging System for Germ Cell Tumors, and all patients should be treated with curative intent. Locally advanced and bulky disease should be treated initially with cisplatin-based combination chemotherapy, which is most often four cycles of cisplatin and etoposide with or without supradiaphragmatic radiotherapy. Patients with distant metastases should undergo chemotherapy alone as the initial treatment. Salvage chemotherapy (vinblastine, ifosfamide, and cisplatin) may be required for persistent or recurrent disease.¹⁵⁴

Despite a recent report of 76.9% long-term survival patients using primary surgical resection followed by adjuvant therapy,¹⁵⁵ most authors believe that surgery does not play a role in the definitive treatment of a seminoma.¹⁵² In addition, surgical debulking of large tumors has not been shown to be of benefit in improving local control or survival.¹⁴⁷

The management of patients with residual radiographic abnormalities after chemotherapy is controversial. Studies have shown that the residual mass is a dense scirrhous reaction or fibrosis in 85% to 90% of patients, and the presence of a viable seminoma is rare. Others have shown a 25% incidence of residual viable seminoma in these patients treated with chemotherapy followed by resection of residual masses larger than 3 cm.¹⁵⁵ Close observation without surgery is recommended for residual masses after chemotherapy unless the mass enlarges.^{147,152} An evaluation with PET scans is superior to CT alone in seminoma patients with a sensitivity and specificity of 80% and 100%, respectively, versus 73% and 73% for CT alone. There were no false-positive scans in lesions larger than 3 cm, and all 11 lesions greater than 3 cm with a residual tumor were PET avid, making this a useful modality to avoid unnecessary surgery and empiric radiation therapy.^{147,152}

Nonseminomatous Germ-Cell Tumors

The mainstay of treatment of nonseminomatous germ-cell tumors is cisplatin-based chemotherapy, which is identical to that of gonadal nonseminomatous germ-cell tumors and is discussed more completely in Chapter 70. Overall complete remission rates of 40% to 64% were obtained in most series.^{147,148,150,153} In an international review of 287 patients, responses were noted in 178 (64%), and the progression-free and overall survival were 62% and 45%, respectively.¹⁵³ Patients with relapsing mediastinal nonseminomatous germ-cell tumors do extraordinarily poorly even with salvage therapy, such as vinblastine, ifosfamide, and cisplatin,¹⁵⁴ with only 9 of 79 patients (11%) becoming disease free in one study.¹⁵³ Surgical resection of the residual disease despite persistently elevated tumor markers has been reported by several authors to be beneficial.¹⁵⁵⁻¹⁵⁷

Prognosis

Immature teratomas are potentially malignant tumors, and their prognosis is influenced by the anatomic site of the tumor, the patient's age, and the fraction of the tumor that is immature.¹⁴⁸ In patients younger than 15 years, immature teratomas behave similarly to their mature counterparts. In older patients, they may behave as highly malignant tumors. Nonseminomatous MGC tumors carry a poorer prognosis than either pure extragonadal seminomas or their gonadal nonseminomatous counterparts. All primary mediastinal nonseminomatous germ-cell tumors fall into the poor-risk category of the International Germ Cell Consensus Classification.¹⁵⁸

44 Molecular Biology of the Esophagus and Stomach

Anil K. Rustgi

INTRODUCTION

This chapter will deal with the molecular biology of esophageal and gastric cancers. The reader is referred to Chapters 45 and 46 for detailed information about the epidemiology, etiology, pathology, clinical manifestations, diagnosis, and therapy of esophageal and gastric cancers. There are several key aspects in the elucidation of the genetic basis of esophageal and gastric cancers through molecular biology approaches. These include, but are not limited to, new insights into underlying pathogenesis, possibilities for risk stratification and prognosis, correlations with traditional pathology classification schemes, the development of new diagnostics, and potential applications in molecular imaging and therapy. In considering the genetic underpinnings of esophageal and gastric cancers, critical appraisal is required of oncogenes, tumor suppressor genes, and DNA mismatch repair genes as they modulate, either positively or negatively, growth factor receptor–mediating signaling cascades, transcription of target genes, and cell-cycle progression. These molecular networks conspire to influence cellular behaviors, such as proliferation, differentiation, apoptosis, senescence, and response to stress and injury. The exquisite equilibrium that is the signature of normal cellular homeostasis is perturbed in uncontrolled cell growth, resulting in the eventual evolution of premalignant stages and malignant transformation. However, the time required for malignant transformation varies, depending on cellular- and tissue-specific context, and is affected by environmental factors.

The salient features of tumorigenesis and the acquisition of the malignant phenotype that are required, as described by Hanahan and Weinberg,¹ include growth signal autonomy, the ability to surmount antigrowth signals, the evasion of apoptosis, unlimited replicative ability, angiogenesis, and invasion and metastatic potential. More recently, the role of inflammation in carcinogenesis has gained much attention.

MOLECULAR BIOLOGY OF ESOPHAGEAL CANCER

The vast majority of esophageal cancers are of two subtypes: esophageal squamous cell cancer (ESCC) and esophageal adenocarcinoma (EAC). ESCC is preceded by squamous dysplasia, whereas EAC is preceded by a Barrett esophagus (BE) or an incomplete intestinal metaplasia of the normal squamous epithelium of the esophagus (Fig. 44.1). A BE undergoes transition from low-grade and high-grade dysplasia before progressing into EAC. ESCC and EAC have common and divergent genetic features as manifest by alterations in canonical oncogenes and tumor suppressor genes in somatic cells of tumors (Table 44.1). However, inherited predisposition to ESCC is rare, as described in *tylosis palmaris et*

plantaris. Although the gene mutation for tylosis has remained elusive, the region of allelic deletion is on chromosome 17p.² Similarly, there is no classic syndrome that distinguishes familial BE or familial EAC. That being said, studies continue to analyze families with BE in an effort to identify relevant genes or single-nucleotide polymorphisms. It is estimated that about 7% of patients with BE may have a family history. In a model-free linkage analysis of concordant-affected and discordant sibling pairs with BE/EAC, and tested independently prospectively in BE/EAC patients (and ancestry-matched controls), three genes—*MSRI*, *ASCC1*, and *CTHRC1*—were associated with BE/EAC.³ An initial genome-wide association study (GWAS) revealed that common variants at chromosome 16q24.1 (the closest gene is *FOXF1*, which may be involved in esophageal organogenesis) and major histocompatibility complex (MHC) locus (chromosome 6p21) are associated with BE.⁴ Subsequently, another GWAS revealed new susceptibility loci in BE/EAC in the following chromosomes and genes: chromosome 19p13-*CRTC1* (encoding cAMP response element binding protein [CREB]-regulated transcription coactivator) gene; chromosome 9q22-*BARX1* gene, which is a transcription factor important in esophageal and gastric organogenesis; and chromosome 3p14—near the *FOXP1* gene, which regulates esophageal development).⁵

Epidermal Growth Factor Receptor

The epidermal growth factor receptor (EGFR) family of receptor tyrosine kinases stimulates a number of signal transduction cascades (e.g., *Ras/Raf/MEK/ERK*, *PI3K/AKT*) that regulate diverse cellular processes, such as proliferation, differentiation, survival, migration, and adhesion. These signaling pathways are important in normal cellular homeostasis, but aberrant activation of the EGFR members is crucial in esophageal carcinogenesis. This family of receptors comprises EGFR (also referred to as *erbB1*, *erbB2*, *erbB3*, and *erbB4*). The receptors have the ability to homo- or heterodimerize on engagement with one of several ligands: transforming growth factor α (TGF- α), EGF, amphiregulin, heparin-binding EGF-like growth factor, betacellulin, and epiregulin. The tyrosine phosphorylation of homo- or heterodimers of EGFRs creates docking sites for signaling proteins or adapter proteins. EGFR is commonly overexpressed in early-stage esophageal cancer, and overexpression correlates with a poor prognosis.^{6–9} EGFR overexpression is typically due to increased engagement with ligands and decreased turnover. However, the mutation of a tyrosine residue in the cytoplasmic domain is rare. Increased expression of TGF- α and EGF has been detected in BE, EAC, and ESCC.^{10–14} EGFR overexpression may predict a poor response to chemoradiotherapy^{15,16} and is associated with decreased survival in patients with squamous cell carcinoma.¹⁵ Furthermore, EGFR overexpression was associated with recurrent disease and diminished overall survival in patients undergoing an esophagectomy for ESCC.^{16,17}

Normal esophagus → Squamous dysplasia → Squamous cell cancer

Normal esophagus → Intestinal metaplasia → Low-grade dysplasia → High-grade dysplasia → Adenocarcinoma

Figure 44.1 Progression of stages in esophageal squamous cell cancer and esophageal adenocarcinoma.

Cyclin D1 and p16INK4a

Cyclins, cyclin-dependent kinases (CDK), and cyclin-dependent kinase inhibitors (CDKi [such as p15, p16, p21, and p27]) regulate the mammalian cell cycle. During the G1 phase, the cyclin D1 oncogene complexes with either CDK4 or CDK6 to phosphorylate the retinoblastoma (pRb) tumor suppressor protein and, in so doing, relieves the negative regulatory effect of pRb, allowing the E2F family of transcription factors to propel the cell cycle toward the G1/S phase transition.¹⁸ Toward the late G1 phase, cyclin E complexes with CDKs to phosphorylate p107, which is related to pRb, and liberates more E2F members to navigate the cell cycle into S phase. As with EGFR, cyclin D1 overexpression is found in premalignant lesions, such as esophageal squamous dysplasia or BE, and the majority of early-stage ESCC or EAC.^{19,20} Additionally, cyclin D1 overexpression correlates with poor outcomes and survival as well as poor response to chemotherapy.^{21,22}

Although cyclin D1 overexpression accounts for cyclin D1 dysregulation, other mechanisms include mutations in cyclin D1 and mutations in Fbx4, which is the E3 ligase for cyclin D1, thereby preventing degradation of cyclin D1 in the cytoplasm and reimportation into the nucleus, where it exerts its oncogenic effects.²³

In a similar vein, *p16INK4a* is an early genetic alteration, via promoter hypermethylation, point mutation, or allelic deletion, in BE and EAC, but interestingly, is a late event in ESCC. Loss of heterozygosity of 9p21, the locus for both p16 and p15, has been demonstrated with high frequency in both dysplastic Barrett epithelium and Barrett adenocarcinoma (90% and more than 80% of cases, respectively).^{24,25} Promoter hypermethylation, which prevents tumor suppressor function by blocking transcription, has been documented and correlates with the degree of dysplasia in BE. It is present in up to 75% of specimens with high-grade dysplasia and is found in almost 50% of patients with adenocarcinoma of the esophagus.^{24,26} Point mutations of p16 in ESCC have been found, and promoter hypermethylation has been noted in up to 50% of these tumors.^{27,28} An *Rb* gene mutation is not found in either type of esophageal neoplasm, but allelic loss of 13q, where the locus of the *Rb* gene resides, is found in up to 50% of patients with Barrett adenocarcinoma and squamous cell carcinoma.²⁹ This can correlate with diminished or loss of pRb protein in BE with dysplasia, EAC, and ESCC.³⁰

DNA Mismatch Repair Genes (*hMLH1*, *hMSH2*)

Mismatch repair instability

TP53 Tumor Suppressor Gene

TP53 is the most commonly known mutated gene in human cancer.^{31–33} *TP53* is a tumor suppressor that interrupts the G1 phase to evaluate and permit the repair of damaged DNA, which may arise from environmental exposure (e.g., irradiation, ultraviolet light) or cellular stress.³⁴ In the face of irreparable damage, *p53* induces apoptosis. The *p53* transcription factor binds DNA to activate or suppress a large repertoire of target genes.³⁵ *TP53* mutations induce the loss of cell-cycle checkpoints and promote genomic instability. The majority of *TP53* mutations occur in the DNA-binding region, and more than 80% of them are missense mutations resulting in loss of wild-type *p53* function.³⁶ Wild-type *TP53* has a short half-life and is difficult to detect by immunohistochemistry; a mutation in *p53* results in the stabilization of the protein and allows for easier detection by immunohistochemistry.

The detection of the mutated *p53* protein by immunohistochemistry has been demonstrated with increasing frequency during histologic progression from BE (5%) through dysplasia (65% to 75%) to frank adenocarcinoma (up to 90%).^{37–39} Thus, the *p53* mutation or loss of heterozygosity appears early in BE and EAC. Both mutant *p53* protein detected by immunohistochemistry and specific *p53* gene mutations detected by genomic sequencing have been identified in 40% to 75% of patients with ESCC.^{40–42} The presence of a *p53* point mutation correlates with a response to induction chemoradiotherapy and predicted survival after esophagectomy in patients with either ESCC or EAC.⁴³

Telomerase Activation

The maintenance of telomere length allows DNA replication to be sustained indefinitely. The aberrant expression of telomerase has been observed in most esophageal cancers examined to date.⁴³ Morales et al.⁴⁴ observed increased telomerase expression in 100% of adenocarcinoma and BE cases with high-grade dysplasia. Telomerase activation is important, but alternative mechanisms to maintain the length of telomeres may operate in these cancers as well.⁴⁵

Tumor Invasion and Metastasis

The loss of cell–cell adhesion can lead to both invasion and metastases. Alterations in expression of E-cadherin, a cell–cell adhesion molecule, or its associated catenins (e.g., p120 catenin or p120ctn) disrupt cell–cell interactions, which results in the potential for tumor progression.⁴⁶ Reduced expression of E-cadherin has been correlated with progression from BE, to dysplasia, and finally to adenocarcinoma, and is also observed in ESCC.^{47,48}

Models of Esophageal Squamous Cell Cancer and Esophageal Adenocarcinoma

Advances in the diagnosis and therapy of esophageal neoplasms will ultimately be fostered through cell lines, xenotransplantation mouse models, surgically based rodent models, and genetically engineered mouse models. There is a vast array of cell lines established from primary and metastatic human esophageal cancers that allow the perturbation of gene expression to gauge effects on cellular behavior. Recently, organotypic (three-dimensional) cell culture models, which mimic human tissue, have revealed that the combination of EGFR and mutant *p53* results in the transformation of human esophageal epithelial

cells immortalized with human telomerase reverse transcriptase (hTERT).⁴⁹

In transgenic mice in which cyclin D1 is targeted to the esophagus, esophagi reveal evidence of dysplasia that evolves into squamous cell cancer on crossbreeding the mice with *p53* loss.⁵⁰ More recently, the conditional knockout of *p120ctn* in the esophagus of mice results in invasive ESCC.⁵¹ Rodents have also been treated with nitrosamines to yield esophageal papillomas and ESCC.⁵²

A classic rodent model involves a total gastrectomy followed by an esophagojejunostomy.⁵³ This creates a milieu whereby the esophagus is exposed to high concentrations of bile (*nonacid reflux*) with the development of BE and EAC. Recently, two genetically engineered mouse models have changed our views of BE and EAC. The targeted expression of the interleukin-1 β , a cytokine, to the mouse esophagi, results in esophageal and gastroesophageal inflammation, the development of BE, and long latency to EAC.⁵⁴ However, the time for EAC development is hastened by adding bile acid to drinking water consumed by the mice or by crossbreeding these mice with mice null for the *p16INK4a* allele.⁵⁴ Another model involves the global knockout of *p63*, which is important in squamous stem cells and progenitor cells, revealing Barrett-like cells in the postnatal period when the mice die from other causes.⁵⁵ In each of these two models, the cells that give rise to the Barrett cells or Barrettlike cells migrate from the gastric–squamous forestomach junction to the junction–distal esophagus.^{54,55}

Functional Genomics

The underlying fate switch between ESCC and EAC may also be influenced by the expression and function of *lineage*-specific transcriptional factors as demonstrated through functional genomics. To that end, *SOX2*, found to be part of an amplicon on chromosome 3q26.33 in human ESCC, fosters growth of these cancers. This may have implications in the therapy of human ESCC.⁵⁶ Similarly, *GATA6*, a known transcriptional factor, has been reported to be overexpressed in EAC.⁵⁷ Exome and whole-genome sequencing of EAC has revealed >20 genes that are mutated significantly, some of which include newly identified chromatin-modifying factors.⁵⁸

MOLECULAR BIOLOGY OF GASTRIC CANCER

The most common type of gastric cancer is adenocarcinoma, of which there are two subtypes: intestinal and diffuse. They are distinguished by different anatomic locations within the stomach, variable clinical outcomes, and different pathogenesis. The intestinal type of sporadic gastric adenocarcinoma has a hallmark progression from normal gastric epithelium, to chronic atrophic gastritis (typically due to *Helicobacter pylori* infection), to intestinal metaplasia (which has some overlapping but also different features than intestinal metaplasia of BE), to dysplasia, to cancer (Fig. 44.2). Diffuse-type gastric adenocarcinoma is even more invasive and aggressive in its behavior, has overlap with lobular-type breast cancer, and may be highlighted by E-cadherin loss.

Inherited Susceptibility

Case-control studies have observed consistent—up to threefold—increases in risk for gastric cancer among relatives of patients with gastric cancer.^{59,60} Studies of monozygotic twins have even shown a slight trend toward increased concordance of gastric cancers compared with dizygotic twins.^{61,62} Large families with an

autosomal dominant, highly penetrant inherited predisposition for the development of gastric cancer are rare. However, early-onset diffuse gastric cancers have been described and linked to the *E-cadherin/CDH1* locus on chromosome 16q and associated with mutations in this gene.⁶³ This seminal finding has been confirmed in other studies with gastric cancers at a relatively high (67% to 83%) penetrant rate.^{64–67} Thus, E-cadherin mutation testing should be considered in the appropriate clinical setting. In fact, prophylactic gastrectomy should be strongly considered in families with germ-line E-cadherin mutation even without gross mucosal abnormalities by endoscopic examination of the stomach.⁶⁸ Recently, germ-line alpha-catenin mutations have been described as well in these families.⁶⁹

Lynch syndrome, or hereditary nonpolyposis colon cancer, involves germ-line mutations of DNA mismatch repair genes.⁷⁰ Gastric adenocarcinoma may be observed in some families with Lynch syndrome. Gastric cancers have also been noted to occur in patients with familial adenomatous polyposis and Peutz-Jeghers syndrome.⁷⁰

Role of *Helicobacter pylori* Infection and Other Host–Environmental Factors

As a commensal organism, *H. pylori* infection is widely prevalent throughout the world. Despite its classification by the World Health Organization as a class I carcinogen, infection with *H. pylori* does not typically lead to gastric cancer. This underscores the importance of other factors, such as virulence, environmental factors, and host factors, as well as genetic polymorphisms (e.g., interleukin-1 β , a potent inhibitor of acid secretion).⁷¹ The blood group A phenotype has been reported to be associated with gastric cancers.^{72,73} *H. pylori* may adhere to the Lewis blood group antigen, indicating a factor for increased risk for gastric cancer.⁷⁴ Small variant alleles of a mucin gene, *Muc1*, were found to be associated with gastric cancer patients when compared with a blood donor control population.⁷⁵ Epstein-Barr virus infection has been noted in a certain type of gastric carcinoma (lymphoepithelioid type), although the importance of this is unclear.⁷⁶

Molecular Genetic Alterations

In contrast to ESCC, EAC, pancreatic cancer, and colon cancer, in which certain oncogenes and tumor suppressor genes are altered with high frequency, such degree of alteration is not observed in sporadic gastric cancers. A reasonably prevalent alteration is microsatellite instability, the result of changes in DNA mismatch repair genes (see Table 44.1). Microsatellite instability and associated alterations of the *TGF- β II receptor*, *IGFRII*, *BAX*, *E2F-4*, *hMSH3*, and *hMSH6* genes are found in a subset of gastric carcinomas.^{77–81} Microsatellite instability has been found in 13% to 44% of sporadic gastric carcinomas.⁸² A high degree of microsatellite instability occurs in gastric cancers of the intestinal type, reduced involvement of lymph nodes, enhanced lymphoid infiltration, and better prognosis.⁸³ This is reminiscent of colon cancers associated with Lynch syndrome.

The *p53* tumor suppressor gene is consistently altered in most gastric cancers.⁸⁴ In a study of the promoter region of *p16* in gastric cancers, a significant number (41%) exhibited CpG island methylation.⁸⁵ Many cases with hypermethylation of promoter regions displayed the phenotype with a high degree of microsatellite instability and multiple sites of methylation, including the *hMLH1* promoter region.⁸⁶

E-cadherin may be down-regulated in gastric carcinogenesis by a point mutation, allelic deletion, or promoter methylation.^{87,88}

Normal gastric mucosa \rightarrow chronic atrophic gastritis \rightarrow Intestinal metaplasia \rightarrow Low-grade dysplasia \rightarrow High-grade dysplasia \rightarrow Adenocarcinoma

Figure 44.2 Progression of stages in intestinal-type gastric adenocarcinoma.

In addition, during the epithelial–mesenchymal transition, E-cadherin transcription can be silenced by transcriptional factors such as Snail and Slug. However, it is not clear if the epithelial–mesenchymal transition is an important process in gastric carcinogenesis, as is believed to be the case, for example, in breast cancer.

Alterations in a number of other oncogenes and tumor suppressor genes have been described in a very small subset of gastric cancers by polymerase chain reaction–based or immunohistochemical analysis, but the variability in methods and lack of uniformity in quality control make these observations less compelling. Current efforts in deep sequencing of gastric adenocarcinomas through the Cancer Genome Tumor Atlas (CGTA) consortium should reveal new insights in the near future.

Models of Gastric Cancer

Genetically engineered mouse models of gastric cancer have emerged in rapid fashion in recent years, indicating that activated Wnt signaling and induced downstream effectors, *p53* inactivation, APC gene inactivation, *Smad4* gene inactivation, and gastrin are critical factors.^{89–92} Gastric cancers in these protean mouse models are facilitated by concomitant infection with *Helicobacter*.^{93–96} Furthermore, the recruitment of bone marrow stem cells may augment the effects of *Helicobacter* infection during gastric carcinogenesis.⁹⁶ Recently, it has been demonstrated that overexpression of interleukin-1 β in mice results in gastric inflammation and cancer, with concomitant recruitment of immature myeloid cells (also referred to as *myeloid-derived suppressor cells*).⁹⁷

45 Cancer of the Esophagus

Mitchell C. Posner, Bruce D. Minsky, and David H. Ilson

INTRODUCTION

Esophageal cancer is unique among the gastrointestinal tract malignancies because it embodies two distinct histopathologic types: squamous cell carcinoma and adenocarcinoma. Which type of cancer occurs in a given patient or predominates in a given geographic area depends on many variables, including individual lifestyle, socioeconomic pressures, and environmental factors. In recent decades, the United States, along with many other Western countries, has witnessed a profound increase in incidence rates of adenocarcinoma, whereas squamous cell carcinoma continues to predominate worldwide. Although it would seem appropriate to individualize treatment of these tumors, in the past, they have often been managed as a single entity. Although present-day therapeutic interventions have begun to have an impact, with statistically significant improvement in survival over the most recent 3 successive decades, cancer of the esophagus remains a highly lethal disease as evidenced by the case fatality rate of 90%. However, a more thorough understanding of the initiating events, the molecular biologic basis, and treatment successes and failures has begun to spawn a new era of therapy aimed at targeting both adenocarcinoma and squamous cell carcinoma of the esophagus.

EPIDEMIOLOGY

The epidemiology of esophageal cancer is defined by its substantial variability as a function of histologic type, geographic area, gender, race, and ethnic background.¹ Because of the recent increase in incidence rates of adenocarcinoma, especially in the Western hemisphere, epidemiologic studies are now distinguishing between histologic types when reporting results, whereas in the past, incidence rates of esophageal cancer reflected only squamous cell carcinoma. This remains true in high-incidence areas where published rates are not obtained from population-based tumor registries. These high-incidence areas include Turkey, northern Iran, southern republics of the former Soviet Union, and northern China, where incidence rates exceed 100 per 100,000 person-years. Incidence rates of squamous cell carcinoma may vary 200-fold between different populations in the same geographic area because of unique cultural practices. The highest incidence rates for males (more than 15 per 100,000 person-years) reported from population-based tumor registries were in Calvados, France; Hong Kong; and Miyagi, Japan; and the highest rates for females (more than 5 per 100,000 person-years) were in Bombay, India; Shanghai, China; and Scotland.²

Esophageal cancer is relatively uncommon in the United States, and the lifetime risk of being diagnosed with the disease remains less than 1%.³ It was estimated that 17,990 new cases would be identified in 2013, with 15,210 patients expected to die of the disease.⁴ Age-adjusted incidence rates are essentially equivalent among African American and Caucasian men (Fig. 45.1), although the predominant histologic type in African American men is squamous cell carcinoma. The incidence rates for African American men peaked in the early 1980s, and since then they

have shown a marked decline to the current rate of approximately 7 per 100,000 person-years.³ Incidence rates among Caucasian men increased up until the year 2000, reflecting the marked increase in the incidence of adenocarcinoma of the esophagus of more than 400% in the past 2 decades, but now have stabilized between 7 and 8 per 100,000 person-years.³ Although the incidence of esophageal cancer in Caucasian females (1.6 per 100,000) is lower than that in Caucasian males, rates of adenocarcinoma have increased in women by more than 300% during the past 20 years. Similar trends have been noted in Western European countries. This trend of increased incidence of adenocarcinoma of the esophagus has paralleled the upward trend in rates of both gastroesophageal reflux disease and obesity.

A steady decline in esophageal cancer mortality has been noted since the mid-1980s in the non-Caucasian U.S. population, whereas a marked increase in mortality was noted among Caucasian men and women during the same period (Fig. 45.2).³ The mortality rates among men are markedly higher than women, regardless of race. Although survival rates for all esophageal cancer patients are uniformly dismal, regardless of race or gender, 5-year relative survival rates have significantly improved since the 1970s (5% if diagnosed in 1975 to 1977 versus 19% if diagnosed in 2003 to 2009) based on Surveillance, Epidemiology, and End Results (SEER) population-based tumor registry reporting.³ There is no survival difference related to cell type (squamous cell carcinoma versus adenocarcinoma).

ETIOLOGIC FACTORS AND PREDISPOSING CONDITIONS

Squamous cell carcinoma and adenocarcinoma of the esophagus share some risk factors, whereas other risk factors are specific to one histologic type or the other.

Tobacco and Alcohol Use

Tobacco and alcohol use are considered the major contributing factors in the development of esophageal cancer worldwide. It is estimated that up to 90% of the risk of squamous cell carcinoma of the esophagus in Western Europe and North America can be attributed to tobacco and alcohol use.⁵ Population-based studies demonstrate that tobacco and alcohol use are independent risk factors, and their effects are multiplicative, as evidenced by the association of the highest risk of developing esophageal cancer with heavy use of both agents. Approximately 65% and 57% of squamous cell carcinomas of the esophagus have been attributed to smoking tobacco for longer than 6 months in Caucasian and African American men, respectively, in the United States.⁶ There appears to be a dose-response effect related to the duration and intensity of smoking, and, importantly, there is an impressive (up to 50%) reduction in the risk of developing squamous cell carcinoma of the esophagus for those who quit smoking and an inverse relationship between risk and the length of time since cessation of

Figure 45.1 Surveillance, Epidemiology and End Results (SEER) age-adjusted esophageal cancer incidence rates in the United States. API, Asian/Pacific Islanders; AI/AN, American Indians/Alaska Natives.

tobacco use.⁷ Cigarette smoking in adenocarcinoma of the esophagus leads to a twofold increase in risk for heavy smokers (more than one pack per day).^{7,8} Quitting smoking does not appear to decrease the risk of adenocarcinoma, which remains elevated for decades after smoking cessation.^{7,8} This suggests that tobacco carcinogens may affect carcinogenesis early on in esophageal adenocarcinoma, and, therefore, the decline in prevalence of smoking in the United States has not had an impact on the risk for the disease. Consistent with this hypothesis, cigarette smoking was recently identified as

Figure 45.2 Surveillance, Epidemiology and End Results (SEER) age-adjusted esophageal cancer mortality rates in the United States. API, Asian/Pacific Islanders; AI/AN, American Indians/Alaska Natives.

a risk factor for the development of Barrett's esophagus. Specifically, when analyzing data from five case-control studies involving 1,059 patients with Barrett's esophagus, 1,332 patients with gastroesophageal reflux disease (GERD), and 1,143 population-based controls, patients with Barrett's esophagus were significantly more likely to have ever smoked than either control cohort (odds ratio [OR] = 1.67 versus population-based controls; OR = 1.61 versus GERD controls). Furthermore, increasing the pack-years of smoking increased the risk of Barrett's esophagus.⁹

Alcohol is a major contributing factor in the increased risk of esophageal squamous cell carcinoma in Western countries, likely accounting for 80% of squamous cell carcinoma of the esophagus in men in the United States.⁶ A dose-response relationship exists between the amount of alcohol ingested and the risk of developing squamous cell carcinoma.^{10,11} In most studies, the most commonly consumed beverage in a specific geographic region is the one most frequently associated with increased risk.¹ Although specific carcinogens may be present in a variety of alcoholic beverages, in all likelihood, it is alcohol itself—either as a mechanical irritant, promoter of dietary deficiency, or contributor to susceptibility to other carcinogens—that leads to carcinogenesis. Large population-based case-control studies in both the United States and Australia revealed no relationship between alcohol intake and risk of esophageal adenocarcinoma.¹²

Diet and Nutrition

For both squamous cell carcinoma and adenocarcinoma of the esophagus, case-control studies provide evidence of a protective effect of a diet enriched with fruits and vegetables, especially those eaten raw.^{7,13} These food groups contain a number of micronutrients and dietary components such as vitamins A, C, and E; selenium; carotenoids; and fiber, which may prevent carcinogenesis. Deficiencies of the aforementioned nutrients and dietary components (in particular, selenium), have been associated with an increased risk of esophageal squamous cell carcinoma in some parts of the world.¹⁴ Consumption of hot beverages has been suggested as a risk factor for esophageal cancer in South America.¹⁵ More recently, a diet enriched with “animal products and related components” was significantly associated with the development of esophageal carcinoma (OR = 1.64; 95% confidence interval [CI], 1.06 to 2.55), whereas diets high in “vitamins and fiber” and “other polyunsaturated fatty acids and vitamin D” were protective of developing esophageal carcinoma (OR = 0.50 and 0.48, respectively).¹⁶

Socioeconomic Status

Low socioeconomic status as defined by income, education, or occupation is associated with an increased risk for esophageal squamous cell carcinoma and, to a lesser degree, for adenocarcinoma.^{8,17} In the United States, it is estimated that 39% and 69% of squamous cell carcinomas of the esophagus in Caucasian men and African American men, respectively, are related to low annual income.⁶ A number of occupational and industrial hazards, including exposure to perchloroethylene (e.g., dry cleaners, metal polishers), combustion products, and fossil fuels (e.g., chimney sweeps, printers, gas station attendants, asphalt and metal workers), silica and metal dust, and asbestos, as well as viral exposure via meat packing and slaughtering, have been suggested as possible risk factors for squamous cell carcinoma but not adenocarcinoma of the esophagus.⁷

Obesity

The prevalence of obesity in the United States markedly increased from 12.8% in the early 1960s to almost 23% between 1988 and 1994.¹⁸ This upward trend parallels that seen for incidence rates of esophageal adenocarcinoma. Increased body mass index (BMI) is a risk factor for adenocarcinoma of the esophagus, and individuals

with the highest BMI have up to a sevenfold greater risk of esophageal cancer than those with a low body mass index.^{7,19-21} The mechanism by which obesity contributes to an increased risk of esophageal adenocarcinoma is uncertain, although the linkage between obesity and GERD is presumed to be a chief, but not the sole, factor. Recent reports suggest that the presence of abdominal/intra-abdominal or central obesity rather than BMI itself may increase the risk of Barrett's esophagus and, subsequently, esophageal adenocarcinoma.²²⁻²⁴ Because of the influence of nutritional and socioeconomic factors, the risk of squamous cell carcinoma of the esophagus increases with decreasing BMI.

Gastroesophageal Reflux Disease

GERD has been implicated as one of the strongest risk factors for the development of adenocarcinoma of the esophagus.^{25,26} Chronic reflux is associated with Barrett's esophagus, the premalignant precursor of esophageal adenocarcinoma. Population-based case-control studies that examined the relationship between symptomatic reflux and risk of adenocarcinoma of the esophagus have demonstrated that increased frequency, severity, and chronicity of reflux symptoms are associated with a 2- to 16-fold increased risk of adenocarcinoma of the esophagus, regardless of the presence of Barrett's esophagus.^{25,26} Trends in incidence rates of GERD during the past 3 decades parallel the time trends of increasing incidence of adenocarcinoma in the United States.

Helicobacter pylori Infection

Infection with *Helicobacter pylori*, and particularly with cagA+ strains, is inversely associated with the risk of adenocarcinoma of the esophagus.^{27,28} The mechanism of action is unclear, although an *H. pylori* infection can result in chronic atrophic gastritis, leading to decreased acid production and potentially reducing the development of Barrett's esophagus. Although infection by *H. pylori* cagA+ strains by itself may not increase the risk of squamous cell carcinoma, the concurrent presence of gastric atrophy and *H. pylori* infection has been reported to significantly increase the risk of squamous cell carcinoma.²⁹ Atrophic gastritis may promote bacterial overgrowth, leading to intragastric nitrosation, with the production of nitrosamines increasing the risk of esophageal squamous cell carcinoma.

Barrett's Esophagus

Barrett's esophagus is defined by the presence of intestinal metaplasia (mucin-producing goblet cells) in columnar cell-lined epithelium that replaces the normal squamous epithelium of the distal esophagus.³⁰⁻³² The appearance at endoscopy of salmon-colored columnar epithelium extending about the gastroesophageal junction contrasts with the pale, pink-colored normal squamous epithelium of the esophagus. Although other types of mucosa (gastric, fundic, or junctional type) have been identified in Barrett's esophagus, specialized intestinal metaplasia confirmed by histologic examination of biopsy specimens is required for the diagnosis of Barrett's esophagus. The absolute risk to develop adenocarcinoma in a year, once thought to be 1 in 100, is now estimated to be 0.12% to 0.33%.³³⁻³⁶ Regardless of this revised absolute risk, Barrett's esophagus remains the single most important risk factor for developing esophageal adenocarcinoma, with a relative risk of 11.3 (95% CI, 8.8 to 14.4), implying that patients with Barrett's esophagus are 11-fold more likely to develop esophageal adenocarcinoma than individuals without Barrett's esophagus. Patients with short- and long-segment Barrett's esophagus are at risk of developing dysplasia and subsequently adenocarcinoma.³⁷

The prevalence of Barrett's esophagus in the general population undergoing endoscopy is approximately 1.5%³⁸; for those with reflux symptoms, the presence of Barrett's esophagus is 2.3%, and in those without reflux symptoms, it is 1.2%. The utility of screening

patients with symptomatic reflux is unproven and unlikely to have a significant impact on reducing death from cancer because 40% of patients with adenocarcinoma of the esophagus have no history of reflux,²⁵ and fewer than 5% of patients undergoing resection for adenocarcinoma were documented to have Barrett's esophagus before seeking medical attention for their symptomatic cancer.³⁹ Despite this, the American Gastroenterological Association, the American College of Gastroenterology, and the American Society of Gastrointestinal Endoscopy⁴⁰⁻⁴² recommend selective screening of patients with GERD and multiple risk factors for esophageal cancer. Both medical and surgical antireflux therapies are effective at reducing or eliminating the symptoms of gastroesophageal reflux, but no clear-cut evidence exists that either therapy reduces the risk of esophageal adenocarcinoma. A randomized Veterans Affairs Cooperative Study of medical and surgical antireflux treatment in patients with severe GERD demonstrated superior control of reflux symptoms in the surgical treatment group but no difference between medical and surgical therapy groups in the incidence of esophageal cancer.⁴³ Overall survival was significantly decreased in the surgical treatment group as a result of an unexpected excess of deaths from heart disease.

All three U.S. medical societies mentioned previously recommend surveillance endoscopy for patients with the diagnosis of Barrett's esophagus, and the grade of dysplasia determines the endoscopy interval.⁴⁰⁻⁴² Uncontrolled studies suggest that adenocarcinomas identified by surveillance methods are detected at an earlier stage and are associated with a more favorable outcome after an esophagectomy.⁴⁴⁻⁴⁶ However, the efficacy of surveillance endoscopy is unclear, and there are no convincing data demonstrating that surveillance prevents cancer or improves life expectancy.⁴⁷⁻⁴⁹ Macdonald et al.⁴⁹ followed 143 patients with Barrett's esophagus for an average of 4.4 years with surveillance endoscopy and identified only one patient with asymptomatic esophageal adenocarcinoma. Similar findings were reported by O'Connor et al.⁴⁷ These studies suggest that routine surveillance of patients with Barrett's esophagus is unlikely to alter the natural history of this disease due to the low incidence of adenocarcinoma. Some authors suggest that surgical antireflux therapy causes regression of metaplastic epithelium or interrupts progression from Barrett's esophagus to low-grade and high-grade dysplasia,^{50,51} but convincing evidence is lacking. A prospective, randomized trial of medical treatment versus open Nissen fundoplication in patients with Barrett's esophagus with or without low-grade dysplasia showed no statistically significant difference in progression to dysplasia or adenocarcinoma.⁵² Observational studies suggest that the use of acid suppressive medical therapy—in particular, proton pump inhibitors—may decrease the risk of progression to either high-grade dysplasia or adenocarcinoma.⁵³ Progression from intestinal metaplasia to dysplasia in Barrett's esophagus signifies an unequivocal neoplastic change associated with the potential for malignant degeneration. Dysplasia is classified as low grade or high grade. The experience of the pathologist is crucial in correctly diagnosing high-grade dysplasia, which is the most important predictor for esophageal adenocarcinoma.⁵⁴ The differentiation of high-grade dysplasia from either low-grade dysplasia, indefinite dysplasia, or absence of dysplasia is straightforward (85% interobserver agreement). However, the diagnosis of low-grade dysplasia as differentiated from either indefinite dysplasia or findings negative for dysplasia is less reproducible (50% to 75% interobserver agreement).^{55,56} Any degree of dysplasia warrants endoscopic surveillance. Annual endoscopy is recommended for those patients with low-grade dysplasia, and more frequent screening (i.e., every 3 months) is recommended for those patients with high-grade dysplasia if eradication therapy has not been instituted. The management of high-grade dysplasia is discussed in Treatment of Premalignant and T1 Disease, later in this chapter.

The proposed stepwise carcinogenic sequence in which specialized intestinal metaplasia proceeds to low-grade dysplasia, high-grade dysplasia, and frank carcinoma suggests a potential opportunity for chemoprevention to disrupt the succession to cancer. Buttar et al.,⁵⁷ recognizing that carcinogenesis in Barrett's esophagus is associated

with the increased expression of cyclooxygenase-2 (COX-2), examined the effect of COX-2 inhibitors on the development of Barrett's esophagus and adenocarcinoma in a preclinical model. Both selective and nonselective COX-2 inhibitors were effective at inhibiting Barrett's esophagus-related adenocarcinoma. A meta-analysis of two cohort and seven case-control studies comprising 1,813 cancer cases demonstrated a protective association between aspirin or nonsteroidal anti-inflammatory drugs (NSAID) and esophageal cancer.⁵⁸ These findings suggest that NSAIDs may act as potential chemopreventive agents. A small, phase IIb randomized placebo-controlled trial of celecoxib in 100 patients with Barrett's esophagus and low- or high-grade dysplasia failed to demonstrate a protective effect against progression of Barrett's dysplasia to adenocarcinoma.⁵⁹ The ongoing ASPECT trial in the United Kingdom, a phase III randomized study of aspirin and esomeprazole chemoprevention in Barrett's metaplasia, is evaluating the effect of high- and low-dose esomeprazole, with and without low-dose aspirin, on the progression of Barrett's esophagus to high-grade dysplasia or cancer. More than 2,500 patients have been enrolled in this chemoprevention trial with a planned follow-up of at least 8 years.

Tylosis

Tylosis (focal nonepidermolytic palmoplantar keratoderma) is a rare disease inherited in an autosomal-dominant manner that is characterized by hyperkeratosis of the palms and soles and esophageal papillomas. Patients with this condition exhibit abnormal maturation of squamous cells and inflammation within the esophagus and are at extremely high risk of developing esophageal cancer.^{60,61} The tylosis esophageal cancer (TOC) gene has been mapped to 17q25 by linkage analysis of pedigrees.⁶² The TOC gene is also frequently deleted in sporadic human esophageal cancers.^{63,64} Envoplakin, which encodes a protein component of desmosomes that is expressed in esophageal keratinocytes, has been mapped to the TOC region⁶¹; however, no tylosis-specific mutations involving this gene have been observed.⁶⁵

Plummer–Vinson/Paterson–Kelly Syndrome

Plummer–Vinson syndrome, also known as Paterson–Kelly syndrome, is characterized by iron-deficiency anemia, glossitis, cheilitis, brittle fingernails, splenomegaly, and esophageal webs. Approximately 10% of individuals with Plummer–Vinson/Paterson–Kelly syndrome develop hypopharyngeal or esophageal epidermoid carcinomas.⁶⁶ The mechanisms by which these tumors arise have not been fully defined, although nutritional deficiencies as well as chronic mucosal irritation from retained food particles at the level of the webs may contribute to the pathogenesis of these neoplasms.⁶⁷

Caustic Injury

Squamous cell carcinomas may arise in lye strictures, often developing 40 to 50 years after a caustic injury.⁶⁸ The majority of these cancers are located in the middle third of the esophagus. The pathogenesis of these neoplasms may be similar to that implicated in esophageal cancers arising in patients with Plummer–Vinson/Paterson–Kelly syndrome. These cancers are often diagnosed late because chronic dysphagia and pain caused by the lye strictures obscure symptoms of esophageal cancer.

Achalasia

Achalasia is an idiopathic esophageal motility disorder characterized by increased basal pressure in the lower esophageal sphincter, incomplete relaxation of this sphincter after deglutition, and aperistalsis of the body of the esophagus. A 16- to 30-fold increase in esophageal squamous cancer risk has been noted in achalasia

patients.^{69,70} In a retrospective analysis, Aggestrup et al.⁷¹ observed the development of esophageal carcinomas in 10 of 147 patients undergoing an esophagomyotomy for achalasia. These neoplasms are believed to result from prolonged irritation from retained food in the midesophagus and arise an average of 17 years after the onset of achalasia. The chronic dysphagia and pain attributable to megaesophagus contributes to their late diagnosis in achalasia patients.⁷²

Human Papillomavirus Infection

Human papillomavirus (HPV) infection may contribute to the pathogenesis of esophageal squamous cell cancer in high-incidence areas in Asia and South Africa.⁷³ This oncogenic virus encodes two proteins (E6 and E7) that sequester the *Rb* and *p53* tumor suppressor gene products. Using polymerase chain reaction techniques, de Villiers et al.⁷⁴ detected HPV DNA sequences in 17% of esophageal squamous cell cancers in patients from China. In an additional study using similar techniques, Lavergne and de Villiers⁷⁵ identified a broad spectrum of HPV in approximately one-third of esophageal cancer specimens obtained from patients living in high-incidence areas in China and South Africa. Shibagaki et al.⁷⁶ detected HPV sequences in 15 of 72 (21%) esophageal cancer specimens obtained from Japanese patients. In contrast, neither evidence of HPV infection nor HPV DNA sequences have been observed in cancers arising in low-incidence areas.^{77–80}

Prior Aerodigestive Tract Malignancy

Patients with upper aerodigestive tract cancers develop second primary cancers at a rate of approximately 4% per year.⁸¹ Nearly 10% of secondary neoplasms arising in patients with prior histories of oropharyngeal of lung carcinoma arise in the esophagus.^{82–84} Interestingly, *p53* mutational analysis of multiple primary cancers of the aerodigestive tract in 17 patients demonstrated complete discordance of the *p53* genotype between separate primary tumors from the same patient, which suggests that *p53* is not functioning as a tumor susceptibility gene in this setting.⁸⁵

Comparative Genomics

Cancers of the esophagus and stomach are heterogenous and are noted to have genomic instability, as measured by greater somatic copy number alterations when compared with lower gastrointestinal tract tumors.⁸⁶ For esophageal and gastroesophageal junction (GEJ) adenocarcinomas, amplification of certain genes rather than gene mutations may be more important drivers of oncogenesis, including targetable kinases such as epidermal growth factor receptor (EGFR), ERBB2, fibroblast growth factor receptor (FGFR)1 and 2, and MET. The most commonly affected genes by mutation include TP53 and CDKN2A.⁸⁷ A recent study reported the results of whole-exome sequencing of esophageal adenocarcinoma and esophageal squamous cell carcinoma, and identified notable differences that support the different epidemiology and risk factors for these two distinct diseases.⁸⁸ In addition to mutations in TP53, investigators identified NOTCH1 as an important gene in esophageal squamous cell carcinoma development. Also of note, the investigators found conserved mutations in matched samples of Barrett's esophagus and esophageal adenocarcinoma, supporting the progressive molecular pathogenesis of esophageal adenocarcinoma.⁸⁸

APPLIED ANATOMY AND HISTOLOGY

Anatomy

The esophagus bridges three anatomic compartments: the neck, the thorax, and the abdomen (Fig. 45.3). The esophagus extends from the cricopharyngeus muscle at the level of the cricoid

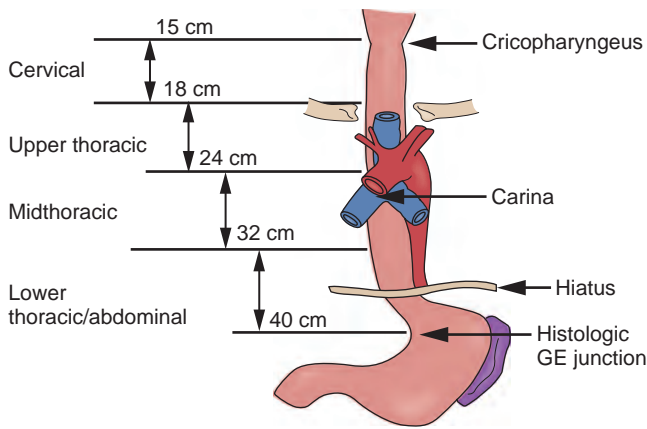

Figure 45.3 Anatomy of the esophagus with landmarks and recorded distance from the incisors used to divide the esophagus into topographic compartments. GE, gastroesophageal.

cartilage to the gastroesophageal junction.⁸⁹ The borders of the cervical esophagus span from the cricopharynx to the thoracic inlet (approximately 18 cm from the incisors). The remainder of the esophagus is commonly divided into thirds, with the upper third extending from the thoracic inlet to the carina (approximately 24 cm from the incisors), the middle third extending from the carina to the inferior pulmonary veins (32 cm from the incisors), and the distal esophagus traversing the remaining distance into the abdomen to the GEJ (40 cm from the incisors). Squamous cell carcinoma of the esophagus is the predominant histology in the cervical esophagus and upper and middle thirds (above the pulmonary vein) of the thoracic esophagus, whereas adenocarcinoma predominates in the distal esophagus.

Adenocarcinomas of the GEJ present a unique challenge because appropriate management of these tumors as either esophageal or gastric cancers has been uncertain. Siewert et al.⁸¹ have offered a classification system based on demographics, histopathologic variables, and patterns of lymphatic spread that provides clarity, is well established, and has been generally accepted worldwide (Fig. 45.4). In this classification scheme, type I tumors are considered adenocarcinomas of the distal esophagus and type II and III lesions are classified as gastric cancers (cardia and subcardia). This classification system allows for a tailored and consistent surgical approach to these tumors as well as consistency in reporting outcome results associated with therapeutic interventions. However, it should be noted that in the most recent guidelines established by the American Joint Committee on Cancer, GEJ tumors are included under the esophageal cancer staging classification.⁹⁰

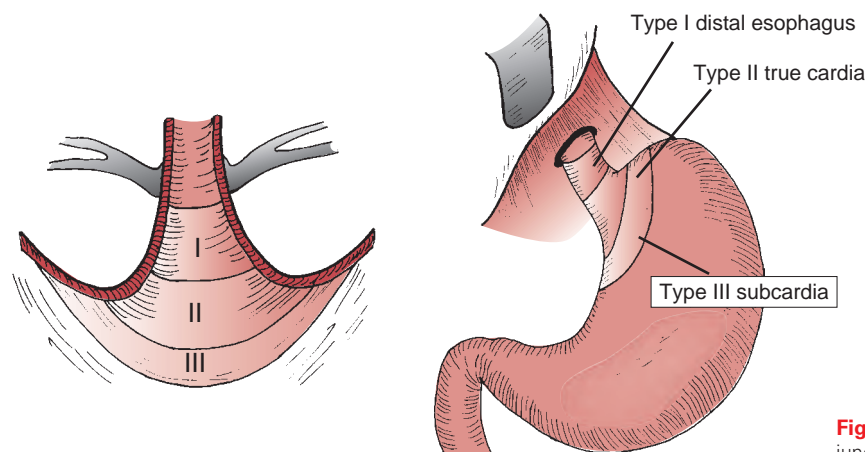

Figure 45.4 Anatomic classification of gastroesophageal junction tumors.

The pattern of lymphatic drainage of the esophagus influences the choice of surgical approach, based on tumor location in the esophagus (Fig. 45.5). Tumors of the cervical and upper third of the thoracic esophagus drain to cervical and superior mediastinal lymph nodes. Tumors of the middle third of the esophagus drain both cephalad and caudad with lymph nodes at risk in the paratracheal, hilar, subcarinal, periesophageal, and pericardial nodal basins. Lesions in the distal esophagus primarily drain to lymph nodes in the lower mediastinum and celiac axis region. Because of the extensive lymphatic network within the wall of the esophagus, skip metastases for upper third lesions have been noted in celiac axis nodal basins, and likewise, cervical lymph node metastases have been noted in as many as 30% of patients with distal esophageal lesions. Some surgeons recommend a more radical oncologic procedure, a combined transthoracic and abdominal approach for lesions of the middle and distal esophagus,^{91,92} and others recommend a three-field (cervical, mediastinal, and abdominal) lymphadenectomy for all tumors of the middle through distal esophagus.^{93,94} However, lymph node metastases are initially limited in an overwhelming majority of patients to regional lymph nodes. Lymph node involvement in lymphatic basins distant from the primary tumor are rarely identified unless metastases to regional lymph nodes have already occurred,⁹⁵ which suggests the potential of sentinel lymph node sampling to direct surgical dissection.⁹⁶

Histology

Squamous cell carcinomas account for approximately 40% of esophageal malignancies diagnosed in the United States and the majority of cases arising in high-incidence areas throughout the world.⁹⁷ Approximately 60% of these neoplasms are located in the middle third of the esophagus, whereas 30% and 10% arise in the distal third and proximal third of the intrathoracic esophagus, respectively. These tumors are associated with contiguous or non-contiguous carcinoma in situ as well as widespread submucosal lymphatic dissemination.

Adenocarcinomas frequently arise in the context of Barrett's esophagus; because of this, these tumors occur in the distal third of the esophagus. No significant survival differences have been noted in adenocarcinoma patients compared with individuals with squamous cell cancers.

Rarer cancers of the esophagus include squamous cell carcinoma with sarcomatous features, adenoid cystic, and mucoepidermoid carcinomas. These neoplasms are indistinguishable clinically and prognostically from the more common types of esophageal carcinoma.

Small cell carcinomas account for approximately 1% of esophageal malignancies and arise from argyrophilic cells in the basal

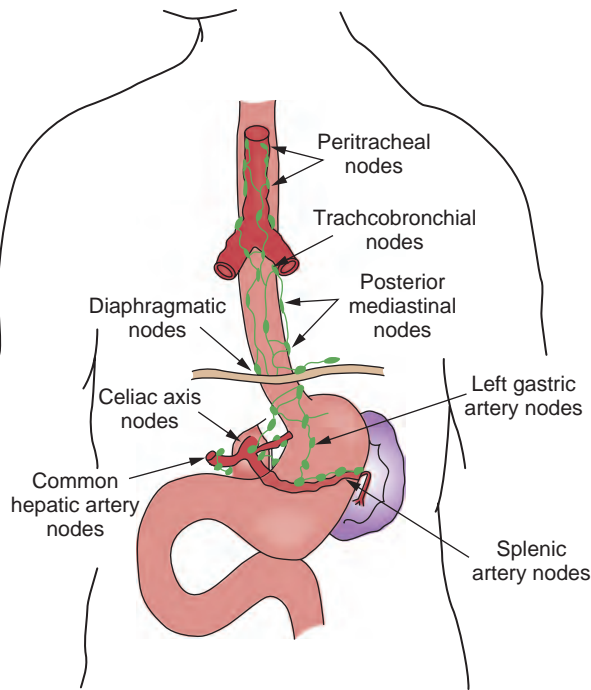

Figure 45.5 Lymphatic drainage of the esophagus with anatomically defined lymph node basins.

layer of the squamous epithelium. These neoplasms are usually located in the middle or lower third of the esophagus and may be associated with an ectopic production of a variety of hormones, including parathormone, secretin, granulocyte colony-stimulation factor, and gastrin-releasing peptide; individuals with these cancers often present with systemic disease.^{98–100} Recent series have reported patients with locally advanced disease treated with systemic chemotherapy in combination with either radiation therapy, surgery, or both, with some patients achieving long-term disease-free survival.¹⁰¹

Leiomyosarcoma is the most common mesenchymal tumor that affects the esophagus, still accounting for less than 1% of esophageal malignancies. These neoplasms are lower third tumors presenting as bulky masses with hemorrhaging and necrosis. Malignant lymphoma and Hodgkin lymphoma rarely involve the esophagus and is usually secondary to extension from other sites. Patients with AIDS may exhibit Kaposi sarcoma involving the esophagus. Malignant melanoma involving the esophagus is exceedingly rare and presents as a bulky polypoid intraesophageal tumor of varying color depending on melanin production.

NATURAL HISTORY AND PATTERNS OF FAILURE

At presentation, the overwhelming majority of patients have locally or regionally advanced or disseminated cancer, irrespective of histologic type.^{4,102} The lack of a serosal envelope and the rich submucosal lymphatic network of the esophagus lead to extensive local infiltration and lymph node involvement. Evidence suggests that occult micrometastases are invariably present, and recurrence patterns confirm that distant failure is a significant and universally fatal component of relapse.^{103–107} Bone marrow samples obtained during rib resections performed at an esophagectomy revealed disseminated tumor cells in up to 90% of patients sampled.^{108,109} The lung, liver, and bone are the most common sites of distant disease, with depth of tumor invasion and lymph node involvement predictive of tumor dissemination.^{89,103,104}

Median survival after esophagectomy for patients with localized disease is 15 to 18 months with a 5-year overall survival rate of 20% to 25%. Patterns of failure after an esophagectomy suggest that both the location of tumor and histologic type may influence the distribution of recurrence. In patients with cancers of the upper and middle thirds of the esophagus, which are predominately squamous cell carcinomas, local–regional recurrence predominates over distant recurrence, whereas in patients with lesions of the lower third, where adenocarcinomas are more frequently located, distant recurrence is more common.^{103,104} Only a very small percentage of patients (fewer than 5%) develop a clinically evident recurrence at cervical sites.⁹⁵

The addition of chemotherapy, radiotherapy, or chemoradiation to surgery alters patterns of failure, although reported results are not consistent. Preoperative radiotherapy and preoperative chemoradiation may reduce the rate of local–regional recurrence but have no obvious effect on the rate of distant metastases.^{107–111} In two prospective randomized trials recently updated with a long-term follow-up of preoperative chemotherapy plus surgery versus surgery alone that reported patterns of failure, one study showed a slight but not statistically significant decrease in distant relapse with chemotherapy,^{105,112} whereas the other demonstrated equivalent distant recurrence rates in both the preoperative chemotherapy and surgery-alone arms.^{106,113} Treatment failure patterns after definitive chemoradiation without surgical resection reveal that the concurrent administration of chemotherapy and radiotherapy provides better local control than radiotherapy alone, and that the administration of chemotherapy may reduce systemic recurrence; however, the long-term follow-up of both randomized and nonrandomized patients treated with primary chemoradiation failed to indicate a clear reduction in distant disease recurrence compared with radiation therapy alone.¹¹⁴ Although the addition of surgery further reduces local failure from 45% to 32%,¹¹⁵ it does not diminish the systemic recurrence and, in fact, may enhance it by allowing patients to manifest distant disease because they do not succumb to local–regional failure.^{116,117} These patterns of relapse suggest that any further improvement in overall outcome for patients with esophageal cancer will be achieved through advances in systemic therapy.

CLINICAL PRESENTATION

The most noticeable symptoms are dysphagia and weight loss. Dysphagia signifies locally advanced disease or distant metastases, or both. Patients describe progressive dysphagia, with initial difficulty in swallowing solids, then liquids. Control of this single symptom impacts most on the patient's quality of life. Patients with squamous cell carcinoma of the esophagus more often have a history of tobacco or alcohol abuse, or both. Weight loss is seen in approximately 90% of patients with squamous cell carcinoma. Patients with adenocarcinoma of the esophagus tend to be Caucasian males from middle to upper socioeconomic classes who are overweight, have a symptomatic gastroesophageal reflux, and have been treated with antireflux therapy.

Approximately 20% of patients experience odynophagia (painful swallowing). Additional presenting symptoms include dull retrosternal pain, bone pain secondary to bone metastases, and cough or hoarseness secondary to paratracheal nodal or recurrent laryngeal nerve involvement. These types of symptoms suggest unresectable locally advanced disease or metastases. Unusual presentations are pneumonia secondary to tracheoesophageal fistula or exsanguinating hemorrhage due to aortic invasion.

DIAGNOSTIC STUDIES AND PRETREATMENT STAGING

Patients with symptoms of dysphagia should undergo an upper endoscopy and a biopsy to establish a tissue diagnosis. Biopsies or cytologic brushings have a diagnostic accuracy approaching 100%.^{118,119}

A targeted biopsy can be enhanced by the use of chromoendoscopy techniques using vital dyes, including indigo carmine, Lugol iodine solution, methylene blue, and toluidine blue.^{120,121} Autofluorescence imaging and narrow band imaging are emerging endoscopic techniques that allow for a detailed inspection of mucosa.¹²²⁻¹²⁵

A focused history taking should elicit information on predisposing factors for esophageal cancer, including tobacco use, alcohol use, symptomatic reflux, a diagnosis of Barrett's esophagus, and history of head and neck or thoracic malignancy. Prior surgery on the stomach or colon may influence the choice of reconstructive conduit to restore alimentary continuity at the time of an esophagectomy. Findings on history and physical examination that would prompt further diagnostic testing include hoarseness, cervical or supraclavicular lymphadenopathy, pleural effusion, or new onset of bone pain.

A chest radiography and a liquid oral contrast examination of the esophagus and stomach have been replaced by a computed tomography (CT) scan and a flexible endoscopy. An esophagogastros-copy allows for a precise evaluation of the extent of esophageal and gastric involvement and can precisely measure the distance of the tumor from the incisors to appropriately categorize the tumor's location. An upper endoscopy also allows for the identification of "skip" lesions or second primaries as well as indicates the presence and extent of Barrett's esophagus. A bronchoscopy should be reserved for those patients with tumors of the middle and upper esophagus to rule out invasion of the membranous trachea and possible tracheoesophageal fistula, although an endoscopic ultrasound is now the procedure of choice to identify these unusual manifestations.

Pretreatment staging procedures establish the depth of esophageal wall penetration, regional lymph nodes, and the presence of distant metastases so that patients can be guided to appropriate treatment. A CT scan of the chest and abdomen is mandatory. A recent single institution review of 201 CT scans in 99 patients undergoing staging for esophageal cancer indicated that imaging of the pelvis did not contribute added staging information, and it may not need to be routinely performed.¹²⁶ CT scans are highly accurate (approaching 100%) at detecting liver or lung metastases and suggesting peritoneal carcinomatosis (e.g., ascites, omental infiltration, peritoneal tumor studding).¹²⁷⁻¹²⁹ Accuracy for detecting aortic involvement or tracheobronchial invasion exceeds 90%.^{128,130,131} A CT scan is inaccurate in determining T stage and N stage.^{127,128,130,132-134} The accuracy of endoscopic ultrasonography (EUS) in determining both T and N stage is a function of its ability to clearly delineate the multiple layers of the esophageal wall^{135,136} and its use of multiple criteria, including shape, border pattern, echogenicity, and size, to determine lymph node involvement.^{137,138} EUS is superior to CT scans in both T and N staging of esophageal cancer.^{139,140} The overall accuracy for T staging is approximately 85%, and for N staging it is approximately 75%.¹⁴¹ The accuracy of determining lymph node involvement has been increased to 85% to 100% with the use of linear-array EUS with a channel that allows for passage of a needle to perform tissue aspiration for cytology.^{134,142,143} EUS is highly operator dependent and is limited in its ability to define relatively superficial lesions as either T1 or T2.^{141,144,145} This distinction is critical to allow for the use of minimal resection techniques for T1 lesions and to avoid preoperative chemoradiation for T1 and T2 tumors. Mini-probe high-frequency (20 MHz) sonographic catheters that can be passed through the working channel of the standard endoscope are now being used and provide improved accuracy.^{146,148} A new generation of endoscopes that are thin caliber may traverse almost all obstructing lesions, allowing for an EUS assessment.¹⁴⁸ The accuracy of EUS in assessing a response to induction chemoradiation is severely limited, and its use frequently leads to over staging because the fibrotic changes induced by treatment mimic residual tumor,^{149,150} although recent data may indicate some utility for posttherapy EUS.¹⁵¹

The fluorine-18 (¹⁸F) fluorodeoxyglucose (FDG) positron emission tomography (PET) scan is being widely applied in the

management of esophageal cancer. The accuracy of FDG-PET scans in assessing regional lymph nodes falls somewhere between the low and high accuracy of CT scans and EUS, respectively.^{152,153} In the detection of distant metastases, an FDG-PET scan is superior to CT, with a sensitivity, specificity, and accuracy all in the range of 80% to 90%.^{153,154} PET scans, in combination with CT (PET-CT fusion or hybrid FDG-PET/CT) scans, further improves specificity and accuracy of noninvasive staging.¹⁵⁵ This leads to the detection of unsuspected metastatic disease (upstaging) in 15% of patients, which leads to alteration of the intended treatment plan in at least 20% of patients. Currently, the utility of PET to detect distant disease not identified by other imaging modalities confirms a role for PET that is complementary to other staging procedures, although it should not supplant them.

FDG-PET may also have value in evaluating response to chemotherapy and radiotherapy. Weber et al.¹⁵⁶ demonstrated that decreased FDG uptake significantly correlated with pathologically confirmed response in patients treated with induction chemotherapy before esophagectomy for esophageal adenocarcinoma. A prospective validation study confirmed that a decrease in the standard uptake value of 35% or more during preoperative chemotherapy may predict histologic response and is associated with improved survival and decreased recurrence.¹⁵⁷ Brucher et al.,¹⁵⁸ from the same institution, Technische Universitat Munchen, showed a similar result of decreased FDG uptake in responders compared with nonresponders in patients with squamous cell carcinoma of the esophagus treated with preoperative chemoradiation. The MUNICON trial from the group led by Lordick et al.¹⁵⁹ examined PET scan response during induction chemotherapy in 110 patients with adenocarcinoma of the GEJ. PET scan nonresponders (54 patients) assessed after 2 weeks of induction chemotherapy were referred for immediate surgery rather than continuing with the full 3-month course of preoperative chemotherapy. Survival in these patients (median, 26 months) was comparable to nonresponding patients in a preceding trial (median, 18 months) who continued the full 3 months of chemotherapy prior to surgery, indicating that discontinuation of an ineffective therapy and referral for earlier surgery did not compromise outcome. Survival, however, was inferior in the PET-nonresponding patients compared with the PET responders. Although PET response may identify patients in whom ineffective preoperative therapy should be discontinued, whether or not referral of such patients for alternative chemotherapy, or chemoradiation, is warranted remains to be established. The MUNICON II trial explored whether PET scan nonresponders could have their outcome improved by further treatment with salvage neoadjuvant chemoradiotherapy consisting of single-agent cisplatin combined with 3,000 cGy of radiation therapy followed by surgery. When comparing PET scan nonresponders from MUNICON II treated with additional chemoradiation to nonresponders from the MUNICON trial, the R0 resection rate was not improved and there was no difference in either time to progression or overall survival across trials.¹⁶⁰ The small sample size and the utilization of suboptimal chemotherapy and radiotherapy dosing on the PET scan nonresponder arm make this trial difficult to interpret. One series of patients treated with induction chemotherapy, followed with serial PET scans, identified some patients who progressed on induction chemotherapy. Several of these patients achieved durable disease control, including pathologic complete response, when changed to an alternative chemotherapy during radiation therapy, suggesting that salvage with alternative treatment may be possible.¹⁶¹ Although pathologic responses on this trial were seen in virtually only early PET scan responding patients, other trials have not shown a clear correlation with early response seen on PET scan during induction chemotherapy with subsequent pathologic response to chemoradiotherapy.¹⁶¹ Two recent systematic reviews of the current available literature that addressed the evaluation of tumor response by PET scan to neoadjuvant therapy concluded that, although PET scans are the best imaging modality available to assess response, the current data

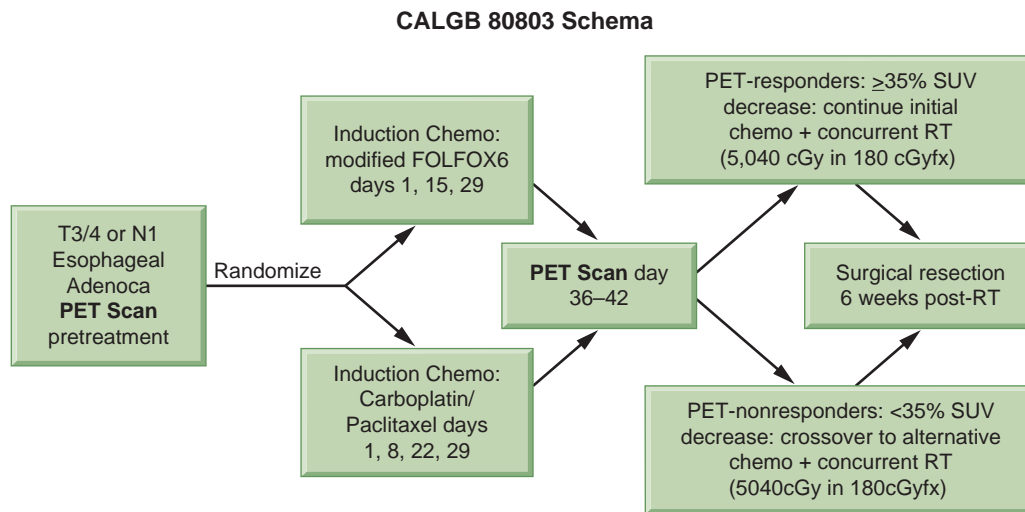

Figure 45.6 Alliance Intergroup randomized phase II trial (CALGB 80803) in resectable adenocarcinoma of the esophagus. SUV, standard uptake value; RT, radiation therapy.

do not support recommending the routine use of PET scans to guide therapeutic decisions.^{162,163} The ALLIANCE Cooperative Group is currently prospectively evaluating the use of PET scans to direct preoperative chemoradiotherapy. Accrual is ongoing to a randomized phase II trial (CALGB 80803) designed to answer the question of whether nonresponders to induction preoperative chemotherapy subsequently treated with a nonoverlapping chemoradiotherapy regimen prior to surgery improves outcome (Fig 45.6).

Minimally invasive surgical techniques (laparoscopy, thoracoscopy, or both) are being used for the staging of both local–regional and distant disease. Performing laparoscopy as the initial procedure at the time of a planned esophagectomy adds little in the way of time and cost to the procedure and allows for the detection of unsuspected distant metastases, which spares the morbidity of laparotomy in 10% to 15% of cases.^{164,165} Although studies suggest improved pretreatment staging with minimally invasive surgical approaches,^{166–168} such approaches have not been embraced because of the morbidity, length of hospital stay, and cost associated with what is considered an additional procedure.

A study comparing the health-care costs and efficacy of staging procedures, including CT scans, EUS fine-needle aspirations (FNA), PET scans, and thorascopies or laparoscopies reported that CT scans plus EUS FNAs were the least expensive and offered the most quality-adjusted life-years on average than all the other strategies. PET scans plus EUS FNAs were somewhat more effective but also more expensive.¹⁶⁹

PATHOLOGIC STAGING

The most recent guidelines established by the American Joint Committee on Cancer (AJCC) for the staging of esophageal cancer are outlined in Tables 45.1 and 45.2.⁹⁰ Changes between the current (seventh edition) and immediate past staging guidelines are highlighted. The tumor location is now defined by the position of the proximal edge of the tumor and is designated as upper, middle, or lower esophagus. Esophagogastric junction tumors are now included in the esophageal cancer staging schema. The primary tumor (T) stage is based on depth of tumor invasion into and through the wall of the esophagus. T stage is now listed as high-grade dysplasia that includes all noninvasive neoplastic epithelium, which was formerly called carcinoma in situ. T1 tumors are now subclassified as T1a (the tumor invades the lamina propria or muscularis mucosae) and T1b (the tumor invades the submucosa). T4 tumors that invade adjacent structures are now subclassified as

TABLE 45.1

Tumor (T), Node (N), Metastasis (M) Staging System for Esophageal Cancer

Primary Tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High grade dysplasia ^a
T1	Tumor invades lumina propria, muscularis mucosae, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
T4a	Resectable tumor invading pleura, pericardium, or diaphragm
T4b	Unresectable tumor invading other adjacent structures, such as aorta, vertebral body, trachea, etc.

Regional Lymph Nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis involving 1 to 2 nodes
N2	Regional lymph node metastases involving 3 to 6 nodes
N3	Regional lymph node metastases involving 7 or more nodes

Distant Metastasis (M)

M0	No distant metastasis (no pathologic M0; use clinic M to complete stage group)
M1	Distant metastasis

^a High-grade dysplasia includes all noninvasive neoplastic epithelium that was formerly called carcinoma in situ, a diagnosis that is no longer used for columnar mucosae anywhere in the gastrointestinal tract. T4a (a resectable tumor invading the pleura, pericardium, or diaphragm) and T4b (an unresectable tumor). The nodal (N) stage is determined by the presence of involved regional lymph nodes and is now subclassified according to the number of regional lymph nodes involved. The subclassification of metastasis (M) based on distant lymph node involvement (e.g., celiac node metastases for distal esophageal tumors) is no longer used. An analysis of 336

esophageal cancer patients who underwent resection alone recommended that the AJCC system be revised to take into account the number of involved lymph nodes, and that 18 lymph nodes should be the minimum harvested to provide for an accurate staging.¹⁷⁰ The current AJCC guidelines do not specify the number of lymph nodes to be removed, but instead suggest that the surgeon resect as many lymph nodes as possible while minimizing morbidity. Future refinements in the staging of esophageal cancer may result from incorporation of computational modalities such as nomograms and artificial neural networks that may predict outcome better than the TNM-based staging systems.¹⁷¹ Successive pathologically determined stage groups are predictive of length of survival.^{89,102} Overall survival for adenocarcinoma and squamous cell carcinoma in patients treated with surgery alone, as staged by the new AJCC staging system is outlined in Figure 45.7.¹⁷²

TREATMENT

The paucity of appropriately designed studies to scientifically determine the most effective therapeutic strategy in esophageal cancer fuels an ongoing debate and undermines the potential for achieving consensus. Although there is no disagreement that esophageal resection prevents progression from high-grade dysplasia to invasive carcinoma and is curative for T1 lesions limited to the mucosa, the morbidity and mortality associated with esophagectomy has created appropriate enthusiasm for alternative approaches such as mucosal ablation and endoscopic resection. Surgery has always been considered the most effective way of ensuring both local–regional control and long-term survival for patients with tumors invading into or beyond the submucosa with or without lymph node involvement. Some investigators suggest that extending the limits of resection will further improve an outcome. However, surgery alone or any other single modality fails in most patients, which has led oncologists to embrace chemoradiation and some to question the necessity for surgical intervention. Chemoradiation with or without resection is the most common therapeutic regimen offered to patients with locally advanced (stage II or III) esophageal carcinoma in the United States and its use has increased dramatically in the past decade.^{102,173}

Treatment of Premalignant and T1 Disease (Localized to the Mucosa Only)

High-grade dysplasia in Barrett's esophagus is the most powerful predictor of subsequent invasive adenocarcinoma and is associated with a per-year cancer incidence of 6%, thereby warranting therapeutic intervention. The rationale for esophagectomy is that resection completely eradicates the mucosa at risk, which prevents progression to invasive carcinoma. This is supported by older surgical series reporting previously unidentified invasive cancer, which was present in up to 40% of resected specimens.^{174–177} The argument against esophagectomies is that most patients with high-grade dysplasia do not develop invasive carcinoma in their lifetimes and, in the era of endoscopic resection, that early cancers can be effectively addressed without an esophagectomy. Those supporting endoscopic methods, ranging from surveillance to mucosal ablative and resection techniques, argue that this allows for the identification of patients with an early invasive lesion that is readily amenable to cure or elimination of the mucosa at risk, thus preventing progression. Indeed, patients with superficial invasive tumors confined to the mucosa, and those with T1a disease in particular, have little or no risk of lymph node metastases^{178,179} and are considered candidates for endoscopic therapies.

Surveillance

Endoscopic surveillance is based on the assumptions that the majority of patients will not progress to invasive carcinoma¹⁸⁰ and

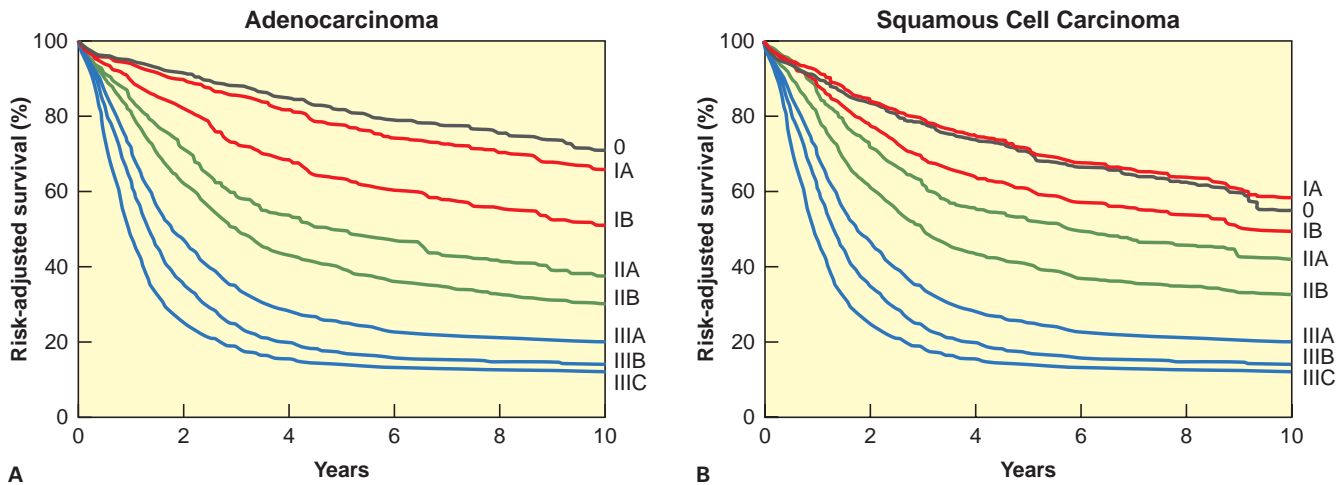

Figure 45.7 Risk-adjusted survival for (A) adenocarcinoma and (B) squamous cell carcinoma of the esophagus according to stage groups based on the seventh edition of the American Joint Commission on Cancer staging system.

that actual cancers detected by surveillance are at an earlier stage and are therefore curable.¹⁸¹ Studies demonstrating that patients with Barrett's esophagus-associated adenocarcinomas detected by surveillance have an earlier stage of disease and have better survival than those detected at an initial endoscopy provide supportive evidence for surveillance.^{44-46,174} Critics counter this argument with reports identifying invasive adenocarcinoma in up to 45% of esophagectomy specimens from patients with a diagnosis of high-grade dysplasia.¹⁷⁵⁻¹⁷⁷ Proponents of surveillance management argue that these patients were not on an endoscopic surveillance program with strict biopsy criteria, and that strict pathologic criteria of invasive disease (submucosal invasion or beyond) were not utilized.¹⁸²

Proposed guidelines for surveillance include serial endoscopy at 3- to 6-month intervals with multiple four-quadrant biopsies at 1- to 2-cm intervals.³³ The downside of endoscopic vigilance is that in a certain percentage of patients, invasive cancer goes undetected and the patients will not be candidates for potentially curative treatment.¹⁸³⁻¹⁸⁵ This must be weighed against the morbidity and mortality of an esophagectomy. It is important to note that the extent of high-grade dysplasia does not predict the presence of occult adenocarcinoma identified at an esophagectomy and, therefore, cannot necessarily be applied to a subjective quantification of disease.¹⁸⁶

Ablative Methods

The mechanism of action of all mucosal ablative techniques, including photodynamic therapy (PDT), laser ablation, multipolar electrocoagulation, argon plasma coagulation, and radiofrequency ablation, is destruction of the mucosal layer. The premise for managing high-grade dysplasia with endoscopic ablative therapy is that mucosal injury in an acid-controlled environment via proton-pump inhibitors eliminates the premalignant mucosa and resurfaces the esophageal lining with regenerated squamous epithelium.¹⁸¹

PDT involves the administration of an inactive photosensitizing agent that, when exposed to light of the proper wavelength, results in oxygen radical production and tissue destruction. Results of a phase III multicenter study that randomized 208 patients on a two to one basis to either PDT plus omeprazole or omeprazole alone demonstrated improved eradication of high-grade dysplasia in the PDT arm (77% versus 39%; $p < 0.0001$) at a 24-month follow-up.¹⁸⁷ A marked reduction in the occurrence of adenocarcinoma was noted in the PDT-treated group (13% versus 28%); however, the results emphasize the risk of development of invasive cancer in a relatively short follow-up interval of 24 months.

These results highlight the limitations of PDT, and due to the complexity of treatment and inconvenience of exposure to photosensitizing agents, PDT has fallen out of favor. Limited experience with thermal ablation for high-grade dysplasia has been reported. Small series of either laser ablation¹⁸⁸⁻¹⁸⁹ or argon plasma coagulation^{190,191} of high-grade dysplasia suggest that high-grade dysplasia can be eradicated; however, the follow-up period in these studies was short, and invasive carcinoma has subsequently been documented. Radiofrequency ablation is now considered the preferred ablation technique. A randomized trial in 127 patients with Barrett's esophagus and either low- or high-grade dysplasia assigned patients to either a sham endoscopic procedure or to treatment with radiofrequency ablation.¹⁹² Patients assigned to receive radiofrequency ablation were treated with a circumferential ablation device employing an inflatable cylindrical balloon, bringing electrodes into contact with the esophageal lining, with four applications performed per session, and up to four sessions performed over 9 months. At 12 months, a complete eradication of metaplasia occurred in 77.4% of the radiofrequency ablation patients compared to 2.3% in the control group. Although the development of cancer in either group was uncommon, progression to cancer in the ablation group was significantly less in the control group. More long-term follow-up beyond the 12 months in this trial as well as other confirmatory studies are required.

Endoscopic Mucosal Resection

Endoscopic mucosal resection (EMR) is now considered an essential diagnostic, staging, and therapeutic option available for patients with either high-grade dysplasia or superficial esophageal cancers (T1a). The EMR technique either involves a submucosal injection of fluid to lift and separate the lesion from the underlying muscular layer or the use of suction to trap the lesion into a cylinder, which allows for a full resection and tissue retrieval with a snare or endoscopic knife for appropriate histologic examination. Ell et al.¹⁹³ prospectively examined the utility of endoscopic resection in 100 consecutive patients with low-risk adenocarcinoma (no ulceration, mucosal lesion, no vascular or lymphatic invasion, less than 20 mm, and not poorly differentiated). Complete local remission was achieved in 99 of 100 patients; at a median follow-up of 33 months, 11% of patients developed recurrent or metachronous carcinomas, all successfully treated with repeat endoscopic resection. The calculated 5-year survival rate was 98% and no patient died of esophageal cancer. In a previous study from the same group,¹⁹⁴ the complete remission rate in patients with less favorable lesions was 59%, which emphasizes the need to adhere to strict criteria to optimize disease eradication.

A report examining the value of EUS and EUS-guided FNA in patients with high-grade dysplasia or intramucosal cancer considered candidates for endoscopic therapy and demonstrated that 20% of patients had unsuspected lymph node metastases and were therefore deemed unsuitable for endoscopic intervention.¹⁹⁵ These results and similar findings in smaller series examining EMR^{196,197} confirm that use of this technique is feasible for the treatment of high-grade dysplasia and carcinoma limited to the mucosa (T1a) and provides an alternative to esophagectomy. Furthermore, one could justifiably conclude that patients carefully screened and confirmed to have mucosa-limited lesions should first be offered EMR prior to considering an esophagectomy.^{198,199}

Minimally Invasive Esophagectomy

In an attempt to reduce morbidity and mortality while achieving an equivalent oncologic outcome, minimally invasive techniques for esophageal resection have been designed and continue to be investigated. A variety of minimally invasive approaches have been used for esophagectomies, including laparoscopic, thoracoscopic, combined laparoscopic and thoracoscopic, and hand-assisted techniques and robotic assisted.^{200–204} These techniques have been described and are similar in conduct to open procedures of transthoracic and transhiatal esophagectomy (detailed in Surgical Resection) except for the nuances of the minimally invasive approach (Figs. 45.8 and 45.9). These procedures have been applied to the treatment of all stages of potentially resectable esophageal cancer, but until oncologic equivalency to open techniques is confirmed, it would seem to be most applicable in the management of premalignant and early-stage disease.

By far the largest single-institution experience with minimally invasive esophagectomies (MIE) has been reported by Luketich et al.,²⁰⁵ which included 1,011 consecutive patients, the vast majority (95%) of whom had malignant disease. Approximately equivalent numbers of patients underwent either a three-incision MIE or, more recently, an Ivor Lewis MIE. The median intensive care unit stay was 2 days, the median length of hospital stay was 8 days, 30-day perioperative mortality was 1.7%, and the R0 resection rate was 98%. Median follow-up was only 20 months, and stage-specific

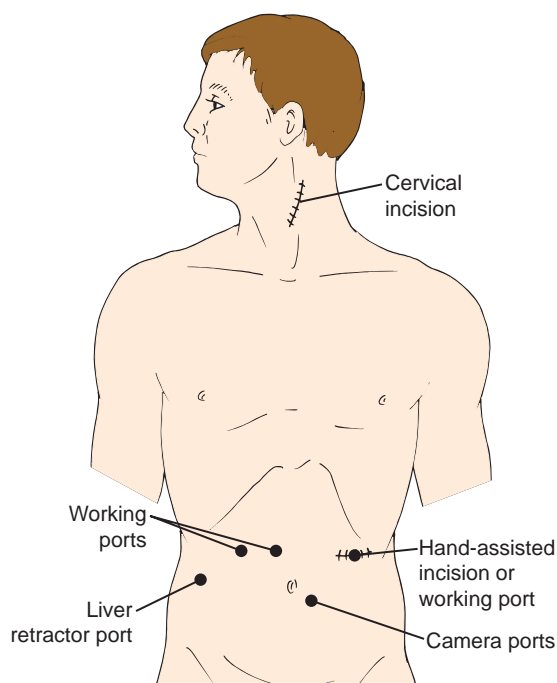

Figure 45.8 Abdominal port sites and incisions used for minimally invasive esophagectomy.

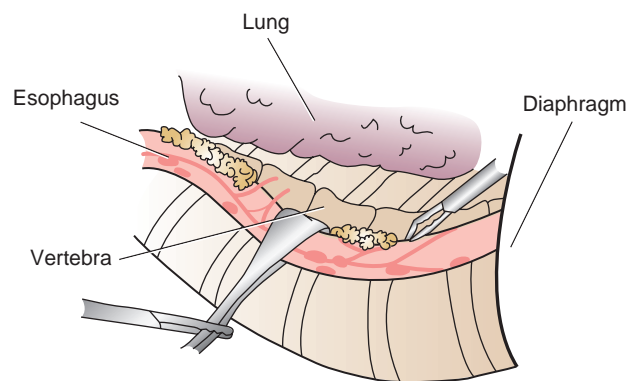

Figure 45.9 Thoracoscopic view and dissection of intrathoracic esophagus.

survival was similar to that reported in a series with open esophagectomies. This group concluded that MIEs are safe and an appropriate surgical approach in experienced hands. The same group reported their experience with 100 consecutive patients with T1 esophageal cancer who underwent esophagectomy, 80% of which were performed via a minimally invasive approach. The 30-day mortality was 0% and a R0 resection was achieved in 99%. N1 disease was present in 21% of patients, the majority of whom (90%) had T1b lesions with submucosal invasion. At a median follow-up of 5.5 years, 5-year overall survival was 62% and 3-year disease-free survival was 80%. The authors concluded that esophagectomies remain the standard of care for patients with T1 esophageal cancer.²⁰⁶ The results following minimally invasive esophagectomies reported by this group at the University of Pittsburgh are both promising and impressive, but whether they are reproducible in other institutions and therefore more broadly applicable needed to be determined through further study.^{207,208} The first, multicenter, randomized controlled trial of MIEs versus open esophagectomies recently reported its short-term results. Patients (n = 115) were randomly assigned to MIEs or open esophagectomies with the primary endpoint of postoperative pulmonary infection within 2 weeks of surgery. MIEs were associated with a statistically significant reduction in pulmonary infections and in length of stay. There was no difference detected in either 30-day or in-hospital mortality, and postoperative complication rates were similar. Patients randomized to the MIE arm had statistically significant longer operative times and decreased operative blood loss. Long-term oncologic outcomes are pending, but R0 resection rates and lymph node retrieval were equivalent between minimally invasive and open approaches.²⁰⁹

Nonresection or Ablative Therapy

There is limited experience with the use of radiation or chemoradiation in the curative setting for patients with cT1N0 disease. Sai et al.²¹⁰ from Kyoto University treated 34 patients who were either medically inoperable or refused surgery with either external beam alone (64 Gy) or external beam (52 Gy) plus 8 to 12 Gy with brachytherapy. With a median follow-up of 61 months, 5-year results were 59% survival, 68% local relapse-free survival, and 80% cause-specific survival. Treating a similar population of 63 patients with chemoradiation plus brachytherapy, Yamada et al.²¹¹ reported 66% survival, 64% disease-free survival, and 76% cause-specific survival at 5 years. In a recent cohort study of patients with clinical stage T1bN0 esophageal squamous cell carcinoma of the thoracic esophagus, nearly 20% of patients in the surgery cohort of 102 patients had nodal involvement on pathologic inspection. Patients who received definitive chemoradiotherapy (n = 71) had a higher risk of disease recurrence. Local recurrence in the definitive chemoradiotherapy cohort could be controlled by salvage esophagectomy

30% of the time, with the remaining ultimately dying of progressive esophageal adenocarcinoma.²¹² These data highlight the importance of patient selection in the decision process for local–regional therapy for early stage esophageal carcinoma.

Treatment of Localized Disease

Surgery has traditionally been the treatment of choice for patients with localized, resectable carcinoma of the esophagus and continues to be a component of a more comprehensive approach to esophageal cancer in a substantial number of patients. Failure of surgery alone to significantly alter the natural history of esophageal cancer has resulted in considerable and appropriate enthusiasm for multimodality therapy approaches. The shift toward multimodal treatment is not only theoretically sound, but is also supported by results from phase III randomized trials. Recent trials, unlike their predecessors, which were statistically underpowered and often came to conflicting conclusions about the worth of preoperative therapeutic regimens (radiation, chemotherapy, or chemoradiation), consistently demonstrate benefit to neoadjuvant therapy compared to surgery alone. Results from clinical trials have also brought into question the role of surgery in a multimodal approach to treatment of esophageal cancer, with studies (almost exclusively in squamous cell cancer) suggesting the absence of a survival benefit for the addition of surgery after chemoradiation, despite improved local disease control. Most clinicians and investigators consider some form of combined modality treatment that includes surgery to be the standard of care for localized, resectable esophageal cancer.

Surgical Resection

Decisions regarding surgical technique are routinely based on personal bias, comfort level of the surgeon, and a subjective view of tumor biology because solid evidence from scientifically designed trials is nonexistent. Studies that used health services–linked databases have demonstrated a statistically significant association between performance of surgery in hospitals designated as high-volume esophagectomy institutions with lower complication and mortality rates.^{214–217} A study from the Netherlands noted a significant reduction in postoperative morbidity, decrease in length of stay, reduction in in-hospital mortality, and improved 2-year survival following centralization of esophageal resections in high volume units when compared to before the centralization project was introduced.²¹⁸ Importantly, the strength of the inverse volume–outcome relationship for esophagectomy has significantly increased over time (2008 to 2009 versus 2000 to 2001) with the adjusted odds ratio of mortality in very low volume hospitals increasing substantially compared to that of very high volume hospitals.²¹⁹

Transhiatal Esophagectomy. The transhiatal route for esophageal resection has gained favor, especially among surgeons in the United States, concurrent with the rising incidence of adenocarcinoma of the distal esophagus, which is readily approachable and effectively dissected through the diaphragmatic hiatus (Table 45.3). The technique is as follows.^{220,221} It is prudent to initially perform laparoscopic exploration to rule out disseminated disease and, if it is confirmed, to abort the intended resection before exposing the patient to the risks of laparotomy. Through a midline incision, the stomach is mobilized by dividing all vascular attachments while preserving the right gastroepiploic and right gastric vessels on whose pedicle the reconstructive conduit will be based. The duodenum is fully mobilized via a Kocher maneuver and a pyloric drainage procedure is performed, which has been demonstrated in prospective randomized trials to reduce gastric stasis and minimize pulmonary complications such as aspiration.^{222,223} Cautionary division of the diaphragmatic crus allows for wide access to the mediastinum and dissection under direct vision of the middle and lower third of the esophagus. A left cervical incision provides

TABLE 45.3

Conventional Approaches to Esophageal Resection for Cancer

Transhiatal

- Left thoracoabdominal
 - Left thoracoabdominal approach
 - Peritumoral or two-field lymph node dissection
 - Intrathoracic anastomosis

exposure to the cervical esophagus, and circumferential dissection of the cervical esophagus is carried down to below the thoracic inlet to the upper thoracic esophagus, with care to avoid injury to the recurrent laryngeal nerve. The remainder of the dissection at the level of and superior to the carina is completed by blunt dissection through the esophageal hiatus.

The cervical esophagus is then divided, the stomach and attached intrathoracic esophagus are delivered through the abdominal wound, and a gastric tube, which will serve as the reconstructive conduit, is fashioned using multiple applications of a linear stapling device. The gastric tube is then transposed through the posterior mediastinum to the cervical wound, where a cervical esophago-gastric anastomosis is performed. The stomach is considered by most surgeons as the replacement conduit of choice for the resected esophagus. A segment of colon, usually based on the ascending branch of the inferior mesenteric artery, is an effective esophageal substitute if for any reason the stomach is deemed unsuitable for reconstruction or if it is the surgeon's preference. Although the original intent of this approach was not to perform a methodical lymph node dissection, a standard two-field lymphadenectomy (abdominal and lower mediastinal) can readily be achieved, and for that matter, if the surgeon is so inclined, a radical en bloc resection can be performed, as described by Bumm et al.²²⁴

The stated advantages attributed to the transhiatal approach to esophagectomy include avoidance of a thoracotomy incision, which thereby minimizes pain and subsequent postoperative pulmonary complications; elimination of the lethal complications of mediastinitis associated with an intrathoracic anastomotic leak; and a shorter duration of operation, which results in decreased morbidity and mortality.²²¹ Limitations and disadvantages of transhiatal esophagectomy include poor visualization of upper and middle thoracic esophageal tumors, increased anastomotic leak rate with subsequent stricture formation, the possibility of chylothorax, and the possibility of recurrent laryngeal nerve injury. The largest experience with transhiatal esophagectomy was reported by Orringer et al.²²⁵ and included 1,525 patients with esophageal

A, adenocarcinoma; S, squamous cell carcinoma.

cancer, 79% of whom had adenocarcinoma and 21% of whom had squamous cell carcinoma. Tumors were located in the lower third of the esophagus in 82% and in the middle or upper third in 18%. In-hospital mortality was 3%. The most common complications were anastomotic leak (12%) and recurrent laryngeal nerve palsy (4.5%). Leak of a cervical esophageal gastric anastomosis was handled simply, in most patients with opening of the cervical wound, followed by local wound care. Hoarseness from recurrent laryngeal nerve injury resolved spontaneously in 99% of cases. Overall 5-year survival was 29%, and stage-specific 5-year survival was 65% for stage I, 28% for stage II, 29% for stage IIB, and 11% for stage III. These results reflect those reported from other surgical series of transhiatal esophagectomy (Table 45.4).²²⁶⁻²³¹

Transthoracic Esophagectomy. The transthoracic esophagectomy has been the most common surgical approach used to resect carcinomas of the esophagus and is the standard procedure against which all other techniques are measured (see Table 45.3). Although a left thoracotomy provides adequate exposure to tumors of the distal esophagus, a right thoracotomy affords access to upper, middle, and distal esophageal lesions and is the preferred route for transthoracic exposure. A right thoracotomy combined with an upper midline laparotomy (Ivor Lewis esophagectomy) is the technique most commonly used for esophageal resection and is briefly described here.²²¹ The abdominal portion of the procedure duplicates that of the transhiatal approach previously detailed and includes mobilization of the stomach and distal esophagus, upper abdominal lymphadenectomy, pyloromyotomy, and placement of a feeding jejunostomy before abdominal wound closure and repositioning for the thoracic component of the procedure. A muscle-sparing right lateral thoracotomy is performed through the fifth or sixth intercostal space. The azygos vein is divided, the mediastinal pleura incised, the intrathoracic esophagus mobilized, and a mediastinal lymph node dissection performed.

After division of the proximal esophagus in the chest to ensure an adequate margin, the GEJ and stomach are pulled into the thoracic cavity. The stomach is then divided with a linear stapler, the specimen is removed, and an esophagogastric anastomosis is performed. An alternative approach has been described in which the right thoracotomy is the initial stage of the procedure followed by repositioning of the patient supine for an abdominal and left cervical incision to achieve a cervical esophagogastric anastomosis.^{232,233} Initial experience with a minimally invasive Ivor Lewis esophagectomy has also been reported.²³⁴

The transthoracic approach provides direct visualization and exposure of the intrathoracic esophagus, facilitating a wider dissection to achieve a more adequate radial margin around the primary tumor and more thorough lymph node dissection, which theoretically results in a more sound cancer operation. In patients with significant comorbid conditions, the combined effects of an abdominal and thoracic incision may compromise cardiorespiratory function. An intrathoracic anastomotic leak can lead to mediastinitis, sepsis, and death. In addition, esophagitis in the nonresected thoracic esophagus may occur secondary to bile reflux. The three-incision (cervical, thoracic, and abdominal) modification of the procedure effectively eliminates the potential for complications associated with an intrathoracic esophagogastric anastomosis.

Numerous authors have reported results of transthoracic esophagectomy; however, most, if not all, of these reports include patients who were resected via other surgical approaches and underwent a more extended lymphadenectomy (Table 45.5).²³⁵⁻²⁴⁰ Both overall and stage-specific 5-year survival rates were similar to those seen with a transhiatal esophagectomy. The most reliable data may be derived from prospective randomized trials in which there is a surgery-alone control arm. In only one of those trials²⁴⁰ was a transthoracic approach the only surgical procedure allowed. In that trial, median survival time on the surgery alone arm was 18.6 months and 5-year survival rate was 26%.

Transhiatal Versus Transthoracic Esophagectomy. The controversy regarding the optimal surgical approach for esophageal cancer remains unresolved. Two large meta-analyses have compared transhiatal esophagectomy with transthoracic esophagectomy based on collective reviews of numerous individual studies.^{241,242} Both reports include studies that compared transhiatal with transthoracic esophagectomies, studies of transhiatal esophagectomies only, and studies of transthoracic esophagectomies only. Rindani et al.²⁴¹ reviewed 5,483 patients from 44 series published between 1986 and 1996. Perioperative mortality was significantly higher in the transthoracic esophagectomy group than in the transhiatal group (9.5% versus 6.3%), whereas overall perioperative complications were not significantly different. Transhiatal esophagectomies resulted in a higher incidence of anastomotic leak, anastomotic stricture, and recurrent laryngeal nerve injury. Overall 5-year survival was similar: 24% for transhiatal esophagectomies and 26% for transthoracic esophagectomies. Hulscher et al.²⁴² performed a collective review of 50 studies performed between 1990 and 1999 yielding 7,527 patients. Postoperative mortality was significantly greater in the transthoracic group than in transhiatal group (9.2% versus 5.7%). Transthoracic esophagectomies were associated with a significantly higher risk of pulmonary complications (18.7% versus 12.7%), whereas patients treated with a transhiatal esophagectomy had a higher anastomotic leak rate (13.6% versus 7.2%). Five-year survival was not significantly different, with a 23% 5-year survival for transthoracic and a 21.7% 5-year survival with transhiatal esophagectomies. A third meta-analysis of over 50 comparative studies with a total of 5,905 patients included studies published up to 2010 and also included the largest randomized controlled trial. In-hospital or 30-day mortality was significantly higher in the transthoracic group (10.6% versus 7.2%) as was pulmonary complications and length of stay (4 days greater). Anastomotic leak (16.9% versus 10.6%), anastomotic stricture and vocal cord paralysis was significantly higher in the transhiatal group. Five-year overall survival was not statistically different between the transthoracic (26.6%) and transhiatal (25.8%) groups.²⁴³ A prospective database based on the Veterans Administration National Surgical Quality Improvement Program analyzed perioperative outcome in 945 patients: 562 who underwent transthoracic esophagectomy and 383 who underwent resection through a transhiatal approach.²⁴⁴ There was no difference in overall mortality (10% for transthoracic approach versus 9.9% for transhiatal approach) or morbidity (47% for transthoracic versus 49% for transhiatal). A large population-based study evaluated transhiatal and transthoracic esophagectomies through the SEER Medicare-linked database from 1992 to 2002.²⁴⁵ A lower operative mortality was found after transhiatal esophagectomies (6.7% versus 13.1%). Although observed 5-year survival was higher after a transhiatal esophagectomy, after adjusting for stage, patient, and provider factors, no significant 5-year survival difference was found.

Four phase III trials have prospectively examined the outcomes for patients randomly assigned to undergo either a transhiatal or a transthoracic esophagectomy.²⁴⁶⁻²⁴⁹ No definitive conclusions can be drawn from three of these trials because of the extremely small sample size. The trial in the Netherlands, however, deserves special attention. Hulscher et al.²⁴⁹ randomly assigned 220 patients with middle or distal esophageal carcinoma to undergo either a transhiatal esophagectomy or a transthoracic esophagectomy. The transthoracic group underwent a systematic mediastinal and upper abdominal lymph node dissection. Although the number of lymph nodes retrieved was significantly higher in the transthoracic group (31 versus 16; $p < 0.001$), there was no difference in the radicality of the two procedures with equivalent R0, R1, and R2 resections. Postoperative pulmonary complications, ventilatory time, intensive care unit stay, and hospital stay were significantly higher in those patients assigned to the transthoracic group. Despite the higher perioperative morbidity, there was no statistically significant increase in in-hospital mortality (4% versus 2% for transthoracic versus transhiatal esophagectomy, respectively; $p = 0.45$).

At a median follow-up of 4.7 years, there were no significant differences between the transhiatal and transthoracic esophagectomy groups with respect to median disease-free interval (1.4 years versus 1.7 years) and median overall survival time (1.8 years versus 2.0 years), respectively. Likewise, no significant differences were noted in local–regional recurrence, distant recurrence, and combined local–regional and distant recurrence for patients randomly allocated to the transthoracic or transhiatal esophagectomy arm. The investigators point out that a trend toward improved disease-free survival (39% versus 27%) and overall survival (39% versus 29%) at 5 years favored the transthoracic approach group. However, a recent update on this study that provided complete 5-year survival data demonstrated that survival was equivalent in patients randomized to either a transhiatal (34%) or transthoracic (36%) resection.²⁵⁰

Either the transhiatal or transthoracic procedure can be performed with acceptable morbidity and mortality in experienced hands and, with either technique, the outcome is remarkably similar.

Extended Esophagectomy. In an attempt to improve on the dismal results reflected in high local recurrence rates and poor overall survival with standard transhiatal and transthoracic esophagectomy techniques, some surgeons have examined extending the limits of resection to accomplish a more effective primary tumor excision and lymph node dissection. Two concepts guide the intent of these more extended resections: en bloc resection of the primary tumor with its adjacent surrounding tissue and systematic lymph node dissection, encompassing either two (mediastinal and abdominal) or three (cervical, mediastinal, and abdominal) lymph node basins (Fig. 45.10). Although some investigators have focused and reported separately on en bloc esophagectomies and extended lymphadenectomies, most of the techniques described encompass both components of this “radical” approach. An en bloc esophagectomy involves the resection of middle and lower esophageal tumors with an envelope of adjacent tissue that includes the mediastinal pleura laterally, the pericardium anteriorly, and the azygos vein and thoracic duct posterolaterally with the surrounding periesophageal tissue and lymph nodes. For tumors traversing the esophageal hiatus, a cuff of diaphragm is resected. In addition to a thorough mediastinal lymph node dissection extending from the tracheal bifurcation to the esophageal hiatus, an upper abdominal lymph node dissection incorporating lymph nodes along the portal vein, common hepatic artery, celiac trunk, left gastric artery, and splenic artery is included to achieve a two-field lymph node dissection.²⁵¹ A three-field lymph node dissection extends the lymphadenectomy to the superior mediastinum, including nodes along the course of the right and left recurrent laryngeal nerves, and, through a separate collar incision in the neck, completes the dissection with removal of the lower cervical nodes, including the deep external and lateral cervical lymph node basins.^{96,97}

Most of the series that examine the utility of extended esophagectomies are retrospective and involve a single institution. Hagen et al.⁹¹ reported on 100 consecutively treated patients who had undergone an en bloc esophagectomy with two-field lymphadenectomies; none of the patients received additional preoperative or postoperative chemotherapy or radiotherapy. The perioperative mortality was 6%, with the most common complications being pneumonia (19%), subphrenic abscess (13%), respiratory failure (9%), anastomotic leak (10%), and empyema (7%). Local recurrence was detected in only one patient and overall actuarial 5-year survival was 52%. Patients with stage III lesions had a 25% actuarial 5-year survival. Altorki et al.⁹² reviewed the results for 128 patients who underwent an esophagectomy at a single institution; 61% received an en bloc esophagectomy and the remainder underwent a standard esophageal resection. Approximately 40% of those undergoing the more extended resection had a three-field lymphadenectomy; the others had a systematic two-field lymphadenectomy. The in-hospital mortality for the en bloc resection

Figure 45.10 Left to right: Standard, two-field, and three-field lymphadenectomy.

group was 5.1%, similar to that for those undergoing a standard resection. The most common postoperative complications in the extended resection group were respiratory events (24%) and anastomotic leak (12.8%), but no significant differences were noted in comparison to the standard resection group. Four-year survival for the en bloc group was 41.5% overall and 34.5% for stage III patients, with both of these survival figures markedly better than those for the standard resection group. However, both of the studies described here are single-institution, retrospective analyses for which the results, at least in part, if not completely, can be attributed to selection bias and enhanced staging, leading to stage migration. It is interesting to note that similar results have been achieved without a thoracotomy using a transhiatal approach as described earlier in Transhiatal Esophagectomy.²²⁴

A group at Cornell University also separately examined 80 patients who underwent an esophagectomy with a three-field lymphadenectomy.⁹⁴ Overall 30-day mortality was 5%, with 31% of patients developing major postoperative complications, including the need for reintubation (16%), anastomotic leak (11%), and recurrent laryngeal nerve injury (9%). Overall 5-year survival was 51%. Cervical lymph node metastases were identified in 36% of patients, and the 5-year survival rate for those with positive cervical lymph nodes was 25%. Lerut et al.²⁵² reported on 174 patients, equally divided between squamous cell and adenocarcinoma histology, who underwent a three-field lymphadenectomy. Hospital mortality was only 1.2%, with an overall mortality of 58%. Five-year survival for stage III patients was 36.8%. Twenty-three percent of patients with adenocarcinoma and 25% of those with squamous cell carcinoma had positive cervical nodes. Five-year survival for patients with positive cervical lymph nodes was 27% and 12%, respectively, for squamous cell and adenocarcinoma histology. The authors suggest that a three-field lymphadenectomy may have a role in patients with squamous cell carcinoma, but this remains investigational for patients with adenocarcinoma. These results, although impressive, may also reflect both selection bias and stage migration. In addition, the expertise required to perform these technically demanding procedures effectively limits their application to specialized centers only and a fraction of the patients who might benefit from these procedures if an actual advantage were proven.

The Hulscher trial, discussed previously, which also employed an en bloc resection of the esophagus, compared to transhiatal esophagectomies, failed to improve outcome.²⁵⁰ A small study by Nishihira et al.²⁵³ of 62 patients showed an improved, but not statistically significant, survival advantage for extended lymphadenectomies (66.2% versus 48%; $p = 0.19$). Patients in this study were also randomly assigned to receive either chemoradiation or

chemotherapy alone after surgery, confounding the interpretation of the results.

The body of evidence confirms that extended resections improve staging and may enhance local-regional control; however, there are no reliable data confirming a survival benefit for these procedures.

Adjuvant Therapy

Preoperative Chemotherapy. Nearly three-fourths of patients newly diagnosed with esophageal cancer present with locally advanced (stage IIB or III) disease. The poor survival rate achieved with surgery alone, and given the patterns of both local and systemic disease recurrence, has provided the impetus for the evaluation of preoperative (induction) chemotherapy in patients with resectable esophageal cancer.

The benefits of induction chemotherapy include the potential downstaging of the disease to facilitate surgical resection, improvement in local control, relief of dysphagia in patients responding to induction chemotherapy, and the potential eradication of micrometastatic disease. An esophagectomy after induction therapy enables a comprehensive pathologic assessment of treatment response, which may be important in selecting patients for postoperative adjuvant therapy. The disadvantages of preoperative chemotherapy include the potential development of chemotherapy resistance and the delay in definitive treatment with the risk of further spread of the disease. These are important concerns because approximately 50% of patients do not respond to current chemotherapeutic regimens. Further compromise of the patient's already marginal nutritional status due to a delay in local disease control is also of concern when surgery is not the initial treatment.

Trials evaluating the use of induction chemotherapy followed by surgery for the treatment of esophageal cancer have been underway since the late 1970s. This strategy was evaluated in parallel with studies of concurrent chemoradiation followed by surgery or chemoradiation as definitive therapy. Early trials used cisplatin and bleomycin-based chemotherapy.²⁵⁴⁻²⁵⁷ Use of cisplatin and 5-fluorouracil (5-FU)²⁵⁸⁻²⁶² led to the initiation of randomized trials in the 1980s. For lesions of squamous histology, the response rate to two or three cycles of cisplatin (100 mg/m² on day 1) and 5-FU (1,000 mg/m² per day for 96 or 120 hours) every 3 weeks ranged between 42% and 66%, with a 0% to 10% pathologically confirmed complete-response rate; curative resection rates were between 40% and 80%, and median survival was from 18 to 28 months.²⁵⁸⁻²⁶² Lesions were staged with a barium esophagogram and CT scan initially and then again before surgery to assess the response to induction therapy.

Preop, preoperative; C, cisplatin; B, bleomycin; VDS, vindesine; S, squamous cell carcinoma; A, adenocarcinoma; ECF, epirubicin/cisplatin; 5-FU, 5-fluorouracil; postop, postoperative.

Nine randomized trials evaluating the use of preoperative chemotherapy in esophageal cancer patients are summarized in Table 45.6.^{105,106,263–269} Four of the trials enrolled only patients with squamous cell carcinoma,^{263–265,267–269} whereas half to two-thirds of patients enrolled in the two more recent and largest trials (U.S. Intergroup and Medical Research Council) had adenocarcinoma of the esophagus, GEJ, or cardia.^{105,106} Another large randomized trial treated mostly gastric cancer, although one-fourth of patients enrolled had adenocarcinoma of the distal esophagus or GEJ.²⁶⁶ Two recent small European trials treated only adenocarcinoma of the esophagus and stomach with half or more of patients having esophageal or GEJ adenocarcinoma.^{267,268}

No improvement in survival was noted in three small trials enrolling fewer than 100 patients each, with the small sample size making study interpretation difficult.^{263–266} Boonstra et al.²⁶⁹ reported a survival advantage for preoperative chemotherapy in the final report of a study initially published in abstract form back in 1997. This study, enrolling 171 patients with squamous cell carcinoma, differed from other trials by requiring a response assessment after two courses of preoperative chemotherapy. Patients showing no response underwent immediate surgery, whereas patients showing a response received two more courses of chemotherapy before surgery. The regimen consisted of cisplatin (80 mg/m² on day 1) and etoposide (100 mg/m² intravenously on days 1 to 2 and 200 mg/m² orally on days 3 to 5). Median overall survival in the surgery arm was 12 months compared to 16 months for surgery plus chemotherapy. Fewer patients went on to surgery after preoperative chemotherapy (89%) compared to patients undergoing immediate surgery (97%). Rates of R0 resection favored the chemotherapy arm, but the difference was nonsignificant ($p = 0.09$). Overall survival was superior with preoperative chemotherapy (hazard ratio [HR], 0.71; $p = 0.03$) with the 5-year survival for chemotherapy plus surgery 26% compared to 17% for surgery alone.

The U.S. Intergroup mounted a large, potentially definitive trial, INT-0113. A total of 467 patients with resectable esophageal cancer were randomly assigned to one of two treatment groups: (1) three cycles of cisplatin and 5-FU followed by surgery and then, for those patients whose resection was curative (R0), two additional cycles of cisplatin and 5-FU as adjuvant treatment; or (2) immediate surgery.¹⁰⁵ In contrast to other trials, a barium esophagogram was the only test required to assess clinical response to preoperative chemotherapy. Thus, it is not surprising that only a 19% response rate was reported. Survival and pattern of failure were the major study end points. No differences were observed between the surgery control group and the preoperative cisplatin and 5-FU group in terms of curative resection rate (59% versus 62%), treatment mortality (6% versus 7%), overall median survival (16.1 months versus 14.9 months), or 3-year survival (26% versus 23%) (Fig. 45.11). Furthermore, the median survival of patients who had a curative resection was the same in both treatment groups (27.4 months versus 25.0 months). The pattern of failure was also similar for the two treatment groups (local recurrence 31% versus 32%, and distant recurrence of 50% versus 41% in the surgery-alone group compared to those receiving induction chemotherapy followed by surgery, respectively). Tumor histologic type did not influence response to treatment. A recent update of the trial reported no late benefit for preoperative chemotherapy.¹¹² The importance of achieving an R0 resection in the updated analysis was emphasized, with these patients achieving long-term survival, whereas patients with an R1 resection treated only with surgery all died of recurrent disease. The only patients with R1 resection achieving long-term survival were those receiving protocol-permitted postoperative chemoradiotherapy: Among 34 patients treated with surgery alone with R1 resection, 18 received postoperative chemoradiotherapy and 9 (21%) achieved long-term survival. These results indicated that R1 resection patients may be salvaged with postoperative chemoradiotherapy.

Figure 45.11 Overall survival US Intergroup trial INT-0113 comparing patients randomized to preoperative chemotherapy versus surgery alone.

Although no improvement in survival was demonstrated for preoperative chemotherapy on INT-0113, the trial importantly provides a contemporary surgical experience in the treatment of esophageal squamous carcinoma and adenocarcinoma. Important outcomes in this trial include a postoperative death rate well below 10%, the lack of difference in survival for lesions of different histologic types, and the fact that an R0 curative resection (regardless of treatment) conferred a median survival time of more than 2 years.

In contrast to the results of the 467-patient U.S. Intergroup trial, the Medical Research Council (MRC) Oesophageal Cancer Working Group demonstrated a statistically significant 9% improvement in 2-year survival rate (43% versus 34%) (Fig. 45.12) with preoperative cisplatin and 5-FU.¹⁰⁶ A total of 802 patients, 31% with squamous lesions and 69% with adenocarcinoma or lesions of undifferentiated histologic type, were enrolled. Patients were randomly assigned either to receive two courses of cisplatin (80 mg/m²) and 5-FU (1,000 mg/m² per day, continuous infusion for 4 days) 3 weeks apart followed by surgery or to undergo immediate surgery. The curative resection (R0) rate (60% versus 54%) and the percentage of randomly assigned patients undergoing surgery (92% versus 97%) were similar for the two treatment groups, although the improvement in curative resection rate did reach statistical significance. Patients receiving preoperative chemotherapy had improved median survival (16.8 months versus 13.3 months) and 2-year survival rate (43% versus 34%) (Fig. 45.12). Overall survival was significantly improved with preoperative chemotherapy

Figure 45.12 Overall survival Medical Research Council (MRC) Oesophageal Cancer Working Group trial comparing patients randomized to preoperative chemotherapy (CS) versus surgery alone (S).

($p = 0.004$; HR, 0.79; 95% CI, 0.67 to 0.93). The estimated reduction in risk of death was 21%. The postoperative mortality rate was 10% in both treatment groups. Pathologic complete responses were rare and were reported in 4% of patients undergoing preoperative chemotherapy. These authors recently reported an update of this trial at a median follow-up of 6 years.¹¹³ Although a survival benefit was maintained in the preoperative chemotherapy arm, it had diminished to only 6% at 5 years (23.0% for preoperative therapy versus 17.1% for surgery; HR, 0.84; $p = 0.03$). There was no difference in pattern of failure—in particular, the development of distant metastatic disease—in the chemotherapy surgery versus surgery alone group, with the authors attributing the survival improvement with preoperative chemotherapy to the enhancement of rate of curative resection. The modest survival improvement with preoperative chemotherapy in this trial update is consistent with a 4.3% survival benefit observed in a recent meta-analysis of preoperative chemotherapy reported in abstract form, in which updated survival data from individual trials were obtained in over 2,000 patients in nine studies.²⁷⁰

There is no clear explanation for the discrepancy in survival outcome for the INT and MRC trials, whereas survival of the surgery control groups was essentially the same. The MRC study had the advantage of a larger sample size and greater power to observe a small difference. A greater proportion of patients who received chemotherapy underwent surgery in the MRC study, 92% compared with 80% in the INT trial. Although a microscopically complete resection (R0) was performed in similar proportions in the two trials, the MRC trial indicated a higher rate of R0 resection with preoperative chemotherapy compared to surgery alone. The duration of preoperative chemotherapy in the MRC trial was shorter and may have lessened the risk to patients of disease progression during induction therapy.

Positive results of another recent trial of perioperative chemotherapy in gastric and distal esophagus or GEJ cancer have been reported. In a trial by Cunningham et al.,²⁶⁶ 503 patients were assigned to three cycles of preoperative and three cycles of postoperative epirubicin/cisplatin/5-FU or surgery alone. Preoperative chemotherapy resulted in significant improvement in patient survival, with a 6-month improvement in progression-free survival, a 4-month improvement in median survival, and a 13% improvement in 5-year overall survival (23% to 36%), all of which are statistically significant. Despite the survival improvement with pre- and postoperative chemotherapy, there was no improvement in the rate of curative resection in patients treated with preoperative chemotherapy compared with surgery alone (66% to 69%), and there were no cases of pathologic complete response to preoperative chemotherapy. Downstaging was also observed with preoperative chemotherapy, with a shift to earlier T and N stage tumors with preoperative chemotherapy compared to surgery alone. Because 26% of patients on this trial had tumors in the GEJ and lower esophagus, the results may apply to locally advanced esophageal cancer. The median follow-up was 47 months in the surgery-alone arm and 49 months in the chemotherapy arm.

Two recent studies from Europe also came to conflicting results for any benefit for preoperative chemotherapy. Ychou and colleagues²⁶⁷ randomized 234 patients with esophageal, GEJ, or gastric adenocarcinoma to immediate surgery or to perioperative chemotherapy with cisplatin and fluorouracil. Rates of R0 resections were improved with preoperative chemotherapy to 84% compared to 74% for surgery alone ($p = 0.04$). At a median follow-up of 5.7 years, preoperative chemotherapy improved 5-year survival from 24% to 38%. On the other hand, Schuhmacher and colleagues²⁶⁸ for the European Organisation for Research and Treatment of Cancer (EORTC) reported a negative trial of 144 patients with GEJ junction or gastric adenocarcinoma randomized to surgery alone or to two 48-day cycles of infusional fluorouracil and cisplatin.²⁶⁸ In contrast to all earlier studies reported, this trial performed modern presurgical staging including endoscopic ultrasound, CT scan, and laparoscopic staging, and only

endoscopic stage T3 to T4 tumors were eligible. The R0 resection was improved from 67% for surgery to 82% for preoperative chemotherapy ($p = 0.036$). At a median follow-up of 4.4 years, median survival was 65 months for the chemotherapy arm versus 63 months for surgery alone (HR, 0.84; $p = 0.466$) and 2-year overall survival was equivalent (70% for surgery alone, and 73% for the chemotherapy arm). Both arms had higher than expected median survival.

Despite the inconsistency of these outcomes, preoperative cisplatin and 5-FU is now the standard of care for resectable esophageal cancers—in particular, adenocarcinoma of the esophagus and GEJ—in the United Kingdom and in much of Europe, whereas this approach has not been generally accepted for esophageal cancer in the United States.

Preoperative Radiation Therapy. The high rate of local failure after esophagectomies engendered interest in the use of radiation therapy in conjunction with surgery. The incidence of local failure in the surgical control arms of randomized trials of preoperative radiation therapy reported by Mei et al.²⁷¹ and Gignoux et al.²⁷² was 12% and 67%, respectively. The local failure rate in the surgical control arm of the randomized trial of postoperative radiation therapy conducted by Teniere et al.²⁷³ was 35% for patients with negative local–regional lymph nodes and 38% for patients with positive local–regional lymph nodes. The surgical control arm of INT-0113 provides a modern, more relevant baseline for the results of surgery alone. As discussed in Preoperative Chemotherapy, there was a 31% local failure rate in patients undergoing an R0 resection and a total local failure rate (including the additional 30% of patients with persistent disease) of 61%. Six randomized trials of preoperative radiation therapy for patients with clinically resectable disease have been reported.^{263,271,272,274–276} Overall, preoperative radiation therapy did not increase the resectability rate, and only two series reported local failure rates. Although Mei et al.²⁷¹ reported no difference in local failure, Gignoux et al.²⁷² observed a significantly lower local failure rate in patients who received preoperative radiation therapy than in those treated with surgery alone (46% versus 67%, respectively).

Two trials have reported an improvement in survival. In the series of Nygaard et al.,²⁶³ patients who received preoperative radiation therapy (with or without chemotherapy) had a significant improvement in overall 3-year survival (18% versus 5%; $p = 0.009$). The 48 patients who received preoperative radiation therapy without chemotherapy had a 20% 3-year survival rate; however, this did not reach statistical significance. This was not a pure radiation study, and the benefit may have been partly because of the chemotherapy. A similar improvement in survival was reported by Huang et al.²⁷⁶ (46% versus 25%). A meta-analysis from the Oesophageal Cancer Collaborative Group also showed no clear evidence of a survival advantage with preoperative radiation therapy.¹¹⁰

Design flaws in these trials include the failure to use conventional doses of radiation therapy, the use of split-course radiation therapy, and failure to allow an adequate interval (4 to 8 weeks) between the completion of radiation therapy and surgery. The only study that allows an analysis of the effect of radiation fractionation is a randomized trial performed in France involving patients with squamous cell carcinomas who received chemoradiation using continuous-course versus split-course radiation.²⁷⁷ The 95 patients who received a continuous-course regimen had a significantly higher local control rate (57% versus 29%) and 2-year event-free survival rate (33% versus 23%), and a borderline, significantly higher 2-year survival rate (37% versus 23%). Because it is less effective than continuous-course therapy, split-course radiation therapy is not recommended.

In summary, because only two of the six series have reported local failure rates, it is difficult to draw firm conclusions regarding the influence of preoperative radiation therapy on local control. Nonrandomized trials^{278,279} also reported no survival benefit. Based on the available data from randomized trials, preoperative

radiation therapy does not appear to significantly decrease local failure rate or improve survival in esophageal cancer patients.

Preoperative Chemoradiation. The rationale for trimodal therapy—chemoradiation followed by surgery—is based on the pattern of both local and distant failure associated with surgery alone or chemoradiation without surgery, which are the two treatment options established as standards of care based on data from randomized controlled trials. The results for patients randomly assigned to the surgery control arm of the INT-0113 trial revealed a 61% rate of failure in controlling local disease.¹⁰⁵ Similarly, the two Intergroup trials (RTOG-85-01 and INT-0123) that evaluated nonsurgical treatment (concurrent cisplatin and 5-FU, and radiotherapy), which are discussed in greater detail later in this chapter, showed unacceptably high rates of local failure (44% to 53%).^{280,281} Most of the agents active against esophageal cancer (i.e., 5-FU, cisplatin, carboplatin, mitomycin C, paclitaxel, irinotecan, docetaxel, capecitabine, and oxaliplatin) are known to enhance radiosensitivity in cancer cells. Chemotherapy in conjunction with radiotherapy may both sensitize radiation therapy to improve local control as well as impact a reduction on systemic disease recurrence. Treatment with chemoradiation followed by an esophagectomy has the potential to: (1) downstage the disease, (2) increase the rate of complete resection with negative circumferential margins, and (3) eradicate occult micrometastatic disease.

Nonrandomized Trials. Most trials have used 5-FU and cisplatin-based chemotherapy combined with radiation therapy.^{111,282–301} although more recent trials incorporate paclitaxel, docetaxel, oxaliplatin, or irinotecan in two- or three-drug combination regimens.^{101,302–314}

Since the initial trials by Leichman et al.³¹⁵ and the Southwest Oncology Group (SWOG-8037),²⁸² results of many phase II single-institution or multicenter trials of preoperative chemoradiation have been published.³¹⁶ Most trials used cisplatin (75 to 100 mg/m²) and 5-FU (1,000 mg/m² per day continuous infusion for 4 or 5 days) with concurrent radiotherapy followed by surgery in 4 to 8 weeks. In most series, the pathologic complete-response rate (based on total number treated) was approximately 25%. The highest pathologic complete-response rates have been reported in trials treating mainly squamous cancers, and as more modern series predominantly treat adenocarcinoma, pathologic complete-response rates are consistently lower. Intensive chemoradiation regimens using hyperfractionated radiotherapy were evaluated by Forastiere et al.,^{284,285} Raoul et al.,²⁹⁵ and Adelstein et al.²⁹² Some of these regimens achieved higher pathologically determined complete-response rates and survival rates, usually with corresponding increases in acute toxicity. However, no clear advantage to altered fractionation schedules has been shown. The total dose of radiotherapy with concurrent chemotherapy varied from 30 Gy in earlier series up to 60 Gy, followed by surgery. Pathologic complete-response rates are uniformly in the 15% to 20% range with lower doses of radiation,^{282,286,297,298} whereas total doses exceeding 50 Gy are associated with increased toxicity and perioperative complications.²⁹⁶ Doses of 44 to 50 Gy using standard fractionation and concurrent therapy with cisplatin plus 5-FU generally result in pathologic complete-response rates of 25% to 40%^{111,284,286,287,290,292,295,299} and acceptable toxicity with postoperative mortality rates well below 10%. As will be discussed later, the CROSS randomized trial of preoperative chemoradiation used 41.4 Gy and achieved a significant survival benefit with neoadjuvant therapy.³¹⁷

Most trials use conventional fractionation and doses of radiotherapy (45.0 to 50.4 Gy) with concurrent chemotherapy. In addition to overall outcome, some investigators have sought to determine whether preoperative endoscopy with biopsy can accurately assess response to treatment and whether achievement of pathologically confirmed complete response after chemoradiation improves overall survival. Bates et al.²⁸⁷ reported a 65% 3-year survival rate in patients who achieved a pathologic confirmed

complete response, compared with a 25% survival rate in those who did not. In 106 of 262 (41%) patients who achieved a pathologic complete response with preoperative chemoradiation, the 5-year survival was 52% compared with 38% in partial responders ($p < 0.001$) and 19% in nonresponders ($p < 0.001$).³⁰¹

In other trials with long-term follow-up, investigators observed 5-year survival rates of 60% to 67% and 27% to 32% for those with pathologic complete response and those with residual disease after induction therapy, respectively.^{111,284} In addition, the fact that long-term survival was observed in approximately 30% of patients with a residual tumor in the resected specimen suggests that surgery is an important component following chemoradiation.

At present, no methods short of surgical resection can accurately determine which patients will be found to have no residual tumor in the resected esophageal specimen after chemoradiation. Bates et al.²⁸⁷ noted a 41% false-negative rate with preoperative endoscopy and biopsy. Sarkaria et al.³¹⁸ reported the correlation of postchemoradiotherapy endoscopy findings and surgical pathologic findings in 156 patients with esophageal cancer. Although 76% had a biopsy-negative endoscopy after preoperative therapy, only 31% of these patients were found to be pathologic complete responders at subsequent surgery. Chedella et al.³¹⁹ reported the results of 284 patients who received preoperative chemoradiation at M.D. Anderson Cancer Center, and at 5 to 6 weeks posttreatment, underwent restaging with endoscopy, biopsy, and PET-CT scan. The 24% of patients who achieved a pathologic complete response (pCR) had a higher median survival compared to those who did not achieve a pCR (95 versus 55 months).³¹⁹ Of note, only 31% of patients who achieved a clinical complete response were found to have a pCR.

Yang et al.³²⁰ made similar observations about the accuracy of posttherapy biopsy. Jones et al.³²¹ reported that CT scans had a sensitivity of 65%, a specificity of 33%, a positive predictive value of 58%, and a negative predictive value of 41% in evaluating pathologic response after preoperative chemoradiation in esophageal cancer patients. Many studies show that EUS performed after chemoradiation is also a poor predictor of complete response because of the inability to distinguish postirradiation fibrosis and inflammation from residual tumor. Reported staging accuracy is below 50%.³²³⁻³²⁴

To further pursue the selective surgical approach as a treatment modality, it will be critical to establish the definition of an adequate response. However, the ability to predict a pCR prior to surgery is variable. A multivariate analysis by Gaca and colleagues³²⁵ reported that posttreatment nodal status ($p = 0.03$), but not the degree of primary tumor response, predicted disease-free survival. Fields et al.³²⁶ reviewed 714 patients treated at Memorial Sloan Kettering Cancer Center (MSKCC) and reported that there was a significant improvement in 5-year survival in the 60 patients who achieved a pCR compared with the 549 who did not (55% versus 35%; $p = 0.036$).³²⁶

The value of FDG-PET scans for restaging after chemoradiation remains to be established. Several studies of esophageal cancer patients show that an early decrease in FDG uptake after chemotherapy can predict clinical response.^{156,327,328} In addition, multiple studies have evaluated the ability of FDG-PET scans to predict a pCR following chemoradiation.³²⁸⁻³³² Flamen et al.³²⁸ evaluated the predictive value of PET scans after chemoradiation in patients receiving preoperative treatment. The sensitivity and positive predictive value of PET scans for identifying a pathologically determined complete response were 67% and 50%, respectively. Both false-positive PET findings (residual FDG activity in an area of intense inflammatory activity on histopathologic analysis) and false-negative findings occurred at the primary tumor site. Vallbohmer et al.³²⁹ treated 119 patients with preoperative chemoradiation (cisplatin, 5-FU, and 36 Gy) and reported a nonsignificant association between major responders and FDG-PET results ($p = 0.056$). However, there was no clear standardized uptake value threshold that predicted a response.

Possible reasons for discrepant findings include the inflammatory effect of chemoradiation as well as a lack of standardization of FDG-PET protocols and techniques and definitions of a pathologic response.

Few studies have reported a long-term follow-up to determine actual survival rates at 5 years. Rates range from 25% reported by Bedenne et al.²⁹⁷ for a series of 96 patients with squamous cell esophageal cancer to as high as 39% reported by Meredith et al.³⁰¹

Taken together, data from nonrandomized trials accumulated during nearly 3 decades suggest an approximate 5% to 10% improvement in survival compared with historical surgery controls. However, substantially greater improvement in survival is seen in patients who are downstaged to pathologically confirmed complete response or minimal residual disease.

Patterns of failure after chemoradiation and resection are influenced by histologic type, with a greater likelihood of local recurrence for patients with squamous cell carcinoma of the esophagus and predominantly distant recurrence for those with adenocarcinoma of the distal esophagus, GEJ, and cardia. In a literature review of trials of preoperative chemoradiation published between 1980 and 2000, Geh et al.³¹⁶ found that the overall risk of relapse was 46%, but that the majority of relapses, 80%, were at distant sites; local-regional recurrence alone constituted only 9% of treatment failures. These cumulative data correspond with individual reports from other major centers^{111,287,292,294} and suggest that preoperative chemoradiation followed by surgery leads to better local-regional control than does surgery alone or chemoradiation without surgery.

Newer regimens employing various combinations of 5-FU, cisplatin or oxaliplatin, taxanes, and irinotecan with radiotherapy report pathologic complete-response rates similar to those for previous cisplatin and 5-FU plus radiotherapy preoperative regimens, and rates of survival are also similar.

Meluch et al.³⁰⁶ reported mature trial results for a combination of carboplatin, 5-FU, and paclitaxel plus concurrent radiotherapy. Among a total of 123 patients, the pathologic complete-response rate was 38%, and after a median follow-up of 45 months, the 3-year survival rate was 41%. Grade 3 or 4 leukopenia (73% of patients), esophagitis (43%), and hospitalization (57%) suggest that this regimen added toxicity without providing incremental improvement in survival. Toxicity on trials of paclitaxel and cisplatin on a once-weekly schedule, with conventional dose fractionation of radiation therapy, have reported lesser degrees of esophagitis.^{303,308,333} McCurdy et al.³³⁴ from the M.D. Anderson Cancer Center reported that the addition of taxanes to chemoradiation increased both the FDG-PET scan-determined pulmonary metabolic response and the radiation pneumonitis response compared with non-taxane-containing regimens. Weekly carboplatin combined with weekly paclitaxel and concurrent radiotherapy also appeared to have a favorable toxicity profile in a recent phase II trial treating 54 patients with adenocarcinoma and squamous cell carcinoma of the esophagus, and this regimen formed the basis of the recent Dutch CROSS Trial, which will be discussed.^{310,317} The rate of pathologic complete response was 25%. Rates of grade 3 and 4 neutropenia (15%) and esophagitis (8%) were relatively low, but were in agreement with other trials employing a weekly paclitaxel and platinum drug chemotherapy regimen.

Swisher et al.,³⁰⁸ Ajani et al.,³⁰⁹ Bains et al.,³⁰⁷ Ilson et al.,¹⁰¹ and Rivera et al.³¹⁴ have published pilot experiences in the administration of induction chemotherapy before chemoradiotherapy and then surgery as a strategy to increase pathologically determined complete-response rate and to reduce distant failure. Some trials of induction chemotherapy have noted significant relief of patients' dysphagia and the rare need to place feeding tubes for nutritional support in patients.^{101,307} The RTOG-0113 performed a phase II randomized trial comparing paclitaxel and 5-FU to paclitaxel and cisplatin plus radiation therapy.³¹² Both arms were associated with significant toxicity, and the study did not meet its 1-year survival end point.

In summary, some of these newer regimens appear to be more toxic than cisplatin and 5-FU plus radiotherapy, whereas others suggest a potentially more favorable toxicity profile; the pathologic complete-response rates and survival estimates show no consistent benefit, but longer follow-up is needed. The interpretation of survival rates from these studies must be done cautiously, given the likelihood of stage migration due to the incorporation of EUS and PET scans into routine staging evaluation. Roof et al.³⁰⁰ reported a single-institution experience of 177 patients treated with either cisplatin, 5-FU, or paclitaxel in combination with cisplatin, 5-FU, and radiation therapy as preoperative treatment in esophageal cancer. The 3-year overall survival was similar for the 5-FU/cisplatin-treated patients (39%) compared with those receiving paclitaxel in combination with 5-FU/cisplatin (42%). Pathologic complete-response rates were also comparable for two-drug (42%) compared with three-drug therapy (37%). In two sequential trials from Urba et al.^{335,336} that evaluated two-drug paclitaxel cisplatin therapy plus radiation in one trial, and three-drug 5-FU, cisplatin, and paclitaxel plus radiation in another trial, there was also no difference in pathologic complete-response rates (17% to 19%). These rates of pathologic complete response were significantly lower than other trials reporting pathologic complete-response rates of 37% to 38% for three-drug therapy.³⁰⁰

The Eastern Cooperative Oncology Group (ECOG) reported response and survival³³⁷ outcomes in a randomized phase II trial testing two of these combinations (E1201), limited to patients with resectable adenocarcinoma of the distal esophagus, GEJ, and cardia. The two preoperative treatments tested were (1) paclitaxel (50 mg/m², 1-hour infusion) followed by cisplatin (30 mg/m²) on days 1, 8, 15, 22, 29, and concurrent radiotherapy (45 Gy); and (2) cisplatin (30 mg/m²) followed by irinotecan (65 mg/m²) on days 1, 8, 22, 29, and concurrent radiotherapy (45 Gy). Patients in each arm proceeded to esophagectomy followed by three cycles of adjuvant paclitaxel and cisplatin (arm 1) or cisplatin and irinotecan (arm 2). Staging with esophageal EUS was an eligibility requirement. A preliminary report indicated comparable rates of pathologic complete response for the two regimens of 15% to 16%,

with the lower than expected pathologic complete-response rate likely partly due to the exclusive treatment of adenocarcinoma on this trial.³³⁸ The median survival on the paclitaxel arm was 20.9 months, and 34.9 months on the irinotecan arm (difference nonsignificant). Although the results are comparable to other modern phase II trials in esophageal adenocarcinoma, neither regimen appeared superior to more conventional 5-FU and cisplatin-based therapy.

Randomized Trials. Randomized trials comparing preoperative chemoradiation with surgery alone in patients with clinically resectable disease are listed in Table 45.7.^{107,114,240,317,339-344} The series of Le Prise et al.³⁴⁵ is not included because patients received sequential rather than concurrent chemotherapy and radiotherapy. Most trials combined cisplatin and 5-FU³³⁹⁻³⁴¹ or single-agent cisplatin²⁴⁰ with concurrent radiotherapy.

The Bosset et al.²⁴⁰ trial was limited to patients with stage I or II squamous cell carcinoma based on a previously defined CT scan staging system, whereas the trials of Urba et al.,¹⁰⁷ Burmeister et al.,³⁴¹ Tepper et al.,³⁴² and van Hagen et al.³¹⁷ treated adenocarcinoma and squamous cell carcinoma, and the trial of Walsh et al.^{339,340} was designed for locally advanced, resectable adenocarcinoma. A significant difference in the median and 3-year survival rates was observed in the Walsh, Tepper, and Van Hagen et al. trials. It is noteworthy that the pathologically determined complete-response rate was consistent for all studies, 25% to 28%, with the exception of the Burmeister et al. trial, which indicated a statistically significant lower pathologic complete-response rate for adenocarcinoma (9%) compared to squamous cell carcinoma (27%). Van Hagen et al. reported a pathologic complete response rate of 24% for adenocarcinoma and 49% for squamous cell carcinoma. Comparable rates of 3-year survival for patients in each of the investigational treatment groups (30% to 40%) was also observed. Higher 5-year survival rates, however, were reported on the Tepper et al. trial (39%) and the Van Hagen et al. trial (47%).

Urba et al.¹⁰⁷ at the University of Michigan randomly assigned 100 patients (75 with adenocarcinoma, 25 with squamous cell

S, squamous cell carcinoma; C, cisplatin; RT, radiation therapy; A, adenocarcinoma; NS, not stated; Ca, carboplatin; P, paclitaxel.

carcinoma) to receive (1) preoperative cisplatin (20 mg/m² on days 1 to 5 and 17 to 21), vinblastine (1 mg/m² on days 1 to 4 and 17 to 20), 5-FU (300 mg/m² per 24 hours on days 1 to 21), and concurrent radiotherapy (1.5 Gy twice a day to 45 Gy), followed on day 42 by a transhiatal esophagectomy, or (2) immediate surgery. A survival analysis after a median follow-up of 8.2 years for surviving patients revealed a nonsignificant improvement favoring preoperative chemoradiation (3-year survival, 30% versus 16%; $p = 0.15$). A significant decrease in local-regional recurrence as a component of first failure was observed (19% recurrence rate for the combined treatment group versus 42% for the group undergoing immediate surgery; $p = 0.02$). However, there was no difference in the rates of distant metastases, 60% and 65%, respectively. Although overall survival rates were not significantly different, there was a 31% lower risk of death, after adjustment for other prognostic factors, for patients randomly assigned to receive trimodal therapy, which suggests a possible benefit and the need for a trial adequately powered to detect a smaller survival difference. Consistent with phase II trial data, patients who achieved a pathologically confirmed complete response had better survival outcomes, with a median survival time of 50 months and 3-year survival rate of 64%, compared to those with residual disease in the resected specimen, who had a median survival time of 12 months and a 3-year survival rate of 19%. The low statistical power of this trial may have failed to detect a potential modest survival benefit for chemoradiation compared to surgery alone.

In their series, Walsh et al.³³⁹ reported a significant survival advantage for patients receiving preoperative chemoradiation. A total of 113 patients with adenocarcinoma of the esophagus, GEJ, and cardia were randomly assigned to receive (1) two cycles (weeks 1 and 6) of 5-FU (15 mg/kg per 24 hours on days 1 to 5), cisplatin (75 mg/m² on day 7), plus concurrent radiotherapy (2.67 Gy per day to 40 Gy) followed by esophagectomy; or (2) immediate surgery alone. Chemoradiation was well tolerated. The incidence of acute toxicity of grade 3 or higher was 15%. The operative mortality was 9% in the multimodality treatment arm compared with 4% in the surgery control arm. After a median follow-up of surviving patients of 18 months, a significant improvement in both median survival time (16 months versus 11 months; $p = 0.01$) and 3-year survival rate (32% versus 6%; $p = 0.01$) was observed in patients who received preoperative therapy compared with those treated with surgery alone. A major criticism of this trial was the low 3-year survival rate (6%) in the surgical control arm. This probably reflects a patient population with more advanced disease than in those enrolled in the other two trials. CT scan staging was not required. More than 80% of patients had lymph node metastases.³⁴⁰

A third randomized trial of preoperative chemoradiation was reported by Bosset et al.²⁴⁰ of the EORTC. A total of 282 patients with clinically resectable (early stage I and II) squamous cell carcinoma were randomly assigned to undergo either preoperative chemoradiation or surgery alone. The preoperative regimen consisted of five daily fractions of 3.7 Gy each followed by a 2-week rest and another 3.7 Gy for 5 days. Chemotherapy was limited to cisplatin, 80 mg/m², 0 to 2 days before starting each 5 days of radiotherapy. Rates of curative resection were significantly higher in patients undergoing preoperative chemoradiation (81%) compared with immediate surgery (69%). After a median follow-up of 55 months, patients who received preoperative chemoradiation had a significantly better 3-year disease-free survival rate (40% versus 28%) and local disease-free survival (relative risk [RR], 0.6), yet had no improvement in median survival time (19 months) or overall 3-year survival (36%) compared with patients treated with surgery alone. However, this chemoradiation regimen was unconventional in design; not only was the radiation split course and delivered with unusually high doses per fraction, but the doses of chemotherapy would not be considered adequate for systemic therapy. The threefold higher postoperative mortality in the com-

bined modality arm (12%) compared with the surgery-alone arm (4%) may have undercut any potential overall survival benefit for chemoradiation.

The trial reported by Burmeister et al.³⁴¹ treated 256 patients with adenocarcinoma and squamous cell carcinoma with either surgery alone, or preoperative cisplatin, 5-FU, and radiation followed by surgery. The combined modality arm received one cycle of 5-FU dosed at 800 mg/m² per day during a 4-day continuous infusion in combination with cisplatin 80 mg/m² on day 1, plus concurrent radiotherapy (2.33 Gy per day to 35 Gy) followed by esophagectomy. Chemoradiation was well tolerated, with the most common toxicities grade 3 or 4 esophagitis (16%) or nausea and vomiting (5%). There was no difference in surgical complications in either treatment group, with an overall operative mortality of 5%. After a median follow-up of 65 months, no significant difference was seen in either median overall survival time (22 months versus 19 months with surgery alone) or 3-year survival rate. The chemoradiation group had a higher rate of curative resection (80%) compared with the surgery-alone arm (59%). Pathologic complete responses were significantly less common in adenocarcinoma (9%) compared with squamous cell carcinoma (27%). A univariate analysis indicated that patients with squamous cell cancer had significantly better progression-free and overall survival when treated with preoperative chemoradiation. The low rate of pathologic complete responses in patients with adenocarcinoma on this trial raises concern about the adequacy of chemotherapy delivered (one cycle) during radiotherapy.

A similar trial was reported by Lee et al.³⁴³ from Korea. A total of 102 patients with squamous cell cancer were randomized to surgery alone versus preoperative therapy with 45.6 Gy (1.2 Gy twice a day) plus 5-FU/cisplatin. There was no difference in median survival (28 months versus 27 months).

The sixth randomized trial by Tepper et al.³⁴² reported the results of an Intergroup trial led by the Cancer and Leukemia Group B (CALGB-9781), in which patients were randomly assigned to receive either (1) immediate surgery or (2) two cycles of cisplatin, 5-FU, and concurrent radiotherapy (total dose, 50.4 Gy) followed by surgery. This trial, activated in July 1998 and projected to enroll 475 patients, was terminated early because of failure to meet accrual targets. However, follow-up was available in 56 patients ultimately randomized and treated on protocol. With a median follow-up of 6 years, 5-year survival was significantly improved with the addition of preoperative chemoradiation (39% versus 16%; $p = 0.005$). Interpretation of this trial is confounded by the small number of patients treated.

The most contemporary trial recently reported by Van Hagen et al., the CROSS Trial,³¹⁷ has for many practitioners established a new standard of care for preoperative chemoradiotherapy. This study randomized 366 patients with squamous cell carcinoma or adenocarcinoma of the esophagus or GEJ to treatment with (1) preoperative carboplatin at an area under the curve of 2 mg/mL per minute and paclitaxel 50 mg/m² once weekly for 5 weeks, and concurrent radiotherapy (1.8 Gy daily to 41.4 Gy in 23 fractions, followed by transthoracic esophagectomy or transhiatal esophagectomy for GEJ cancers, or (2) immediate surgery. Unlike earlier trials, this more modern trial staged all patients by endoscopic ultrasound and CT scan, and patients were required to have either node-positive or T2-3Nany disease. The majority of patients treated had adenocarcinoma (75%), and most tumors involved the distal third of the esophagus (58%). The majority of patients were node positive (65%), and slightly more patients on the chemoradiotherapy arm had T3 tumors (84%) compared to the surgery-alone arm (78%). At a median follow-up of 45 months, the trial showed a significant survival benefit (Fig 45.13) for chemoradiotherapy added to surgery, with a median survival increased from 24 to 49 months (HR, 0.0657; $p = 0.003$), and improvement in 2- and 5-year overall survival (67% and 47% versus 50% and 34%; HR, 0.665). The rate of R0 resection was significantly improved on the chemoradiotherapy arm (95% compared

Figure 45.13 Overall survival CROSS trial comparing patients randomized to preoperative chemoradiotherapy (CRT + surgery) versus surgery alone.

to 69%; $p < 0.001$). Pathologic complete responses were seen in 24% of adenocarcinomas and 49% of squamous cancers. Survival benefits were significant for both histologies, but with an even greater benefit for squamous cancers (HR, 0.453) compared to adenocarcinomas (HR, 0.741). Therapy was well tolerated with grade 3 or 4 hematologic toxicity seen in 7% patients, and grade 3 or 4 nonhematologic toxicity seen in less than 13%. There was no difference in either operative morbidity or mortality, and mortality was below 4% in each arm, which is considered consistent and appropriate with modern day surgical outcomes in high-volume centers. Many investigators feel that this well-conducted chemoradiotherapy trial using a well-tolerated, relatively easy to administer therapeutic regimen established a new standard of care for squamous cell carcinomas and adenocarcinomas of the distal esophagus or GEJ.

Some additional insight may be obtained from a small trial reported by Stahl et al.,³⁴⁴ a multicenter phase III trial directly comparing preoperative chemotherapy to combined chemoradiotherapy followed by surgery in patients with GEJ adenocarcinoma. The trial did not meet accrual goals and randomized only 119 eligible patients with Siewert I to III GEJ adenocarcinoma. The strength of the trial was the rigorous pretherapy staging, including EUS and laparoscopy, and the balance in treatment arms by clinical stage. Patients were assigned to (1) 2.5 cycles of a 6-week schedule of weekly 5-FU 2 g/m², 24-hour infusion and leucovorin 500 mg/m², 2-hour infusion plus biweekly cisplatin 50 mg/m², or (2) two cycles of the same regimen, followed by 3 weeks of radiotherapy given in 15 fractions at a dose of 2 Gy combined with cisplatin 50 mg/m² on day 1 and 8 and etoposide 80 mg/m² on days 3 to 5. The primary end point was 3-year overall survival. Comparable numbers of patients had an R0 resection after chemotherapy (69.5%) compared to chemoradiotherapy (72%). More patients on the chemoradiotherapy arm achieved a pathologic complete response (15.6%) compared to the chemotherapy arm (2.0%), and more patients were node negative (64.4% compared to 36.7%, respectively). Three-year survival trended superior in the chemoradiotherapy group (47.4%) compared to the chemotherapy group (27.7%; $p = 0.07$), and freedom from local tumor progression also favored the chemoradiotherapy group (76.5% versus 59%; $p = 0.06$). More in-hospital deaths occurred in the chemoradiotherapy arm (10.2% versus 3.8%; not statistically significant). The authors concluded that preoperative chemoradiotherapy could be considered a standard of care based on the favorable comparison to preoperative chemotherapy alone.

The accumulated experience from phase II and III trials indicates the following concerning chemoradiation using cisplatin and infusional 5-FU-based therapy followed by an esophagectomy:

- In approximately two-thirds of patients, the disease is downstaged.
- A survival advantage exists for patients experiencing downstaging to pathologically confirmed complete response or minimal residual disease status.
- Surgery appears to be an important component of treatment to eliminate persistent disease after chemoradiation, especially for adenocarcinoma. Of this group, 20% to 30% will be long-term survivors. The higher rates of pathologic complete response for squamous cancers make an argument for primary chemoradiotherapy without surgery, and this issue will be reviewed in the Radiation Therapy section.
- Local-regional control is improved, whereas distant failure is frequent and is the major cause of death.
- Rates of curative resection may be improved with preoperative chemoradiation.

Controversy continues about the optimal management of adenocarcinoma of the distal esophagus or GEJ, in particular the relative merits of preoperative chemotherapy versus combined chemoradiotherapy followed by surgery. Two ongoing randomized trials may shed light on this debate once completed. One trial, the CRITICS trial being run in the Netherlands and Sweden (NCT00407186), assigns patients with adenocarcinoma of the distal esophagus, GEJ, and stomach to all receive pre- and postoperative chemotherapy in addition to surgery; patients are randomized postoperatively to continue to receive either chemotherapy alone, or to chemotherapy combined with postoperative radiotherapy. Another trial, TOPGEAR (NCT01924819), being run by the Australasian Gastro-Intestinal Trials Group (AGITG) will treat patients with esophageal, GEJ, or gastric cancers with perioperative chemotherapy, with patients randomized to receive combined radiation therapy with preoperative chemotherapy or to preoperative chemotherapy alone.

Meta-analyses lend support to the inclusion of chemotherapy and radiation therapy as part of surgical management. Two studies evaluated in a combined analysis randomized trials predominantly of preoperative chemotherapy³⁴⁶ and preoperative chemotherapy and radiation therapy compared to surgery alone.³⁴⁷ These studies pooled the results of 11 to 25 randomized trials treating between 2,300 and nearly 4,200 patients. Preoperative chemotherapy improved 2-year survival by 5.1% to 6.3% for preoperative chemotherapy alone, and preoperative combined chemoradiation improved 2-year survival by 8.7%. Because of the toxicity and ongoing controversy about the benefit associated with preoperative combined chemoradiation, the priority should be given to enrolling patients in clinical trials.

Targeted Agents

Limited studies have evaluated the combination of a targeted agent with either definitive, nonoperative chemoradiotherapy, or preoperative chemoradiotherapy. Two pilot trials combining the vascular endothelial growth factor (VEGF) ligand-targeted agent, bevacizumab, added to chemoradiotherapy failed to improve outcome compared to historical controls.^{313,348} The EGFR-targeted agent cetuximab was combined with definitive chemoradiotherapy in two recently reported trials. First is the SCOPE-1 trial where 258 patients with stages I through III cancer (25% adenocarcinoma) were randomized to 50 Gy/capecitabine/cisplatin ± cetuximab without planned surgery.³⁴⁹ The trial was stopped early since it met its futility rules. Patient who received cetuximab had inferior 2-year survival (41% versus 56%) and higher nonheme grade 3+ acute toxicity (79% versus 63%). The second is the recently completed RTOG 0436 trial in which patients with nonoperable esophageal cancer were randomized to 50.4

Gy/paclitaxel ± cetuximab, reported only in abstract form.³⁵⁰ On this nonoperative trial, of the 328 patients, the majority had adenocarcinoma. There was no difference in outcome with the addition of cetuximab to chemoradiotherapy, with no increase in rates on endoscopic clinical complete response, and no differences in overall survival and no impact on either adenocarcinoma or squamous cell carcinoma histology. These negative results add to the accumulating literature, also discussed in the section on metastatic disease, that currently available EGFR-targeted therapies are ineffective in esophageal cancer. A phase I/II trial combining the HER2-targeted agent trastuzumab with chemoradiotherapy³⁵¹ in esophageal cancer led to a randomized phase III trial in esophageal adenocarcinoma being conducted by RTOG (NCT01196390). Patients with esophageal or GEJ adenocarcinoma whose tumors test HER2 positive are randomized to chemoradiotherapy with weekly carboplatin AUCS 2 and paclitaxel 50 mg/m² for six doses combined with 50.4 Gy of radiotherapy followed by surgery, with or without the addition of trastuzumab during chemoradiotherapy and as a surgical adjuvant therapy for 1 year after surgery. As will be reviewed in the section covering advanced disease, with the exception of trastuzumab, suitable targets as well as active targeted agents remain to be established in the combined modality treatment of esophageal cancer.

Postoperative Chemotherapy. Administering chemotherapy after surgery to patients who have already received chemotherapy or chemoradiation preoperatively has not been easily achieved in phase II^{257,258,299} and phase III trials.^{105,264} This is exemplified by the INT-0113 trial, in which only 38% of patients who were candidates for adjuvant cisplatin and 5-FU therapy received the two planned courses.¹⁰⁵

In Japan, surgery includes the removal of the primary lesion plus extended dissection of lymph nodes in the mediastinum, neck, and abdomen. The Japanese Oncology Group has evaluated postoperative chemotherapy in a series of randomized trials.^{352–355} One study of 205 patients who had undergone resection compared observation with two courses of adjuvant cisplatin and vindesine.³⁵⁴ Median follow-up was 59 months, and the 5-year survival rate was 45% in the control arm and 48% in the adjuvant treatment arm, which indicated no survival benefit from this chemotherapy regimen.

A second trial of adjuvant chemotherapy in 242 patients had the same study design, except that the chemotherapy was cisplatin and 5-FU administered for two courses after curative resection.^{353,355} At a median follow-up of 40.4 months, no differences were observed in the 5-year survival estimates (51% versus 61% for adjuvant chemotherapy; $p = 0.3$). The estimated 5-year disease-free survival rate was improved with chemotherapy (58% for the chemotherapy versus 46% for observation; $p = 0.05$). Disease-free survival for node-negative patients was 77% in the surgery-alone group versus 82% in the adjuvant treatment group ($p = 0.3$), and for node-positive patients 35% in the surgery-alone group versus 53% in the adjuvant treatment group ($p = 0.06$). These data suggest that adjuvant chemotherapy may benefit node-positive patients, but this was an unplanned subset analysis on this trial. The ECOG completed a phase II trial (E8296) to evaluate adjuvant therapy consisting of cisplatin (75 mg/m²) and paclitaxel (175 mg/m² during 3 hours) every 3 weeks for four courses in 55 patients with completely resected, T3, or node-positive adenocarcinoma of the esophagus, GEJ, or cardia.³⁵⁶ The majority (89%) had lymph node involvement. The majority of these (84%) were able to complete all four cycles of chemotherapy. The 2-year survival rate was 60%, which compared favorably with results for contemporary historical controls.¹⁰⁵

In summary, the available data for postoperative adjuvant chemotherapy suggest a possible prolongation of survival for patients who have had a potentially curative (R0) resection and have lymph node-positive (N1) disease. There are no data to indicate or suggest

that the administration of postoperative adjuvant chemotherapy will prolong survival for patients who have undergone a curative resection and have negative nodes (N0). Patients who have positive margins of resection should be considered for postoperative radiation. Those who have had R0 resections but have regional nodal metastases (stages IIB and III) should be enrolled in clinical trials to evaluate adjuvant therapies.

Postoperative Radiation Therapy. Several reports of nonrandomized trials have suggested that postoperative radiation therapy may be effective after esophagectomy. Yamamoto et al.³⁵⁷ reported a 94% 2-year local control rate in node-positive patients. For patients who underwent a three-field dissection, Hosokawa et al.³⁵⁸ added intraoperative radiation followed by 45 Gy postoperatively. The 5-year survival rate was 34%.

Two randomized trials were limited to patients treated in the adjuvant setting. Teniere et al.²⁷³ reported the results for 221 patients with squamous cell carcinoma randomly assigned to receive either surgery alone or postoperative radiation therapy (45 to 55 Gy at 1.8 Gy per fraction). Postoperative radiation therapy was found to have no significant impact on survival. In the series of Fok et al.,³⁵⁹ patients with both squamous cell carcinomas and adenocarcinomas receiving either curative or palliative resections were evaluated; although the total dose of radiation therapy was conventional, the dose per fraction (3.5 Gy) was unconventional. No significant decrease in local failure or distant failure or improvement in the median survival time was achieved with the addition of postoperative radiation therapy.

Postoperative Chemoradiation. The only randomized trial of postoperative chemoradiation is the Intergroup trial INT-0116.³⁶⁰ Although the goal of this trial was to examine the role of postoperative adjuvant chemoradiation in gastric cancer, 20% of patients had adenocarcinoma of the GEJ. Eligible patients included those with stage IB, II, IIIA, IIIB, or IV nonmetastatic adenocarcinoma of the stomach or GEJ after curative resection. Patients were randomly assigned to receive either observation alone or postoperative chemoradiation consisting of four monthly cycles of bolus 5-FU and leucovorin plus 45 Gy concurrent radiation with cycle two. A total of 603 patients were registered. Pretreatment characteristics were similar in both arms, and most patients had locally advanced disease. Approximately two-thirds of the patients had pT3 or pT4 tumors and approximately 85% had positive local-regional nodes.

Patients randomly assigned to receive postoperative chemoradiation had a significant decrease in local failure as the first site of failure (19% versus 29%) and an increase in median survival (36 months versus 27 months), 3-year relapse-free survival (48% versus 31%), and overall survival (50% versus 41%; $p = 0.005$). Although 17% of patients could not complete all therapy as planned, there was only one treatment-related death. With a median follow-up of 10 years, the improvement in survival with postoperative chemoradiation remains statistically significant.³⁶⁰ An analysis of the impact of HER2 status in the INT-0116 trial revealed that HER2-negative patients had a survival benefit from chemoradiation whereas patients who underwent surgery only did not.³⁶¹

The other role for postoperative radiation therapy is in cases of positive surgical margins. Based on the RTOG-85-01 trial, patients selected for treatment with postoperative radiation should receive chemoradiation.^{280,362,363}

Definitive Chemoradiation

Although definitive chemoradiation is a treatment option for patients with localized resectable esophageal carcinoma, especially those with cervical esophageal squamous cell carcinoma or those not considered ideal resection candidates, this therapeutic approach is discussed in detail in Chemoradiation in the next section.

Treatment of Locally Advanced Disease

Radiation Therapy

The 1996 to 1999 patterns of care study examined 414 patients who received radiation therapy as part of definitive or adjuvant management at 59 institutions.³⁶⁴ Overall, 51% had adenocarcinoma and 49% had squamous cell carcinoma. With a median follow-up of 8 months, a multivariate analysis revealed that patients who received chemoradiation followed by surgery had a significant decrease in local–regional recurrence (HR, 0.40; $p < 0.0001$) and survival (HR, 0.32; $p = 0.001$) compared with those who did not undergo surgery. A similar significant decrease in local–regional recurrence (HR, 1.36; $p = 0.01$) and survival (HR, 1.32; $p < 0.03$) was seen in those patients who received their care at large radiation oncology centers (treating 500 or more new cancer patients per year) compared with small centers (treating fewer than 500 new cancer patients per year). In a similar patterns of care study of 767 patients treated in Japan from 1998 to 2001, 220 (29%) received preoperative or postoperative radiation, or both, with or without chemotherapy.³⁶⁵

The effect of histologic type (adenocarcinoma versus squamous cell carcinoma) is unclear. Most series suggest that squamous cell cancers have a higher response rate compared with adenocarcinomas; however, no clear difference in outcome was found. The National Cancer Institute Intergroup has randomized trials that stratify patients by lesion histologic type. Until these data are available, the impact of histologic type cannot be adequately assessed, and it is reasonable to treat both types of lesions in a similar fashion.

Primary Nonsurgical Therapy. Primary therapy for esophageal cancer is either surgical or nonsurgical. The patient population selected for treatment with each modality is usually different. For several reasons, this results in a selection bias against nonsurgical therapy. Patients with unfavorable prognostic features are more commonly selected for treatment with nonsurgical therapy. These features include medical contraindications and primary unresectable or actual metastatic disease. Surgical series report results based on pathologic stage, whereas nonsurgical series report results based on clinical stage. Pathologic staging has the advantage of excluding some patients with metastatic disease not identified during clinical staging. Because some patients treated without surgery are approached in a palliative rather than a curative fashion, the intensity of chemotherapy and the doses and techniques of radiation therapy used may be suboptimal.

The difficulty of accurately staging esophageal cancer preoperatively is discussed in Diagnostic Studies and Pretreatment Staging, earlier in this chapter. The efficacy of FDG-PET scans as a complement to CT scans and EUS must be emphasized. Undetected metastatic disease was identified by PET scans in 15% of patients in the series by Flamen et al.³²⁸ and in 20% of patients in the series by Downey et al.³²⁷
