Gemtuzumab ozogamicin (GO), a newer agent consisting of an antibody to CD33 coupled to calicheamicin (a toxic antitumor antibiotic), has shown some promise in relapsed AML and was recently tested in a randomized, prospective trial for frontline disease by the Children's Oncology Group.¹¹⁸ GO was significantly associated with improved EFS, but not OS. Other adult and pediatric trials of GO in AML have yielded mixed results, and at present, it has been voluntarily withdrawn from the commercial market and its role in AML therapy remains to be determined. Two promising novel biologic agents, the proteasome inhibitor bortezomib¹¹⁹ and the kinase inhibitor sorafenib (which inhibits FLT3)¹²⁰ are currently being tested for efficacy in combination with frontline conventional chemotherapy. The indications for HSCT in pediatric AML, preparative regimens, timing (CR1 or later), and type of donor are the focus of intensive ongoing controversy and research.^{116,121,122}

Pediatric APL has among the highest cure rates in pediatric AML. These patients should receive all-*trans*-retinoic acid (ATRA), which directly binds to the t(15;17) translocation, which forms a fusion protein combining the promyelocytic leukemia (*PML*) gene with the retinoic acid receptor alpha (*RAR α*) gene, which is causative for this form of AML.¹²³ They should also receive conventional chemotherapy during both induction and consolidation phases. Patients who respond to this therapy have an 80% to 85% survival rate and should not be subjected to HSCT.¹²⁴ Similar to adult therapies for APL (see Chapter 107), arsenic trioxide, found to be useful for salvage in patients who became resistant to ATRA, is currently being tested in upfront pediatric APL regimens (both alone and in combination with ATRA and conventional chemotherapy) in an effort to improve DFS in CR1.¹²⁵ Rapid initiation of therapy is particularly important in APL due to the risk of severe bleeding complications in untreated disease. Early deaths from bleeding are often not captured on clinical trials, but population-based studies indicate that they are a significant cause of mortality.¹²⁶ Despite the remarkable successes with ATRA and arsenic trioxide with and without conventional chemotherapy, there remain patients with APL with relapsed and refractory disease, and many of these can still be cured with HSCT.¹²⁷

DS patients with AMKL (see earlier discussion) do well with lower dose ara-C regimens and standard timing of their induction cycles. Current results in DS AMKL are the best of any AML subgroup outside of APL, with 70% to 85% EFS, with patients under 2 years showing the best results, and thus not requiring intensive chemotherapy or HSCT.¹²⁸⁻¹³⁰

The prognosis for pediatric patients who relapse after either conventional or HSCT therapy for AML is poor. A second CR can be obtained using similar ara-C and anthracycline-containing regimens in 20% to 70% of patients, but the likelihood of obtaining a cure is approximately half the rate for de novo AML.¹³¹ Clofarabine alone and in combination (see ALL relapse discussion) with other chemotherapeutic agents also shows some efficacy.^{100,101} HSCT in early relapse or CR2 for AML patients who were previously transplanted in CR1 is a strategy that has had some success.¹³¹⁻¹³³ Other novel therapies, including FLT3 inhibitors and hypomethylating agents, are currently being studied.¹³⁴

Rarer Forms of Leukemia in Children

Chronic leukemias, with the exception of CML, do not occur in children. Ph+ CML is rare in childhood (<1% to 2% of all pediatric leukemia cases).¹³⁵ When it does occur, it typically presents in adolescents and is in the chronic phase. Therapy is similar to that recommended in adults, with imatinib (along with hydroxyurea if the initial counts are high, and/or the patient presents with a high degree of hepatosplenomegaly) as the mainstay of induction and maintenance therapy. The use of alternative tyrosine kinase inhibitors such as dasatinib and nilotinib are being investigated in children as well as adults.¹³⁶ Because there is no clear end point for when or whether any of these tyrosine kinase inhibitors can be safely discontinued, many pediatric oncologists continue to consider hematopoietic stem cell transplantation in remission.

JMML, a myeloproliferative disorder unique to childhood, is characterized by extreme monocytosis, hepatosplenomegaly, thrombocytopenia, and increased fetal hemoglobin.¹³⁷ Bone marrow morphology is often consistent with myelodysplasia as well as myeloproliferation, and cytogenetics frequently reveals a monosomy 7 clone. Mutations in *PTN11*, *CBL*, and other RAS pathway genes have also been noted.^{138,139} Although the clinical course can be indolent (requiring only intermittent blood product and antibiotic support), JMML patients often progress to frank marrow failure. Neither aggressive AML-type chemotherapy nor splenectomy has been shown to significantly prolong survival, so these approaches are starting to be reserved for those patients who are symptomatic. The most definitive therapy in JMML is an allogeneic BMT.¹⁴⁰ Overall

DFS with BMT in JMML has been in the 40% to 55% range, with relapse the major reason for failure. Novel therapies targeting the rat sarcoma (*RAS*), rapidly accelerated fibrosarcoma (*RAF*), mitogen activated protein kinase (*MEK*), mammalian target of rapamycin (mTOR), signal transducer and activator of transcription 5 (*STAT5*), and other signaling pathways are currently under investigation.¹³⁷

Mixed phenotype acute leukemia (MPAL) is a new designation established by the World Health Organization (WHO) 2008 classification, replacing the prior diagnosis of biphenotypic acute leukemia, which was based on the European Group for the Immunological Classification of Leukemias (EGIL) and the WHO 2001 classification.¹⁴¹ MPALs constitute only approximately 0.5% to 1% of acute leukemias, with combined lineage differentiation that is most often B- and myeloid, followed by T- and myeloid, and rarely B- and T- or trilineage. The WHO classification recognizes two specific subgroups, characterized by a *BCR-ABL* rearrangement and *MLL* rearrangement, as well as a subgroup for the remainder of cases, which have other nonspecific chromosomal abnormalities. There are little systematic data about this rare form of leukemia, but outcomes are generally poor. Some data suggest that ALL-directed therapy may be more effective than AML-directed therapy. Allogeneic stem cell transplant is frequently employed.

LYMPHOMAS

Lymphomas constitute approximately 10% of cancer in children, and are the third most common pediatric malignancy (behind leukemias and brain tumors).¹⁴² Two-thirds of lymphomas in children are a heterogeneous group of lymphomas categorized as non-Hodgkin lymphomas (NHL), and the remainder are Hodgkin lymphomas (HL). Table 100.5 compares the differences in presenting and staging features between pediatric NHL and HL. The histology, biology, and management of lymphoma differs in children compared to adults. For example, the indolent, low-grade lymphomas seen in adults are rarely seen in children. Additionally, radiation and certain types of chemotherapy are minimized when possible to reduce detrimental effects on growth and development and other late effects of therapy such as second malignancies.

Non-Hodgkin Lymphoma

The Revised European–American Classification of Lymphoid Neoplasms (REAL) classification, which has served as the basis for the WHO classification of hematopoietic and lymphoid tumors, categorizes lymphomas according to phenotype and differentiation.¹⁴³

TABLE 100.5

Comparison of Hodgkin Lymphoma and Non-Hodgkin Lymphoma in Pediatric Patients

Feature	Hodgkin Lymphoma	Non-Hodgkin Lymphoma
Age	Mostly >10 y	Any age in children
Stage at diagnosis	Mostly localized	Commonly widespread
Constitutional symptoms	Alter prognosis	Do not affect prognosis
CNS involvement	Rare	Occurrence increases with AIDS
Mediastinal involvement	Most common with nodular sclerosing Hodgkin lymphoma	Most common with lymphoblastic lymphoma
Gastrointestinal involvement	Rare	Occurs
Abdominal nodal involvement	Can be small or large, mesenteric rare	Usually enlarged, mesenteric common
Bone involvement	Rare	Occurs
Marrow involvement	Rare	Common

Adapted from Rademaker, J. Hodgkin's and non-Hodgkin's lymphomas. *Radiol Clin North Am* 2007;45:69-83.

Pediatric NHLs appear in four major categories: (1) precursor T- and, less commonly, precursor B-lymphoblastic lymphoma (30% of pediatric NHLs), (2) Burkitt and Burkitt-like lymphoma (40% to 50%), (3) diffuse large B-cell lymphoma (15%), and (4) anaplastic large cell lymphoma (10%).¹⁴² These subtypes are high-grade, acute diseases and, rarely, truly localized diseases. Major improvement in the survival of children with NHL has occurred during the past 20 years, correlating with the advent of systemic multiagent chemotherapy regimens, as opposed to a reliance on localized therapies such as surgery and radiation.

The Cotswold revision of the Ann Arbor NHL staging and classification system used in adult NHLs has mostly been replaced in pediatrics by the St. Jude's Research Hospital staging system outlined in Table 100.6, which incorporates common presentations of pediatric NHL including increased extranodal involvement, bone marrow and CNS involvement, and on contiguous spread of disease.¹⁴⁴ Surgical/pathologic staging is no longer carried out in either pediatric NHL or HL cases. Diagnosis generally relies on biopsy and radiologic scans, usually a combination of computed tomography (CT) and nuclear medicine scans and, occasionally, magnetic resonance imaging.¹⁴⁵ The current 5-year EFS rates for early low-stage disease are in the 90% to 95% range and from 70% to 90% for the higher stage presentations.^{4,142}

Unlike ALL or HL, there is no sharp age peak for the occurrence of NHL in children. There is a marked imbalance in the male to female incidence, which approaches a 3:1 ratio.^{142,146} With the exception of children with rare, inherited, or acquired immunodeficiency syndromes (e.g., Wiskott-Aldrich syndrome, common variable immune deficiency, ataxia-telangiectasia, X-linked lymphoproliferative syndrome, HIV/AIDS, or exposure to immunosuppressive drugs after solid organ or bone marrow transplants), most children who develop NHL have a history of normal health and no known risk factors. The main exception to this concerns the possible etiologic role of the Epstein-Barr virus (EBV). EBV is strongly associated with lymphomas in HIV patients, lymphoproliferative diseases found in posttransplant patients, and endemic Burkitt lymphoma, and it is found in many cases of HL (see later discussion) in otherwise healthy children.^{147,148}

Lymphoblastic lymphomas share many molecular, biologic, cytogenetic, and therapeutic characteristics with ALL, and are now treated with similar chemotherapy protocols.^{12,146} The distinction between ALL and lymphoblastic lymphoma is somewhat arbitrary

because those patients with more than 25% lymphoblasts in their bone marrow at diagnosis (despite the existence of a large lymphomatous mass elsewhere in the body) are designated as having ALL. Morphologically, the cells are indistinguishable, and the immunophenotypes generally overlap.^{146,149} In contrast to ALL however, precursor T-lymphoblastic lymphoma is more common than precursor B-lymphoblastic lymphoma, with more than 75% of lymphoblastic lymphoma cases demonstrating precursor T-cell immunophenotype.

The typical presentation of children with lymphoblastic lymphoma is that of a patient with rapidly enlarging neck and mediastinal lymphadenopathy. Particular attention needs to be paid to hydration status, kidney function, and whether the kidneys are directly involved with the disease. CT and positron-emission tomography (PET) are helpful for assessing the degree of organ involvement, but care must be taken in requiring children with mediastinal masses to lie supine (which can compress both central blood vessels and airways) or undergo sedation (which causes vasodilation and decreased blood return to the heart).¹⁵⁰ A histologic diagnosis should be sought in the least invasive way possible. Prebiopsy steroids or *postage stamp irradiation* (use of a small radiation field to emergently relieve airway compression) can be done, but the steroids may jeopardize obtaining the histologic diagnosis or accurate staging. CNS status should be assessed prior to systemic chemotherapy, and prophylactic intrathecal chemotherapy should be administered early.¹⁴⁶ Prognostic factors include the level of bone marrow involvement at diagnosis and CNS involvement at diagnosis.

Primary therapy for lymphoblastic lymphoma (of either B- or T-cell histology) consists of multiagent chemotherapy without radiation. Stage I lymphoblastic cases do very well with short treatments (three to five cycles) of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP regimen or similar), and a relatively short (24 weeks versus 2 to 3 years with ALL) maintenance phase of antimetabolite (6-mercaptopurine daily and weekly oral methotrexate).^{142,146} Higher stage (stages II, III, and IV) lymphoblastic cases require more intensive regimens and a prolonged maintenance phase such as that used for ALL. The benefit of high-dose methotrexate and cranial radiation remain controversial in lymphoblastic lymphoma.¹⁵¹⁻¹⁵³ Nelarabine is a novel nucleoside analog with preferential cytotoxicity in T-lineage lymphoid malignancies that is being studied in current protocols.¹⁵⁴ Because activating NOTCH1 mutations are found in the majority of T-cell

TABLE 100.6

St. Jude Children's Research Hospital Staging System for Pediatric Non-Hodgkin Lymphoma

Stage	Description
I	A single tumor (extranodal) or single anatomic area (nodal), with the exclusion of mediastinum or abdomen
II	A single tumor (extranodal) with regional node involvement Two or more nodal areas on the same side of the diaphragm Two single (extranodal) tumors with or without regional node involvement on the same side of the diaphragm A primary gastrointestinal tract tumor, usually in the ileocecal area, with or without involvement of associated mesenteric nodes only ^a
III	Two single tumors (extranodal) on opposite sides of the diaphragm Two or more nodal areas above and below the diaphragm All the primary intrathoracic tumors (mediastinal, pleural, thymic) All extensive primary intra-abdominal disease ^a All paraspinal or epidural tumors, regardless of other tumor sites
IV	Any of the previous with initial central nervous system or bone marrow involvement ^b

^a Stage II abdominal disease typically is limited to a segment (usually distal ileum) of the gut plus or minus the associated mesenteric nodes only, and the primary tumor can be completely removed grossly by segmental excision. Stage III abdominal disease typically exhibits spread to para-aortic and retroperitoneal areas by implants and plaques in mesentery or peritoneum, or by direct infiltration of structures adjacent to the primary tumor. Ascites may be present, and the complete resection of all gross tumor is not possible.

^b If bone marrow involvement is present at diagnosis, the percentage of blasts or abnormal cells must be 25% or less to be classified as stage IV non-Hodgkin lymphoma. If there are more than 25% blasts, the patient is classified as having acute leukemia (either precursor B- or T-acute lymphoblastic leukemia or L3 acute lymphoblastic leukemia).

leukemias, gamma-secretase inhibitors that block Notch 1 signaling are another class of agents whose role in treatment regimens is being assessed.^{155,156} Relapse in lymphoblastic lymphoma is, fortunately, an uncommon problem, but when it does occur it happens either during or shortly after completion of therapy. Relapse of low-stage disease can frequently be salvaged using the more intensive chemotherapy designed for high-stage disease.¹⁵⁷ Lymphoblastic lymphoma patients who relapse after higher stage treatment have a poor prognosis and are candidates for nelarabine, phase I agents and/or BMT if response is obtained to salvage therapy.¹⁵⁷ Radiation to areas of bulk disease and total-body irradiation are incorporated into the transplant regimens, but, in general, radiation does not have a role in primary treatment or reinduction at relapse.

Burkitt and Burkitt-like lymphoma are mature B-cell lymphomas. Endemic Burkitt lymphoma (usually presenting with localized head and neck masses—most frequently, the jaw) in Africa is quite common (100 cases per million children), and 95% are associated with EBV. Sporadic Burkitt lymphoma, as seen in the United States, typically presents with an abdominal mass, occurs in 1 to 2 cases per million children, and only 15% are associated with EBV.¹⁵⁸ The most common presentation in the United States is of a boy age 5 to 10 years, with a right lower quadrant mass and/or acute abdomen secondary to an ileocecal intussusception. If the tumor is limited to the distal ileum or cecum, it should be completely excised along with its associated mesentery, and the bowel repaired with an end-to-end anastomosis.¹⁵⁹ These children have low-stage disease, require less chemotherapy, and have an excellent outcome. More frequently, the abdominal involvement is much more diffuse.

Burkitt lymphoma cells have a mature B-cell immunophenotype (expressing cell surface immunoglobulin, usually IgM) and are characterized morphologically by homogeneous round-to-oval nuclei, multiple nucleoli, and intensely basophilic cytoplasm with large vacuolated areas containing fat. Burkitt-like lymphoma shares pathologic and molecular features with diffuse large B-cell lymphoma and responds to similar chemotherapy as Burkitt lymphoma. The majority of Burkitt lymphoma cases display the t(8;14)(q24;q32) translocation in which *c-myc* from chromosome 8 is translocated to the Ig heavy-chain locus on chromosome 14. In this translocation and in two less common variants, t(2;8)(p12;q24) and t(8;22)(q24;q11), the *c-myc* oncogene is overexpressed because of the influence of Ig regulatory regions (enhancers).¹⁶⁰

The diagnosis of Burkitt lymphoma must be done very expeditiously as these tumors grow swiftly and patients are at high risk of intestinal obstruction (from intussusception) and metabolic problems related to tumor lysis syndrome. Tumor lysis often begins even before chemotherapy. Special attention must be paid to serum electrolyte balance (including calcium/phosphate balance), and vigorous intravenous hydration and alkalinization to improve uric acid excretion is essential. Allopurinol or recombinant urate oxidase, rasburicase, is used to block uric acid production. Occasionally, the lysis syndrome can be severe enough to cause acute renal failure, and dialysis must be used to maintain fluid and reestablish electrolyte balance.

Children with low-stage, African-endemic Burkitt lymphoma have been successfully treated with single or multiple doses of cyclophosphamide. Therapies as brief as 4 weeks have been successfully employed.¹⁶¹ These strategies result in lower cure rates, but they make it feasible to treat large numbers of children with lower toxic death and complication rates in resource-poor settings.¹⁶² Higher stage Burkitt lymphoma (stages 3 and 4) requires significantly more intensive chemotherapy, involving much higher doses of cyclophosphamide, and the addition of an anthracycline, high-dose ara-C, methotrexate, and VP-16 to the CHOP schemas. Many current high-stage Burkitt lymphoma protocols use hematopoietic growth factor support to enhance bone marrow recovery in order to allow intensive cycles to be given approximately every 3 weeks. These protocols are intensive, but they are usually of a short (6- to 8-month) duration. There have been some efforts to reduce chemotherapy and to add biologic agents like rituximab (anti-CD20 antibody) to reduce

toxicity of treatment in patients who have HIV or other medical problems.^{163,164} Currently, the efficacy of the addition of rituximab to advanced stage Burkitt lymphoma protocols is being investigated.¹⁶⁵ The cure rate for pediatric patients with higher stage (stage III and IV) Burkitt lymphoma is now 80% to 90%.¹⁶⁶ The management of relapsed Burkitt lymphoma is problematic. Relapses usually occur during therapy or shortly after the cessation of therapy. Low-stage patients can sometimes be effectively treated using a high-stage primary protocol. Higher stage relapsed patients may try a salvage therapy such as R-ICE (rituximab, ifosfamide, carboplatin, etoposide) or phase I therapies, and BMT should be considered if a response is achieved.¹⁶⁷

The workup and staging of large cell lymphomas are similar to that described for other forms of NHL. Diffuse large B cell lymphoma (DLBCL) tends to present with large mediastinal masses, but bone, lymph node, and abdominal presentations are also seen. Bone marrow and CNS involvement are not common. Combination chemotherapy is effective against DLBCL, and radiation does not have a role in therapy for most cases. DLBCL and anaplastic large cell lymphoma (ALCL) used to be treated similarly as large cell lymphomas, the mature B-cell lymphomas (DLBCL and Burkitt lymphoma) are now grouped together on contemporary treatment protocols. However, it is not clear that DLBCL requires as much CNS-directed therapy as Burkitt lymphoma because CNS involvement is less common for DLBCL. Primary mediastinal B-cell lymphoma (PMBL) is a subtype of DLBCL that often presents with sclerosis and has a less favorable prognosis. PMBL shares some biologic features with Hodgkin lymphoma, and alternate treatment regimens are being investigated for PMBL based on differences in biology and prognosis.¹⁶⁸

ALCL tends to present with involvement of lymph nodes and extranodal sites including the skin, the lung, other soft tissues, and bone. Bone marrow and CNS involvement are uncommon. The majority of ALCL cases have T-cell immunophenotype. ALCL is also known for cytogenetically presenting with the t(2;5)(p23;q35) translocation, which fuses nucleophosmin with a transmembrane tyrosine-specific protein kinase known as anaplastic lymphoma kinase. Three to five cycles of CHOP or APO (adriamycin, prednisone, Oncovin/VCR) have been used, and more recently, Associazione Italiana Ematologia Oncologia Pediatrica (AIEOP) ALCL-99 with EFS that ranges from 70% to 85%.¹⁶⁹ Targeted therapy with crizotinib, an inhibitor of the anaplastic lymphoma kinase (ALK), a tyrosine kinase, has produced promising responses in early studies in relapsed ALK-positive ALCL.¹⁷⁰ Another targeted therapy demonstrating promising activity against both ALCL and Hodgkin lymphoma is brentuximab vedotin, an anti-CD30 directed monoclonal antibody conjugated to a microtubule-disrupting agent.¹⁷¹

Hodgkin Lymphoma

The natural history and outcome of treatment in HL is similar in young children and adults, but treatment decisions (and regimens) are different in children based on the need for attention to late effects of therapy. Risk-adapted therapy seeks to maintain excellent cure rates of 80% to 90%, whereas limiting radiation and certain types of chemotherapy that may cause long-term organ damage, growth problems, infertility, and second malignancies.^{3,172} HL is rare below the age of 5 years, with the majority of pediatric cases presenting in children older than 11 years. Young patients (<10 years) have a 3:1 male to female ratio. This imbalance returns to the approximately equal male to female ratio seen in adult disease as the age of presentation climbs. The age of HL incidence in industrialized countries is bimodal, with the first peak in adults 20 to 30 years of age and the second peak occurring much later in adulthood.¹⁷³

The etiology of HL is unknown, but EBV is found in up to 40% of cases.¹⁷⁴ There are also familial and geographic clusters that suggest an inherited, environmental, or infectious contribution to etiology.¹⁷⁴ Most children (90%) present with painless adenopathy in the neck, and 60% have involvement of anterior mediastinum,

paratracheal, or hilar lymph nodes. The Cotswold modification of the Ann Arbor Staging System (described in Chapter 103) is used for all ages. B symptoms (defined as in adults) include unexplained fever (more than 38°C [100.4°F]), drenching night sweats, and more than 10% weight loss. B symptoms are present in approximately 30% of newly diagnosed pediatric HL cases.¹⁷⁵ The process of clinical staging includes both site of involvement and the presence of B symptoms and is described in detail for adult patients in Chapter 102. There is no longer any role for staging laparotomy, because localized radiation is no longer used as a sole treatment modality in pediatric HL. Increasingly, PET scans are being used to assess staging and early response and to guide further treatment, as opposed to exclusive reliance on CT.¹⁷⁶

The malignant cells in HL constitute a minority (estimated at 0.1% to 10%) of the cell population of the discernible tumor.¹⁷⁷ Inflammatory cells (histiocytes, plasma cells, lymphocytes, eosinophils, and neutrophils) make up the bulk of the tumor. The malignant cells are actually malignant lymphocytes with specific, characterized immunophenotypes. The WHO classifies four subtypes of classic HL: (1) nodular sclerosing, (2) mixed cellularity, (3) lymphocyte rich, and (4) lymphocyte depleted. Nodular lymphocyte-predominant HL (NLPHL) is another important subtype of HL.

The most common presenting histology in pediatric HL is nodular sclerosing type, which accounts for more than 50% of the cases (40% of the younger patients but 70% of the adolescents).¹⁷³ It is characterized by bands of fibrosis and a thickened lymph node capsule that are discernible even in a gross pathologic section. These nodes and masses tend to form scars that can lead to residual masses, which appear as opacified lesions on radiologic studies for years after a full clinical response. Mixed cellularity is responsible for approximately 30% of pediatric cases. It is commonly seen in children less than 10 years of age and is highly associated with EBV positivity. The lymphocyte-depleted form of HL is quite rare, except in children with HIV. The lymphocyte-rich variant is quite rare in children (approximately 5% of the cases), has a high incidence of mediastinal masses and stage III disease, but has an older average age of presentation (32 years).¹⁷³

With the exception of NLPHL, treatment for all of the various HL histologies is the same and is based on staging. Risk-adapted therapy in pediatric HL is composed of three to six cycles of combination chemotherapy followed by involved field radiation therapy (IFRT) for higher risk patients. The composition of the chemotherapy regimens has varied during the years, but combinations of vinca alkaloids, alkylating agents (cyclophosphamide commonly used now), steroids, anthracyclines, and bleomycin have been used. Current therapies for low-risk HL attempt to reduce exposure to alkylators, anthracyclines, and bleomycin and IFRT to reduce the risk of late effects.

Therapy for higher risk HL (higher stage at presentation or slow response to therapy) currently involves additional cycles of higher dose combination chemotherapy and IFRT, with EFS rates still in the 80% to 90% range when risk-adapted therapy is given.³ Targeted therapy such as brentuximab vedotin, discussed previously, will be studied in frontline therapy regimens. Treatment for relapsed or refractory pediatric HL is beyond the scope of this chapter, but the medications (e.g., ifosfamide and vinorelbine) and approaches (e.g., BMT) are usually similar to those used in adults (see Chapter 102). Novel therapies under investigation include antibodies targeting CD30 (brentuximab vedotin), CD25, and other antigens; the proteasome inhibitor bortezomib; and histone deacetylase inhibitors; as well as cytotoxic T-cell based therapies directed against both EBV-associated and EBV-negative lymphomas.³

NLPHL disease affects 10% to 15% of pediatric patients, is more common among male and younger patients, and is usually clinically localized (low stage). Stage I patients do well with surgical resection only (no chemotherapy or radiotherapy) and close follow-up.¹⁷⁸ For stage II/III, most would be treated with several cycles of relatively low-dose chemotherapy (i.e., avoiding the use of alkylators, topoisomerase inhibitors) and radiation therapy. Preliminary evidence suggests that this approach for NLPHL leads

to an overall survival close to 100%, and should decrease the late effects of secondary malignancy and infertility.¹⁷⁹ Many current study protocols would forgo even low-dose IFRT for these young patients who achieve a complete response with low-dose chemotherapy, but this should still be considered an experimental approach because combination low-dose chemotherapy and IFRT has been the standard of care, and there are reports of relapse after chemotherapy-only treatments.

SUPPORTIVE CARE

There is no question that a large part of the success of modern leukemia and lymphoma treatment is related to the major improvements in supportive care that coincided with improvements in chemotherapy. These advances have included improved blood products, antibiotics, antifungals, and better intensive care unit support of critically ill pediatric patients. Erythropoietin has been used sparingly in pediatric oncology, and is not generally incorporated in frontline therapies for any of the lymphoid cancers. Leukocyte growth factors (granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, and PEGylated forms, such as pegfilgrastim) are used sparingly in pediatric leukemia and lymphoma therapies for multiple reasons, including (1) concerns (mostly not substantiated in the literature) that these factors may stimulate the growth of these diseases, (2) multiple studies that show no changes in overall outcome when these factors are used, (3) financial burden, and (4) the addition of needle sticks and/or the increased infection risk from entering central lines daily. Growth factors are, however, used routinely in many relapse and higher stage lymphoma protocols to enable a dose-intensive chemotherapy schedule and avoid long periods of profound neutropenia.

LONG-TERM, PALLIATIVE, AND HOSPICE CARE IN PEDIATRIC ONCOLOGY

The survivors of current lower risk (less intensively treated) forms of ALL, NHL, and HL in childhood can now expect prolonged DFS, intact fertility, lesser cognitive and social disruption, and an easier integration into standard medical and social environments than in the past. Survivors from higher doses and larger radiation fields used in the 1960s and 1970s, as well as from regimens involving higher cumulative doses of chemotherapy, continue to have an increased risk of important long-term toxicities, including endocrine, growth, fertility, and learning disabilities, along with cardiac, renal, liver, and other end-organ toxicities.¹⁸⁰ Second malignancies are another serious problem, arising from carcinogenic exposures to chemotherapy and radiotherapy, as well as possibly an innate propensity to develop cancer.¹⁸¹ It has been estimated that pediatric cancer survivors will soon represent as many as 1 in 250 adult Americans in the 15- to 45-year-old population.¹⁸² Reducing late effects of therapy while preserving cure rates is a crucial goal in improving outcomes in childhood leukemia and lymphoma.¹⁸³

Even with cure rates that reach, in many categories of disease, into the over 90% region, a substantial number of children still die of leukemia and lymphoma. A small number die after failing their first regimens, but many succumb after alternately succeeding and then failing several attempts at cure. A discussion of hospice and palliative care for these children and support for their families is beyond the scope of this chapter, but this is an area of active interest and involvement in most pediatric oncology programs. Hospice and palliative care treatments in pediatrics share some of the same concerns, goals, and methods as programs for adults. However, the unique requirements of psychosocial support in children, and the impact of a possible death of a child on a family, lead most experts to guide these patients to pediatric centers.

INTRODUCTION

The term lymphoma identifies a heterogeneous group of biologically and clinically distinct neoplasms that originate from cells in the lymphoid organs and have been historically divided into two distinct categories: non-Hodgkin lymphoma (NHL) and Hodgkin lymphoma (HL).¹ During the past few decades, significant progress has been made in elucidating the molecular pathogenesis of lymphoid malignancies as a clonal expansion of B cells (in the majority of cases) or T cells. The molecular characterization of the most frequent genetic abnormalities associated with lymphoma has led to the identification of multiple proto-oncogenes and tumor suppressor genes, whose abnormal functioning contributes to lymphoma pathogenesis. Relatively less is known about the pathogenesis of T-cell NHL (T-NHL) and HL. This chapter will focus on the molecular pathogenesis of the most common and well-characterized types of lymphoma, including B-cell NHL (B-NHL), T-NHL, HL, and chronic lymphocytic leukemia (CLL), which also derives from mature B cells. Emphasis will be given to the mechanisms of genetic lesion and the nature of the involved genes in relationship to the normal biology of lymphocytes.

THE CELL OF ORIGIN OF LYMPHOMA

The number of B and T cells in the adult are not significantly different; however, 85% of lymphomas originate from mature B cells, whereas only 10% to 15% derive from the T-cell lineage. This bias may be explained in part by the unique DNA modification events that take place in normal B lymphocytes in order to enable the production of highly efficient neutralizing antibodies and that are mechanistically more complex than those utilized by T cells to encode T-cell receptors. The biology of these processes thus represents a key concept for the understanding of lymphomagenesis.

B-Cell Development and the Dynamics of the Germinal Center Reaction

B lymphocytes are generated from a common pluripotent stem cell in the bone marrow, where precursor B cells first assemble their immunoglobulin heavy chain locus (*IGH*) followed by the light chain loci (*IGL*) through a site-specific process of cleavage and rejoining, known as V(D)J recombination.² Cells that fail to express a functional (and nonautoreactive) antigen receptor are eliminated within the bone marrow, whereas B-cell precursors that have successfully rearranged their antibody genes are positively selected to migrate into peripheral lymphoid organs as mature, naïve B cells.³ In most B cells, the subsequent maturation steps are linked to the histologic structure of the germinal center (GC), a specialized microenvironment that forms following the

encounter of naïve B cells with a foreign antigen, in the context of signals delivered by CD4+ T cells and antigen-presenting cells (Fig. 101.1).³⁻⁵

GCs are highly dynamic structures in which B cells transit back and forth between two zones that are conserved across several species: the dark zone (DZ), which consists of rapidly proliferating centroblasts (CB) (doubling time: 6 to 12 hours), and the light zone (LZ), which consists of more quiescent cells termed centrocytes (CC), amidst a network of resident accessory cells (follicular dendritic cells [FDC] and human T follicular helper [Tfh] cells).⁶⁻⁹ According to currently accepted models, the DZ is the site where GC B cells modify the variable region of their *IG* genes (IgV) by the process of somatic hypermutation (SHM), which introduces mostly single nucleotide substitutions with few deletions and duplications in order to change their affinity for the antigen.^{3,5,10-12} Conversely, the LZ is the site of selection based on affinity to the antigen. A critical regulator of the GC reaction is *BCL6*,^{13,14} a transcriptional repressor¹⁵ that negatively modulates the expression of a broad set of genes, including those involved in B-cell receptor (BCR) and CD40 signaling,^{16,17} T-cell mediated B-cell activation,¹⁶ induction of apoptosis,^{16,18} response to DNA damage (by modulation of genes involved in the sensing and execution of DNA damage responses),¹⁹⁻²² various cytokine and chemokine signaling pathways (e.g., those triggered by interferon and transforming growth factor beta [*TGFβ*]),^{16,18} and plasma cell differentiation, via suppression of the *PRDM1/BLIMP1* master regulator.²³⁻²⁶ This transcriptional program suggests that *BCL6* is critical to establish the proliferative status of CBs and to allow the execution of antigen-specific DNA modification processes (SHM and class-switch recombination) without eliciting responses to DNA damage; furthermore, *BCL6* keeps in check a variety of signaling pathways that could lead to premature activation and differentiation prior to the selection for the survival of cells producing high affinity antibodies.

CBs are then believed to cease proliferation and shuttle to the LZ, where they are rechallenged by the antigen through the interaction with CD4+ T cells and FDCs.^{3,4,7,8} CCs expressing a BCR with reduced affinity for the antigen will be eliminated by apoptosis, whereas a few cells with greater affinity will be selected for survival and differentiation into memory cells and plasma cells,⁴ or reenter the DZ following stimulation by a variety of different signals.⁹ Iterative rounds of mutations and selections lead to affinity maturation at the population level. In the GC, CCs also undergo class-switch recombination (CSR), a DNA remodeling event that confers distinct effector functions to antibodies with identical specificities.²⁷ SHM and CSR represent B-cell-specific functions that modify the genome of B cells via mechanisms involving single- or double-strand breaks and which depend on the activity of the activation-induced cytidine deaminase (AID) enzyme,²⁸⁻³⁰ a notion that will become important in the understanding of the mechanisms generating genetic alterations in B-NHL.

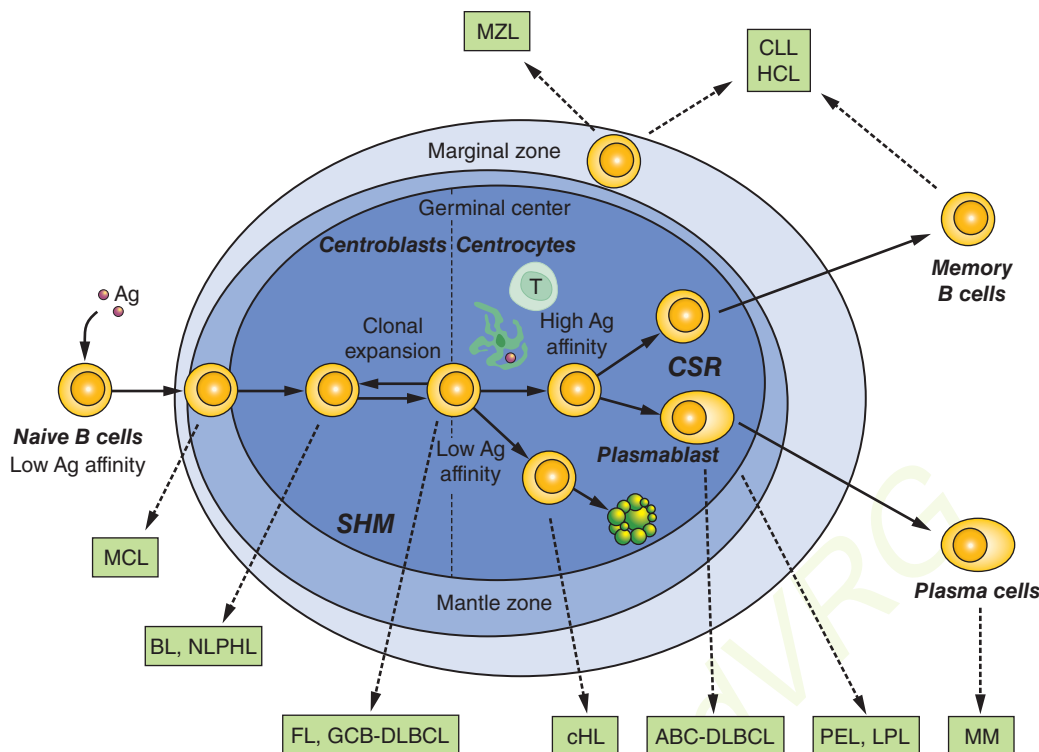

Figure 101.1 Normal B-cell development and lymphomagenesis. Schematic representation of a lymphoid follicle, constituted by the germinal center (GC), the mantle zone, and the surrounding marginal zone. B cells that have successfully rearranged their *IG* genes in the bone marrow move to peripheral lymphoid organs as naive B cells. Upon encounter with a T-cell dependent antigen, B cells become proliferating centroblasts in the GC and eventually transition into centrocytes, which shuttle back and forth between the dark and light zone while undergoing iterative rounds of SHM and selection. Only GC B cells with high affinity for the antigen will be positively selected to exit the GC and further differentiate into plasma cells or memory B cells, whereas low-affinity clones are eliminated by apoptosis. *Dotted arrows* link various lymphoma types to their putative normal counterpart, identified based on the presence of somatically mutated IgV genes, as well as on distinctive phenotypic features. CSR, class-switch recombination; SHM, somatic hypermutation; MCL, mantle-cell lymphoma; FL, follicular lymphoma; BL, Burkitt lymphoma; GCB-DLBCL, germinal center B cell-like diffuse large B-cell lymphoma; ABC-DLBCL, activated B cell-like diffuse large B-cell lymphoma; PEL, primary effusion lymphoma; LPL, lymphoplasmacytic lymphoma; NLPHL, nodular lymphocyte predominance Hodgkin lymphoma; cHL, classical Hodgkin lymphoma; MZL, marginal zone lymphoma; HCL, hairy cell leukemia; CLL, chronic lymphocytic leukemia; MM, multiple myeloma.

Once these processes are completed, two critical signals for licensing GC exit are represented by engagement of the BCR by the antigen and activation of the CD40 receptor by the CD40 ligand present on CD4+ T cells. These signals induce the downregulation of BCL6 at the translational and transcriptional level, respectively, thus restoring DNA damage responses, as well as activation and differentiation capabilities.

Although oversimplified, this schematic description of the GC reaction is useful to introduce two basic concepts for the understanding of B-NHL pathogenesis. First, the activity of SHM, which introduces irreversible DNA changes in the genome, allowed for the conclusion that most B-NHL types, with the exception of most mantle-cell lymphoma (MCL), derive from GC-experienced B cells that underwent clonal expansion within the GC, because the malignant clones harbor hypermutated IgV sequences containing largely identical mutations, suggesting the derivation from a single founder cell.³¹ Second, two common mechanisms of oncogenic lesions in B-NHL—namely, chromosomal translocations and aberrant somatic hypermutation (ASHM)—result from mistakes in the machinery that normally diversifies the Ig genes during B lymphocytes differentiation, further supporting the GC origin of most B-NHL (Fig. 101.2).³² Finally, the definition of two distinct phases during GC development reflects different transient states within the same B-cell developmental step, which can be recognized in different B-NHL subtypes to some extent.

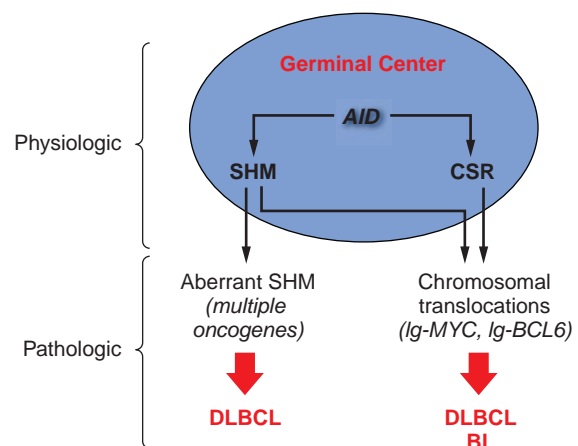

Figure 101.2 Model for the initiation of chromosomal translocations and ASHM during lymphomagenesis. B-NHL-associated genetic lesions are favored by mistakes occurring during the physiologic processes of SHM and CSR in the highly proliferative environment of the GC (top). These events lead to chromosomal translocations, which in most cases juxtapose the *IG* genes to one of several proto-oncogenes (e.g., *BCL2* or *MYC*), and ASHM of multiple target genes, thus contributing to the pathogenesis of lymphoma. DLBCL, diffuse large B-cell lymphoma; BL, Burkitt lymphoma.

T-Cell Development

The process of T-cell development proceeds through sequential stages defined according to the expression of the molecules CD4 and CD8. Committed lymphoid progenitors exit the bone marrow and migrate to the thymus as early T-cell progenitors or double negative 1 (DN1) cells, which lack the expression of both CD4 and CD8 and harbor unrearranged T-cell receptor (TCR) genes.³³ In the thymic cortex, T cells advance through the double negative stages DN2, DN3, and DN4, while undergoing specific rearrangements at the TCR β locus in order to acquire expression of the pre-TCR.³³ Those thymocytes that have successfully recombined the pre-TCR will be selected to further differentiate into double positive cells (CD4+CD8+), which express a complete surface TCR and can then enter a process of positive and negative selection in the medulla, before exiting the thymus as single positive T cells.³³ The end result of this process is a pool of mature T cells that exhibit coordinated TCR and coreceptor specificities, as required for effective immune responses to foreign antigens. Most mature T-NHLs arise from postthymic T cells in the lymphoid organs.

GENERAL MECHANISMS OF GENETIC LESIONS IN LYMPHOMA

Analogous to other cancers, lymphoma represents a multistep process deriving from the accumulation of multiple genetic lesions affecting oncogenes and tumor suppressor genes, including chromosomal translocations, point mutations, genomic deletions, and copy number (CN) gains/amplifications.

Chromosomal Translocations

Although also found in nonlymphoid tumors, chromosomal translocations represent the genetic hallmark of malignancies derived from the hematopoietic system. These events are generated through the reciprocal and balanced recombination of two specific chromosomes and are often recurrently associated with a given tumor type, where they are clonally represented in each tumor case.

The precise molecular mechanisms underlying the generation of translocations remain partially unclear; however, significant advances have been made in our understanding of the events that are required for their initiation.³⁴ It has been documented that

chromosomal translocations occur at least in part as a consequence of mistakes during *Ig* and TCR gene rearrangements in B and T cells, respectively, and, based on the characteristics of the chromosomal breakpoint, can be broadly divided into three groups: (1) translocations derived from mistakes of the recombination activating gene RAG-mediated V(D)J recombination process, as is the case for translocations involving *IGH* and *CCND1* in MCL or *IGH* and *BCL2* in follicular lymphoma (FL)^{34–36}; (2) translocations mediated by errors in the AID dependent CSR process, such as those involving the *Ig* genes and *MYC* in sporadic Burkitt lymphoma (BL)³⁴; (3) translocations occurring as by-products of the AID-mediated SHM mechanism, which also generates DNA breaks, such as those joining the *Ig* and *MYC* loci in endemic BL.³⁴ Conclusive experimental evidence for the involvement of antibody-associated remodeling events has been provided through in vivo studies performed in lymphoma-prone mouse models, where the removal of the AID enzyme was sufficient to abrogate the generation of *MYC-IGH* translocations in normal B cells undergoing CSR^{37,38} and to prevent the development of GC-derived B-NHL.³⁹

The common feature of all NHL-associated chromosomal translocations is the presence of a proto-oncogene in the proximity of the chromosomal recombination sites. In most lymphoma types, and in contrast with acute leukemias, the coding domain of the oncogene is not affected by the translocation, but its pattern of expression is altered as a consequence of the juxtaposition of heterologous regulatory sequences derived from the partner chromosome (proto-oncogene deregulation) (Fig. 101.3). This process of proto-oncogene deregulation is defined as homotopic if a proto-oncogene whose expression is tightly regulated in the normal tumor counterpart becomes constitutively expressed in the lymphoma cell, and heterotopic when the proto-oncogene is not expressed in the putative normal counterpart of the tumor cell and undergoes ectopic expression in the lymphoma. In most types of NHL-associated translocations, the heterologous regulatory sequences responsible for proto-oncogene deregulation are derived from antigen receptor loci, which are expressed at high levels in the target tissue.³⁴ However, in certain translocations, such as the ones involving *BCL6* in diffuse large B-cell lymphoma (DLBCL), different promoter regions from distinct chromosomal sites can be found juxtaposed to the proto-oncogene in individual tumor cases, a concept known as *promiscuous translocations*.^{40–47}

Less commonly, B-NHL associated chromosomal translocations juxtapose the coding regions of the two involved genes to form a chimeric unit that encodes for a novel fusion protein, an outcome typically observed in chromosomal translocation

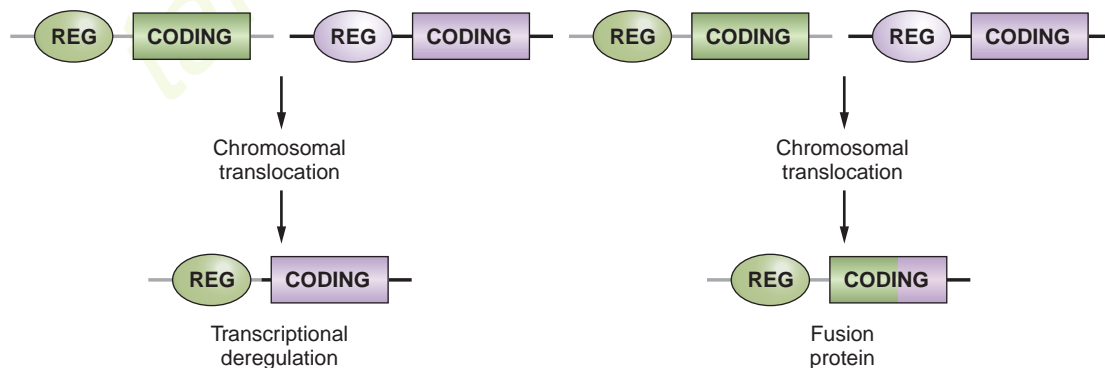

Figure 101.3 Molecular consequences of chromosomal translocations. *Top panel:* The two genes involved in prototypic chromosomal translocations are graphically represented, with their regulatory (REG) and coding sequences. Only one side of the balanced, reciprocal translocations is indicated in the figure. *Bottom panel:* Distinct outcomes of chromosomal translocations. In the case of transcriptional deregulation (*left scheme*), the normal regulatory sequences of the proto-oncogene are substituted with regulatory sequences derived from the partner chromosome, leading to deregulated expression of the proto-oncogene. In most B-NHLs, the heterologous regulatory regions derive from the *IG* loci. In the case of fusion proteins (*right scheme*), the coding sequences of the two involved genes are joined in frame into a chimeric transcriptional unit that encodes for a novel fusion protein, characterized by novel biochemical and functional properties.

associated with acute leukemia (see Fig. 101.3). Examples are the t(11;18) of mucosa-associated lymphoid tissue (MALT) lymphoma and the t(2;5) of anaplastic large-cell lymphoma (ALCL). The molecular cloning of the genetic loci involved in most recurrent translocations has led to the identification of a number of proto-oncogenes involved in lymphomagenesis.

Aberrant Somatic Hypermutation

The term aberrant somatic hypermutation defines a mechanism of genetic lesion that appears to derive from a malfunction in the physiologic SHM process, leading to the mutation of multiple non-Ig genes.⁴⁸ This phenomenon is uniquely associated with B-NHL and particularly with DLBCL, where over 10% of actively transcribed genes have been found mutated as a consequence of ASHM.

In GC B cells, SHM is tightly regulated both spatially and temporally to introduce mutations only in the rearranged IgV genes⁴⁹ as well as in the 5' region of a few other genes, including *BCL6* and the *CD79* components of the B-cell receptor,⁵⁰⁻⁵³ although the functional role of mutations found in these other genes remains obscure. On the contrary, multiple mutational events were found to affect numerous loci have been found mutated in over half of DLBCL cases and, at lower frequencies, in few other lymphoma types.⁵⁴⁻⁵⁸ The identified target loci include several well known proto-oncogenes such as *PIM1*, *PAX5*, and *MYC*, one of the most frequently altered human oncogenes.⁴⁸ These mutations are typically distributed within ~2 kb from the transcription initiation site (i.e., the hypermutable domain in the Ig locus)⁵⁹ and, depending on the genomic configuration of the target gene, may affect nontranslated as well as coding regions, thus holding the potential of altering the response to factors that normally regulate their expression or changing key structural and functional properties.⁴⁸ This is the case of *MYC*, where a significant number of amino acid substitutions have proven functional consequences in activating its oncogenic potential. Nonetheless, a comprehensive characterization of the potentially extensive genetic damage caused by ASHM is still lacking, and the mechanism involved in this malfunction has not been elucidated.

Copy Number Gains and Amplifications

In addition to chromosomal translocations and ASHM, the structure of proto-oncogenes and their pattern of expression can be altered by CN gains and amplifications, leading to overexpression of an intact protein. Compared to epithelial cancer, only a few genes have been identified so far as specific targets of amplification in B-NHL, as exemplified by *REL* and *BCL2* in DLBCL⁶⁰⁻⁶³ and by the genes encoding for programmed cell death 1 PD-1 ligands in primary mediastinal B-cell lymphoma (PMBCL).^{64,65}

Activating Point Mutations

Somatic point mutations in the coding sequence of a target proto-oncogene may alter the biologic properties of its protein product, leading to its stabilization or constitutive activation. Over the past few years, the use of genome-wide, high throughput sequencing technologies has allowed for the identification of numerous previously unsuspected targets of somatic mutations in cancer, including lymphoid malignancies. These genes will be discussed in individual disease sections. Of note, mutations of the *RAS* genes, a very frequent proto-oncogene alteration in human neoplasia, are rare in lymphomas.⁶⁶

Inactivating Mutations and Deletions

Until recently, the *TP53* gene, possibly the most common target of genetic alteration in human cancer,⁶⁷ remained one of few bona fide tumor suppressor genes involved in the pathogenesis of NHL, although at generally low frequencies and restricted to specific

disease subtypes, such as BL and DLBCL derived from the transformation of FL or CLL.^{68,69} The mechanism of *TP53* inactivation in NHL is analogous to the one observed in human neoplasia in general, entailing a point mutation of one allele and a chromosomal deletion or mutation of the second allele. However, recent efforts taking advantage of genome-wide technologies revealed several additional candidate tumor suppressor genes that are lost in B-NHL through specific chromosomal deletions and/or deleterious mutations. Two such genes lie on the long arm of chromosome 6 (6q), a region long known to be deleted in a large percentage of aggressive lymphomas associated with poor prognoses.^{70,71} The *PRDM1/BLIMP1* gene on 6q21 is biallelically inactivated in ~25% of ABC-DLBCL cases,⁷²⁻⁷⁴ and the gene encoding for the negative nuclear factor kappa B (NF- κ B) regulator A20 on chromosome 6q23 is commonly lost in ABC-DLBCL, PMBCL, and subtypes of marginal zone lymphoma and HL.⁷⁵⁻⁷⁸ Monoallelic inactivating mutations and deletions were found to affect the acetyltransferase genes *CREBBP* and *EP300* in a significant proportion of DLBCL and FL, suggesting a role as haploinsufficient tumor suppressors.⁷⁹ These two lymphoma types also harbor truncating mutations of *MLL2*,⁸⁰ which is emerging as one of the most commonly mutated genes in cancer. Among the tumor suppressors preferentially inactivated by CN losses, it is important to mention the *DLEU2/miR15-a/16.1* cluster on chromosome 13q14.3, the most frequent alteration in CLL (>50% of cases),⁸¹ and *CDKN2A/B (p16/INK4a)*, which is inactivated by focal homozygous deletions in transformed FL (tFL), Richter syndrome (RS), and ABC-DLBCL,⁸²⁻⁸⁴ and less frequently, by epigenetic transcriptional silencing in various B-NHL.⁸⁵

Infectious Agents

Viral and bacterial infections have both been implicated in the pathogenesis of lymphoma. At least three viruses are associated with specific NHL subtypes: the Epstein-Barr virus (EBV), the human herpesvirus-8/Kaposi sarcoma-associated herpesvirus (HHV-8/KSHV), and the human T-lymphotropic virus type 1 (HTLV-1). Other infectious agents, including HIV, hepatitis C virus (HCV), *Helicobacter pylori*, and *Chlamydomphila psittaci* have an indirect role in NHL pathogenesis by either impairing the immune system and/or providing chronic antigenic stimulation.

EBV was initially identified in cases of endemic African BL,^{86,87} and was subsequently also detected in a fraction of sporadic BL, HIV-related lymphomas, and primary effusion lymphomas (PEL).⁸⁸⁻⁹² Upon infection, the EBV genome is transported into the nucleus of the B lymphocyte, where it exists predominantly as an extrachromosomal circular molecule (episome).⁹³ The formation of circular episomes is mediated by the cohesive terminal repeats, which are represented by a variable number of tandem repeats (VNTR) sequence.^{93,94} Because of this termini heterogeneity, the number of VNTR sequences enclosed in newly formed episomes may differ considerably, thus representing a clonal marker of a single infected cell.⁹⁴ Evidence for a pathogenetic role of the virus in NHL infected by EBV is at least twofold. First, it is well recognized that EBV is able to significantly alter the growth of B cells.⁹³ Secondly, EBV-infected lymphomas usually display a single form of fused EBV termini, suggesting that the lymphoma cell population represents the clonally expanded progeny of a single infected cell.^{88,89} Nonetheless, the role of EBV in lymphomagenesis is still unclear, because the virus infects virtually all humans during their lifetime and its transforming genes are commonly not expressed in the tumor cells of BL.

HHV-8 is a gammaherpesvirus initially identified in tissues of HIV-related Kaposi sarcoma⁹⁵ and subsequently found to infect PEL cells as well as a substantial fraction of multicentric Castlemann disease.⁹⁶⁻⁹⁸ Phylogenetic analysis has shown that the closest relative of HHV-8 is herpesvirus saimiri (HVS), a gamma-2 herpesvirus of primates associated with T-cell lymphoproliferative disorders.⁹⁹ Like other gammaherpesviruses, HHV-8 is also lymphotropic, and

infect lymphocytes both in vitro and in vivo.^{95,97,98} Lymphoma cells naturally infected by HHV-8 harbor the viral genome in its episomal configuration and display a marked restriction of viral gene expression, suggesting a pattern of latent infection.⁹⁹

The HTLV-1 RNA retrovirus was first isolated from a cell line established from an adult T-cell leukemia/lymphoma (ATLL) patient.¹⁰⁰ Unlike acutely transforming retroviruses, the HTLV-1 genome does not encode a viral oncogene nor does it transform T cells by cis-activation of an adjacent cellular proto-oncogene, because the provirus appears to integrate randomly within the host genome.^{101–103} The pathogenetic effect of HTLV-1 was initially attributed to the viral production of a trans-regulatory protein (HTLV-1 tax) that can activate the transcription of several host genes.^{104–110} However, Tax expression is suppressed in vivo, most likely to allow for an immune escape of the infected cells, questioning its role in transformation. More recently, a viral factor has been identified, which is thought to be involved in cell proliferation and viral replication and which may be responsible for HTLV-1-mediated lymphomagenesis.

An association between B-NHL and infection by HCV, a single stranded RNA virus of the Flaviviridae family, has been proposed based on the increased risk of developing lymphoproliferative disorders observed among HCV-positive patients¹¹¹ and also on the results of interventional studies demonstrating that eradication of HCV with antiviral treatment could directly induce lymphoma regression in seropositive patients affected by indolent NHL.¹¹² Although the underlying mechanisms remain unclear, current models suggest that chronic B-cell stimulation by antigens associated with HCV infection may induce nonmalignant B-cell expansion, which subsequently evolves into B-NHL by accumulating additional genetic lesions.

The causative link between antigen stimulation by *H. pylori* and MALT lymphoma originating in the stomach is documented by the observation that *H. pylori* can be found in the vast majority of the lymphoma specimens,^{113–115} and eradication of infection with antibiotics leads to long-term complete regression in 70% of cases.¹¹⁶ However, cases with t(11;18)(q21;21) respond poorly to antibiotic eradication,¹¹⁷ suggesting additional players.

C. psittaci, an obligate intracellular bacterium, was recently linked to the development of ocular adnexal marginal zone B-cell lymphoma (MZL), although variations in prevalence among different geographical areas remain a major investigational issue.^{118,119} In this indolent lymphoma, *C. psittaci* causes both local and systemic persistent infection, and presumably contributes to lymphomagenesis through its mitogenic activity and its ability to promote polyclonal cell proliferation and resistance to apoptosis in the infected cells in vivo. Notably, bacterial eradication with antibiotic therapy is often followed by lymphoma regression.¹²⁰

MOLECULAR PATHOGENESIS OF B-NHL

The following section will focus on well-characterized genetic lesions that are associated with the most common types of B-NHL, classified according to the World Health Organization (WHO) classification of lymphoid neoplasia.¹ The molecular pathogenesis of HIV-related NHL will also be addressed, whereas the pathogenesis of other B-cell NHLs remains far less understood. Lymphoblastic lymphoma, which is considered the same disease as T- and B-acute lymphoblastic leukemia, will not be covered in this chapter.

Mantle Cell Lymphoma

Cell of Origin

Mantle cell lymphoma is an aggressive disease representing ~5% of all NHL diagnoses and generally regarded as incurable.¹ Based on immunophenotype, gene expression profile, and molecular features, such as the presence of unmutated IgV genes in the vast

majority of cases, MCL has been historically considered as derived from naïve, pre-GC peripheral B cells located in the inner mantle zone of secondary follicles (see Fig. 101.1).¹²¹ More recently, the observation of BCR diversity, including *IGHV* hypermutation, in a subset of tumor cases (15% to 40%) has shifted this paradigm, suggesting the existence of distinct molecular subtypes, including one influenced by the CG environment.

Genetic Lesions

MCL is typically associated with the t(11;14)(q13;q32) translocation, that juxtaposes the *IGH* gene at 14q32 to a region containing the *CCND1* gene (also known as *BCL1*) on chromosome 11q13.^{122–124} The translocation consistently leads to homotopic deregulation and overexpression of cyclin D1, a member of the D-type G1 cyclins that regulates the early phases of the cell cycle and is normally not expressed in resting B cells.^{125–127} By deregulating cyclin D1, t(11;14) is thought to contribute to malignant transformation by perturbing the G1-S phase transition of the cell cycle.¹²¹ Importantly, the frequency and specificity of this genetic lesion, together with the expression of cyclin D1 in the tumor cells, provides an excellent marker for MCL diagnosis.¹

In addition to t(11;14), up to 10% of MCLs overexpress aberrant or shorter cyclin D1 transcripts, as a consequence of secondary rearrangements, microdeletions, or point mutations in the gene 3' untranslated region.^{128–130} These alterations lead to cyclin D1 overexpression through the removal of destabilizing sequences and the consequent increase in the mRNA half-life, and are more commonly observed in cases characterized by high proliferative activity and a more aggressive clinical course. The pathogenic role of cyclin D1 deregulation in human neoplasia is suggested by the ability of the overexpressed protein to transform cells in vitro and to promote B-cell lymphomagenesis in transgenic mice, although only when combined to other oncogenic events^{131,132}; however, an animal model that faithfully recapitulates the features of the human MCL is still lacking.

Other genetic alterations involved in MCL include biallelic inactivation of the *ATM* gene by genomic deletions and mutations,¹³³ loss of *TP53* (20% of patients, where it represents a marker of poor prognosis),¹³⁴ and inactivation of the *CDKN2A* gene by deletions, point mutations, or promoter hypermethylation (approximately half of the cases belonging to the MCL variant characterized by a blastoid cell morphology).¹³⁵ Also associated with aggressive tumors are mutations activating the Notch signaling pathway, including *NOTCH1* (12% of clinical samples) and *NOTCH2* (5% of samples); these lesions, which are mutually exclusive, mostly consist of truncating events that remove the PEST sequences required for NOTCH protein degradation and, thus, lead to protein stabilization.^{136,137} Other recurrent mutations were reported in genes encoding the antiapoptotic protein BIRC3, the Toll-like receptor 2 (TLR2), the chromatin modifiers WHSC1 and MLL2, and the MEF2B transcription factor.¹³⁶ In a small number of cases, *BMI1* is amplified and/or overexpressed, possibly as an alternative mechanism to the loss of *CDKN2A*.^{138,139}

Burkitt Lymphoma

Cell of Origin

BL is an aggressive lymphoma comprising three clinical variants, namely sporadic BL (sBL), endemic BL (eBL), and HIV-associated BL, often diagnosed as the initial manifestation of AIDS.¹ In all variants, the presence of highly mutated IgV sequences^{140–145} and the expression of a distinct transcriptional signature^{144,145} unequivocally confirm the derivation from a GC B cell.

Genetic Lesions

All BL cases, including the leukemic variants, share a virtually obligatory genetic lesion (i.e., chromosomal translocations

involving the *MYC* gene on region 8q24 and one of the *Ig* loci on the partner chromosome).^{146,147} In ~80% of cases, this is represented by the *IGH* locus, leading to t(8;14)(q24;q32), whereas in the remaining 20% of cases, either *IGK* (2p12) or *IGL* (22q11) are involved.^{146–149} Although fairly homogeneous at the microscopic level, these translocations display a high degree of molecular heterogeneity, the breakpoints being located 5' and centromeric to *MYC* in t(8;14), but mapping 3' to *MYC* in t(2;8) and t(8;22).^{146–150} Further molecular heterogeneity derives from the exact breakpoint sites observed on chromosomes 8 and 14 in t(8;14): Translocations of eBL tend to involve sequences at an undefined distance (>1,000 kb) 5' to *MYC* on chromosome 8 and sequences within or in proximity to the *IGHJ* region on chromosome 14.^{151,152} In sBL, t(8;14) preferentially involves sequences within or immediately 5' to *MYC* (<3 kb) on chromosome 8 and within the *IGH* switch regions on chromosome 14.^{151,152}

The common consequence of t(8;14), t(2;8) and t(8;22) is the ectopic and constitutive overexpression of the *MYC* proto-oncogene,^{153–155} which is normally absent in the majority of proliferating GC B cells,¹³ in part due to *BCL6*-mediated transcriptional repression.¹⁵⁶ Oncogenic activation of *MYC* in BL is mediated by at least three distinct mechanisms: (1) juxtaposition of the *MYC* coding sequences to heterologous enhancers derived from the *Ig* loci;^{153–155} (2) structural alterations of the gene 5' regulatory sequences, which affect the responsiveness to cellular factors controlling its expression¹⁵⁷—in particular, the *MYC* exon 1/intron 1 junction encompasses critical regulatory elements that are either decapitated by the translocation or mutated in the translocated alleles; and (3) amino acid substitutions within the gene exon 2, encoding for the protein transactivation domain.^{158,159} These mutations can abolish the ability of *p107*, a nuclear protein related to *RBI*, to suppress *MYC* activity¹⁶⁰ or increase protein stability.^{161,162}

MYC is a nuclear phosphoprotein that functions as a sequence-specific DNA-binding transcriptional regulator controlling proliferation, cell growth, differentiation, and apoptosis, all of which are implicated in carcinogenesis.¹⁶³ In addition, *MYC* controls DNA replication independent of its transcriptional activity, a property that may promote genomic instability by inducing replication stress.¹⁶⁴ Consistent with its involvement in multiple cellular processes, the *MYC* target gene network is estimated to include ~15% of all protein-coding genes as well as noncoding RNAs.^{163,165} In vivo, *MYC* is found mainly in heterodimeric complexes with the related protein *MAX*, and such interaction is required for *MYC*-induced stimulation of transcription and cell proliferation.^{166–172} In NHL carrying *MYC* translocations, constitutive expression of *MYC* induces the transcription of target genes with diverse roles in regulating cell growth by affecting DNA replication, energy metabolism, protein synthesis, and telomere elongation.^{163,172,173} Furthermore, deregulated *MYC* expression is thought to cause genomic instability, and thus contributes to tumor progression by facilitating the occurrence of additional genetic lesions.¹⁷⁴ Dysregulation of *MYC* expression in a number of transgenic mouse models leads to the development of aggressive B-cell lymphomas with high penetrance and short latency.^{162,175,176} These mouse models confirm the pathogenetic role of deregulated *MYC* in B cells, although the resulting tumors tend to be more immature than the human BL, most likely due to the early activation of the promoter sequences used for the expression of the *MYC* transgene.

More recently, the application of new genomics technologies revealed additional oncogenic mechanisms that cooperate with *MYC* in the development of this aggressive lymphoma. Mutations of the transcription factor 3 (*TCF3*) (10% to 25%) and its negative regulator *ID3* (35% to 58%) are highly recurrent in all three subtypes of BL, where they promote tonic (antigen-independent) BCR signaling and sustain survival of the tumor cell by engaging the phosphoinositide 3-kinase (PI3K) pathway (Fig. 101.4).¹⁷⁷ In addition, *TCF3* can promote cell-cycle progres-

Figure 101.4 Most common genetic lesions identified in BL. Lightning bolts indicate activating mutations and crosses denote inactivating events. mTOR, mammalian target of rapamycin.

sion by transactivating *CCND3*. Notably, *CCND3* is itself a target of gain-of-function mutations in 38% of sBL, where these events affect conserved residues in the carboxyl terminus of this D-type cyclin, which are implicated in the control of protein stability, leading to higher expression levels. Interestingly, *CCND3* mutations occur in only 2.6% of eBL, suggesting alternative oncogenic mechanisms in this subtype.¹⁷⁷ Other common genetic lesions include the loss of *TP53* by mutation and/or deletion (35% of both sBL and eBL cases),⁶⁸ inactivation of *CDKN2B* by deletion or hypermethylation (17% of samples),⁸⁵ and deletions of 6q, detected in ~30% of cases, independent of the clinical variant.⁷⁰ Finally, one contributing factor to the development of BL is monoclonal EBV infection, present in virtually all cases of eBL and in ~30% of sBL.^{86,88,178,179} The consistent expression of EBV, a class of small RNA molecules, has been proposed to mediate the transforming potential of EBV in BL.¹⁸⁰ However, EBV infection in BL displays a peculiar latent infection phenotype characterized by negativity of both EBV-transforming antigens LMP1 and EBNA2; thus, the precise pathogenetic role of this virus has remained elusive.¹⁸¹

Follicular Lymphoma

FL represents the second most common type of B-NHL (~20% of diagnoses) and the most common low-grade B-NHL.¹ It is an indolent but largely incurable disease, characterized by a continuous pattern of progression and relapses that often culminates in its histologic transformation to an aggressive lymphoma with a diffuse large cell architecture and a dismal prognosis (20% to 30% of cases).^{182,183}

Cell of Origin

The ontogeny of FL from a GC B cell is supported by the expression of specific GC B-cell markers such as *BCL6* and *CD10*, together with the presence of somatically mutated *Ig* genes showing evidence of ongoing SHM activity.¹

Genetic Lesions

The genetic hallmark of FL is represented by chromosomal translocations affecting the *BCL2* gene on chromosome band 18q21, which are detected in 80% to 90% of cases independent of cytologic subtype, although less frequent in grade 3 FL.^{184–187} These rearrangements join the 3' untranslated region of *BCL2* to an *IGH* segment, resulting in the ectopic expression of *BCL2* in GC B cells,^{184,185,188–192} where its transcription is normally repressed by *BCL6*.^{18,193} Approximately 70% of the breakpoints on chromosome 18 cluster within the major breakpoint region, whereas the remaining 5% to 25% map to the more distant minor cluster region, located ~20 kb downstream of the *BCL2* gene.^{184,185,188,189} Rearrangements involving the 5' flanking region of *BCL2* have been described in a minority of cases.¹⁹⁴ The *BCL2* gene encodes a 26-kd integral membrane protein that controls the cell apoptotic threshold by preventing programmed cell death and, thus, may contribute to lymphomagenesis by inducing apoptosis resistance in tumor cells independent of antigen selection. Nevertheless, additional genetic aberrations are required for malignant transformation. Most prominent among them are mutations in multiple epigenetic modifiers, including the methyltransferase *MLL2* (80% to 90% of cases),⁸⁰ the polycomb-group oncogene *EZH2* (7% of patients),¹⁹⁵ the acetyltransferases *CREBBP* and *EP300* (40% of cases),^{79,80} and multiple core histones,¹⁹⁶ which may all contribute to transformation by remodeling the epigenetic landscape of the precursor tumor cell. A major role is also played by chronic antigen stimulation.^{197,198}

Whole-exome sequencing and CN analysis of sequential, clonally related FL and tFL biopsies has recently provided the ability to characterize the molecular events that are specifically acquired during histologic progression to DLBCL, and thus presumably play a major role in conferring this more aggressive phenotype. tFL-specific lesions include inactivation of *CDKN2A/B* through deletion, mutation, and hypermethylation (one-third of patients),^{84,136,199} rearrangements and amplifications of *MYC*,^{84,200} *TP53* mutations/deletions (25% to 30% of cases),^{69,201–203} loss of chromosome 6 (20%),⁷⁰ *ASHM*, and although larger cohorts of patients will need to be studied, biallelic loss of the immune regulator *B2M*.⁸⁴ Chromosomal translocations of the *BCL6* gene are detected in 6% to 14% of all FL cases, and were shown to have a significantly higher prevalence in the group of patients that undergo transformation into aggressive DLBCL.^{204–207}

Diffuse Large B-Cell Lymphoma

DLBCL is the most common form of B-NHL, accounting for ~40% of all new diagnoses in adulthood and including cases that arise de novo, as well as cases that derive from the clinical evolution of various, less aggressive B-NHL types (i.e., FL and CLL).^{1,208}

Cell of Origin

Based on gene expression profile analysis, at least three well-characterized molecular subtypes have been recognized within this diagnostic entity, which reflect the derivation from B cells at various developmental stages. Germinal center B-cell-like (GCB) DLBCL appears to derive from proliferating GC cells; ABC-DLBCL shows a transcriptional signature related to BCR-activated B cells or to B cells committed to plasmablastic differentiation; and PMBCL is postulated to arise from post-GC thymic B cells. The remaining 15% to 30% of cases remain unclassified.^{209–212} Stratification according to gene expression profiles has prognostic value, because patients diagnosed with GCB-DLBCL display better overall survival compared to ABC-DLBCL,⁶³ but is imperfectly replicated by immunophenotyping or morphology and does not presently inform differential therapy^{213,214}; thus, it is not officially incorporated into the WHO classification. A separate classification schema identified three discrete subsets defined by the expression of genes involved in oxidative phosphorylation, B-cell receptor/

proliferation, and tumor microenvironment/host inflammatory response.²¹⁵

Genetic Lesions

The heterogeneity of DLBCL is reflected in the catalog of genetic lesions that are associated with its pathogenesis, and include balanced reciprocal translocations, gene amplifications, chromosomal deletions, single point mutations, and relatively unique among all NHL, *ASHM*. During the past few years, the application of genomewide approaches such as whole-exome/transcriptome/genome sequencing and single nucleotide polymorphism (SNP) array analysis have provided a comprehensive picture of the DLBCL genomic landscape. One important finding of these studies is that, compared to other B-cell malignancies, DLBCL shows a significantly higher degree of genomic complexity, harboring on average 50 to more than 100 lesions per case, with great diversity across patients.^{80,216,217} Although many of the identified lesions can be variably found in both molecular subtypes of the disease, consistent with a general role during transformation, others appear to be preferentially or exclusively associated with individual DLBCL subtypes, indicating that GCB and ABC-DLBCL utilize distinct oncogenic pathways (Fig. 101.5).

GCB and ABC Shared Lesions. The most prominent program disrupted in DLBCL, independent of subtype, is represented by epigenetic regulation of chromatin due to mutations in the *CREBBP/EP300* acetyltransferase genes (35% of cases) and the *MLL2* H3K4 trimethyltransferase (~30% of cases).^{79,80,217} These lesions may favor tumor development by reprogramming the cancer epigenome and, in the case of *CREBBP/EP300*, by altering the balance between the activity of the *BCL6* oncogene, which is typically inactivated by acetylation, and the tumor suppressor p53, which requires acetylation at specific residues for its function.⁷⁹

Deregulated activity of the *BCL6* oncoprotein due to a multitude of genetic lesions is also a major contributor to DLBCL pathogenesis, in both GCB and ABC-DLBCL. Chromosomal rearrangements of the *BCL6* gene at band 3q27 are observed in up to 35% of cases,^{71,205,218} although with a twofold higher frequency in the ABC-DLBCL subtype (see Fig. 101.4).²¹⁹ These rearrangements juxtapose the intact coding domain of *BCL6* downstream and in the same transcriptional orientation to heterologous sequences derived from the partner chromosome, including *IGH* (14q23), *IGK* (2p12), *IGA* (22q11), and at least 20 other chromosomal sites unrelated to the *IG* loci.^{40–47} The majority of these translocations result in a fusion transcript in which the promoter region and the first noncoding exon of *BCL6* are replaced by sequences derived from the partner gene.^{41,220} Because the common denominator of these promoters is a broader spectrum of activity throughout B-cell development, including expression in the post-GC differentiation stage, the translocation is thought to prevent the downregulation of *BCL6* expression that is normally associated with differentiation into post-GC cells. Deregulated expression of an intact *BCL6* gene product is also sustained by a variety of indirect mechanisms, including gain-of-function mutations in its positive regulator *MEF2B* (~11% of cases),²²¹ inactivating mutations/deletions of *CREBBP/EP300*,⁷⁹ and mutations/deletions of *FBXO11* (~5%),²²² which encodes a ubiquitin ligase involved in the control of *BCL6* protein degradation. These lesions play a critical role in lymphomagenesis by enforcing the proliferative phenotype typical of GC cells, while suppressing proper DNA damage responses; moreover, constitutive expression of *BCL6* blocks terminal differentiation, as confirmed by a mouse model in which deregulated *BCL6* expression causes DLBCL.²²³

DLBCL cells have also acquired the ability to escape both arms of immune surveillance, including cytotoxic T lymphocytes (CTL)-mediated cytotoxicity (through genetic loss of the *B2M*/human leukocyte antigen class I [*HLA-I*] genes) and natural killer (NK) cell-mediated death (through genetic loss of the CD58 molecule).²²⁴ Analogous effects may be achieved in PMBCL by disruption of the major histocompatibility complex class II

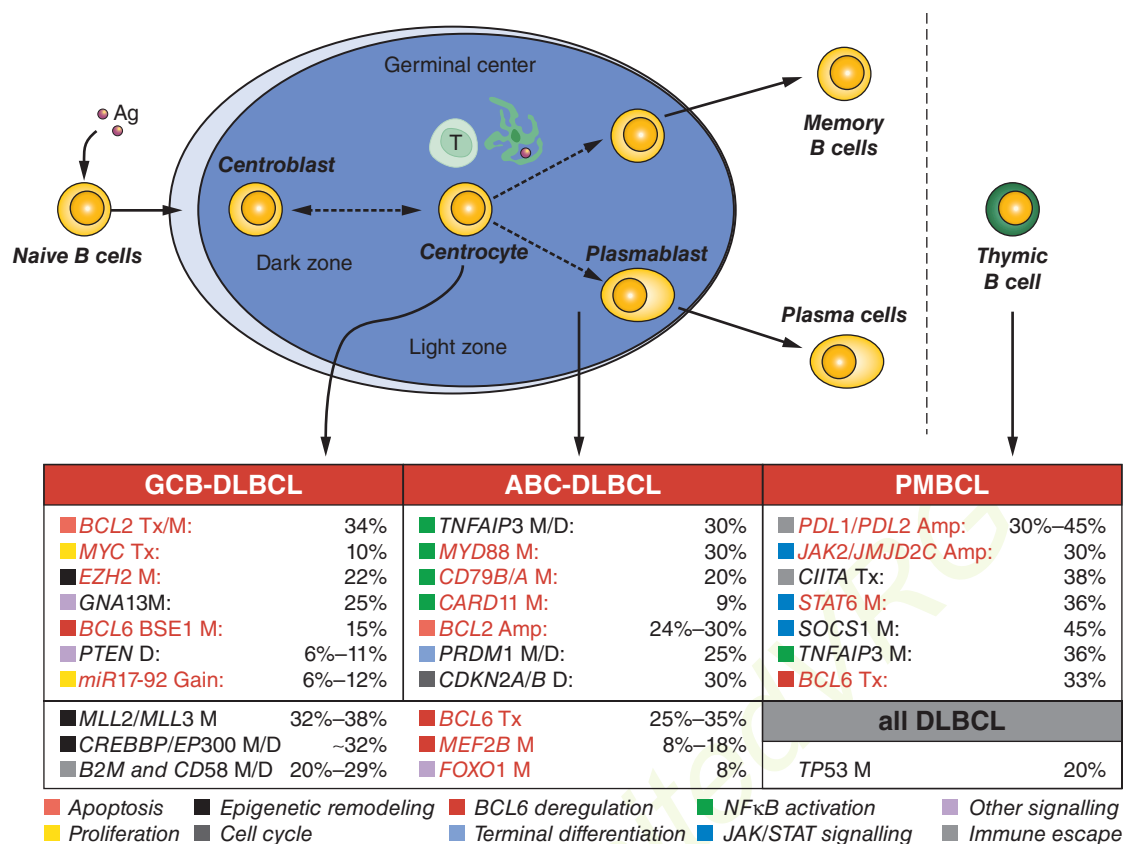

Figure 101.5 Genetic lesions associated with DLBCL. Most common genetic lesions identified in the three major DLBCL subtypes, including lesions that are shared between GCB- and ABC-DLBCL and lesions that are preferentially segregating with individual molecular subtypes. Loss-of-function alterations are in black and gain-of-function events are in red. Color-coded squares denote the biologic function/signaling pathway affected by the alteration.

(MHC-II) transactivator class II major histocompatibility complex transactivator (*CIITA*) and amplification of the genes encoding for the immunomodulatory proteins *PDL1/PDL2*.

Finally, approximately 50% of all DLBCL are associated with ASHM.⁴⁵ The number and identity of the genes that accumulate mutations in their coding and noncoding regions due to this mechanism varies in different cases and is still largely undefined. However, preferential targeting of individual genes has been observed in the two main DLBCL subtypes, with mutations of *MYC* and *BCL2* being found at significantly higher frequencies in GCB-DLBCL, and mutations of *PIM1* almost exclusively observed in ABC-DLBCL. ASHM may, therefore, contribute to the heterogeneity of DLBCL via the alteration of different cellular pathways in different cases. Mutations and deletions of the *TP53* tumor suppressor gene are detectable in ~20% of cases, including those that originate from the transformation of FL, and are more often associated with chromosomal translocations involving *BCL2*.⁶⁹

GCB-DLBCL. Genetic lesions specific to GCB-DLBCL include the t(14;18) and t(8;14) translocations, which deregulate the *BCL2* and *MYC* oncogenes in 34% and 10% of cases, respectively.^{63,193,225,226} Also exquisitely restricted to this subtype are mutations of the *EZH2* gene,¹⁹⁵ which encodes a histone methyltransferase responsible for trimethylating Lys27 of histone H3 (H3K27), mutations of the *S1PR2* adaptor protein *GNA13*, mutations affecting an autoregulatory domain within the *BCL6* 5' untranslated exon 1,^{219,227,228} and deletions of the tumor suppressor *PTEN*.^{83,229}

Somatic mutations of the *BCL6* 5' regulatory sequences are detected in up to 75% of DLBCL cases^{52,230,231} and reflect the activity of the physiologic SHM mechanism that operates in normal GC B cells.^{52,53} However, a functional analysis of numerous mutated

BCL6 alleles uncovered a subset of mutations that are specifically associated with GCB-DLBCL and that are not observed in normal GC cells or in other B-cell malignancies.²²⁷ These mutations deregulate *BCL6* transcription by disrupting an autoregulatory circuit through which the *BCL6* protein controls its own expression levels via binding to the promoter region of the gene^{227,228} or by preventing CD40-induced *BCL6* downregulation in post-GC B cells.²³² Because the full extent of mutations deregulating *BCL6* expression has not been characterized, the fraction of DLBCL cases carrying abnormalities in *BCL6* cannot be determined.

ABC-DLBCL. Several genetic abnormalities are observed almost exclusively in ABC-DLBCL, including amplifications of the *BCL2* locus on 18q24^{233,234}, mutations within the *NF-κB* (*CARD11*, *TNFAIP3/A20*),^{75,235} B-cell receptor (*CD79B*),²³⁶ and TLR (*MYD88*)²³⁷ signaling pathways; inactivating mutations and deletions of *BLIMP1*^{72–74}; chromosomal translocations deregulating the *BCL6* oncogene; and deletion or lack of expression of the p16 tumor suppressor. Mutations of the *ATM* gene have been reported in a small subset of cases.²³⁸

A predominant feature of ABC-DLBCL is the constitutive activation of the *NF-κB* signaling pathway, initially evidenced by the selective expression of a signature enriched in *NF-κB* target genes, and by the requirement of *NF-κB* for proliferation and survival of ABC-DLBCL cell lines. This phenotype is sustained by a variety of alterations affecting positive and negative regulators of *NF-κB*, as well as other adaptor molecules converging on activation of *NF-κB*, specifically in this disease subtype. In up to 30% of cases, the *TNFAIP3* gene, encoding for the negative regulator A20, is biallelically inactivated by mutations and/or deletions, thus preventing termination of *NF-κB* responses.^{75,76} The tumor suppressor role

of A20 was documented by the observation that reconstitution of A20 knockout cell lines with a wild-type protein induces apoptosis and blocks proliferation, in part due to suppression of NF- κ B activity.^{75,76} In an additional ~10% of ABC-DLBCL, the *CARD11* gene is targeted by oncogenic mutations clustering in the protein coiled-coil domain and enhancing its ability to transactivate NF- κ B target genes.²³⁵ Less commonly, mutations were found in a variety of other genes encoding for NF- κ B components, overall accounting for over half of all ABC-DLBCL⁷⁵ and suggesting that yet unidentified lesions may be responsible for the NF- κ B activity in the remaining fraction of cases.

In addition to constitutive NF- κ B activity, ABC-DLBCLs display evidence of chronic active BCR signaling, which is associated with somatic mutations affecting the immunoreceptor tyrosine-based activation motif (ITAM) signaling modules of *CD79B* and *CD79A* in 10% of ABC-DLBCL biopsy samples, but rarely in other DLBCLs.²³⁶ Moreover, silencing several BCR proximal and distal subunits is toxic to ABC-DLBCL. These findings provided genetic evidence in support of the development of therapies targeting BCR signaling,²³⁶ and indeed, kinase inhibitors that interfere with this signaling pathway are emerging as a new treatment paradigm for ABC-DLBCL.

Approximately 30% of ABC-DLBCL patients harbor a recurrent change in the intracellular Toll/interleukin-1 receptor domain of the MYD88 adaptor molecule, which has the potential to activate NF- κ B as well as JAK/STAT3 transcriptional responses.²³⁷ Although the relationship between MYD88 mutations and TLR signaling has not been studied, MYD88 was shown to be required for the survival of ABC-DLBCLs, indicating a pathogenic role for TLR in this disease type.

A second important program that is disrupted by genetic lesions in ABC-DLBCL includes terminal B-cell differentiation. In up to 25% of ABC-DLBCL cases, the *PRDM1* gene is inactivated by biallelic truncating or missense mutations and/or genomic deletions, as

well as by transcriptional repression through constitutively active, translocated *BCL6* alleles.⁷²⁻⁷⁴ The *PRDM1* gene encodes for a zinc finger transcriptional repressor that is expressed in a subset of GC B cells undergoing plasma cell differentiation and in all plasma cells,^{239,240} and is an essential requirement for terminal B-cell differentiation.²⁴¹ Thus, BLIMP1 inactivation contributes to lymphomagenesis by blocking post-GC B-cell differentiation. Consistently, translocations deregulating the *BCL6* gene are exceedingly rare in *BLIMP1* mutated DLBCLs, suggesting that *BCL6* deregulation and BLIMP1 inactivation represent alternative oncogenic mechanisms converging on the same pathway (Fig. 101.6).

PMBCL. PMBCL is a tumor observed most commonly in young female adults, which involves the mediastinum and displays a distinct gene expression profile, largely similar to HL.^{211,212} A genetic hallmark of both PMBCL and HL is the amplification of chromosomal region 9q24, detected in nearly 50% of patients.^{83,242} This relatively large interval encompasses multiple genes of possible pathogenetic significance, including the gene encoding for the *JAK2* tyrosine kinase and the *PDL1/PDL2* genes, which encode for inhibitors of T-cell responses^{64,83,242} and have been linked to impaired antitumor immune responses in several cancers. Other lesions affecting regulators of immune responses in PMBCL include genomic breakpoints and mutations of the MHC class II transactivator gene *CIITA*, which may reduce tumor cell immunogenicity by downregulating surface HLA class II expression.^{64,65,243} The ability of the previously mentioned lesions to interfere with the interaction between the lymphoma cells and the microenvironment suggests a central role for escape from immuno-surveillance mechanisms. Besides contributing to lymphomagenesis, elevated expression levels of these genes may, in part, explain the unique features of these lymphoma types, which are characterized by a significant inflammatory infiltrate. PMBCL also shares with HL the presence of genetic lesions affecting the NF- κ B pathway and

Figure 101.6 Pathway lesions in ABC-DLBCL. Schematic representation of a germinal center centrocyte, expressing a functional surface BCR, a CD40 receptor and a TLR. In normal B cells, engagement of the BCR by the antigen (*spheres*), interaction of the CD40 receptor with the CD40L presented by T-cells, and activation of the TLR converge on activation of the NF- κ B pathway, including its targets IRF4 and A20 among others. IRF4, in turn, downregulates BCL6 expression, allowing the release of BLIMP1 expression, a master plasma cell regulator required for terminal differentiation. In ABC-DLBCL, multiple genetic lesions disrupt this pathway at multiple levels in different cases (percentages as indicated); these lesions contribute to lymphomagenesis by favoring the antiapoptotic and pro-proliferative function of NF- κ B, as well as chronic active BCR and JAK/STAT3 signaling, while blocking terminal B-cell differentiation through mutually exclusive deregulation of BCL6 and inactivation of BLIMP1.

the deregulated expression of receptor tyrosine kinases.^{78,244-246} In particular, mutations of the transcription factor *STAT6*, amplifications/overexpression of *JAK2* (which promote *STAT6* activation via interleukin 3 (IL-3)/IL-4), and inactivating mutations of its negative regulator *SOCS1* are highly recurrent in PMBCL, pointing to the JAK/STAT signaling pathway as a major disease contributor.

DLBCL Derived from CLL and FL Transformation. Recently, exome sequencing studies examining sequential biopsies of CLL/RS or FL/tFL have provided insights onto the molecular mechanisms that drive the transformation process. These analyses extended the set of genetic lesions that are specifically acquired during transformation and include *CDKN2A/B* loss, *TP53* loss, and *MYC* translocations (in both conditions), along with *ASH1* and *B2M* inactivation in tFL, or *NOTCH1* mutations in RS.^{82,84} They also allowed for reconstruction of the evolutionary history of the dominant tumor clone during transformation, revealing that FL and tFL derive from a common ancestor mutated clone through divergent evolution, as opposed to RS, which, analogous to CLL progression,²⁴⁷ arises from the predominant CLL clone through a linear pattern. Finally, comparison with de novo DLBCL showed that, despite their morphologic resemblance, the genomic landscapes of RS and tFL are largely unique in that they are characterized by distinct combinations of alterations otherwise not commonly observed in de novo DLBCL/NOS.^{82,84}

Extranodal Marginal Zone Lymphoma of Mucosa-associated Lymphoid Tissue (MALT)

Cell of Origin

Mucosa-associated lymphoid tissue (MALT) lymphoma represents the third most common form of NHL,¹ and has steadily risen in incidence over the last 2 decades.²⁴⁸ The presence of rearranged and somatically mutated IgV genes,^{31,249} together with the architectural relationship with MALT,¹ indicate the post-GC origin of these tumors, possibly from a marginal zone memory B cell (see Fig. 101.1). A number of observations support a critical role for antigen stimulation, particularly in the pathogenesis of gastric MALT lymphoma: (1) This disease is associated with chronic infection of the gastric mucosa by *H. pylori* in virtually all cases¹¹³⁻¹¹⁵; (2) eradication of *H. pylori* by antibiotic treatment can lead to tumor regression in ~70% of cases^{116,250}; and (3) MALT lymphoma cells express autoreactive BCR, in particular to rheumatoid factors.^{251,252} Whether the development of MALT lymphoma arising in body sites other than the stomach also depends on antigen stimulation remains an open question. In this respect, it is remarkable that salivary gland and thyroid MALT lymphoma are generally a sequela of autoimmune processes, namely Sjögren syndrome and Hashimoto thyroiditis, respectively.

Genetic Lesions

Most of the structural aberrations that are selectively and recurrently associated with MALT lymphoma target the NF-κB signaling pathway, suggesting a critical role in the disease pathogenesis. The most common among these lesions is the t(11;18)(2;33) translocation, which involves the *BIRC3* gene on 11q21 and the *MALT1* gene on 18q21,^{253,254} and is observed in 25% to 40% of gastric and pulmonary MALT lymphomas.²⁵⁵⁻²⁵⁷ *BIRC3* plays an evolutionary conserved role in regulating programmed cell death in diverse species, whereas *MALT1*, together with *BCL10* and *CARD11*, is a component of the ternary complex that plays a central role in BCR and NF-κB signaling activation.²⁵⁸ Notably, the wild-type proteins encoded by these two genes are incapable of activating NF-κB, in contrast to the *BIRC3/MALT1* fusion protein, suggesting that the translocation confer a survival advantage to the tumor by leading to inhibition of apoptosis and constitutive NF-κB activation without the need for upstream signaling.^{253,254,259} In an additional 15% to 20% of cases, *MALT1* is translocated to the

IGH locus as a consequence of t(14;18)(q32;q21),^{260,261} whereas ~5% of patients harbor abnormalities of chromosomal band 1p22, generally represented by t(1;14)(p22;q32); the latter deregulates the expression of *BCL10*, a cellular homolog of the equine herpesvirus-2 *E10* gene, which contains an amino-terminal caspase recruitment domain (CARD) homologous to that found in several apoptotic molecules.^{262,263} *BCL10*, however, does not have proapoptotic activity *in vivo*, where it functions as a positive regulator of antigen-induced activation of NF-κB.^{258,264,265} Thus, the translocation may provide both antiapoptotic and proliferative signals mediated via NF-κB transcriptional targets.

A more recently identified translocation associated, although not restricted to, MALT lymphoma is t(3;14)(p13;q32),^{266,267} which leads to the deregulated expression of *FOXP1*, a member of the Forkhead box family of winged-helix transcription factors involved in the regulation of *Rag1* and *Rag2* and essential for B-cell development.²⁶⁸ Finally, homozygous or hemizygous loss of *TNFAIP3* due to mutations and/or deletions has been reported in 20% of MALT lymphoma patients, typically in a mutually exclusive pattern with other alterations leading to NF-κB activation.⁷⁷ Other recurrent genetic lesions in this disease include trisomy 3,^{269,270} *BCL6* alterations, and *TP53* mutations.²⁷¹⁻²⁷³

Chronic Lymphocytic Leukemia

Cell of Origin

CLL is a malignancy of mature, resting B lymphocytes that originates from the oncogenic transformation of a common precursor resembling an antigen-experienced B cell.²⁷⁴ This notion was conclusively demonstrated when gene expression profile studies revealed that, although CLL can express somatically mutated or unmutated IgV genes at approximately equal percentages,^{275,276} all cases share a homogeneous signature more related to that of CD27+ memory and marginal zone B cells.^{277,278} Moreover, an analysis of the Ig gene repertoire in these patients indicates very similar, at times almost identical, antigen receptors among different individuals.²⁷⁹⁻²⁸⁴ This finding, known as *stereotypy*, strongly supports a role for the antigen in CLL pathogenesis. The histogenetic heterogeneity of CLL carries prognostic relevance, because cases with mutated Ig genes are associated with a significantly longer survival.^{285,286} Intriguingly, 6% of the normal elderly population develops a monoclonal B-cell lymphocytosis (MBL) that is considered the precursor to CLL in 1% to 2% of cases.²⁸⁷

Genetic Lesions

Different from most mature B-NHL and consistent with the derivation from a post-GC or GC-independent B cell, CLL cases are largely devoid of balanced, reciprocal chromosomal translocations.⁸¹ On the contrary, CLL is recurrently associated with several numerical abnormalities, including trisomy 12 and monoallelic or biallelic deletion/inactivation of chromosomal regions 17p, 11q, and 13q14 (Table 101.1).⁸¹ Of these, the deletion of 13q14 represents the most frequent chromosomal aberration, being observed in up to 76% of cases as a monoallelic event, and in 24% of cases as a biallelic event. Interestingly, this same deletion is also found in subjects with MBL.²⁸⁷ In all affected cases, the minimal deleted region (MDR) encompasses a long noncoding RNA (*DLEU2*) and two microRNAs expressed as a cluster, namely miR-15a and miR-16-1.²⁸⁸⁻²⁹⁰ The causal involvement of 13q14-MDR-encoded tumor suppressor genes in CLL pathogenesis was demonstrated *in vivo* in two animal models, which developed clonal lymphoproliferative diseases with features of MBL, CLL, and DLBCL at 25% to 40% penetrance.²⁹¹ Trisomy 12 is found in approximately 16% of patients evaluated by interphase fluorescent *in situ* hybridization and correlates with poor survival, but no specific gene(s) have been identified.²⁹²⁻²⁹⁴ Deletions of chromosomal region 11q22-23 (18% of cases) almost invariably encompass the

GCB, germinal center B-cell-like; ABC, activated B-cell-like; M, mutation; D, deletion. See also Fig. 101.5 for a more complete list of the recurrent genetic lesions in DLBCL.

^a In the adult population; 85% in childhood.

^b Sixty percent in Epstein-Barr Virus-negative cases.

ATM gene and may thus promote genomic instability.^{295–297} These lesions can be observed in the patient germ line, and may thus account, at least in part, for the familial form of the disease. Another important target within the 11q22–23 deleted region is the *BIRC3* gene, encoding for a negative regulator of NF-κB.²⁹⁸ The identification of inactivating mutations and the evidence of constitutive NF-κB activation in these cases suggests that NF-κB could serve as a therapeutic target in this poor prognostic category of patients. Deletions of 17p13, which include the *TP53* tumor suppressor and which are frequently accompanied by a mutation of the second allele,^{68,299} are observed in ~7% of CLL at diagnosis but are enriched in cases that underwent transformation to RS, a highly aggressive lymphoma with poor clinical outcome.⁸² More recently, gain-of-function mutations of *NOTCH1* and mutations of *SF3B1* were discovered in 5% to 10% of diagnostic CLL samples,^{300–303}

where they seem to predict an adverse outcome, as supported by their preferential enrichment in RS (30% of cases) and fludarabine refractory cases (25%), respectively (Fig. 101.7).^{82,300–304}

HIV-Related Non-Hodgkin Lymphoma

The association between an immunodeficiency state and the development of lymphoma has been recognized in several clinical conditions, including congenital (e.g., Wiskott-Aldrich syndrome), iatrogenic (e.g., treatment with immunosuppressive agents), and viral-induced (e.g., AIDS) immunodeficiencies. Detailed investigations have been conducted on the molecular pathophysiology of HIV-related NHL, which are primarily classified into three clinico-pathologic categories: BL, DLBCL, and PEL.^{1,305,306} Based

Figure 101.7 Genetic lesions associated with CLL. Frequency of common genetic alterations observed in unselected CLL cases at diagnosis, fludarabine-resistant CLL and RS. Blue, loss of function mutations; Red, gain-of-function mutations.

on the site of origin, HIV-related NHLs are generally grouped into systemic HIV-related NHL (i.e., DLBCL and BL) and HIV-related PCNSL, which is characterized by a uniform morphology consistent with a diffuse architecture of large cells.^{1,305,306}

Cell of Origin

HIV-related NHLs invariably derive from B cells that have experienced the GC reaction, as indicated by the presence of somatic mutations in the *IG* and *BCL6* genes, as well as by several phenotypic and transcriptional features.^{305–307} Based on the presence or absence of immunoblastic features and on the expression pattern of *BCL6*, *CD138*, and the EBV-encoded *LMP1*, both HIV-related DLBCL and PCNSL can be segregated into two distinct histogenetic categories. Cases displaying the *BCL6*⁺/*CD138*⁻/*LMP1*⁻ phenotype closely resemble the phenotype of GC B cells, whereas *BCL6*⁻/*CD138*⁺/*LMP1*⁺ cases are morphologically consistent with immunoblastic lymphoma, plasmacytoid, and reflect a post-GC stage of B-cell differentiation.^{305,306} PEL consistently derives from B cells, reflecting a preterminal stage of differentiation.^{97,308–310}

Genetic Lesions. The three categories of HIV-related NHL associate with distinctive molecular pathways. HIV-related BLs consistently displays activation of *MYC* due to chromosomal translocations that are structurally similar to those found in sBL, whereas rearrangements of *BCL6* are always absent.³⁰⁷ HIV-related BLs also frequently harbor mutations in *TP53* (60%), *BCL6* 5' noncoding sequences (60%), and, in 30% of cases, infection of the tumor clone by EBV, although the EBV-encoded antigens *LMP1* and *EBNA2* are not expressed.^{311,312} Stimulation and selection by antigens, frequently represented by autoantigens, appear to be a prominent feature.^{142,313}

Different from BL, the most frequent genetic alteration detected in HIV-related DLBCL is infection by EBV, which occurs in approximately 60% to 70% of cases and is frequently, although not always, associated with the expression of *LMP1*.^{89,91,312} Moreover, HIV-related DLBCLs carry *BCL6* rearrangements in 20% of cases,³¹⁴ and mutations of the *BCL6* 5' noncoding region in 70% of cases.³¹⁵

All HIV-related PCNSLs show evidence of EBV infection.³¹⁶ However, only the subset with immunoblastic morphology expresses the *LMP1* transforming protein.³¹⁷ These tumors display *ASHM*⁵⁷ and harbor oncogenic mutations in the *CARD11* gene (16% of cases),³¹⁸ which may explain, in part, the constitutive *NF-κB* activity previously recognized in this lymphoma subtype. Although some reports have suggested that HHV-8 may be related to PCNSL pathogenesis in immunocompromised patients, extensive analyses have unequivocally ruled out this hypothesis.^{319,320}

The last type of HIV-related NHL that has been characterized at the molecular level is PEL, also known as body cavity-based

lymphoma.^{97,308,309} This entity is associated with HHV-8 infection in 100% of cases and clinically presents as effusions in the serosal cavities of the body (pleura, pericardium, peritoneum) in the absence of solid tumor masses.^{97,308,309} In addition to HHV-8, PEL cases frequently show coinfection of the tumor clone by EBV.^{90,92,97,308,309}

MOLECULAR PATHOGENESIS OF T-CELL NON-HODGKIN LYMPHOMA

Peripheral T-cell lymphoma (PTCL) encompasses a highly heterogeneous and relatively uncommon group of diseases representing 5% to 10% of all NHLs worldwide, with significant geographical variation in both incidence and relative prevalence.¹ PTCLs arise from mature post-thymic T cells and, according to the clinical presentation of the disease, are listed as leukemic or disseminated, predominantly extranodal, cutaneous, and predominantly nodal.¹ Although the study of T-cell neoplasms is hampered by the rarity of these diseases and the difficulty of collecting homogeneous sample series, significant advances were made over the past decades in our understanding of their biology, classification, and prognosis.

Adult T-Cell Lymphoma/Leukemia (HTLV-1 Positive)

Cell of Origin

The term ATLL identifies a spectrum of lymphoproliferative diseases associated with HTLV-I infection that is mainly restricted to southwestern Japan and the Caribbean basin.^{1,321} The United States and Europe are considered low-risk areas, because less than 1% of the population are HTLV-I carriers³²² and only 2% to 4% of seropositive individuals eventually develop ATLL.^{1,101,102} Clonal rearrangement of the TCR is evident in all cases, and clonal integration of the virus has been observed.^{323,324}

Genetic Lesions

Compared to other mature T-cell tumors, the molecular pathogenesis of ATLL has been elucidated to a wider extent. Particularly, the role of HTLV-I has been linked to the production of a transregulatory protein (HTLV-1 tax), that markedly increases expression of all viral gene products and transcriptionally activates the expression of certain host genes, including *IL-2*, *CD25*, *c-sis*, *c-fos*, and granulocyte-macrophage colony-stimulating factor (*GM-CSF*).^{104–106,107,108} Indeed, a property of ATLL cells is the constitutively high expression of the *IL-2* receptor. The central role of

these genes in normal T-cell activation and growth, together with the results of *in vitro* studies, support the notion that tax-mediated activation of these host genes represents an important mechanism by which HTLV-1 initiates T-cell transformation.¹⁰⁴ In addition, tax interferes with DNA damage repair functions and with mitotic checkpoints,^{109,110,325} which is consistent with the fact that ATLL cells harbor a high frequency of karyotypic abnormalities.

The long period of clinical latency that precedes the development of ATLL (usually 10 to 30 years), the small percentage of infected patients that develop this malignancy, and the observation that leukemic cells from ATLL are monoclonal suggest that HTLV-1 is not sufficient to cause the full malignant phenotype.^{101–103} A model for ATLL, therefore, implies an early period of tax-induced polyclonal T-cell proliferation that, in turn, would facilitate the occurrence of additional genetic events leading to the monoclonal outgrowth of a fully transformed cell. In this respect, a recurrent genetic lesion in ATLL is represented by mutations of the *TP53* tumor suppressor gene, which is inactivated in 40% of cases.^{326,327}

Peripheral T-Cell Lymphoma, Not Otherwise Specified

This category represents the largest and most heterogeneous group of PTCLs, and includes all cases that lack specific features allowing classification within another entity. The majority of these cases derive from $\alpha\beta$ CD4+ T cells and show aberrant defective expression of one or several T-cell-associated antigens.³²⁸ Based on gene expression profiling, peripheral T cell lymphoma/not otherwise specified (PTCL/NOS) as a group appears to be most closely related to activated T cells than to resting T cells and can be segregated according to similarities with the transcriptional signature of CD4+ and CD8+ T cells. However, no correlation is observed between gene expression profiles (GEP) and immunophenotype, likely reflecting the variable detection of T-cell antigens in the disease.

Genetic Lesions

Clonal numerical and structural aberrations are found in most PTCL/NOS by conventional cytogenetics and in all cases by more sensitive approaches such as array-based methods. For a few loci, the correlation between gene CN and expression has been confirmed, suggesting a pathogenetic role. Candidate genes include *CDK6* on chromosome 7q, *MYC* on chromosome 8, and the NF- κ B regulator *CARD11* at 7p22, whereas losses of 9p21 are associated with a reduced expression of *CDKN2A/B*.³²⁹ Chromosomal translocations involving the *TCR* loci have been reported in rare cases and remain poorly understood, because the identity of the translocation partner has not been identified, with few exceptions: the *BCL3* gene, the poliovirus receptor-related 2 (PVRL2) gene found in the t(14;19)(q11;q13) translocation, and the *IRF4* gene, which is cloned in two cases.^{330–332} More recently, whole-exome sequencing studies revealed the presence of recurrent heterozygous mutations in the *RHOA* small GTPase gene (18% of patients), including a hot-spot Gly17Val substitution that was shown to have inhibitory effects in the Rho-signaling pathway, potentially via the sequestration of GEP proteins.^{333,334} These mutations appear to segregate with a subset of Tfh-like PTCL/NOS, characterized by the expression of CD10 and PD-1, the proliferation of CD21+*FDCs*, and EBER positivity. In a smaller number of cases, mutations were also found in *TET2*, *DNM3TA*, *IDH2*, *TET3*, *FYN*, and *B2M*.^{333,334}

Angioimmunoblastic T-Cell Lymphoma

Cell of Origin

Angioimmunoblastic T-cell lymphoma (AITL) is an aggressive disease of the elderly and accounts for about one-third of all PTCL cases in Western countries.³³⁵ The tumor cells display a mature CD4+CD8-

T-cell phenotype, with frequent aberrant loss of one or several T-cell markers and coexpression of *BCL6* and *CD10* in at least a fraction of cells. Gene expression profile studies have conclusively established the cellular derivation of AITL from follicular helper T cells,³³⁶ as initially suspected based on the expression of single markers.³³⁷

Genetic Lesions

Until recently, the scarce number of genetic studies had failed to provide any significant clues regarding the oncogenic pathways involved in AITL. However, a major discovery emerged in 2013 from two whole-exome sequencing studies that identified highly recurrent mutations of *RHOA* in 67% of all AITL cases.^{333,334} These mutations are analogous to those observed in PTCL/NOS, but are not found in other mature B- and T-cell neoplasms, strongly suggesting a role for the disruption of the RHO-signaling pathway in the pathogenesis of this disease. Additional clonal aberrations have been reported in up to 90% of AITL patients and include chromosomal imbalances as well as mutations in *TET2*, *IDH2*, and *DNMT3A*, which are common to various hematologic malignancies, whereas chromosomal translocations affecting the *TCR* loci are extremely rare.^{329,333,334}

Cutaneous T-Cell Lymphoma

Genetic lesions are involved in a limited but significant fraction of primary CTCLs showing a molecular marker of clonality. Most notable among them are rearrangements of the *NFKB2* gene at 10q24, leading to a chimeric protein that retains the rel effector domain and can bind κ B sequences *in vitro*,^{338,339} but that lacks the ankyrin regulatory domain required for regulating the physiologic nuclear/cytoplasmic distribution. The translocation may thus contribute to lymphoma development by causing constitutive activation of the NF- κ B pathway.

Anaplastic Large Cell Lymphoma

Cell of Origin

ALCL is a distinct subset of T-NHL (~12% of cases), whose normal cellular counterpart has not yet been established.^{1,321} The tumor is composed of large pleomorphic cells that exhibit a unique phenotype characterized by positivity for the CD30 antigen and the loss of most T-cell markers.^{1,340} Based on the expression of a chimeric protein containing the cytoplasmic portion of anaplastic lymphoma kinase (ALK) (see the following), ALCL may be subdivided in two groups, displaying distinct transcriptional signatures³⁴¹: The most common and curable is ALK-positive ALCL, and the more aggressive is ALK-negative ALCL.^{1,342–344} However, the identification of a common 30-genes predictor that can discriminate ALCL from other T-NHL, independent of ALK status, suggests that these two subgroups are closely related and may derive from a common precursor.³⁴⁵

Genetic Lesions

The genetic hallmark of ALK+ALCL is a chromosomal translocation involving band 2p23 and a variety of chromosomal partners, with t(2;5)(p23;q35) accounting for 70% to 80% of the cases.^{1,346} Cloning of the translocation breakpoint in t(2;5) demonstrated the involvement of the *ALK* gene on 2p23 and the nucleophosmin (*NPM1*) gene on 5q35.³⁴⁷ As a consequence, the aminoterminal of *NPM* is linked in frame to the catalytic domain of *ALK*, driving transformation through multiple molecular mechanisms³⁴⁷: (1) the *ALK* gene, which is not expressed in normal T-lymphocytes, becomes inappropriately expressed in lymphoma cells, conceivably because of its juxtaposition to the promoter sequences of *NPM*, which are physiologically expressed in T cells; and (2) all translocations involving *ALK* produce proteins with constitutive tyrosine activity, due in most cases to spontaneous dimerization induced by the various fusion partners.³⁴⁶ Constitutive *ALK* activity, in turn, results

in the activation of several downstream signaling cascades, with the JAK/STAT and PI3K/AKT pathways playing central roles.^{348–351} The transforming ability of the chimeric NPM/ALK protein has been proven both in vitro and in vivo in transgenic mouse models.^{352–354}

In a minority of cases, fusions other than NPM/ALK cause the abnormal subcellular localization of the corresponding chimeric ALK proteins and the constitutive activation of ALK. Among these alternative rearrangements, the most frequent involve *TPM3/TPM4*, TRK-fused genes,³⁵⁵ *ATIC*,^{356,357} *CLTCL1*, and *MSN*. The diversity of known ALK fusion partners was further expanded by the recent identification of a novel TRAF1/ALK fusion transcript leading to constitutive NF- κ B expression.³⁵⁸ No recurrent cytogenetic abnormality has been described in ALK-negative ALCL, leaving the molecular events responsible for this disease subtype largely unknown.

MOLECULAR PATHOGENESIS OF HODGKIN LYMPHOMA

HL is a B-lymphoid malignancy characterized by the presence of scattered large atypical cells—the mononucleated Hodgkin cells and the multinucleated Reed-Sternberg cells (HRS)—residing in a complex admixture of inflammatory cells.^{1,359} Based on the morphology and phenotype of the neoplastic cells, as well as on the composition of the infiltrate, HL is segregated in two major subgroups: nodular lymphocyte-predominant HL (NLPHL) (~5% of cases) and classic HL (cHL), comprising the nodular sclerosis, mixed cellularity, lymphocyte-depleted, and lymphocyte-rich variants. Until recently, molecular studies of HL have been hampered by the paucity of the tumor cells in the biopsy (typically less than 1%, although occasional cases can present more than 10% HRS cells). However, the introduction of sophisticated laboratory techniques allowing for the isolation and enrichment of neoplastic cells has markedly improved our understanding of HL histogenesis.

Cell of Origin

Despite the fact that HRS of cHL cells have lost the expression of nearly all B-cell-specific genes,^{360–362} both HL types represent clonal populations of B cells, as revealed by the presence of

clonally rearranged and somatically mutated Ig genes.^{363,364} In about 25% of cHL cases, nonsense mutations disrupt originally in-frame *IGHV* gene rearrangements (crippling mutations), thereby preventing antigen selection. These data suggest that HRS cells of cHL have escaped apoptosis through a mechanism not linked to antigen stimulation.³⁶⁴

Genetic Lesions

A number of structural alterations lead to the constitutive activation of NF- κ B in cHL. Nearly half of the cases display amplification of *REL*, which is associated with increased protein expression levels^{365,366}; gains or translocations of the positive NF- κ B regulator *BCL3* were also reported.³³⁰ More recently, a number of inactivating mutations were found in genes coding for negative regulators of NF- κ B, including *NFKBIA* (20% of cases), *NFKBIE* (15%), and *TNFAIP3* (40%), among others.^{78,367–369} Notably, *TNFAIP3*-mutated cases are invariably EBV negative, suggesting that EBV infection may substitute, in part, for the pathogenic function of its protein product A20 in causing NF- κ B constitutive activation.^{78,369} In the past few years, genetic aberrations that modulate the tumor microenvironment have been uncovered using massively parallel DNA sequencing techniques, including genomic gains of PD-L1 (CD274) and PD-L2 (CD273) and translocations of *CIITA*.^{64,65,243} Amplification of *JAK2*, mutations of *STAT6*, and inactivating mutations of *SOCS1*, a negative regulator of the JAK/STAT signaling pathway, are often found in NLPHL^{242,246}; in an additional large fraction of cases, constitutive JAK/STAT activity is sustained by autocrine and paracrine signals.³⁵⁹ *BCL6* translocations have been reported in the lymphocytic and histiocytic (L&H) cells of NLPHL, but only rarely in cHL,^{370,371} and translocations of *BCL2* or mutations in positive or negative regulators of apoptosis (e.g., TP53, FAS, BAD, and ATM) are virtually absent.³⁶⁹ As mentioned, an important pathogenic cofactor in cHL, but not NLPHL, is represented by monoclonal EBV infection, which occurs in approximately 40% of cHLs and up to 90% of HIV-related HLs, suggesting that infection precedes clonal expansion.³⁵⁹ Of the viral proteins encoded by the EBV genome, infected HRS cells most commonly express LMP1, LMP2, and EBNA1, but not EBNA2.³⁵⁹

102 Hodgkin's Lymphoma

Anas Younes, Antonino Carbone, Peter Johnson, Bouthaina Dabaja, Stephen Ansell, and John Kuruvilla

INTRODUCTION

Although a relatively rare type of cancer, with an estimated 8,000 new cases per year in the United States, Hodgkin's lymphoma (HL) have fascinated scientists and clinicians for more than a century.^{1,2} Remarkably, before the cell of origin and the biology of HL were elucidated, it became one of the earliest human cancers to be cured with multiagent chemotherapy.^{1,3} Over the past 50 years, a significant progress has been made toward our understanding of HL biology, cell of origin, pathology, and treatment options. Therefore, many seminal observations that were made during the past few decades are now considered of historical value. For example, HL histologic classification evolved through multiple systems, starting from the initial histologic classification by Jackson and Parker in 1944, to the current system which is based on the World Health Organization (WHO) classification (Fig. 102.1).^{4,5}

BIOLOGY OF HODGKIN'S LYMPHOMA

Cell of Origin

Molecular studies of isolated tumor cells have demonstrated that lymphocyte-predominant (LP) cells of nodular lymphocyte-predominant Hodgkin's lymphoma (NLPHL) are derived from antigen-selected germinal center (GC) B cells, whereas Reed-Sternberg (RS) cells in classic HL (cHL) appear to be derived from preapoptotic *crippled* GC B cells (Table 102.1).⁶⁻⁹ Molecular features of LP cells include the presence of clonally rearranged and somatically mutated immunoglobulin (Ig)V gene cells, with signs of ongoing somatic hypermutation in a fraction of cases (see Table 102.1). These data linked the origin of LP cells in NLPHL to GC B cells. Another important feature supporting this linking was the immunohistochemical expression of BCL6 (a typical GC B-cell marker) in LP cells (Table 102.2).^{10,11} Accordingly, LP cells can morphologically be observed in an environmental architecture resembling the structure of a secondary follicle, which contains a reactive GC. In fact, in the early phases of NLPHL, LP cells can be found in follicular structures in association with follicular dendritic cells (FDC) and GC type T-helper cells, in this regard resembling GC.¹²

The derivation of NLPHL from GCs is supported by the following features: (1) the expression of the BCL6 gene product and CD40 by LP cells^{13,14}; (2) the occurrence of numerous CD4+/CD57+/PD1 T cells surrounding the LP cells, as seen in normal GCs and progressively transformed GCs (PTGC)⁶; (3) the presence of an FDC meshwork (CD21+/CD35+) within the tumor nodules¹⁵; and (4) the global gene expression profile.¹⁶ Conversely, molecular features of RS cells in cHL demonstrate that they are probably derived from GC B cells that have acquired disadvantageous immunoglobulin variable chain gene mutations and normally would have undergone apoptosis.^{6,8} In parallel to

molecular investigations, biologic markers identifying distinct subsets of *mature* B cells have been used to study the cell of origin (see Table 102.2). According to the differential expression of these markers, LP and RS cells resemble *mature* B cells deriving from different stages of B-cell differentiation (i.e., GC and post-GC, respectively).

Reed-Sternberg Cells Lack Common B-Cell Markers

The loss of the B-cell phenotype in RS cells is unique among human lymphomas in the extent to which the lymphoma cells have undergone reprogramming of gene expression. As shown in gene expression profiling (GEP) studies, RS cells have lost the expression of most B-cell-typical genes and acquired expression of multiple genes that are typical for other types of cells in the immune system. Moreover, RS cell gene expression is most similar to that of Epstein-Barr virus (EBV)-transformed B cells, and cell lines derived from diffuse large-cell lymphomas showing features of *in vitro* activated B cells.¹⁷

The deregulated expression of inhibitors of B-cell molecules (inhibitor of differentiation and DNA binding 2 [ID2], activated B-cell factor 1 [ABF1], and notch 1), the downregulation of B-cell transcription factors (OCT2, BOB1, and PU.1), and the epigenetic silencing of B-cell genes (CD19 and immunoglobulin H [IgH]) all seem to be involved in the loss of the B-cell phenotype in RS cells.^{17,18}

Multiple Signaling Pathways and Transcription Factors Have Deregulated Activity in Reed-Sternberg Cells

Very recently, biologic studies on HL cell lines using new technologies have shown that multiple signaling pathways and transcription factors have deregulated activity in RS cells. Involved pathways and transcription factors included nuclear factor kappa B (NF- κ B), Janus kinase/signal transducers and activators of transcription (Jak-Stat), phosphoinositide 3-kinase (PI3K)-Akt, extracellular signal-regulated kinase (ERK), activating protein-1 (AP-1), notch 1, and receptor tyrosine kinases.^{7,19} Functional studies have shown that in normal B GC cells, the activation of the CD40 receptor leads to NF- κ B-mediated induction of the interferon regulatory factor 4/multiple myeloma oncogene 1 (IRF4/MUM1) transcription factor. CD40 engagement in HL cell lines by both soluble (s) CD40L and membrane-bound (mb) CD40L upregulates IRF4/MUM1 expression by HL cells.²⁰ CD40 engagement in HL cells by both sCD40L and mbCD40L enhances both clonogenic capacity and colony cell survival of HL cell lines, stimulates proliferation and rescue from apoptosis, mediates *in vitro* rosetting of activated CD4+ T cells to HL cells, and increases ERK phosphorylation and cell survival.^{14,21}

PATHOLOGY OF HODGKIN'S LYMPHOMA

The REAL Classification and the WHO Proposal

The most recent contribution is provided by the Revised European American Lymphoma (REAL) classification²² and the WHO proposal, which, on the basis of a combination of phenotypic and morphologic features, subdivided HL into two distinct pathologic and biologic entities: NLPHL and cHL. cHL includes four subtypes (see Table 102.2) (see the following). LP cells of NLPHL

and RS cells of cHL have different morphology, different phenotype, and different infection pattern with the EBV.²² LP cells express CD20, CD45, and epithelial membrane antigen (EMA) antigens, whereas RS cells display CD15-positive, CD30-positive, and CD45-negative phenotypes. EBV infection is usually present only in the RS cells of cHL, which express EBV encoded latent membrane protein 1 (LMP1) (Table 102.3).^{22,23}

Nodular Lymphocyte-Predominant Hodgkin's Lymphoma

Morphology

NLPHL is characterized by a nodular, or a nodular and diffuse, proliferation of RS cell variants known as LP cells. LP cells are large and usually have one large multilobated nucleus and scant cytoplasm. The nucleoli are usually multiple, basophilic, and smaller than those seen in classical RS cells.

TABLE 102.1

Cell of Origin and Cell Lineage of Hodgkin's Lymphoma

Feature ¹⁻³ / Expression ^{5,6}	RS Cells of cHL	LP Cells of NLPHL
Proposed cellular origin	Preapoptotic GC B cell	Ag-selected, mutating GC B cell
Ig gene (single-cell PCR)	Rearranged, clonal, mutated, "crippled"	Rearranged, clonal, mutated ongoing
Somatically mutated Ig VAR genes	Yes	Yes
Presence of destructive somatic mutation	Yes (25%)	No
BCR	No	Yes
B-cell specific transcription factors (OCT-2, BOB1, PU1)	Very rarely	Yes
B-lineage commitment and maintenance factor PAX-5	Yes (low level)	Yes

PCR, polymerase chain reaction; Ig, immunoglobulin; VAR, variable; BCR, B-cell receptor.

TABLE 102.2

Expression of Molecular Markers in Hodgkin's Lymphoma

Expression ^{5,6}	RS Cells of cHL	LP Cells of NLPHL
B-cell markers (CD20, CD79)	Rarely	Yes
GC B-cell markers (BCL6, AID)	Rarely	Yes
Plasma cell markers (MUM1, CD138)	Often	No
Molecules involved in Ag presentation (MHC class II, CD40, CD80, CD86)	Yes	Yes
Markers for non-B cells (e.g., TARC, granzyme B, perforin)	Yes (variably)	No
T-cell markers	Yes (rarely)	No

AID, activation-induced cytidine deaminase; MUM1, multiple myeloma oncogene 1; Ag, antigen; MHC, major histocompatibility complex; TARC, thymus and activation-regulated chemokine.

TABLE 102.3

Morphologic, Phenotypic and Virologic Features of Reed-Sternberg Cells of Classic Hodgkin's Lymphoma, and Lymphocyte-Predominant Cells of Nodular Lymphocyte Predominant Hodgkin's Lymphoma²⁵

Features/ Expression	cHL/RS Cells	NLPHL LP Cells
Tumor cells	Diagnostic RS cells	LP or "popcorn" cells
Pattern	Diffuse, interfollicular, nodular	Nodular
Background	Lymphocytes, (T cells > B cells) histiocytes, eosinophils, plasma cells	Lymphocytes, (B cells > T cells) histiocytes
Fibrosis	Common	Rare
CD15	+	-
CD19	+ (20%–30%)	+
CD20	+ (20%–30%)	+
CD22	+ (20%–30%)	-
CD30	+	-
CD40	+	+
CD45	-	+
EMA	-	+
IRF4/MUM1	+	+
BCL6	+ (30%)	+
EBV infection	+ (30%–40%)	-

Phenotype

LP cells are positive for CD20, CD79a, CD75, BCL6, and CD45 and epithelial membrane antigen in nearly all cases (see Table 102.3).^{11,19} CD75, formerly LN1, is superior to CD20 and CD79a in detecting LP cells. LP cells express CD75 strongly, whereas small reactive B cells in the background show weak cytoplasmic positivity in the Golgi area but no membranous staining, in accordance with their mantle cell phenotype. CD20 is expressed in LP cells equally or less than in the small reactive B cells in the background. CD79a is even worse than CD20 in detecting LP cells because preferentially stains of small reactive B cells. The OCT2, BOB1, PAX5, and PU.1 B-cell transcription factors and the activation-induced deaminase enzyme (which is involved in somatic hypermutation and class switch recombination mechanisms in Ig genes), are consistently coexpressed (see Table 102.1).^{11,19}

Microenvironment

The LP cells reside within nodules consisting of spherical meshworks of FDCs that are filled with nonneoplastic inflammatory cells. Inflammatory cells include small B cells, T cells that specifically express CD3 and CD4, and histiocytes. Furthermore, the inflammatory cells of nodules of NLPHL are characterized by an increase in GC-derived CD57+, IRF4/MUM1+, and PD-1+ T cells (see Table 102.3). Tia1 and CD40L-positive CD3/CD4 positive T cells are absent. PD1 ringing is a feature commonly seen in NLPHL.^{15,19,24,25}

In conclusion, LP cells of NLPHL clearly resemble GC B cells in many phenotypic and genetic aspects, and proliferate in association with a cellular microenvironment that retains key features of a

normal GC environment. Although LP cells are found to be even more similar to diffuse large B-cell lymphoma (including T-cell/histiocyte-rich large B-cell lymphoma) in terms of phenotypic and gene expression aspects, the environmental characteristics discriminate between these lymphomas (Table 102.4).

Microenvironment and Histologic Patterns

Well-recognized morphologic features of NLPHL include a nodular, or a nodular and diffuse, proliferation of scattered LP tumor cells, set against a background of reactive lymphocytes reminiscent of a primary follicle. Different patterns are recognizable in NLPHL on morphologic and immunohistologic grounds. Fan and colleagues²⁶ identified six distinct immunoarchitectural patterns (*classical* nodular, serpiginous/interconnected nodular, nodular with prominent extranodular LP cells, T-cell-rich nodular, diffuse with a T-cell-rich background, and diffuse, B-cell-rich pattern) and two variant patterns (presence of small GCs within the nodules and the presence of prominent sclerosis) (Fig. 102.2). In the nodular pattern originally described by Fan and colleagues²⁶ as pattern A, rare LP cells are seen outside of the nodule. In other patterns, however, increasing numbers of LP cells extend outside of the neoplastic nodules and infiltrate the perinodular space (see Fig. 102.2).²⁶

A recent study recognized an additional nodular pattern of NLPHL in which LP cells reside in an environment reminiscent of lymphoid follicles and do not invade the extranodular space (Fig. 102.3).^{12,27} The recognition of this pattern primarily relies on the identification within the nodules of BCL6+ and CD20+ LP cells, surrounded by rosetting PD1+ T cells. CD23 and CD21 immunostaining usually detects meshworks of FDCs, which entrap the LP cells and the surrounding T-cell rosettes. LP tumor cells are localized within an environment reminiscent of a secondary follicle or, more frequently, within neoplastic nodules reminiscent of a primary follicle without residual GCs (see Fig. 102.3).

Regarding the relationship of these histopathologic patterns to the clinical course of the disease, the pattern A of Fan and colleagues was usually seen in those patients presenting with earlier

Figure 102.2 Major patterns on nodular lymphocyte predominate Hodgkin's lymphoma, as described by Fan and colleagues. Schematic representation (to the left), microphotographs of CD20 immunostaining of LP cells (to the right). (Top) Pattern A of Fan and colleagues.²⁶ Classical nodular pattern with rare extranodular LP cells. (Top left) In the classical nodular pattern, described by Fan and colleagues, the B-cell-rich nodules usually contain a prominent FDC meshwork that encompasses the LP cells. In these cases, the neoplastic LP cells are found to be located predominantly within the nodular structures, but rare LP cells extend outside of the nodule. (Top right) Classical nodular pattern. The pattern is characterized by scattered CD20+ LP cells within a nodular, reactive background dominated by small IgD+ B cells (not shown). The nodules contain a prominent CD23+ positive FDC meshwork that encompasses the LP cells (not shown). Rare LP cells can be found outside of the nodules. (Bottom left) Pattern C of Fan and colleagues.²⁶ Nodular pattern with prominent extranodular LP cells. During the progression of the disease, more LP cells extend outside of the nodules and infiltrate the perinodular space. Importantly, the presence of numerous LP cells outside the nodules may predict for progression to a diffuse pattern. The presence of many extranodular LP cells may characterize the pattern described by Fan and colleagues as "nodular with prominent extranodular LP cells" (Bottom right) Microphotograph of CD20 immunostaining of LP cells. This pattern shows more CD20+ LP cells (at the center) extending outside of the nodules. The extranodular LP cells are set in a background of reactive T cells and are not associated with FDC meshworks (not shown). Images were acquired with the Olympus dotSlide Virtual microscopy system using an Olympus BX51 microscopy equipped with PLAN APO 2×/0.08 and UPLAN SApo 40×/0.95 objectives.

clinical stage NLPHL. In general, the clinical impact of the different histopathologic patterns is still uncertain. Understanding this issue is difficult, because more than one pattern is frequently present at the same time.²⁸

Classic Hodgkin's Lymphoma

Morphology

The so-called RS cell is the diagnostic key for this lymphoma because of its typical morphology: a giant cell with bi- or multinucleation and huge nucleoli. The typical morphology of binucleated

and multinucleated RS cells and their mononuclear variant, the so-called Hodgkin's cell, are not specific to cHL, because they can also be observed in B-NHL (especially in diffuse large B-cell lymphoma [DLBCL] of the anaplastic variant), but they are pathognomonic for cHL in conjunction with an abundant cellular background composed of a varying spectrum of nonneoplastic inflammatory cells.⁵

Based on the characteristics of the reactive infiltrate, four histologic subtypes have been distinguished: lymphocyte-rich cHL (LRCHL), nodular sclerosis (NS) cHL, mixed cellularity (MC) cHL, and lymphocyte depletion (LD) cHL. LRCHL accounts for only a small fraction (3% to 5%) of all HLs. Most LRCHLs

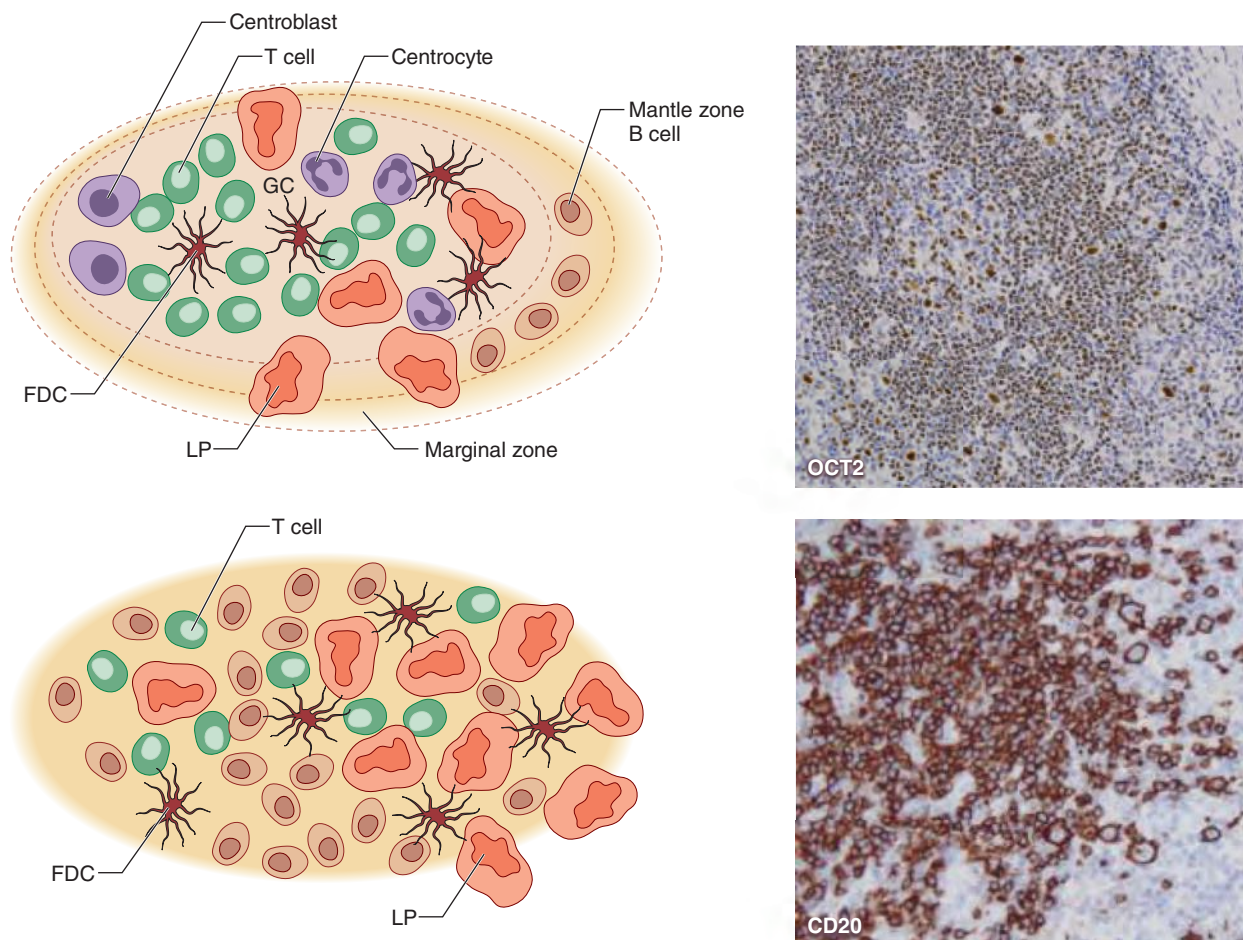

Figure 102.3 Nodular lymphocyte-predominant Hodgkin's lymphoma (NLPHL) may show a nodular pattern in which tumor cells do not invade the surrounding spaces. Schematic representation and microphotographs of OCT2, BCL6, and CD20 immunostaining of LP cells. OCT2+, BCL6+, and CD20+ LP cells, surrounded by rosetting T cells (see schematic representation, *to the left*), are localized in an environment reminiscent of lymphoid follicles with (*Top*) or without (*Bottom*) a recognizable germinal center containing reactive B cells. In this pattern, LP cells do not extend outside of the nodules. *Top*: A schematic figure and microphotographs of OCT2 immunostaining of LP cells located in a follicle with recognizable germinal center. *Bottom*: A schematic figure and microphotograph of CD20 immunostainings of LP cells located in a nodule without a recognizable germinal center. have a better prognosis than do other cHLs and are characterized histologically by a small number of RS cells expressing a cHL immunophenotype. Based on these histologic and clinical features, there is no clear consensus on whether LRCHL represents a distinct disorder or just an early presentation of cHL. On the other hand, LRCHL cases display features intermediate between those of cHL and NLPHL.^{11,19}

Phenotype

Phenotypically, RS cells of cHL are consistently positive for CD30, CD15, CD40, and IRF4/MUM1 (see Table 102.3).²³

Microenvironment

cHL is a lymphoid neoplasm, derived from B cells, composed of mononuclear Hodgkin's cells and multinucleated RS cells residing in an abundant cellular microenvironment. In cHL, microenvironmental cell types include T- and B-reactive lymphocytes, eosinophils, mast cells, histiocytes/macrophages, plasma cells, and granulocytes (Fig. 102.4).^{25,29–33} In addition, a great number of fibroblast-like cells and interdigitating reticulum cells are detectable, often in association with RS cells, within the collagen bands of NS cHL. Fibrosis—considered a common morphologic feature

of HL lesions—is found more frequently in cHL subtypes than in NLPHL. An abnormal network of cytokines and chemokines and/or their receptors in RS cells is involved in the attraction of many of the microenvironmental cells into the lymphoma background (see Fig. 102.4).^{8,34}

Nonmalignant inflammatory/immune cellular components of the HL microenvironment express molecules involved in cancer cell growth and survival, such as CD30L or CD40L, or in immune escape, such as programmed death 1 (PD-1). For example, CD30L+ eosinophils and mast cells, and proliferation-inducing ligand (APRIL)+ neutrophils, are consistently admixed to RS cells, whereas CD40L-expressing CD4+ T lymphocytes rosette RS cells. A considerable fraction of infiltrating CD4+ T cells are regulatory T (Treg) cells. Treg cells and PD-1+ T cells also interact with RS cells, which produce the Treg attractant galectin-1 and the PD-1 ligand (PDL-1).^{7,25,29} The nonmalignant cells that compose most of the cellular background of cHL are recruited and/or induced to proliferate by tumor cells. They in turn produce soluble or membrane-bound molecules involved in tumor cell growth and survival. Numerous molecules are involved directly or indirectly in the recruitment and/or proliferation of cells constituting the cHL microenvironment. Normal cells may be recruited by cytokines/chemokines produced by RS cells or by T cells and

fibroblasts activated by RS cells. RS cells produce molecules capable of inducing proliferation and/or differentiation of eosinophils, Treg cells, and fibroblasts.²⁹

Epstein-Barr Virus Infection

Generally, in the different histologic subtypes of cHL, the immunophenotypic and genetic features of RS cells are identical, whereas their association with EBV shows differences. EBV is found in RS cells in about 40% of cHL cases in the Western world, mostly in cases of MC and LD HL, and less frequently in NS and LRCHL. Conversely, EBV is found in RS cells in nearly all cases of HL occurring in patients infected with HIV.³⁵ Independent studies have recently demonstrated that EBV can transform antigen receptor-deficient GC B cells, which enables their escape from apoptosis. The continued survival of the *rescued* preapoptotic B cells allows their proliferation. The EBV-encoded latent membrane protein (LMP) 2A is likely to function as the surrogate receptor through which B-cell signaling is triggered. This mechanism of EBV/LMP2A-induced the escape of antigen receptor-deficient GC B cells from apoptosis offers an intriguing model of lymphomagenesis. EBV infection might also affect the microenvironment composition by increasing the production of molecules involved in immune escape and T-cell recruitment, such as interleukin 10 (IL-10), CCL5, CCL20, and CXCL10.³⁶ LMP1 could have an interacting role with the microenvironment. Recent evidence indicates that EBV can manipulate the tumor microenvironment through the secretion of specific viral and cellular components into exosomes, small endocytically derived vesicles that are released from cells.^{37,38} Exosomes produced by tumor cells from EBV-infected nasopharyngeal carcinoma contain LMP1, which can activate critical signaling pathways in uninfected neighboring cells, suggesting messenger functions of virus-modified exosomes.³⁷ Moreover, in B-cell lines, EBV-modified exosomes would activate cellular signaling mediated through integrins, actin, interferon, and NF- κ B.³⁸ Further insights in these mechanisms are emerging from

the understanding of the capability of EBV to modulate the (tumor-like) microenvironment.

DIFFERENTIAL DIAGNOSIS

Pathologically, HL subtypes should be distinguished from other B-cell lymphomas showing large and CD30 expressing tumor cells. Figure 102.5 shows B-cell lymphomas, which can be differentiated from NLPHL and cHL on immunophenotypic grounds. The figure also includes lymphomas that have overlapping features with cHL or NLPHL. Most importantly, NLPHL should be differentiated from T-cell/histiocyte-rich large B-cell lymphoma (THRLBCL), a DLBCL subtype, and from the rare cHL variant termed lymphocyte-rich cHL.^{11,19}

Nodular Lymphocyte-Predominant Hodgkin's Lymphoma

According to current criteria, the detection of one nodule showing the typical features of NLPHL in an otherwise diffuse growth pattern is sufficient to exclude the diagnosis of primary THRLBCL. NLPHL may mimic THRLBCL in a subset of cases in which T cells, rather than B cells, are predominant. This typically occurs in older lesions in which T cells have infiltrated the nodules of B cells and disrupted the nodular architecture.¹¹ This finding was previously termed NLPHL with diffuse areas; the current preferred term is NLPHL, THRLBCL-like. These kinds of lesions have not been associated with aggressive clinical behavior. The presence of small B-cells and CD4+/CD57+ T cells points to a NLPHL diagnosis, whereas the absence of small B-cells, and the presence of CD8+ cells and TIA1+ cells points to primary

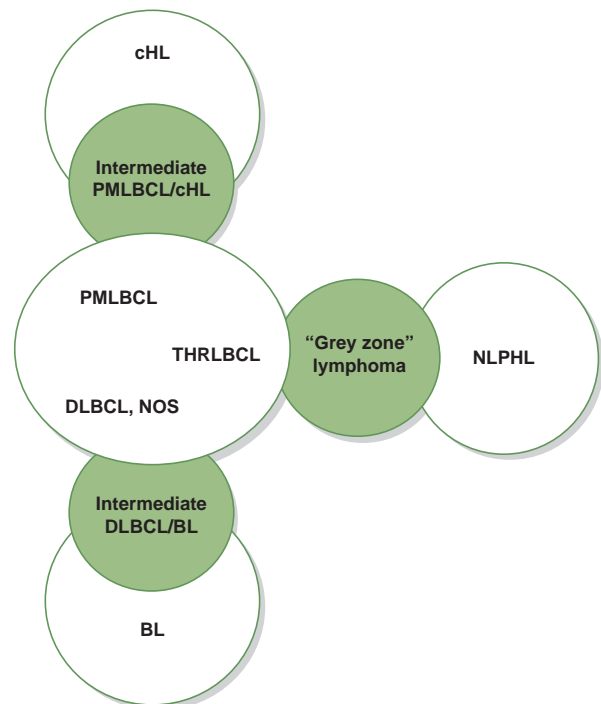

Figure 102.5 Provisional borderline categories for B-cell lymphomas that do not clearly fit into one entity. They include the intermediate PMLBCL/cHL category and a "grey zone" lymphoma between THRLBCL and NLPHL. PMLBCL, primary mediastinal large B-cell lymphoma; THRLBCL, T-cell/histiocyte-rich large B-cell lymphoma; NOS, not otherwise specified.

THRLBCL (see Table 102.4). However, there may be a morphologic and phenotypic gray area between THRLBCL and NLPHL. CD4+/CD57+/PD1 small lymphocytes resetting around typical CD20+/BCL6+ LP cells are useful for the differential diagnosis with PTGC, LRCHL, and THRLBCL. In addition, staining for OCT2, PAX5, and PU1 should be considered as an important diagnostic tool. Interestingly, IgD identifies a subgroup of cases (10% to 20%) with peculiar phenotypic and clinical features.

LRCHL is the most difficult cHL subtype to differentiate from NLPHL, and misclassification has frequently been found in retrospective studies. RS cells in LRCHL can resemble LP cells morphologically; but, immunophenotypically RS cells in LRCHL are positive for CD30 and often express CD15. CD20 can be expressed but is typically weaker and less uniform than CD30 expression. NLPHL is PAX5+, OCT2+, and PU.1+, whereas cHL, including LRCHL, is PAX5+/-, OCT2-, and PU.1-. The distinction between NLPHL and LRCHL is essential, owing to therapeutic and prognostic differences.

cHL

cHL variants should be distinguished from DLBCL subtypes or DLBCL NOS variants that express CD30 (see Fig. 102.5), despite the fact that RS cells have lost much of the B-cell-specific markers. Most or all RS cells also lack the transcription factors OCT2, BOB.1, and PU.1. Instead, RS cells display, in varying frequency, molecules not normally expressed by B cells and B-NHL, such as CD30, CD15, CD70, thymus and activation-regulated chemokine (TARC), A20, fascin, and RANTES.

Finally, cHL cases rich in neoplastic cells may resemble, in particular, large B-cell lymphoma displaying anaplastic morphology and expressing CD30 or primary mediastinal large B-cell lymphoma (PMBCL). There is also a true morphologic and biologic overlap between PMBCL and cHL cases (see Fig. 102.5).

Overlapping Features of PMLBCL with cHL: The So-Called Mediastinal Gray Zone Lymphoma

Mediastinal B-cell lymphomas are mostly represented by NS cHL and PMLBCL. Although PMLBCL and NS cHL have several distinctive pathologic features (Table 102.5),³⁹⁻⁴² these entities exhibit strikingly similar clinical presentations (young women with an anterior mediastinal mass) and, in some cases, show overlap in pathologic, genetic, and molecular features (see Table 102.5). A provisional category, designated *B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and cHL* has been introduced in the WHO proposal to encompass such cases. Table 102.5 shows the main morphologic, phenotypic, and genetic features that may be useful in distinguishing PMLBCL, cHL, and the provisional intermediate category PMLBCL/cHL.

Variant sharing features of DLBCL with anaplastic morphology and cHL may also occur. This shows an expression of CD30, CD15, surface markers, and transcription factors of B cells, commonly absent from RS cells (CD45RB, CD20, CD79, and OCT2).

Molecular Features

In accordance with overlapping phenotypes between cHL and B-cell lymphomas, these lymphomas have a gene expression profile that is intermediate between DLBCL and HL, but closely resembles PMLBCL. Activation of the NF- κ B pathway, known to enhance the survival of RS cells, is also a feature of PMLBCL and may represent a survival pathway shared by both neoplasms, likely through the activation of antiapoptotic genes. Activation of the PI3K/AKT pathway were recently identified as a further shared pathogenic mechanism between PMLBCL and cHL. Taken together, molecular features that are common to both lymphoma

TABLE 102.5

Morphologic and Phenotypic Features that may be Useful in a Differential Diagnosis among Primary Mediastinal Large B-Cell Lymphoma, Classical Hodgkin's Lymphoma, and the Provisional Intermediate Category PMLBCL/cHL^{23,43-48}

cHL	Typical RS cells (CD30+, CD15+) Background containing T cells, B cells, plasma cells, eosinophils, fibroblasts Abundant sclerosis
Intermediate	Large cells resembling RS cells (CD20+, B-cell transcription factors +)
PMLBCL/cHL	Admixed large cells with clear cytoplasm (CD20-, CD15-, B-cell transcription factors + weak) Large cells resembling centroblasts Background containing sparse inflammatory infiltrate with eosinophils, plasma cells, histiocytes, and T cells Sclerosis (variable) Necrosis (frequent)
PMLBCL	Large cells with clear cytoplasm, multilobated nuclei, large cells with RS-like morphology (CD30+, CD15-, CD20+, B-cell transcription factors +). Diminished background containing eosinophils, plasma cells, T cells Fine compartmentalizing sclerosis

entities include a decrease of BCR pathway signaling, constitutive NF- κ B activation, activation of the cytokine-JAK-STAT pathway, and aberrant activation of the PI3K/AKT pathway. The identification of molecular links between PMLBCL and cHL supports the hypothesis that there may be some pathogenetic overlap between the two entities and that these diseases may in fact represent opposite ends of a continuum.³⁹⁻⁴²

HIV-Associated Hodgkin's Lymphoma

The Pre-Highly Active Antiretroviral Therapy Era

In the first years of the AIDS epidemic, HIV-associated HL displayed clinical, pathologic, and biologic peculiarities when compared with HL in people uninfected with HIV. First, HIV-associated HL exhibited unusually aggressive clinical behavior, which mandated the use of specific therapeutic strategies, and it was associated with a poor prognosis. Second, the pathologic spectrum of HIV-associated HL differed markedly from that of HL in people uninfected with HIV. In particular, the aggressive histologic subtypes of cHL, namely MC and LD, predominated among HIV-associated HL.⁴³ Tumor tissue was characterized by an unusually large proportion of RS cells infected by EBV. The fact that LMP1 was expressed in virtually all HIV-associated HL cases suggested that EBV plays an etiologic role in the pathogenesis of HIV-associated HL.

The Highly Active Antiretroviral Therapy Era

People with HIV/AIDS (PWA) seem to be at increased risk of HL than in first years of the epidemic. HL is presently the most common non-AIDS-defining cancer. Patients infected with HIV, who are modestly immunocompromised due to the improvement in CD4 counts associated with this treatment, are more at risk for

the development of the nodular sclerosis subtype.⁴⁴ In this regard, it has been postulated that with increasing CD4+ T cells resulting from highly active antiretroviral therapy (HAART), the appropriate cellular milieu of cHL, surrounding the RS cells, may again be available. In PWHA with improved immunity, CD4+ T cells provide adequate antiapoptotic pathways and mechanisms for immune escape by tumor cells allowing, in this way, the expansion and maintenance of full expression of the disease, as occurs in cHL among people without AIDS.^{35,45-47} Alternatively, HL may arise as part of an immune reconstitution syndrome. Hypothetically, RS cell may already be present in severe immunosuppressed patients, and partial restoration may allow for the recruitment of surrounding immune cells and the manifestation of the tumor.^{48,49} A recent study evaluating the effect of immune reconstitution on HL incidence among a cohort of male veterans infected with HIV ever receiving combination antiretroviral therapy (cART) highlighted that immunosuppression and poor viral control may increase HL risk, specifically during immune reconstitution in the interval post-cART initiation. These findings further suggested an immune reconstitution-type mechanism in HIV-related HL development.⁵⁰

EARLY-STAGE HODGKIN'S LYMPHOMA

The management of early-stage Hodgkin's lymphoma exemplifies several important principles of oncology. These include the progressive improvement of cure rates through careful clinical research; the identification of prognostic features and new markers of optimal response; the refinement of treatment by the exploration of multimodality approaches; the vital importance of long-term follow-up; and a holistic analysis of the outcomes of treatment. Overall, this is one of the success stories of modern oncology, with modern treatment achieving high initial cure rates (up to 90% with the first-line of therapy) and good overall survival at around 95% after 5 years or more. Because it most often affects younger people in the 2nd to 4th decade of life, this has important implications for the goals of treatment, which must include not only the maximization of initial tumor control but also the avoidance of preventable long-term side effects.

Prognostic Features

The relatively orderly progression of cHL has long been recognized.⁵¹ It generally develops through involvement of adjacent nodes in the same anatomical site, then in adjacent nodal areas,

and it is extremely rare to find isolated deposits in two distant nodes. The same is not true for nodular lymphocyte-predominant disease, which, in this respect, more closely resembles a low-grade non-Hodgkin's lymphoma: It often presents with a single isolated node in the neck, but if it does progress, the dissemination is often to distant sites without intervening nodal involvement.

The predictable spread of cHL has allowed for the construction of a staging system based on anatomical extent, so that early-stage disease is defined by involvement of nodal groups on one side of the diaphragm only, more usually the thorax. Stage I disease is confined to a single anatomical nodal group (cervical, supraclavicular, axillary, anterior mediastinal, etc.), whereas a disease affecting more than one such group is stage II.

Beyond this division on the basis of nodal involvement, many studies have identified further prognostic features through retrospective analyses of large series of patients in clinical trials, mostly treated with extended field radiotherapy. This has allowed for the subdivision of early-stage disease into favorable and unfavorable categories. These do not represent biologically distinct processes, but act as a useful indicator of the severity of the illness and its optimum management, even though the current approaches to treatment are different to those in use when the factors were identified. Although a variety of stratification systems have been devised, common features include the presence of bulky disease (usually in the mediastinum), more advanced age (with a cutoff of 40 or 50 years of age), elevated erythrocyte sedimentation rate (ESR), systemic symptoms, and multiple or extranodal sites of involvement (Table 102.6).

Radiation Therapy

The effective treatment of HL by radiotherapy began with the work of Gilbert in the 1920s.⁵² He introduced the rationale for treating both the evident sites of nodal involvement and adjacent but clinically uninvolved lymph nodes, on the basis that these were likely to contain microscopic disease. Peters⁵³ took the same approach at the Princess Margaret Hospital in the 1940s, publishing a landmark paper in the *American Journal of Roentgenology* in 1950, which described the cure of limited HL by high-dose, fractionated radiation. She reported 5- and 10-year survival rates of 88% and 79%, respectively, for patients with stage I disease, which transformed the outlook for an illness previously thought to have no long-term survivors.

In the early days, radiation therapy utilized fields that included the entire lymphatic system, total lymphoid irradiation (TLI), to

TABLE 102.6

Criteria Used to Stratify Early-Stage Hodgkin's Lymphoma

	EORTC	GHSB	NCIC/ECOG	NCCN 2010
Risk factors	a) Large mediastinal mass (>1/3) b) Age ≥50 years c) ESR ≥50 without B symptoms or ≥30 with B symptoms d) ≥4 nodal areas	a) Large mediastinal mass b) Extranodal disease c) ESR ≥50 without B symptoms or ≥30 with B symptoms d) ≥3 nodal areas	a) Histology other than LP/NS b) Age ≥40 years c) ESR ≥50 d) ≥4 nodal areas	a) Large mediastinal mass (>1/3) or >10 cm b) ESR ≥50 or any B symptoms c) ≥3 nodal areas d) >1 extranodal lesion
Favorable	CS I-II (supradiaphragmatic without risk factors)	CS I-II without risk factors	CS I-II without risk factors	CS I-II without risk factors
Unfavorable	CS I-II (supradiaphragmatic with ≥1 risk factors)	CS I or CS IIA with ≥1 risk factors CS IIB with c) or d) but without a) and b)	CS I-II with ≥1 risk factors	CS I-II with ≥1 risk factors (differentiating between bulky disease and other risk factors for treatment guidelines)

relatively higher biologic radiation dosages compared to contemporary treatment. Extended field radiation therapy (EFRT) included all nodal sites using three radiation fields classically known as mantle, para-aortic–spleen, and inverted Y. A variation of EFRT was also used known as subtotal nodal irradiation (STNI).⁵⁴ This was effective, and in many cases curative, but was accompanied by important long-term toxicities, especially the induction of second malignancies and accelerated cardiovascular disease.^{55–60} It remained the principal approach to treatment of early disease until clinical trials demonstrated that a combination strategy with chemotherapy could produce superior cure rates with much less irradiation, leading to a reduction of the irradiated field size to only the involved field (IF); the latter was based on a series of studies aimed at minimizing the toxicity of radiation therapy treatment. The German Hodgkin's Lymphoma Study Group (GHSG) HD8 showed in a randomized trial that reducing the treatment volume from EFRT to involved field radiation therapy (IFRT), when combined with chemotherapy, is equally effective. The European Organisation for Research and Treatment of Cancer (EORTC) H7 showed a similar outcome comparing IFRT to STNI.^{61,62}

The developments in functional imaging, treatment planning, and image-guided radiation therapy have made it possible to better define and further decrease the radiation fields. Thus, IFRT, which is based on anatomic landmarks and encompassing adjacent uninvolved nodal stations, is no longer appropriate. Based on the fact that most recurrences occur in the original nodal sites, involved node irradiation therapy (INRT) was suggested; the field, in this case, is confined to the macroscopically involved nodes on imaging studies at diagnosis. Although this requires a significant margin around the node to allow and ensure adequate coverage, it can still result in significantly lower exposure to adjacent critical structures.⁶³ No formal comparison has been made to the results with IFRT, but multiple studies have shown no loss of efficacy with INRT (Fig. 102.6).^{64,65}

Using INRT requires acquiring images at diagnosis in treatment positions and prior to the start of chemotherapy to minimize anatomic position variations between diagnostic and radiation

treatment planning imaging. Because that is not practical in most cases, new guidelines defining involved site radiation therapy (ISRT) has been introduced by the International Lymphoma Radiation Oncology Group (ILROG). The new standard of care represents a significant reduction in the volume included in the previously used IFRT by using modern imaging and radiation planning techniques to limit the amount of normal tissue being irradiated.

Combined Modality Therapy

The recognition that HL is highly sensitive to cytotoxic chemotherapy led to the testing of systemic treatment in early stage disease. By administering limited doses of chemotherapy, it has been shown possible to reduce both the extent and dose of radiotherapy, while still maintaining high cure rates.^{66–68} The success of this approach has depended on the different treatment of favorable and unfavorable disease, with results in favorable groups excellent even after low impact chemotherapy, such as two cycles of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) or the attenuated EBVP regimen. The EORTC H7-F study compared STNI to six cycles of EBVP followed by IFRT (36 to 40 Gy), with better results from the combined modality treatment: 10-year event-free survival was 88% versus 78%, and overall survival was 92% in both arms.⁶² The GHSG HD10 study in favorable early disease compared results in a 2 × 2 randomization between two or four cycles of ABVD and 20 or 30 Gy of IFRT. All four groups had very high cure rates, with progression-free survival of 92% and overall survival of 97% at 5 years,⁶⁹ suggesting that two cycles of ABVD and 20 Gy of IFRT is sufficient treatment for carefully selected favorable disease.

A slightly different picture has emerged from studies of unfavorable early disease, where many patients present with bulky mediastinal nodes. Here, there is a threshold of treatment intensity below which the results become less favorable, with an apparent interaction between the efficacy of chemotherapy and the dose of irradiation used. Attenuated use of either modality can be compensated by the other, but if both elements are reduced too far, the freedom from treatment failure is lowered as the result of the excess of early recurrences. The EORTC H8-U trial showed the equivalence of either six or four cycles of MOPP-ABV when given before IFRT (36 to 40 Gy), or four cycles of MOPP-ABV before STNI, with 5-year event-free survivals of 84%, 88%, and 87%, respectively, and 10-year overall survival estimates of 88%, 85%, and 84%, respectively, indicating that treatment more intensive than four cycles of MOPP-ABV and IFRT was unnecessary, and that less toxic treatment might be possible.⁷⁰ More recently, the GHSG HD11 study has tested a 2 × 2 randomization between four cycles of ABVD and four cycles of the baseline bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP) regimen before either 20 Gy or 30 Gy IFRT. The least intensive arm, four cycles of ABVD and 20 Gy, showed inferior 5-year progression-free survival at 82%, compared to 87%, although overall survival was unaffected, at 94.5%.⁷¹ This suggests that for the unfavorable early-stage group, it may hazardous to reduce treatment below a threshold of four cycles of ABVD and 30 Gy IFRT, unless some means can be found to select those patients for whom further deintensification can be attempted, such as the use of functional imaging.

Chemotherapy Alone

Recognition of the long-term toxicity of extended field irradiation has led many investigators to test approaches by which radiotherapy may be omitted altogether from the treatment of early HL.^{72,73} Two large randomized trials have been performed, in pediatric and adult patients, respectively, and both demonstrated that the omission of radiotherapy slightly reduced control of the disease,

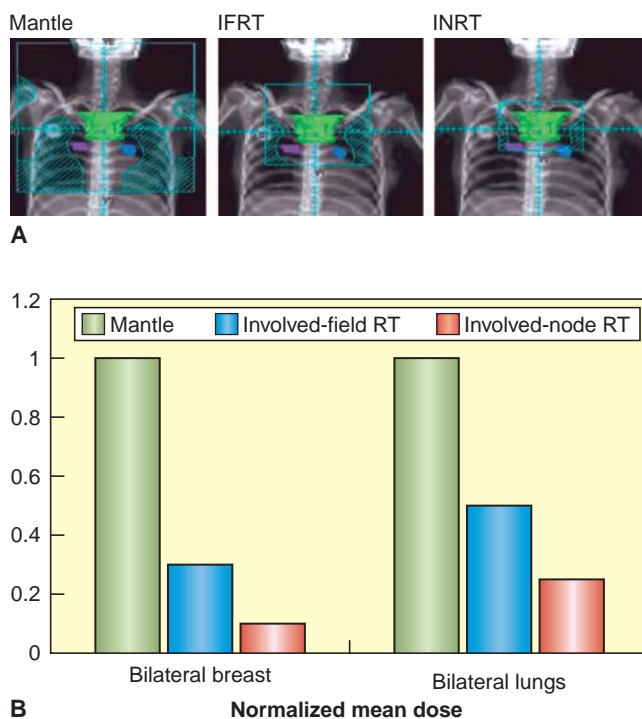

Figure 102.6 Differing radiation volumes in Hodgkin's lymphoma.

reflected in lower progression-free survival, but had no adverse impact on overall survival.

The North American Children's Oncology Group study CCG 5942, tested the omission of low-dose IFRT (21 Gy) for those in complete remission after four cycles of COPP-ABV chemotherapy. The study was closed prematurely when an interim analysis showed a difference in the progression rates in the two arms. With a median 7.7 years follow-up, the event-free survival favored the radiotherapy group (93% versus 83%; $p = 0.004$), with most recurrences in the chemotherapy-alone group seen at the sites of original disease. There was, however, no difference in overall survival, estimated at 97% at 10 years⁷⁴.

In adults with early-stage nonbulky disease, the intergroup Eastern Oncology Cooperative Group (ECOG)/National Cancer Institute of Canada (NCIC) study tested treatment with ABVD alone to either 35 Gy STNI in favorable disease, or two cycles of ABVD followed by STNI in unfavorable cases. The first report of this study, with a median follow-up of 4.2 years, showed inferior freedom from progression in the chemotherapy-alone arms (87% versus 93%), with the unfavorable group particularly disadvantaged by the omission of radiotherapy.⁷⁵ The initial analysis showed no difference in overall survival, but with longer follow-up, a different picture emerged, with inferior 10-year survival among the patients who had received radiotherapy (87% versus 94%, respectively; $p = 0.04$). The risk of death from lymphoma was not different between the arms, but the risk of death from other causes was more than three-fold higher among those treated with radiotherapy, and much of the excess was due to second cancers.⁷⁶ It is important to note, however, that this protocol involved much more extensive irradiation than is currently in use, making extrapolation of the results difficult.

In the absence of direct comparative trials between modern combined modality therapy and chemotherapy alone, a meta-analysis was performed using the intergroup study ABVD-alone group and the comparable patients from the GHSG HD10 and HD 11 studies who received ABVD and IFRT. This showed that the short-term disease control was inferior with ABVD alone, reflected in worse 8-year time to progression (93% versus 87%; hazard ratio [HR], 0.44; 95% confidence interval [CI], 0.24 to 0.78), but that overall survival was not adversely affected in these groups, with 95% alive in the long-term follow-up.⁷⁷ The impact of combined modality treatment was particularly apparent among patients who showed less than complete remission after chemotherapy, suggesting that some means of selecting those with chemosensitive disease for deescalation of therapy would be attractive, and might allow radiotherapy to be omitted without a loss of disease control.

Response-Adapted Treatment

Much interest has been generated in the possible use of functional imaging to give an early indication of chemosensitivity in HL. The technique most widely tested is 2-(18F)fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET), the application of which as an interim readout of efficacy has been enhanced by the development of a highly reproducible five-point scale for reporting the results (Table 102.7).⁷⁸ This approach appears to improve the sensitivity for the detection of residual active lymphoma when compared to conventional computed tomography,⁷⁹ but the data from prospective randomized studies using it as a guide to therapy are not yet mature enough for firm conclusions, and it is clear that there is a small but definite false-negative rate for FDG-PET, probably of the order of 5% to 10%.

Two studies have reported early results, with broadly similar outcomes (Table 102.8). The United Kingdom National Cancer Research Institute RAPID study randomized patients with nonbulky early-stage disease who had an interim PET score of 1 or 2 after three cycles of ABVD to either 30 Gy IFRT or no further therapy, and found that the 3-year progression-free survival and overall survival

TABLE 102.7

Five-Point Scale for the Interpretation of Interim FDG-PET Scanning

Score	PET/CT Result
1	No uptake above background
2	Uptake \leq mediastinum
3	Uptake $>$ mediastinum but \leq liver
4	Uptake moderately increased compared to the liver at any site
5	Uptake markedly increased compared to the liver at any site
X	New areas of uptake unlikely to be related to lymphoma

were not significantly different.⁸⁰ There was, however, a trend toward inferior disease control, which became significant when patients who did not receive the radiotherapy as allocated were excluded (97% versus 90.7%; HR, 2.39; $p = 0.003$). Similarly, the EORTC H10 study compared two strategies of therapy: standard treatment with ABVD and IFRT, stratified according to baseline prognostic factors, versus a nonradiotherapy approach, but using further chemotherapy, for those with negative FDG-PET scans after two cycles of ABVD.⁸¹ The results with a short follow-up suggested inferior disease control in the experimental PET-directed arms, although the number of progressions was small and a much longer follow-up will be required to determine whether there is any detrimental effect on survival.

Taken overall, the evidence suggests that for early HL, the use of combined modality treatment produces optimum results in terms of disease control, with a very high expectation of cure from the initial therapy. There is, however, a large proportion of patients (around 90%) who will be curable with chemotherapy alone, and the number needed to treat with radiation in order to achieve 1 extra cured patient is between 15 and 30 according to these trials. Given these figures and the perceived risks of late toxicity from radiotherapy, many patients may prefer the slightly higher risk of recurrent lymphoma to the potential for longer term morbidity. This will, of course, be subject to other variables such as their age, the sites of involvement (and thus the radiotherapy fields), and their baseline risk category. In general, the results of treatment from either approach are very good, and it is reassuring that in almost all the trials carried out, a small reduction in disease control does not have any detrimental effect on overall survival, thanks to the excellent results of second-line therapy, when it is required.

ADVANCED-STAGE HODGKIN'S LYMPHOMA

In patients with advanced-stage HL (stages IIB to IV), the introduction of more effective and less toxic front-line treatment regimens during the last few decades has steadily improved the prognosis. However, complete remissions after initial therapy are not achieved in approximately 20% of patients with stage III to IV disease, eventually leading to disease progression. The current clinical challenge in patients with advanced stage disease is to increase the number of patients with durable remissions and a favorable outcome after initial treatment, while decreasing the incidence of long-term toxicities. The identification of poor prognostic features may allow for a risk-adapted approach to therapy to potentially increase the likelihood of cure and also to minimize side effects.

TABLE 102.8

Response-Adapted Clinical Trials for Early-Stage Hodgkin's Lymphoma

OS: Overall survival; PFS: Progression free survival.

In general, ABVD chemotherapy remains the most widely used treatment for newly diagnosed patients with advanced-stage HL in the United States. Dose-intense regimens such as escalated BEACOPP are more commonly used in Europe, but are also considered in North America in patients with multiple poor prognostic factors. The future management of advanced-stage HL patients, however, is being shaped by PET-directed approaches and the incorporation of novel agents into these standard combinations.

Prognostic Factors in Advanced Disease

The presence of adverse prognostic factors at diagnosis is one of the methods used to select therapy in HL and the International Prognostic Score (IPS) is an established risk stratification system for advanced disease patients (Table 102.9).⁸² This prognostic

TABLE 102.9

International Prognostic Score (IPS)⁸²

Adverse Prognostic Factors for Advanced Hodgkin's Lymphoma

≥45 years
Stage IV
Male
WBC ≥ 15,000 cells/μl
Lymphocytes < 600 cells/μl or <8% of WBC count, or both
Albumin < 4.0 g/dL
Hemoglobin < 10.5 g/dL

WBC, white blood cell count.

model was constructed using seven factors associated with a poor outcome (serum albumin less than 4 g per deciliter, hemoglobin less than 10.5 g per deciliter, male sex, age 45 years or older, stage IV disease, leukocytosis of at least 15,000 per cubic millimeter, and lymphocytopenia of less than 600 per cubic millimeter or less than 8% of the white cell count). Although the IPS is highly predictive of freedom from disease progression, it does have limitations. The IPS does not adequately define the truly high-risk patients, because only 7% of the patients in the original study were in the high-risk group and their failure-free survival (FFS) at 5 years was still quite reasonable at 42%.⁸² Furthermore, treatment strategies and supportive care have changed since the development of this prognostic model, and although the IPS is still clearly predictive of outcome, its performance may not be as good as originally described.^{83–85}

Therefore, efforts have been made to improve the prognostication of the IPS by the incorporation of additional clinical prognostic factors,^{86,87} the inclusion of biologic parameters,^{88–99} or the addition of an early disease response assessment.^{100,101} Biologic factors that have been studied include molecular profiling of the tumor and the RS cells^{88,93–95}; the measurement of circulating cytokines or receptors including IL-10, CCL17, or soluble CD30^{89–92,98}; and the enumeration of immune cells such as macrophages in the tumor microenvironment.^{96,97,99} Although many of the biologic factors have prognostic significance independent of the IPS, they have not been adopted in everyday practice due to issues of reproducibility and a lack of prospective validation. On the other hand, an early response assessment as measured by an interim PET/computed tomography (PET/CT) scan has been shown to be a very powerful prognostic tool that is independent of clinical and biologic prognostic factors, including the IPS.^{100–102} Interim PET/CT scanning has been introduced into standard

clinical practice and is also being utilized as a method to direct treatment choices.

Choice of Initial Therapy

Combination chemotherapy forms the basis of treatment for patients with advanced-stage HL (Table 102.10). Initially, the MOPP regimen (nitrogen mustard, vincristine, procarbazine, and prednisone) was developed for previously untreated patients with very advanced HL, and a long-term follow-up of patients treated with the MOPP regime has confirmed that this combination can cure advanced HL. MOPP resulted in a freedom from progression rate of 54% and an overall survival of 48% at 20 and now 40 years.¹⁰³ Although the MOPP regimen had a significant impact on the survival of patients who may previously have died of progressive disease, at least one-third of patients relapsed after MOPP chemotherapy and long-term complications were frequently seen in patients who received the combination.

To improve patient outcomes and decrease toxicity, other chemotherapy combinations such as ABVD were developed. An initial randomized trial compared alternating cycles of ABVD and MOPP chemotherapy to a dose and scheduled modified MOPP chemotherapy, and the alternating regimen was found to be superior in respect to the complete remission rate, freedom from progression, and overall survival.¹⁰⁴ Subsequently, a number of randomized trials were performed using ABVD in combination with MOPP chemotherapy or using ABVD alone. MOPP, ABVD, and MOPP alternating with ABVD were compared and the complete response rate and freedom from progression was initially found to be superior in patients receiving ABVD or the alternating program, but subsequent follow-up reports of the study show no difference in disease-free or overall survival when compared to a MOPP program also given at reduced doses.¹⁰⁵ Two further studies compared the MOPP/ABVD hybrid regimen to MOPP alternating with ABVD, and the regimens were found to be equivalent.^{106,107} When the MOPP/ABV hybrid regimen was compared to ABVD, ABVD chemotherapy was found to be superior with less toxicity.⁸³ The results of these trials led to ABVD chemotherapy being regarded as a standard of care for patients with advanced HL based on the clinical efficacy of the combination, the ease of administration, and the acceptable toxicity profile.

As an alternative to ABVD, the Stanford V regimen was developed as a short duration regimen combined with radiation therapy.¹⁰⁸ The initial single institution results with the regimen showed excellent results with a 5-year freedom from progression of 89% and an overall survival of 96%. These promising results were confirmed in a multi-institutional study.¹⁰⁹ The Stanford V regimen has subsequently been compared to ABVD in a number of randomized trials. Initial studies suggested that ABVD might be superior to Stanford V with a 10-year failure-free survival that was superior in ABVD treated patients; however, it has been argued that the differences in outcome may be due to the fact that radiotherapy in the Stanford V arm was administered differently from what was originally described.¹¹⁰ Two subsequent randomized trials comparing ABVD to Stanford V have found no difference in response rate, failure-free survival, or overall survival between the regimens.^{111,112} Overall, ABVD is felt to be superior to Stanford V in patients with advanced disease.

The GHSG also developed new regimens for patients with advanced HL, particularly standard dose and dose-escalated BEACOPP.¹¹³ A randomized trial comparing COPP (cyclophosphamide, vincristine, procarbazine, and prednisone) alternating with ABVD to escalated or standard BEACOPP showed that patients receiving escalated BEACOPP had improved disease control and overall survival.¹¹⁴ The improvement in outcome for patients treated with escalated BEACOPP was sustained with long-term follow-up.¹¹⁵ Although these results were encouraging, long-term complications including acute myeloid leukemia

or myelodysplastic syndrome appeared to be more frequent in patients treated with escalated BEACOPP. A similar Italian study compared six cycles of ABVD to four cycles of escalated BEACOPP followed by two cycles of standard BEACOPP and to six cycles of a multidrug intensive regimen. When the results from the ABVD arm were compared the BEACOPP arm, there was an improved progression-free survival with BEACOPP, but the overall survival was not different. Although more toxicity was seen in the BEACOPP-treated patients, poor-risk patients tended to benefit most when treated with BEACOPP.¹¹⁶

Since these initial studies, a number of randomized studies have been performed to determine the optimal number of cycles of BEACOPP needed to maintain the clinical benefit but potentially decrease toxicity, and also to define the subgroup of patients most likely to benefit from a more intensive treatment approach. In a study restricted to those younger than 60 years of age, the GHSG found that six cycles of escalated BEACOPP followed by radiotherapy to PET-positive masses was more effective in terms of freedom from treatment failure and less toxic than eight cycles of the same regimen.¹¹⁷ This led the GHSG to conclude that six cycles of escalated BEACOPP is their standard for advanced HL. To determine whether the high-risk group of patients are those who benefit most from escalated BEACOPP, the EORTC 2012 trial randomized advanced-stage Hodgkin patients with an IPS ≥ 3 to either eight cycles of ABVD or four cycles of escalated BEACOPP followed by four cycles of standard or baseline BEACOPP.¹¹⁸ At a median follow-up of 3.9 years, event-free survival, which was the primary endpoint, was similar between treatment arms. Although more relapses were observed with ABVD treatment, early discontinuations were more common in BEACOPP-treated patients. In this high-risk group of patients, however, overall survival was not significantly improved with the use of BEACOPP.

Treating physicians who favor using escalated BEACOPP as initial therapy for advanced-stage HL have pointed to the high response rate and improved event-free survival as the reason to use this combination. In contrast, those who favor using ABVD as initial therapy have cited the complication rate with escalated BEACOPP, as well as the ability to salvage relapsing patients with stem cell transplantation, as reasons to use a less intensive treatment first. To compare these approaches, a randomized comparison of ABVD and escalated BEACOPP was reported, but the analysis included second-line therapy if administered.¹¹⁹ Patients with residual or progressive disease after initial ABVD or escalated BEACOPP were treated with salvage therapy, including stem cell transplantation. The authors analyzed the outcome after initial therapy, but also analyzed the outcome after salvage therapy. The freedom from first progression significantly favored patients receiving escalated BEACOPP when compared to patients treated with ABVD (85% compared to 73%; $p = 0.004$). However, after completion of all planned therapy including salvage therapy for those with residual or progressive disease, the 7-year rate of freedom from second progression was not significantly different (88% in the escalated BEACOPP group and 82% in the ABVD group; $p = 0.12$) and the 7-year overall survival rate was 89% and 84%, respectively ($p = 0.39$). Severe adverse events were more commonly seen in patients receiving escalated BEACOPP. These results have led some to suggest that initial therapy may not need to be highly aggressive in all patients due to the fact that relapsing patients may be salvaged with subsequent intensive therapy.¹²⁰ Others have pointed out that overall survival was a secondary endpoint in this study and that the study was small compared to other similar trials.¹²¹ In an attempt to clarify whether a survival difference exists, a meta-analysis was performed that suggested that six cycles of escalated BEACOPP may well improve overall survival when compared to ABVD.¹²²

Overall, it is clear that escalated BEACOPP has greater efficacy than ABVD in patients up to 60 years of age, although escalated BEACOPP-treated patients experience more toxicity, particularly if they are in the upper segment of this age range. Acute and long-term toxicity may, however, be improved by the use of six

TABLE 102.10

Frontline Regimens Commonly Used for Newly Diagnosed Patients with Hodgkin's Lymphoma

Regimen/Drug	Dose	Route	Schedule (Day)	Cycle Length (Days)	Reference
ABVD				28	105
Doxorubicin (adriamycin)	25 mg/m ²	IV	1, 15		
Bleomycin	10 units/m ²	IV	1, 15		
Vinblastine	6 mg/m ²	IV	1, 15

IV, intravenous; PO, by mouth.

rather than eight cycles of escalated BEACOPP. It is also clear that approximately two-thirds of patients with advanced HL may not need intensive therapy such as escalated BEACOPP, because they will be cured with ABVD. Clinical risk factors, treatment burden and cost, fertility issues, the risk of long-term relapses, as well as potential short- and long-term complications should be considered as physicians and patients decide which regimen to use as initial treatment for advanced-stage HL.

Positron-Emission Tomography–Directed Approaches

A strategy to potentially optimize therapy for HL, by possibly increasing efficacy and decreasing toxicity, is to utilize PET scans during treatment. Because changes in glucose metabolism precede changes in tumor size, responses can be assessed earlier during treatment with PET scans than with CT. Early interim PET scan imaging after chemotherapy for HL has been shown to be a sensitive prognostic indicator of outcome in patients with advanced disease.¹²³ In prospective studies, interim PET scans after two cycles of ABVD chemotherapy was a significant predictor of progression-free or event-free survival in patients with advanced-stage disease.^{101,102} Similar findings were reported for patients treated with Stanford V or escalated BEACOPP.^{124,125} Current clinical trials are now testing whether patient outcomes can be improved by modifying treatment based on the interim PET scan results. In patients who have an inadequate response based on the interim PET scan, treatment is either intensified or salvage therapy is contemplated.

Initial studies testing whether deescalation to less intense or abbreviated therapy maintains efficacy in patients who have a complete response by the interim PET scan suggest that this approach is feasible. Avigdor et al.¹²⁶ treated advanced-stage HL patients with two cycles of escalated BEACOPP and deescalated to ABVD chemotherapy for four cycles if the PET scan after the initial two cycles was negative. Patients who did not achieve a negative scan were removed from the study and considered for salvage therapy followed by high-dose chemotherapy and autologous stem-cell transplantation. Seventy-two percent of patients had a negative scan, and deescalation to ABVD resulted in a 4-year progression-free survival of 87%.¹²⁶ In a similar fashion, the GHSG HD18 trial is testing whether the number of cycles of escalated BEACOPP can be reduced from six to four in patients with a negative interim PET scan.

An alternative approach is to intensify therapy in patients who do not have a negative interim PET scan. Initial studies have explored whether patients can start treatment with two cycles of ABVD and escalate to BEACOPP if the interim scan is positive.^{127,128} Initial reports suggest that this strategy, with BEACOPP intensification only in interim PET-positive patients, showed better results than ABVD-treated historic controls, and spared BEACOPP toxicity in the majority of patients.¹²⁷ A similar strategy is being prospectively explored in the UK National Cancer Research Institute Response Adapted Therapy using FDG-PET imaging in the advanced HL (RATHL) trial. In this study, all patients receive two courses of ABVD chemotherapy, and PET-negative patients are randomized between ABVD and AVD, to test whether the omission of bleomycin reduces lung toxicity while achieving an equivalent outcome. Patients who remain PET positive undergo treatment escalation with BEACOPP, thereby attempting to improve remission rates. These studies are still in progress.

Consolidation Radiotherapy

An alternative strategy to modifying the initial treatment for advanced-stage HL is to attempt to consolidate the response following initial chemotherapy. Radiotherapy is commonly used as consolidation following primary chemotherapy, with the goal of improving responses or preventing progression in patients with residual masses.

The precise subgroup of patients with advanced-stage HL who benefit from consolidative radiotherapy has changed over time with the use of different chemotherapy regimens and the routine use of PET scans in clinical practice. For patients treated with standard anthracycline-based chemotherapy, those with only a partial response to treatment as determined by conventional restaging may convert to complete remissions after consolidation radiotherapy. Patients with a complete response to initial treatment, however, do not appear to benefit from consolidation radiotherapy.¹²⁹

As more intensive regimens have been used, resulting in more complete responses, the need for consolidation radiotherapy has decreased. This may be particularly true when intensive approaches are coupled with a PET-based evaluation of residual masses to confirm a complete response. In three successive GHSG trials for advanced HL, the use of radiotherapy was reduced in each study as treatment was intensified and a PET scan analysis was included. In the HD9 trial, two-thirds of patients treated with COPP/ABVD or BEACOPP received radiotherapy. In contrast, in the HD15 trial where PET scans guided the decision, only 11% of patients were treated with radiotherapy after escalated BEACOPP without compromising patient outcome.¹¹⁷ These studies suggest that the use of radiotherapy can possibly be restricted to patients with PET-positive residual masses after escalated BEACOPP treatment; however, the exact role of radiotherapy in ABVD-treated patients in the era of PET scans is not well defined.

Incorporating Novel Agents into Frontline Therapy

Previous strategies to improve the outcome of patients with advanced-stage HL have largely focused on the intensification of therapy. This has resulted in trials becoming focused on younger patients who are in good health and has also resulted in increased toxicity of therapy. However, not all newly diagnosed patients with HL are young with a good performance score. Also, patients and physicians are concerned about toxicity associated with treatment and want to minimize complications. New treatment approaches that benefit a greater proportion of patients and that are associated with less toxicity are, therefore, needed. The most promising strategy to achieve this may be to add novel agents to less intense chemotherapy regimens. Novel agents currently being used in combination with chemotherapy in the frontline setting include brentuximab vedotin, rituximab, and lenalidomide.

The use of brentuximab vedotin is currently attracting substantial interest, and this agent is being combined with modified forms of the ABVD and BEACOPP combinations. Brentuximab vedotin was initially combined with ABVD, and then substituted for bleomycin in a phase 1 study.¹³⁰ In this study, complete responses after the conclusion of front-line therapy were achieved in 95% of the 22 patients receiving ABVD plus brentuximab and in 96% of the 25 receiving AVD plus brentuximab. Significant pulmonary toxicity, however, was seen when brentuximab vedotin was given with the bleomycin-containing regimen, resulting in the concurrent use of bleomycin and brentuximab vedotin being contraindicated. Based on the very high response rate, and the fact that brentuximab vedotin when given with AVD was well tolerated, a randomized phase 3 trial comparing ABVD and AVD plus brentuximab vedotin (ECHELON-1 trial) has been initiated.

The GHSG is also exploring the use of brentuximab in combination with BEACOPP variants, namely a more conservative variant BrECAPP (brentuximab vedotin, etoposide, cyclophosphamide, doxorubicin, procarbazine, and prednisone) and a more aggressive variant BrECADD (brentuximab vedotin, etoposide, cyclophosphamide, doxorubicin, dacarbazine, and dexamethasone). The interim results of a randomized phase 2 trial suggest that use of these anti-CD30 targeted BEACOPP variants is feasible without compromising the efficacy associated with escalated BEACOPP.¹³¹

Two clinical trials have added rituximab to ABVD chemotherapy to deplete intratumoral B cells and that express CD20 and which may support the growth and survival of the malignant cells. Both studies demonstrated high complete response rates, and the event-free survival in both studies suggested promising activity of the combination. Furthermore, the combination was also effective in patients with high IPS scores. However, the efficacy of this combination will need to be confirmed in a randomized trial.^{132,133}

A further strategy being evaluated by the GHSG is the addition of lenalidomide to moderate-dose chemotherapy for newly diagnosed advanced-stage patients. In a recent phase 1/2 study, the efficacy and safety of four to eight cycles of AVD chemotherapy plus lenalidomide at doses of 5 to 35 mg per day, followed by radiotherapy, was tested in elderly patients.¹³⁴ The regimen was well tolerated and the preliminary response results were encouraging, suggesting that adding new drugs to modified chemotherapy regimens holds significant promise for the future.

Complications of Treatment

The initial treatment of patients with HL with chemotherapy, often in combination with radiotherapy, results in a significant proportion of patients who are cured of their disease. The toxicity of treatment, however, is a significant limitation to its use. Although early toxicities of therapy are commonly manageable and of short duration, late toxicities are often irreversible and may result in life-threatening complications. The late effects of treatment determine the long-term morbidity, mortality, and quality of life of patients with HL. In the first 10 years after treatment, most deaths are due to disease progression or relapse, but beyond this time point, deaths due to late effects predominate.¹³⁵

Acute hematologic toxicity, with possible infectious complications and treatment-related mortality, is associated with the intensity of the treatment combination, the age of the patient, and their comorbid conditions.^{136,137} These toxicities are commonly managed by dose modifications and growth factor support. For patients receiving bleomycin, pulmonary toxicity is a concern. Bleomycin lung toxicity is a potentially life-threatening complication and may be more prevalent in patients receiving ABVD chemotherapy.¹³⁸

A significant complication after treatment is the development of second malignancies. These can involve solid organs (most commonly lung, skin, breast, or gastrointestinal) or be hematologic (leukemia, myelodysplasia, or secondary lymphomas).¹³⁹ The risk of second malignancies is highest after treatment for childhood HL.^{140,141} In those patients treated for HL before adulthood, the risk of developing a second malignant disease has been estimated to be almost 20 times greater than the general population, with a 30-year cumulative risk of 18% for male patients and 26% for female patients.¹⁴¹ The most common second malignancy in female patients is breast cancer. Important risk factors for therapy-associated breast cancer are age of younger than 20 years at the time of treatment and treatment with extended field radiotherapy that includes the mediastinum.^{142,143} The risk of breast cancer is estimated to be approximately 30% in patients who received 40 Gy to the mediastinum before 25 years of age.¹⁴⁴

Chemotherapy drugs, especially alkylating agents, contribute to the risk of hematologic malignancies, particularly acute myeloid leukemia (AML) and myelodysplasia. The cumulative risk of developing AML is approximately 1.5% for patients treated for advanced stage Hodgkin lymphoma with chemotherapy regimens such as ABVD.¹⁴⁵ There may be an increase in the incidence of myelodysplasia and AML when more intensive regimens such as escalated BEACOPP are used. The overall rate of other second malignancies, however, appears similar when more intensive and less intensive chemotherapy regimens are compared.¹¹⁵

Other late effects include infertility, cardiac effects, endocrine dysfunction, peripheral neuropathy, and local effects from radiotherapy. Alkylating agents may induce male and female sterility, but

this is far less frequent in patients treated with ABVD-like regimens than alkylating-containing regimens such as BEACOPP.¹⁴⁶⁻¹⁴⁹ An increase in myocardial infarction, congestive cardiac failure, asymptomatic coronary disease, valvular dysfunction, and stroke have been recorded after treatment for HL, and the risk of cardiac mortality may persist for many years after completing therapy.¹⁵⁰

SPECIAL CIRCUMSTANCES

Elderly Patients

Elderly patients with HL are a heterogeneous population, particularly when life expectancy, comorbidities, and functional status are considered. Patients older than 65 years constitute approximately 20% of the HL population, but less than 10% of patients included in clinical trials are >60 years. The results of clinical trials are, therefore, not broadly applicable to the elderly who often have difficulty tolerating aggressive treatment approaches. Elderly patients may even have difficulty tolerating ABVD chemotherapy, and response rates to ABVD in elderly patients are typically lower than those seen in younger patients. Older patients often have a poorer event-free survival after ABVD treatment when compared to younger patients.¹⁵¹

One reason for the relatively poor outcome in elderly patients is their susceptibility to the toxic effects of intensive therapy, and many have coexisting conditions that affect their ability to tolerate standard treatments. Although fit elderly patients can be treated with curative intent using the same therapeutic regimens as used in younger patients, toxicities and complications are more frequent.^{151,152} For more frail elderly patients or those with significant comorbidities, alternative regimens such as VEPEMB (vinblastine, cyclophosphamide, procarbazine, prednisolone, etoposide, mitoxantrone, and bleomycin) or VBM (vinblastine, bleomycin, and methotrexate) could be considered.¹⁵³⁻¹⁵⁵ New targeted agents such as brentuximab vedotin, alone or in combination with less toxic agents, are being studied in the treatment of elderly patients with HL.

Pregnancy

HL is one of the most common cancers in pregnant patients, with concurrent pregnancy reported in approximately 3% of all patients.^{156,157} Overall, the prognosis and clinical course of HL diagnosed in pregnant women are similar to other patients.¹⁵⁸

If possible, treatment of asymptomatic, early-stage, pregnant patients should be delayed until after the second trimester or until they complete their pregnancy. If treatment is required, it may be possible to control the disease with single-agent vinblastine to allow the pregnancy to go to term.^{156,158,159} Patients who progress while receiving vinblastine can be treated with ABVD chemotherapy during the second or third trimester. Although radiotherapy should be generally avoided during pregnancy, advances in radiotherapy techniques have significantly reduced the risk of fetal complications and radiotherapy could be used if needed.¹⁶⁰ Treatment should not be delayed if the patient has symptomatic, advanced-stage, or progressive HL. If treatment is required and the patient does not want a therapeutic abortion, the successful completion of pregnancy without fetal malformation is possible with the use of ABVD or similar regimens.¹⁶¹

Salvage Chemotherapy and Stem Cell Transplantation

Salvage chemotherapy followed by autologous stem cell transplantation (ASCT) has become the treatment of choice in patients with relapsed HL or if the disease is refractory to initial chemotherapy.^{162,163} Two randomized phase 3 clinical trials showed improved progression-free survival in patients receiving high-dose chemotherapy (HDCT), compared to those treated with standard-dose salvage

chemotherapy, although there was no statistically significant difference in overall survival.^{164,165}

Although these randomized controlled trials form the basis for the management of patients with relapsed or refractory HL (RR-HL), the challenge to clinicians remains how best to apply these data to patients as primary treatment strategies evolve. Improvements in the management of patients undergoing ASCT (the use of peripheral blood stem cells [PBSC] and modern supportive care) and allogeneic stem cell transplantation (alloSCT; the use of nonmyeloablative or reduced-intensity conditioning techniques and increased experience with matched unrelated and alternative donor stem cell sources) have led to improved safety, increasing age, and comorbidity cutoffs for transplant patients. These technical advances have granted further accessibility to stem cell transplant therapies. With the advent of active novel agents, the role of stem cell transplantation in the management of HL may need to be addressed again in randomized controlled trials.

Prognostic Factors in Relapsed/Refractory Hodgkin's Lymphoma

Multiple studies have identified prognostic factors in RR-HL who undergo salvage chemotherapy and ASCT. The largest studies of prognostic factors in patients not specifically selected for ASCT have been performed by the GHSG. Separate studies have examined prognostic factors in primary refractory HL (defined as progressing while on primary treatment or within 3 months of completion) and the second paper examined patients who relapsed beyond 3 months after completion of primary therapy. In the primary treatment setting, 206 patients were identified with the significant adverse prognostic factors identified from multivariate analysis being poor performance status (ECOG >0), age >50 years, and failure to obtain a temporary remission to initial therapy.¹⁶⁶ In the relapse setting, 422 patients were studied and the significant adverse prognostic factors for overall survival identified in multivariate analysis were anemia (hemoglobin <120 in males, <105 in females), advanced clinical stage (III or IV), and time to treatment failure of <12 months.¹⁶⁷

In summary, other series and institutional reviews generally confirm that that time to relapse after initial therapy along with advanced stage and poor performance status at relapse are consistent predictors of poor outcome. Time to relapse is of clinical significance because the GHSG primary refractory series had a 5-year OS of 26% compared to 46% for early relapsers after chemotherapy (3 to 12 months) and 71% for late relapsers (after 12 months) in their series studying relapsers.^{16,18} Prospective validation of the predictors of outcome identified by Josting et al.^{16,18} have yet to be performed.

TREATMENT

Salvage Chemotherapy Prior to Autologous Stem Cell Transplantation and Peripheral Blood Stem Cell Mobilization

Despite a multitude of published phase 2 studies reporting results of salvage regimens for RR-HL,¹⁶⁸⁻¹⁷⁸ Randomized control trial (RCTs) of second-line regimens have not been performed and, thus, there is no obvious *standard of care* regimen. The published RCTs of ASCT for RR-HL employed mini-BEAM or dexta-BEAM and the control arm of the most recent GHSG trial used dexamethasone, cytarabine, and cisplatin (DHAP), so these regimens can be considered as *standard* regimens in this setting.^{164,165,179} Because the goal of salvage chemotherapy is to enable patients to proceed to ASCT, the ideal regimen should have a high response rate with minimal toxicity, and not impair the collection of peripheral blood stem cells for ASCT. Although the RCTs of ASCT support the use

of multidrug regimens including carmustine (BCNU), etoposide, cytarabine, and melphalan (mini-BEAM), these regimens have significant hematologic toxicity, requiring frequent hospitalization for febrile neutropenia, and a high incidence of transfusion support (Table 102.11). Stem cell mobilization appears to be compromised following treatment with mini-BEAM.¹⁸⁰

Given the multicenter experience with DHAP reported by the GHSG, a platinum-based regimen such as DHAP is a reasonable choice given comparable response rates and less toxicity.¹⁷⁹ When given prior to randomization in the HD-R2 study, DHAP lead to complete response (CR)/complete response unconfirmed (CRu) in 24%, PR in 46%, and SD in 20%. As the trial allowed patients to proceed to randomization as long as they did not have PD, 90% of patients proceeded toward transplant. Several published and widely used salvage chemotherapy regimens are summarized in Figure 102.1. These trials report similar response rates to DHAP, and there is no evidence to demonstrate that one is superior over others. Although the dexta-BEAM regimen had an overall response rate (ORR) of 81% in the GHSG/EBMT phase 3 ASCT trial, treatment related mortality (TRM) from salvage chemotherapy in that study was 5%. Other trials have reported a lower TRM between zero to 2%, a more acceptable level given the typically young age and lack of comorbidity typical of patients in this setting. Although the optimal number of cycles of salvage chemotherapy is unknown, two to three cycles of treatment are usually given by convention with a need to balance optimizing response and the risk of further toxicity.

The available institutional series reporting response rates to salvage chemotherapy often include a mixture of patients with primary refractory and relapsed disease with most series likely unable to demonstrate differences due to a lack of statistical power. Patients with primary refractory HL have an inferior response rate to second-line chemotherapy (51% versus 83%; $p < 0.0001$),¹⁸¹ which highlights the unique and inferior biology in this group of patients. The proportion of primary refractory patients in reported series along with other imbalances of prognostic factors and typically small sample sizes in these series likely explain any potential variation in reported response rates.^{163,166,176,182-184}

Despite aggressive combination chemotherapy, between 10% to 40% of patients do not achieve a response to salvage chemotherapy and there are no RCT data supporting ASCT in nonresponders. Courses of alternative salvage chemotherapy have been given in an attempt to demonstrate chemosensitive disease prior to transplant. Studies have largely assessed responses using CT scan-based criteria. These series have largely reported selected patient populations and are characterized by small numbers, although the goal of achieving a response and proceeding to ASCT occurs in approximately half of the patients.¹⁸⁵⁻¹⁸⁸

An important issue related to salvage chemotherapy is the potential for second-line therapy to impair the ability to mobilize peripheral blood stem cells to support potentially curative high-dose chemotherapy. The efficacy of salvage chemotherapy for HL must be balanced by toxicity and the impact on subsequent PBSC mobilization. Success rates for PBSC mobilization have not been consistently reported in the RCTs or trials assessing the efficacy of salvage therapy. Some studies report that regimens containing melphalan, such as dexta-BEAM or mini-BEAM, may result in reduced stem cell mobilization.¹⁸⁹⁻¹⁹¹ Available results for commonly employed regimens demonstrate that at least 80% of patients undergoing PBSC mobilization reach a minimum threshold of 2.0×10^6 CD34 cells per kilogram.^{180,192}

The Role of Functional Imaging in Response Assessment Prior to Autologous Stem Cell Transplantation

The use of FDG-PET in response assessment postsalvage chemotherapy and prior to ASCT is increasing despite a lack of large prospective data. Outside of response assessment, FDG-PET

scanning can also be viewed as a biomarker with a positive test after salvage therapy, suggesting a higher rate of relapse post-ASCT (whether this is due to tumor-related or other factors in the FDG-PET avid lesion remains to be elucidated). Retrospective institutional series suggest that abnormal functional imaging (FI; either gallium or FDG-PET scan) after salvage therapy and prior to ASCT are predictive of poor outcome (3-year OS of 58% versus 87% if negative FI). In particular, patients who had achieved a PR with CT imaging could be discriminated by FI; in those with negative FI, outcome was similar to patients in CR (3-year OS of 90% in CR, 80% in PR with negative functional imaging) but significantly inferior if positive (65%).¹⁹³ A large series studying FI after ifosfamide, carboplatin, etoposide (ICE) chemotherapy reported similar results with a 5-year event-free survival (EFS) of 31% for FI-positive disease compared to 75% if negative.¹⁹⁴

The group at MSKCC has reported results of a prospective study that tested the strategy of attempting to achieve a negative FDG-PET scan prior to ASCT.¹⁹⁵ In patients that had a positive FDG-PET scan following ICE salvage chemotherapy, a non-cross-resistant chemotherapy regimen to ICE (GVD [gemcitabine, vinorelbine, and liposomal doxorubicin]) was given as a second-line salvage chemotherapy regimen. A positive FDG-PET scan was seen in 38% of cases post-ICE; 26 of 33 patients that received GVD achieved a response (CR, PR, or MR) and went onto transplant. Of these 33 patients, a negative FDG-PET scan was achieved in 52% and their outcome appeared similar to the patients who were FDG-PET negative after ICE. These data demonstrate that the goal of FDG-PET negativity prior to autograft is likely of value and that the use of a non-cross-resistant regimen can be successful in approximately half of patients. Unfortunately, the outcome of FDG-PET-avid patients that were transplanted remains poor with an EFS of 25% at a median follow-up beyond 4 years. Validation of this observation in other series and with other commonly used regimens would help to confirm this treatment approach.

Autologous Stem Cell Transplantation High-Dose Therapy Regimens and Strategies

The role of ASCT in HL has been defined by two published phase 3 RCTs.^{164,165} The GHSG/EBMT assigned 161 patients with relapsed HL to receive two cycles of dexamethasone-BEAM chemotherapy, and randomized responding patients to either two additional

cycles of dexamethasone-BEAM or high-dose therapy and ASCT. Freedom from treatment failure at 3 years was significantly improved in the ASCT group (55 versus 34%; $p = 0.02$), although there was no difference in overall survival.¹⁶⁵ These trials of ASCT did not include chemorefractory patients; only cohort and registry data address the benefit of ASCT in these patients.^{162,163,166}

The role of ASCT in lymphoma overtly refractory to chemotherapy has not been well defined in the modern literature. The Seattle group reported the outcome of 64 chemoresistant (defined as less than a partial remission) HL patients who were transplanted on protocols conducted between 1986 and 2005. At a median follow-up of 4.2 years post-ASCT, 5-year PFS and OS were 17% and 31%, respectively, suggesting inferior outcomes when compared to ASCT in chemosensitive patients.

The two randomized trials of ASCT for RR-HL used BCNU, etoposide, Ara-C, melphalan (BEAM) HDCT. Other single institution studies report outcomes with diverse regimens.^{50,196–200} The lack of randomized comparisons of HDCT regimens makes it difficult to conclude that there is an optimum regimen in terms of toxicity and efficacy. Late effects including second primary malignancies, cognitive deficits, and chronic fatigue are important considerations, but the impact of HDCT on these outcomes and if they vary between regimens remain unclear.

Further intensification of high-dose regimens has not been a successful strategy in RR-HL,⁵⁰ but single-arm studies augmented-dose mobilization regimens,⁴⁷ or additional therapy after stem cell collection⁵² have been reported to improve outcomes. The Cologne high-dose sequential (HDS) protocol begins with an induction phase of two cycles of DHAP chemotherapy followed by response assessment. Responders proceed to HDS, which consists of 4g/m² of cyclophosphamide followed by G-CSF and subsequent PBSC collection, 8 g/m² of methotrexate with vincristine 1.4 mg/m², etoposide 2 g/m² with G-CSF and an optional second PBSC collection, and finally, BEAM HDCT and ASCT. Based on a multicenter phase 2 pilot trial showing HDS to be feasible with acceptable toxicity, the GHSG subsequently led an RCT.²⁰¹ The HD-R2 trial, a randomized comparison of HDS therapy followed by ASCT to standard DHAP and ASCT failed to show any benefit for the experimental HDS arm over the standard arm with no significant differences in freedom from treatment failure, progression-free, or overall survival were observed.²⁰²

An alternative intensification strategy that has been tested is the use of tandem autologous transplants.²⁰³ This approach was prospectively tested in a large GELA cohort study. The multicenter

GELA-led H96 trial tested a risk-adapted approach in which patients were assigned to a single or tandem autograft based on the presence of risk factors at the initiation of salvage therapy. Patients with primary refractory disease or at least two poor risk factors (time to relapse <12 months, relapse in a prior radiation field, or stage III/IV disease at the time of relapse) were considered high risk and planned to receive tandem ASCT, whereas patients with standard risk received a single autograft.²⁰⁴ With an acceptable TRM of 6% and a 5-year OS of 46% in the poor-risk group, this trial demonstrated feasibility, but it does not address the benefit of this strategy in a controlled trial.

Consolidation Strategies: Radiation Postautograft and Maintenance

Many transplant centers use radiation therapy (RT) peri- and post-ASCT in order to maximize treatment because autograft remains the last standard curative treatment option in RR-HL. Unfortunately, the role of radiation around ASCT has not been evaluated in prospective randomized trials. In the GHSG randomized study of ASCT versus dexamethasone-BEAM, 11 of the randomized patients (approximately 10% of the patients on trial) received radiation (6 in the ASCT arm) for what was felt to be residual disease.¹⁶⁵ In the HD-R2 study, consolidative IFRT of 30 Gy was given per protocol in patients who had a >1.5 cm lesion on CT scan at day 100 post-BEAM HDCT and ASCT.¹⁷⁹ In total, 25 of 241 patients randomized (10%) received radiation for residual CT findings.

Outside of the RCT setting, institutional practice incorporating RT varies substantially. The transplant regimens used at MSKCC employ either subtotal or total lymphoid irradiation (STLI or TLI) to 18 Gy, accelerated involved field radiation (IFRT to 18-Gy total given as twice per day fractions for 5 days) or IFT with a total dose of 18.36 Gy in patients who have received prior radiation or had a contraindication to TLI. Thus, effectively all patients receive some radiation as part of their salvage therapy.¹⁹⁵ In contrast, patients at Princess Margaret would receive IFRT if they had a localized recurrence prior to salvage therapy or the presence of a lesion >5 cm if technically feasible. This policy led to the use of posttransplant radiation in 26% of patients.²⁰⁵

In contrast, maintenance therapy has been tested in two RCTs, although there are no data currently unavailable. The histone deacetylase inhibitor panobinostat was tested in patients post-ASCT with the trial terminated early and without meaningful numbers to report. The other study tested brentuximab vedotin (an antibody-drug conjugate targeting CD30) against placebo in a large RCT. Results are expected in 2014.

Allogeneic Stem Cell Transplants

AlloSCT continues to be emphasized as a treatment option in advanced HL due to the young age and lack of comorbidity in many patients. Historically, myeloablative alloSCT has been employed in advanced phases of the disease but with poor results because NRM often exceeded 50% and relapses were not uncommon.^{206–209} The role of myeloablative alloSCT in HL appeared limited; although dose intensity can be delivered in the context of a myeloablative allograft and donor stem cells are free of tumor cell contamination, the presence of a clinically significant graft-versus-Hodgkin's lymphoma (GVHL) effect has not been clearly demonstrated.

More recently, reports have demonstrated signs of GVHL following donor lymphocyte infusion (DLI).^{210–213} In addition to this antitumor effect, the safety of allogeneic transplantation has improved with the use of reduced intensity allogeneic stem cell transplantation (RIC-allo). These approaches have become increasingly popular due to decreased rates of early treatment-related

mortality.^{214–217} Despite early favorable outcomes, mature results of RIC-allo available in the literature consistently demonstrate a lack of long-term disease control with progression-free survival estimates of approximately 25% to 30% and overall survival estimates of 35% to 60% at least 2 years post-SCT.^{212,214–217}

The Grupo Español de Linfomas/Trasplante Autólogo de Médula Ósea (GEL/TAMO) and EBMT have reported the results of a large prospective study of RIC-allo in RR-HL.²¹⁸ Although the trial was incompletely accrued over 7 years, 78 patients ultimately proceeded through a RIC-allo transplant with a preparative regimen consisting of fludarabine 150 mg/m², melphalan 140 mg/m², and Graft versus host disease (GVHD) prophylaxis of cyclosporine and short-course methotrexate. With a median follow-up of 38 months, 3-year outcomes included a relapse rate of 59%, PFS of 25%, and OS of 43%. Although post-SCT outcomes were similar in matched sibling and unrelated donors, patients with chemorefractory disease had an inferior PFS (25% versus 64% at 1 year). Chronic GVHD was associated with a reduced rate of relapse posttransplant. In patients with relapse after allo-SCT, DLI alone generate an overall response rate of 40%. These results suggest the presence of a GVHL effect in a prospective multicenter trial, but highlight the high relapse rate and not insignificant toxicity even with RIC-allo approaches.

Given the increasing usage of unrelated and alternative donors for allografts, it becomes critical to review disease-specific results in homogeneous patient populations because there are few prospective or multicenter trials. The M.D. Anderson Cancer Center has reported a prospective trial of RIC-allo in both sibling and matched unrelated donor (MUD) using fludarabine-based regimens with the majority accrued onto the fludarabine-melphalan 140 mg/m² arm.²¹⁹ The 2-year OS and PFS were reported at 64% and 32%, respectively, with no differences in OS, PFS, or relapse between related and MUD transplants. The study is limited by sample size, with 58 patients in total, although the majority (33) received MUD allografts. In a series from the United Kingdom, investigators reported the outcome of RIC-allo in 49 patients (31 related, 18 MUD) who underwent transplants using a regimen consisting of fludarabine-melphalan 140 mg/m² and alemtuzumab.²¹¹ Although OS and PFS were not statistically significantly different, nonrelapse mortality was significantly inferior in MUD transplants (34.1% versus 7.2%). Four-year OS and PFS estimates were 55.7% and 39%, respectively.

Retrospective institutional and registry series have also been published. The Center for International Blood and Marrow Transplant Research (CIBMTR) reviewed 143 allografts from matched unrelated donors using reduced intensity or nonmyeloablative regimens reported between 1999 and 2004.²²⁰ The results demonstrate feasibility with a 2-year TRM of 33% and 2-year OS and PFS of 37% and 20%, respectively. Reduced intensity and nonmyeloablative transplants did not differ significantly in outcome. Another large study reported the outcome of 90 nonmyeloablative transplants from related (n = 38), MUD (n = 24), or haploidentical (n = 28) donors at the Baltimore and Seattle programs.²¹⁵ A multivariate analysis did not demonstrate any differences in OS between the three donor sources; however, significantly improved PFS (HR, 0.3) was found in haploidentical transplants compared to related or unrelated transplants. Matched related and unrelated donors had similar PFS. NRM was also significantly lower for haploidentical recipients (HR, 0.14) compared to related recipients. An interpretation of this result is difficult given the patient inclusion from two centers and how biases may influence the prognostic factors in patients undergoing allograft from these varied donor sources.

Finally, the outcome of umbilical cord blood transplants (UCBT) has also been reported in RR-HL. The Minnesota group reported their results in lymphoma in which 23 patients received cord blood transplants for HL; the TRM was 13%, the cumulative relapse rate was 43%, PFS was 33%, and the OS at 3 years was 43%.

The age range for the entire lymphoma cohort was 6 to 68 years of age (median of 46 years of age), and 86% of patients received double cord transplants.²²¹ A slightly larger series of 29 UCBT patients older than 15 years was reported by Eurocord-Netcord with the Lymphoma Working Party of the EBMT. At 1-year posttransplant, PFS was 30%; OS, NRM, and relapse rates were not reported for the HL subgroup.²²²

In summary, the available data regarding allo-SCT in HL only confirms the feasibility of the procedure. In the datasets that present homogeneous patient populations, it appears that there are signs of reasonable efficacy, although the relapse rates remain troubling and few studies are being performed to address this issue. Given advances in the field of alternative donor transplantation, it is reasonable to consider MUD, haploidentical, and UCBT in the management of patients with RR-HL. Unfortunately, prospective trials have done little more than demonstrate a potential role for these procedures in the management of the disease; they have not established the optimal timing of RIC-allo, and these series include a heterogeneous patient population, including patients who have not received an autograft. Given the evidence and lack of toxicity with ASCT, it becomes difficult to justify the toxicity and mortality of an allograft from any donor source prior to an autograft regardless of the perceived risk of the disease without high quality data.

The role of allograft is best established in patients who have failed an autograft. There are many possible options for treatment in this setting, which include conventional cytotoxics, radiation therapy, and investigational agents. In the absence of randomized comparisons with standard therapy, RIC-allo transplant has been compared to retrospective cohorts by two groups.^{223,224} Both the UK and Italian reports demonstrated an overall survival advantage favoring allografting. Unfortunately, both studies suffer from the standard issues surrounding retrospective cohort comparisons and relatively small sample sizes. These results can only remain hypothesis generating. Patient selection remains a potential confounding issue in all allo-SCT reports (particularly in retrospective institutional or registry reviews), and the benefit of RIC-allo to patients with RR-HL remains open to debate.

Second Autologous Stem Cell Transplants

A second autograft has been considered an option for patients who relapse after a prior ASCT. In such cases, stem cells must be available from the initial procedure or need to be collected a second time. There are limited institutional and registry data to support such a strategy and such cases are obviously highly selected. The CIBMTR reported a series that included 21 HL patients who underwent a second autograft.²²⁵ With day 100 TRM of 11%, 5-year PFS and OS were 30% for the entire cohort, with no difference in outcome between NHL and HL cases. Outcomes were inferior in patients who were retransplanted within 1 year of the initial autograft (5-year PFS of zero versus 32%; $p = 0.001$).

The role of a second autograft remains unclear but can be considered in patients with a time to relapse of greater than 1 year after the initial transplant. Integrating the data regarding second autografts, allografts along with the increasing number of targeted therapies, conventional palliative systemic approaches, and radiation becomes more challenging as options continue to increase.

The challenge remains how best to manage patients who progress or relapse after ASCT given the variety of standard treatment options (single and multiagent chemotherapy, radiation therapy), intensive treatment strategies (second autografts, RIC-allo transplants) or drug development trials that are currently available. Because no comparative prospective data are available to inform this decision, clinicians and patients will have to make careful choices.

Management of Patients with Relapsed Hodgkin's Lymphoma After Stem Cell Transplant

Approximately 20% of patients with HL will not be cured with currently available first-line and second-line treatment modalities, and will require additional therapy. Patients with relapsed or refractory HL after receiving ASCT have unmet medical needs, and are considered candidates for drug development. The median survival following relapse from ASCT is estimated to be only 2.4 years, which is even shorter for those whose disease relapsed within 1 year from the transplant.²²⁶ Because of the poor prognosis, several novel agents are being evaluated in this patient population, but brentuximab vedotin remains the only drug approved by the U.S. Food and Drug Administration (FDA) for this indication.

Brentuximab Vedotin

Since its initial identification as a possible Hodgkin's and Reed-Sternberg (HRS)-associated antigen, CD30 became a widely sought after target for novel therapy of patients with HL. In the following 3 decades, the expression and function of CD30 were further clarified by several independent groups. CD30 is a member of the tumor necrosis factor cell receptor superfamily. CD30 is highly expressed in HRS cells, but is also expressed by the malignant cells of anaplastic large cell lymphoma, peripheral T-cell lymphoma, primary mediastinal diffuse large B-cell lymphoma, and other uncommon solid tumors. Several attempts to develop naked anti-CD30 antibody therapy failed to produce meaningful clinical responses. In contrast, major clinical responses were achieved by conjugating the naked anti-CD30 antibody SGN30 to antitubulin monomethyl auristatin E (MMAE), to generate the antibody drug-conjugate (ADC) brentuximab vedotin.

Based on promising preclinical activity, a first-in-man phase 1 study of brentuximab vedotin was initiated to evaluate its safety. The study rapidly enrolled 45 patients with relapsed or refractory CD30-positive HL (93%) and anaplastic large cell lymphoma, of whom 73% received prior ASCT.²²⁷ Escalating doses of brentuximab vedotin (from 0.1 mg per kg to 3.6 mg per kg) were administered intravenously every 3 weeks. Treatment was very well tolerated, but rare dose-limiting toxicities were observed, including grade 4 thrombocytopenia, grade 3 hyperglycemia, and febrile neutropenia. The recommended phase 2 dose was established as 1.8 mg per kg every 3 weeks. Although the study primary objective was to evaluate the safety of brentuximab vedotin, 86% of the patients had tumor reductions, and 17 patients achieved complete or partial remissions. A second phase 1 study investigated the safety and tolerability of brentuximab vedotin administered on a weekly schedule for 3 weeks, followed by 1 week of rest.²²⁸ A total of 37 patients (31 had HL) were enrolled and treated, of whom 62% previously received an ASCT. The dose-limiting toxicities were grade 3 diarrhea and/or vomiting and grade 4 hyperglycemia. Complete and partial clinical remissions were observed in 46% of the patients. Collectively, these two phase 1 studies demonstrated the safety of brentuximab vedotin, and provided valuable information on the potential clinical efficacy in patients with relapsed and refractory HL.

In a follow-up pivotal phase 2 clinical trial, 102 patients with relapsed HL after receiving ASCT were treated with 1.8 mg per kilogram brentuximab vedotin given every 3 weeks.²²⁹ Of 102 patients, 76 (75%) achieved partial or complete remissions (34% CRs). The median duration of response in patients who achieved complete remissions was approximately 2 years. The most common treatment-related side effects were peripheral neuropathy (42%), nausea (35%), and fatigue (34%). Grade 3 or higher neuropathy was seen in 8% of patients and was the most common

reason for the discontinuation of brentuximab vedotin. Results of this study lead to the approval of brentuximab vedotin by the FDA in 2011.

Current strategies are aiming at incorporating brentuximab vedotin in front-line and second-line chemotherapy regimens. In the front-line setting, brentuximab vedotin was initially combined with standard ABVD in patients with advanced stage HL. In this phase 1 study, 51 patients with newly diagnosed patients with advanced stage HL were treated with brentuximab vedotin administered every 2 weeks on the same day of each ABVD therapy. The phase 2 recommended dose was established at 1.2 mg per kilogram of brentuximab vedotin given with standard dose and the schedule of ABVD. However, this combination was associated with an unexpected increase in pulmonary toxicity that was similar to bleomycin lung toxicity. Subsequently, an additional cohort of patients was treated without bleomycin (brentuximab vedotin + AVD), which resulted in a similar high response rate, but with no pulmonary toxicity. Of 22 patients, 21 (95%) patients given brentuximab vedotin and ABVD achieved complete remission, as did 24 (96%) of 25 patients given brentuximab vedotin and AVD. Based on these data, an international randomized study comparing standard ABVD with AVD plus brentuximab vedotin was initiated. In the second-line setting, a sequential therapy of brentuximab vedotin followed by ICE chemotherapy is currently being investigated in transplant-eligible patients with relapsed and refractory HL.

Investigational Agents

Histone Deacetylase Inhibitors

Histone deacetylase (HDAC) inhibitors are good candidates for HL therapy due to their unique mechanisms of action. HDAC inhibitors have been shown to have a direct antitumor effect by activating the intrinsic caspase pathway and downregulating antiapoptotic proteins, in addition to an indirect effect by disrupting the favorable microenvironment and activating the immune response.²³⁰ For example, HDAC inhibitors can alter the phenotype and function of T cells in the HL microenvironment by

decreasing the expression of the chemotaxis chemokine CCL17 (TARC).^{230,231} Furthermore, HDAC inhibitors may restore antitumor immunity by upregulating OX40L.²³²

Several HDAC inhibitors have recently been evaluated for the treatment of relapsed HL with variable results. Vorinostat demonstrated the weakest clinical activity, with only 1 of 25 patients achieving a partial remission.²³³ On the other hand, panobinostat and mocetinostat demonstrated higher response rates, but also more toxic effects. Mocetinostat (MGCD0103) is an oral non-hydroxamate HDAC inhibitor that preferentially inhibits HDAC class I and IV.^{234,235} In a phase 2 study, 51 patients with relapsed or refractory HL were treated with 110 mg or 85 mg of mocetinostat three times a week.²³⁶ Approximately 60% of patients had a reduction in their tumor measurements, with 24% achieving partial remissions. Toxicities include thrombocytopenia, fatigue, pneumonia, anemia, and pericardial effusion.²³⁶ Panobinostat, a pan HDAC inhibitor, also demonstrated a promising clinical activity in patients with relapsed HL. In a phase 2 study, 129 patients were treated with 40 mg panobinostat and 27% achieved partial or complete remissions.²³⁷

PI3K/AKT/mTOR Pathway Inhibitors

The PI3K signaling pathway regulates a wide variety of essential cellular functions, including glucose metabolism, cell survival, and proliferation.²³⁸⁻²⁴⁰ The PI3K signaling pathway is activated in many malignancies, including in Hodgkin's and non-Hodgkin's lymphomas, making it an appealing target for therapeutic intervention. There are four isoforms of PI3K (α , β , γ , and δ) that can be selectively inhibited by a variety of small molecules. Idelalisib (GS-1101 or CAL101) is an oral PI3K- δ -selective small molecule inhibitor that demonstrated promising clinical activity in a variety of B-cell malignancies, but it showed a limited clinical activity in patients with relapsed HL.²⁴¹ In a different study, the dual PI3K- δ/γ inhibitor IPI-145 produced a 33% response rate in an ongoing phase 1 clinical trial. Targeting the downstream mammalian target of rapamycin (mTOR) kinase also demonstrated promising clinical activity in patients with relapsed HL. For example, everolimus produced an overall response rate of 42% of patients.²⁴²

INTRODUCTION

Non-Hodgkin's lymphomas (NHL) are neoplastic transformations of mature B, T, and natural killer (NK) cells. Although NHLs and Hodgkin's lymphoma (HL) both infiltrate lymphohematopoietic tissues, their biologic and clinical behaviors are distinct. And although both are among the most sensitive malignancies to radiation and cytotoxic therapy, their cure rates differ. HLs are cured in about 80% of all patients employing both conventional and salvage treatment strategies, whereas NHLs are cured in less than 50% of patients.

EPIDEMIOLOGY AND ETIOLOGY

In 2014, there were an estimated 70,890 new cases of NHL in the United States, which constituted 4% of all new cancers in both males and females.¹ This is more than seven times the incidence of HL. There is a slight male-to-female predominance and a higher incidence for Caucasians than for African Americans. The incidence rises steadily with age, especially after age 40. Lymphomas are among the most common malignancies in patients between the ages of 20 and 40 years. Moreover, the incidence of NHL nearly doubled between 1970 and 1995. Although the rate of increase has slowed since the mid 1990s the incidence has continued to rise by 1.5% to 2% each year. NHL ranks as the ninth most common cause of cancer-related death in men in the United States and eighth in women. In 2014, 18,990 deaths from NHL were predicted. The 5-year survival rates for NHL is 72% for Caucasians and 63% for African Americans.

There are striking differences in the age-dependent incidence of NHL by histologic subtype. In children, diffuse large B-cell lymphoma (DLBCL), Burkitt's lymphoma (BL), and lymphoblastic lymphoma are most common. Although DLBCL is also the most common histologic subtypes in adults, the indolent lymphomas (small lymphocytic and follicular lymphomas [FL]) are extremely rare in children.

Exposures and Diseases Associated with Non-Hodgkin's Lymphoma

Infectious agents are involved in the pathogenesis of some NHLs. Epstein-Barr virus (EBV) is most commonly associated with a variety of B-cell NHLs, including endemic, sporadic, and AIDS-associated BL, lymphomas that arise in the setting of immunosuppression, including after organ transplantation and treatment of autoimmune diseases, in the setting of HIV infection, and a subset of lymphomas that arise in otherwise normal elderly individuals (Table 103.1).² EBV infection is also implicated in extranodal NK cell and T-cell lymphomas that involve the upper aerodigestive tract as well as other extranodal sites, as well as a small number of other unusual and uncommon T-cell malignancies.³ Infection with human T-lymphotropic virus type 1 (HTLV-1) has been implicated in adult T-cell leukemia-lymphoma (ATLL) seen in the

Caribbean and Japan.⁴ Human herpes virus 8 (HHV-8) infection is associated with primary effusion lymphoma, where the viral genome is found within tumor cells in virtually 100% of cases.⁵ Chronic hepatitis B infection has also been associated with an increased risk of NHL.⁶ The marginal zone lymphomas (MZL) have been linked to many infectious agents. The gastric extranodal MZLs are associated with *Helicobacter pylori* infection.⁷ Splenic MZL has been associated with hepatitis C infections.⁸ The ocular adnexal MZL has been linked with *Chlamydia psittaci* infections,⁹ and immunoproliferative small intestinal disease (Mediterranean lymphoma, alpha heavy chain disease) has been associated with *Campylobacter jejuni*.¹⁰ *Borrelia burgdorferi* infection has been associated with extranodal MZLs of the skin in cases from Europe.¹¹

An increased risk of NHL has been associated with a number of environmental exposures and/or disease states (see Table 103.1).^{12,13} There is controversial evidence that certain chemical exposures, specifically the herbicide phenoxyacetic acid, increase the risk of NHL.¹⁴ Other potential environmental associations include exposure to arsenic, pesticides, fungicides, chlorophenols, or organic solvents, halomethane, lead, vinyl chloride, or asbestos.^{15,16} Occupational exposures associated with an increased risk include agricultural work, welding, and work in the lumber industry.¹⁷ NHL has been observed as a late complication of prior chemotherapy and/or radiation therapy. Specifically, patients with HL treated with radiation therapy and chemotherapy exhibit an increased risk of developing secondary DLBCL.¹⁸

Diseases of inherited and acquired immunodeficiency as well as autoimmune diseases are associated with an increased incidence of lymphoma (see Table 103.1). The association between immunosuppression and induction of NHLs is compelling because, if the immunosuppression can be reversed, a percentage of these lymphomas regress spontaneously.¹⁹ The incidence of NHL is nearly 100-fold increased for patients undergoing organ transplantation necessitating chronic immunosuppression, and is greatest in the first year posttransplant. About 30% of these arise as a polyclonal B-cell proliferation that evolves into a clonal B-cell malignancy. The NHLs that occur in the context of immunosuppression or immunodeficiency, including human immunodeficiency virus 1 (HIV-1) infection, are frequently associated with EBV.²⁰ Histologically, DLBCLs are most frequently associated with immunosuppression and autoimmune diseases, although almost all histologies can be seen. The rare inherited immunodeficiency diseases (X-linked lymphoproliferative syndrome, Wiskott-Aldrich syndrome, Chédiak-Higashi syndrome, ataxia telangiectasia, and common variable immunodeficiency syndrome) are complicated by highly aggressive lymphomas. The elevated incidence of lymphoma in iatrogenic immunosuppression, AIDS, and autoimmune disease argues strongly for immune dysregulation contributing in the pathogenesis of some lymphomas.^{21,22} An increased risk of NHL has been observed in first-degree relatives with NHL, HL, or chronic lymphocytic leukemia (CLL). In large databases studies, about 9% of patients with lymphoma or CLL have a first-degree relative with a lymphoproliferative disorder.^{23,24}

TABLE 103.1

Conditions Associated with the Development of Lymphoma

Inherited Immunodeficiency States	Acquired Immunodeficiency States	Autoimmune and Inflammatory Disorders	Chemicals and Drugs	Infectious Agents (Other than HIV)
Klinefelter's syndrome	Acquired agammaglobulinemia	Rheumatoid arthritis	Phenytoin	Epstein-Barr virus
Chédiak-Higashi syndrome	HIV-1 infection	Autoimmune hemolytic anemia	Dioxin, agent orange, pesticides	HTLV-1
Ataxia telangiectasia	Iatrogenic	Systemic lupus erythematosus	Ionizing radiation	HHV-8
Wiskott-Aldrich syndrome	Multicentric Castleman's disease	Sjögren's syndrome	Chemotherapy, radiation therapy	<i>Helicobacter pylori</i>
Common variable immunodeficiency		Hashimoto's thyroiditis	Tumor necrosis factor agonists	<i>Campylobacter jejuni</i>
X-linked lymphoproliferative disease		Acquired angioedema	Hair dyes	<i>Chlamydia psittaci</i>
Autoimmune lymphoproliferative disease		Inflammatory bowel disease		<i>Borrelia afzelii</i>
Bloom syndrome		Celiac disease		HCV MTB

HIV-1, human immunodeficiency virus-1; HTLV-1, human T cell lymphotropic virus-1; HHV-8, human herpes virus-8; HCV, hepatitis C virus; MTB, *Mycobacterium tuberculosis*.

BIOLOGIC BACKGROUND FOR CLASSIFICATION OF LYMPHOID NEOPLASMS

Current lymphoma classification systems divide the lymphomas into different entities based, in part, on their perceived cell of origin (Fig. 103.1, Table 103.2). During embryogenesis, hematopoietic stem cells (HSC) from the liver and the placenta give rise to progenitor cells that migrate to the thymus and bone marrow where they undergo a program of antigen-independent differentiation into T- and B-cell lineage precursor cells, directed largely by the microenvironment.²⁵ Postnatally, all lymphoid cells are derived from bone marrow HSCs, which give rise to very early lymphoid progenitors with B, T, and NK lymphocyte potential. These cells, in turn, yield B-cell progenitors in the marrow, the site of early stages of B-cell differentiation, as well as other progenitors that migrate to the thymus and undergo T-cell differentiation.

B-Cell Development

The initial commitment to B-cell differentiation by lymphoid progenitors in the bone marrow requires the expression of the master B lineage transcription factor PAX5, which directly upregulates the expression of early B lineage markers such as CD19.²⁶ Subsequent precursor B-cell development depends on a transcriptional program that is driven by PAX5 and downstream transcription factors and prosurvival signals produced by stepwise rearrangement of immunoglobulin (Ig) genes, which requires the lymphoid-specific recombination factors RAG1 and RAG2 and also involves the specialized DNA polymerase terminal deoxynucleotidyl transferase (TdT).²⁷ During development, pre-B cells pass through checkpoints that correspond to specific stages of Ig gene assembly, beginning with rearrangement of the Ig heavy chain locus (*IgH*).²⁸ Productive (in-frame) rearrangement of *IgH* leads to the expression of IgM heavy chain, which combines with a lambda-like polypeptide to enable the assembly of pre-B-cell receptors. The pre-B-cell receptor generates signals that prevent apoptosis, turns off further *IgH* gene rearrangement (contributing to allelic exclusion, the

expression of only a single IgH in each B-cell clone), and turns on rearrangements of the Ig light chain loci, first the kappa loci and, if these rearrangements are nonproductive, then the lambda light chain loci. During the period of Ig gene rearrangement, pre-B cells lack complete surface Ig and express CD19 and CD10, the common acute lymphoblastic leukemia antigen.²⁹ Precursor B cells that productively rearrange one or another light chain locus express the surface Ig receptor (sometimes referred to as the B-cell receptor [BCR]), which also transmits key survival signals that prevent apoptosis. Cells that express surface Ig upregulate additional B-cell markers such as CD79a, cytoplasmic and surface CD22, and CD20, as well as prosurvival factors such as BCL2, and downregulate CD10 and TdT emerging from the process as mature, immunologically naïve B cells.

In mice, two major types of naïve B cells have been defined. Roughly 90% of circulating and tissue-based B cells fall into the B2 class. B2 cells are widely distributed and largely respond to antigens in a T-cell-dependent fashion, a process that yields class-switched plasma cells expressing high-affinity Ig. B1 cells can be further subdivided into those that do or do not express the antigen CD5.³⁰ CD5⁺ B1a cells produce broadly reactive natural IgM, whereas CD5⁻ B1b cells can generate T-independent, long-lasting memory-type IgM responses to some infectious pathogens. Whether B1 cells exist as a distinct B-cell lineage in humans has been (and remains) controversial, but it is notable that some human B-cell tumors, particularly CLL, is comprised of cells bearing some similarity to murine B1 cells.

From the marrow, naïve B cells migrate through the blood and extravasate into secondary lymphoid tissues, such as the spleen, the lymph nodes, and mucosa-associated lymphoid tissues in the gut. Homing of B cells to specific tissues appears to be controlled largely by chemokines that activate chemokine receptors expressed on B cells.³¹ Upon encountering an antigen in peripheral tissues, B cells may either be induced to differentiate directly into short-lived IgM secreting plasma cells or may migrate to B-cell follicles. Antigen-mediated B-cell activation requires the transcription factor MYC and is accompanied by an increase in cell size and entry into cell cycle.^{32,33} Once in follicles, the B cells downregulate MYC and BCL2 and upregulate the transcriptional repressor

B Cell	Precursor Cell	Disease
Bone marrow	Common Lymphocyte Progenitor	
	↓ Pre-B Lymphoblast	Precursor B lymphoblastic lymphoma/leukemias
	↓ Naïve B cell	Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL)
	↓ Plasma cell	Multiple myeloma
Lymph node	↓ Mantle B cell	Mantle cell lymphoma
	↓ Germinal center B cell	Follicular lymphoma, Burkitt's lymphoma, diffuse large B-cell lymphoma (DLBCL)
	↓ Marginal zone B cell	Marginal zone lymphoma, DLBCL, CLL/SLL
T cell		
Thymus	Double-negative T cell	Precursor T lymphoblastic lymphoma/leukemias
	↓ Double-positive T cell	
	↓ CD4-positive or CD8-positive T cell	
Lymph node	Peripheral T cell	Peripheral T-cell lymphomas

Figure 103.1 B- and T-cell development and cell of origin of lymphomas.

TABLE 103.2

Cluster Designations (CD) of Antigens Useful in Non-Hodgkin Lymphoma Classification

CD	Normal Lymphocyte Expression	Neoplastic Lymphocyte Expression
1a	Cortical thymocytes; Langerhans cells	Precursor T-lymphoblastic lymphoma/leukemia; Langerhans cell neoplasms
2	T and NK cells	T and NK cell lymphomas
3	T (cytoplasmic and surface) and NK (cytoplasmic only) cells	T and NK cell lymphomas
4	T and NK cells	T and NK cell lymphomas
5	T cells, naïve B cells	Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL); mantle cell lymphoma; T-cell neoplasms
7	T and NK cells	T and NK cell lymphomas
8	T and NK cell subsets	Some T and NK cell lymphomas
10	Precursor and germinal center B cells	Precursor B and T lymphoblastic lymphoma/leukemia; follicular lymphoma; Burkitt's lymphoma; diffuse large B cell lymphoma (DLBCL)
11c	B cell subset; CD8 T cells; NK cells	Hairy cell leukemia; splenic marginal zone lymphoma; CLL/SLL
16	NK cells	NK cell and some T-cell lymphomas
19	B cells	B-cell lymphomas
20	Mature B cells (except plasma cells)	Mature B-cell lymphomas
23	Activated B cells, follicular dendritic cells	CLL/SLL
25	Activated T and B cells	Hairy cell leukemia; adult T-cell leukemia/lymphoma
30	Activated lymphocytes (B, T, and NK cells)	Anaplastic large cell lymphoma (ALCL)
56	NK and activated T cells	NK and T-cell lymphomas; plasma cell neoplasms
57	NK and T-cell subsets	NK and T-cell lymphomas
103	Mucosal intraepithelial lymphocytes	Hairy cell leukemia; enteropathy-type T-cell lymphoma
138	Plasma cells	Plasma cell neoplasms; plasmablastic lymphoma

BCL6, which, like MYC, is essential for secondary B-cell follicle formation; secondary follicles are also known as germinal centers.³⁴ Downregulation of BCL2 may permit the elimination of B cells making low affinity antibodies, and in fact, most B cells entering into the germinal centers undergo apoptosis and are phagocytosed by resident macrophages (often referred to as tingible body macrophages because they contain a readily visible nuclear fragment derived from defunct B cells). The key roles of MYC, BCL2, and BCL6 in this process explain why the genes encoding these factors are commonly mutated in B-cell lymphomas (discussed later). Follicular B cells also upregulate the expression of activation-induced cytosine deaminase (AID), a gene product required for both somatic hypermutation and Ig class switching. Cells that by chance acquire mutations that increase Ig affinity for an antigen survive thanks to signals transmitted through the Ig receptor and go on to undergo class-switching, a process that is regulated by cytokines.³⁵ The germinal center reaction also requires follicular dendritic cells and a special class of CD4-positive follicular T cells that express the CD40 ligand.³⁶ B cells that survive this process may leave the germinal centers to take up residence in surrounding marginal zones to become long-lived memory B cells, or may terminally differentiate into plasma cells, which may take up residence in the medulla of the lymph nodes or the red pulp of the spleen, or home back to the bone marrow.

It is notable that the most common human lymphomas are B-cell tumors composed of lymphocytes with somatically mutated Ig genes, an alteration that marks these tumors as having arisen from cells that have experienced a germinal center reaction. Many of these same tumors also have mutations that bear the molecular hallmarks of mistakes that occurred during attempted somatic hypermutation or class-switching in germinal centers; indeed, mutations involving MYC, BCL2, and BCL6 identical to those found in lymphomas are also found at a low frequency in normal germinal center B cells obtained from both children and adults. Thus, the relatively high frequency of tumors derived from germinal center B cells likely reflects the error-prone nature of the molecular events that permit antibody class-switching and affinity maturation.

T-Cell Development

Progenitors from the bone marrow that travel to the thymus become committed to T-cell differentiation via interactions with thymic epithelial cells (TEC) (see Fig. 103.1). TECs express ligands for Notch receptors such as DLL4, leading to activation of the receptor NOTCH1, which is essential for early stages of T-cell development.³⁷ As during early B-cell development, early T-cell development is controlled by a transcriptional program induced by a master transcription factor (NOTCH1) and by survival signals mediated by complexes containing components of the T-cell receptor (TCR).³⁸ In most developing T cells, this begins with rearrangement of the *TCRβ* genes, which (as in B cells) requires RAG1 and RAG2 and involves the participation of TdT. Productive, in-frame rearrangement of the *TCRβ* gene permits expression of the *TCRβ* polypeptide, which pairs with pre-Tα polypeptides and assembles into the pre-T-cell receptor. Prosurvival signals transmitted by pre-Tα allow cells to go on to rearrange the *TCRα* genes, and cells with productive *TCRα* rearrangements express TCRαβ receptors on their cell surfaces in complex with CD3 polypeptides. Surviving cells also upregulate the CD4 and CD8 coreceptors and proceed through both negative and positive antigenic selection, during which cells expressing autoreactive TCRs or TCRs that fail to recognize antigen in the context of major histocompatibility complex (MHC) antigens are eliminated by apoptosis.³⁹ Cells emerging from the thymus as naïve T cells express either CD4, a coreceptor for MHC class II antigens, or CD8, a coreceptor for MHC class I antigens. A much smaller subset of thymic T-cell progenitors productively rearrange their δ and γ TCR genes, and emerge from the thymus as naïve γδ-TCR-expressing T cells.

Like naïve B cells, naïve T cells home to peripheral tissues under the influence of chemokines, with most γδ T cells homing to gut and skin, and αβ T cells homing much more widely to secondary lymphoid tissues and other sites. γδ T cells are considered to be relative primitive cells that contribute to *natural* immunity, whereas αβ T cells can differentiate further into a number of different types of effector cells, depending on the dose, timing, and context of subsequent antigenic exposures. αβ T cells recognize antigen when it is presented in the context of an MHC molecule. CD4+ T cells, or T-helper cells, bind to and recognize an antigen presented by MHC class II molecules, whereas CD8+ T cells or cytotoxic T cells bind to and recognize antigen presented by MHC class I molecules. Activation also requires CD40 and CD40L interaction and CD28/CTLA4 and B7 interaction between the T cell and the antigen presenting cell (APC).⁴⁰ Antigen stimulation of CD8-positive T cells may give rise to CD8-positive effector cytotoxic cells or to long-lived CD8-positive memory cells. By contrast, antigen stimulation of CD4-positive cells can produce a number of CD4-positive effector cell types, including: T helper 1 (Th1) cells, which activate macrophages and cytotoxic T cells through their production of interleukin 2 (IL-2) and interferon gamma; T helper 2 (Th2) cells, which activate B cells through their production of IL-4, -5, -6, and -13^{41,42}; T helper 17 (Th17) cells, which stimulate neutrophils through production of IL-17 and IL-22; and regulatory T cells (Treg), which produce immunosuppressive cytokines such as IL-10. Finally, follicular helper T cells are CD4+ T cells that home to the germinal center via CXCR5 and CXCL13 interactions and play a role in B-cell Ig class switching and Ig production.⁴³

Natural Killer Cells

There is a third class of lymphocytes that can kill targets without MHC restriction, namely NK cells, which are a component of the innate host immune system. NK cells recognize and kill cells that lack MHC class I molecules (including virally infected cells and malignant cells), as well as antibody-coated targets through interactions with Fc receptors on the NK cell surface. NK cells lack surface CD3 and do not have rearranged TCR genes. Morphologically, these cells are slightly larger than resting T and B cells and have paler cytoplasm that contains azurophilic granules, an appearance similar to that of activated cytotoxic T cells.

Immunophenotyping of Lymphoid Cells

As has been alluded to, lymphocytes at various stages in ontologic development can be defined and differentiated by the detection of certain antigens on the cell surface (see Table 103.2). This antigen footprint is referred to as the immunophenotype of the cell. It can be detected by a flow cytometric analysis of single cell suspensions from whole blood, bone marrow, body fluid, or disaggregated tissue using fluorescently labeled antibodies against these antigens or by immunohistochemistry, which involves the incubation of paraffin-embedded tissue sections with enzyme-linked antibodies against these antigens followed by a colorimetric reaction. These techniques have become vital in diagnosing and monitoring lymphomas, and have provided insight into the normal counterparts of the malignant lymphocyte.

Chromosomal Translocations and Oncogene Rearrangements

Given the mechanism of Ig and TCR gene rearrangements in lymphoid cells—namely, the formation of DNA breaks with the joining of new pieces of DNA—it is not surprising that lymphomas are frequently found to have chromosomal translocations that involve the activation of an oncogene or inactivation of a tumor suppressor

MALT, mucosa-associated lymphoid tissue; CTLC, clathrin heavy chain 1.

gene (Table 103.3). The former is more common, whereby a proto-oncogene is brought under the control of a constitutively active promoter. The resulting overexpression of the involved gene (now called an oncogene) conveys oncogenic properties on the gene and its protein product, which is responsible for induction and/or maintenance of some aspect of the transformed phenotype. Examples of this type of event include the (8;14)(q24;q32) translocation in BL, involving the *MYC* proto-oncogene and the *IgH* gene; the (14;18)(q32;q32) translocation in follicular lymphoma, involving the *BCL2* proto-oncogene and the *IgH* gene; and the (11;14)(q13;q32) translocation in mantle cell lymphoma, involving the gene encoding cyclin D1 (*CCND1*) and the *IgH* gene. Less commonly, chromosomal translocations produce fusion genes that encode chimeric oncogenic proteins. Examples of this include the (2;5)(p23;q35) translocation involving the *ALK* and *NPM1* genes in anaplastic large cell lymphoma (ALCL) and the t(11;18)(q21;q21) translocation involving the *API2* and *MLT* genes in mucosa-associated lymphoid tissue (MALT) lymphoma. These translocations and rearrangements can be detected by polymerase chain reaction (PCR) using probes that span the chromosomal breakpoints, reverse transcriptase PCR (RT-PCR) to detect the RNA product of the fusion gene, or fluorescence in situ hybridization (FISH) using probes to specific chromosomal segments. In cases where the translocation results in the expression of a protein or portion of a protein that is never expressed in normal lymphocytes (e.g., anaplastic lymphoma kinase [ALK]

kinase), immunohistochemistry can be used to detect the protein and infer the presence of a rearrangement involving the gene that encodes that protein.

LYMPHOMA CLASSIFICATION: THE PRINCIPLES OF THE WORLD HEALTH ORGANIZATION (WHO) CLASSIFICATION OF LYMPHOID NEOPLASMS

In 2001, the World Health Organization (WHO) published a new classification of tumors of the hematopoietic and lymphoid tissues (Table 103.4).⁴⁴ It was the end result of a project that began in 1995 with 10 committees of pathologists and a Clinical Advisory Committee of international experts to ensure the clinical utility of the classification system. It incorporated, with minor edits, the 1994 consensus by the International Lymphoma Study Group regarding a list of lymphoid neoplasms that were distinct and recognizable by pathologists called the Revised European and American Lymphoma (REAL) classification.⁴⁵ The principle behind the classification system is to use and integrate all of the relevant information, including morphology, immunophenotype, genetics, and clinical features, to define disease entities with the relative importance of each type of information varying from disease to disease. The WHO classification system was recently updated and diseases were

reclassified in 2008 based on new and evolving information with regard to each of these disease characteristics.

Categories of Lymphoid Neoplasms

There are five main categories of lymphoid neoplasms defined by the WHO: precursor B- and T-cell neoplasms, mature B-cell neoplasms, mature T/NK cell neoplasms, HL, and immunodeficiency-associated lymphoproliferative disorders (see Table 103.4). Each category is a set of distinct diagnoses that are not further classified or grouped by grade, prognosis, or clinical behavior but instead are considered unique entities. In 2001, there were 48 such entities plus additional variants. In 2008, several additions were made, and several provisional diagnostic categories were created that reflect the additional information being gleaned from technology, such as gene expression profiling (GEP) and the consequent recognition of heterogeneity within existing disease entities. For example, within DLBCL, GEP can differentiate between two broad categories of disease, namely the germinal center B-cell type (GCB) and the activated B-cell type (ABC), with different prognoses.⁴⁶

These categories have not yet been adopted into the WHO because they are not yet relevant to differential treatment strategies, but new treatments are being developed with these GEPs in mind, and treatment effect is being stratified by DLBCL subtype in ongoing clinical trials, and this will likely become clinically relevant in the near future. Furthermore, disease location is being recognized as important in distinguishing one DLBCL from another, with DLBCL of certain locations like the central nervous system (CNS) or primary cutaneous DLBCL, leg type, having unique clinical presentations, clinical behavior, and GEPs compared with nodal DLBCL; these have been added as distinct entities to the 2008 WHO. The microenvironment is another important defining feature of some lymphomas and, as such, T-cell/histiocyte-rich large B-cell lymphoma was added to the updated classification. Finally, two provisional categories have been created to recognize lymphomas that have features intermediate between two types of lymphoma, the so-called gray zone lymphomas: B-cell lymphoma unclassifiable (BCLU) with features intermediate between BL and DLBCL (BCLU-BL/DLBCL) and BCLU with features intermediate between HL and DLBCL (BCLU-HL/DLBCL). These categories were created recognizing that they are likely a heterogeneous

group of disease, with some most closely resembling BL or HL, some most closely resembling DLBCL, and some belonging to distinct entities, helping to create a more systematic approach to their study and classification.

PRINCIPLES OF MANAGEMENT OF NON-HODGKIN'S LYMPHOMA

Differential Diagnosis and Sites of Disease at Presentation

More than two-thirds of patients with NHL present with persistent painless peripheral lymphadenopathy. At the time of presentation, a differential diagnosis of generalized lymphadenopathy necessitates the exclusion of infectious etiologies such as bacteria (including mycobacteria), viruses (e.g., infectious mononucleosis, cytomegalovirus, hepatitis B, HIV), and parasites (toxoplasmosis) as well as inflammatory and autoimmune diseases, and metastatic malignancies. It is generally agreed that a lymph node larger than 1.5×1.5 cm that is not associated with a documented infection and that persists longer than 4 weeks should be considered for a biopsy.⁴⁷ A biopsy should be performed immediately for patients with other findings suggesting malignancy (e.g., systemic complaints or B symptoms, such as fever, night sweats, weight loss). However, lymph nodes in several histopathologic subtypes of NHLs frequently wax and wane. In teenagers and young adults, infectious mononucleosis and HL should be placed high in the differential diagnosis. Involvement of Waldeyer's ring, epitrochlear, and mesenteric nodes are more frequently observed in patients with NHL than in patients with HL. About 40% of all patients with NHL present with systemic complaints. B symptoms are more common in patients with aggressive histologies approaching 50%. Less frequent presenting symptoms, occurring in less than 20% of patients, include fatigue, malaise, and pruritus.

NHLs also present with thoracic, abdominal, and/or extranodal symptoms. Although much less common than with HL, approximately 20% of patients with NHL have mediastinal adenopathy. These patients most frequently present with persistent cough, chest discomfort, or without clinical symptoms but have an abnormal chest radiograph. Occasionally, a superior vena cava syndrome accompanies presentation. A differential diagnosis of mediastinal presentation includes infections (e.g., histoplasmosis, tuberculosis, infectious mononucleosis), sarcoidosis, HL, as well as other malignancies. Involvement of retroperitoneal, mesenteric, and pelvic nodes is common in most histologic subtypes of NHL. Unless massive or leading to obstruction, nodal enlargement in these sites often does not produce symptoms. In contrast, patients with an abdominal mass, massive splenomegaly, or primary gastrointestinal (GI) lymphoma present with complaints similar to those caused by other space-occupying lesions. These complaints include chronic pain, abdominal fullness, and early satiety, symptoms associated with visceral obstruction or even acute perforation and GI hemorrhage. Rarely, patients present with symptoms of unexplained anemia. Those with aggressive NHLs can present with primary cutaneous lesions, testicular masses, acute spinal cord compression, solitary bone lesions, and rarely, lymphomatous meningitis. Symptoms of primary NHL of the CNS include headache, lethargy, focal neurologic symptoms, seizures, and paralysis.

When NHL involves an extranodal site, the differential diagnosis is more difficult. NHL uncommonly presents in the lungs as bronchovascular, lymphangitic, nodular, or alveolar patterns of involvement.⁴⁸ Between 25% and 50% of patients with NHLs present with hepatic infiltration, although relatively few present with large hepatic masses. Of the advanced-stage indolent lymphomas, nearly 75% of patients have microscopic hepatic infiltration at presentation. In contrast, primary hepatic lymphoma is rare and is nearly always an aggressive histology. Primary lymphoma of bone

is another uncommon extranodal site, occurring in less than 5% of patients and often presenting as bone pain. Most frequently, lytic lesions are observed on standard radiographs. The most common sites of primary lymphoma of bone include the femur, the pelvis, and the vertebrae. Approximately 5% of NHLs are primary GI lymphomas. These tumors are often associated with hemorrhage, pain, or obstruction. The stomach is most frequently involved, followed by the small intestine, and the colon. Most GI lymphomas are of the diffuse aggressive histologies, specifically DLBCL, mantle cell lymphoma (MCL), and intestinal T-cell lymphoma. The most common site for extranodal MZLs is the stomach. A subset of MCLs presents as multiple intestinal polyposis, which may arise at any site in the GI tract. An uncommon presentation (2% to 14%) of NHL is renal infiltration, and even less common is localized presentation in the prostate, testis, or ovary. The typical histologic subtypes of these sites are DLBCL, BL, and gray zone tumors with features intermediate between DLBCL and BL. Rare sites of primary lymphoma include the orbit, heart, breast, salivary glands, the thyroid, and the adrenal gland.

Diagnosis and Initial Management

After the initial biopsy, a careful history and physical exam should be done to help assess the extent and pace of disease. Attention should be paid to the duration of symptoms and pace of symptomatic progression, whether symptoms associated with a poorer prognosis, such as fevers, night sweats, or unexplained weight loss are present, and to localizing symptoms that may point toward lymphomatous involvement of specific sites, such as the chest, abdomen, or CNS. Concurrent illness that may impact therapy or monitoring on therapy should be ascertained, including a history of diabetes or congestive heart failure. A physical exam should pay close attention to all the peripherally accessible sites of lymph nodes; the liver and spleen size; Waldeyer's ring; whether there is a pleural or pericardial effusion or abdominal ascites; whether there is an abdominal, testicular or breast mass; and whether there is cutaneous involvement because all of these findings may influence further evaluation and disease management.

Laboratory studies should be obtained, including complete blood count, routine chemistries, liver function tests, and serum protein electrophoresis to document the presence of circulating monoclonal paraproteins. The serum beta-2 microglobulin level and serum lactate dehydrogenase (LDH) are important independent prognostic factors in NHL. A bone marrow biopsy should be considered for staging and prognostic purposes depending on the disease histology and the results of other laboratory and staging studies. An evaluation of the cerebrospinal fluid (CSF) for lymphomatous involvement may be indicated in the setting of concerning neurologic signs or symptoms or a disease that has a high propensity to spread to the CNS. The latter includes a disease involving the paranasal sinuses, testes, and epidural space, as well as highly aggressive histologies like BL.

Imaging studies depend on the histology of the lymphoma as well as the clinical presentation. Chest, abdominal, and pelvic computed tomography (CT) scans are essential for accurate staging to assess lymphadenopathy for indolent lymphomas. Radionuclide scans have clinical utility as diagnostic and monitoring studies.⁶⁷ Gallium scanning, used based on the ability of this isotope to bind transferrin receptors on tumor cells, has been replaced by positron-emission tomography (PET) using ¹⁸F-fluorodeoxyglucose (FDG). FDG-PET scanning is highly sensitive for detecting both nodal and extranodal sites involved by NHL. PET scanning is particularly useful for the histologically aggressive lymphomas, including BL, DLBCL, plasmablastic lymphoma, and the aggressive T-cell lymphomas, but is less reliable in lower grade histologies like MZLs.⁴⁹ The intensity of FDG avidity, or standardized uptake value (SUV), correlates with histologic aggressiveness.^{50,51} PET scanning detects an actively metabolizing tumor in residual

masses following or during chemotherapy, and persistent abnormal uptake predicts for early relapse and/or reduced survival.⁵² It is more accurate than the detection of a residual mass on CT scans, which can often be a false positive. Consensus recommendations regarding PET scanning were published as a result of an International Harmonization Project. Among the recommendations are that PET only be used for DLBCL and HL, scanning during therapy be only part of clinical trials, and the scan after all therapy is completed should be done at least 3 but preferably 6 to 8 weeks after chemotherapy and 8 to 12 weeks after radiation or chemoradiotherapy. There is no evidence that a long-term follow up should include PET scanning.⁵³ Finally, magnetic resonance imaging (MRI) is useful in detecting bone, bone marrow, and CNS disease in the brain and spinal cord.

Staging and Prognostic Systems

The Ann Arbor staging system developed in 1971 for HL was adapted for staging NHLs (Table 103.5).⁵⁴ This staging system focuses on the number of tumor sites (nodal and extranodal), the location, and the presence or absence of systemic, or B, symptoms. Table 103.5 summarizes the essential features of the Ann Arbor system.

The concept of staging has less impact in NHL than in HL. Only a minority of patients with both indolent and aggressive NHL have localized disease at diagnosis, and there is little therapeutic benefit to distinguish between stage III and stage IV disease because the treatment options are identical. The prognosis is more dependent on histology and clinical parameters than the stage at presentation. Staging in NHLs, therefore, is done to identify the minority of patients who can be treated with local therapy or combined modality treatment and to stratify within histologic subtypes to determine the prognosis and to assess the impact of treatment.

Probably more important than staging is the International Prognostic Index (IPI), which provides risk stratification (Table 103.6).⁵⁵ The IPI was developed based on an analysis of over 2,000 patients with diffuse aggressive NHLs treated with an anthracycline-containing regimen. This analysis identified age (≤ 60 years versus > 60 years); serum LDH (\leq normal versus $>$ normal); performance status (0 or 1 versus 2 to 4); stage (I or II versus III or IV); and extranodal involvement (\leq one site versus $>$ one site) to be independently prognostic for overall survival. Four risk groups were identified based on the number of risk factors: low risk (0 or 1); low intermediate (2); high intermediate (3); and high (4 to 5). The

TABLE 103.5

Ann Arbor Staging for Lymphoma

Stage	Description
I	Involvement of a single lymph node region (I) or single extranodal site (IE)
II	Involvement of two or more lymph node regions or lymphatic structures on the same side of the diaphragm alone (II) or with involvement of limited, contiguous, extralymphatic organ or tissue (IIIE)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may include the spleen (IIIS), or limited, contiguous, extralymphatic organ or tissue (IIIE), or both (IIIES)
IV	Diffuse or disseminated foci of involvement of one or more extralymphatic organs or tissues, with or without associated lymphatic involvement

Note: All stages are further subdivided according to the absence (A) or presence (B) of systemic B symptoms including fevers, night sweats, and/or weight loss ($> 10\%$ of body weight over 6 months prior to diagnosis).

TABLE 103.6

0–1	Low	81	87	91
2	Low Intermediate	69	75	81
3	High Intermediate	53	59	65
4–5	High	50	50	59

ECOG, Eastern Cooperative Oncology Group; EFS, event-free survival; PFS, progression-free survival; OS, overall survival.

Adapted from Ziepert M, Hasenclever D, Kuhnt E, et al. Standard International Prognostic Index remains a valid predictor of outcome for patients with aggressive CD20+ B-cell lymphoma in the rituximab era. *J Clin Oncol* 2010;28:2373–2380.

5-year overall survival rates for patients with scores of 0 to 1, 2, 3, and 4 to 5 were 73%, 51%, 43%, and 26%, respectively. For the patients aged 60 years or less, only stage, LDH, and performance status were of prognostic significance. Patients ≤ 60 years with zero, one, two, or three risk factors had 5-year survival rates of 83%, 69%, 46%, and 32%, respectively. Survival rates for those age > 60 years with the same scores were 56%, 44%, 37%, and 21%, respectively. The IPI has been adapted following treatment with cyclophosphamide, adriamycin, vincristine, and prednisone plus rituximab (CHOP-R) therapy for DLBCL. Within that model, the 4-year progression-free survival is 94%, 80%, and 53% for zero and one, two, or three or more risk factors, respectively.⁵⁶

A similar predictive model has been developed for follicular lymphoma based on the analysis of over 4,000 patients with follicular NHL, known as the follicular lymphoma IPI or FLIPI (Table 103.7).⁵⁷ This study identified the following prognostic

TABLE 103.7

Follicular Lymphoma International Prognostic Index (FL-IPI)

Age > 60 years			
LDH $>$ upper limit normal			
Hgb < 12 g/dL			
Ann Arbor Stage III or IV			
Number of involved nodal areas > 4			
# of Factors	Risk Group	5-year OS (%)	10-year OS (%)

factors: age >60 years, stage III/IV, more than four nodal sites, elevated serum LDH concentration, and hemoglobin less than 12. The 10-year survival rates for patients with zero to one (low risk), two (intermediate risk), or three or more (high risk) of these adverse factors averaged 71%, 51%, and 36%, respectively. Similar disease-specific IPs have been developed for mantle cell lymphoma and peripheral T-cell lymphoma as well. These prognostic indices take into account the proliferative index and cell surface markers, respectively.^{58,59}

More recently, as discussed in the section on the 2008 update to the WHO, GEP has been used to examine DLBCL to identify patients with different prognoses.⁴⁶ Based on gene expression, DLBCLs have been subclassified into GCB or ABC types. Patients with GCB-like DLBCL had significantly better overall survival than those with the ABC-like variant. Based on findings from GEP, immunohistochemical staining of a limited number of proteins has been proposed as an alternative method for subtyping of DLBCL and prognostication.⁶⁰ Germinal center and nongerminal center B-cell derivation can be determined by the expression of markers such as CD10, B cell lymphoma-6 protein (BCL-6), and multiple myeloma oncogene 1 (MUM1). Based on immunohistochemistry, it is estimated that approximately 40% of DLBCLs are of the GCB subtype, with the remainder falling into the non-GCB group.

Restaging after treatment is typically done 6 to 8 weeks following the completion of chemotherapy (or chemioimmunotherapy), or 8 to 12 weeks after the completion of radiotherapy or combination chemotherapy and radiotherapy, to assess for disease response to treatment. The most important prognostic factor is the achievement of a complete response to therapy. Restaging at the completion of treatment is often with the repetition of studies that were abnormal at diagnosis. It should be noted that patients with certain lymphomas or bulky disease may not have complete regression of their lymphadenopathy despite there not being any remaining active lymphoma. Nuclear studies, like PET/CT scans, and/or rebiopsy can be helpful in differentiating residual fibrotic tissue from active lymphoma.

SPECIFIC DISEASE ENTITIES

Precursor B-Cell and T-Cell Leukemia/Lymphoma

Lymphoblastic lymphoma and acute lymphoblastic leukemia appear to be different manifestations of the same disease entity (see Chapter 110). Cytologically, both are composed of blasts with a high nuclear-to-cytoplasmic ratio, scant cytoplasm, and nuclei with slightly coarse chromatin with multiple small nucleoli. The nuclei may be oval, but more often are folded or convoluted. The blasts are usually intermediate in size, but they may be large, or in unusual cases, so small that there may be confusion morphologically with CLL. When lymph nodes are involved, they are diffusely effaced by blasts. Mitotic figures are usually frequent, and (as with all high-grade lymphomas) some cases contain frequent tingible body macrophages, producing a starry-sky appearance that mimics BL.

Approximately 85% to 90% of lymphoblastic lymphomas are of the T-cell lineage, with the remainder being of the B-cell type. Both are comprised of tumor cells with immunophenotypes that correspond to stages of pre-T and pre-B-cell development, respectively. B-lymphoblastic tumors express CD19 and are variably positive for other B lineage markers and negative in most cases for surface immunoglobulin. T lymphoblastic tumors usually express cytoplasmic CD3 but may be surface CD3 negative, and show variable expression of other T-cell markers. Most lymphoblastic tumors are positive for TdT, a specific marker of immature lymphoid cells that can be detected by flow cytometry or immunohistochemistry.

Although lymphoblastic lymphomas represent a major subgroup of childhood NHLs, they are unusual in adults (2% of adult

NHLs). Patients are usually adolescent or young adult males who present with lymphadenopathy in cervical, supraclavicular, and axillary regions (50%) or with a mediastinal mass (50% to 75%). These masses can be associated with superior vena cava syndrome, tracheal obstruction, and pericardial effusions. Less commonly, patients present with extranodal disease (skin, testicular, or bony involvement). More than 80% of patients present with stage III or stage IV disease, almost 50% have B symptoms, and the majority has an elevated LDH. Although the bone marrow can be uninvolved at presentation, virtually all patients develop bone marrow infiltration and a subsequent leukemic phase indistinguishable from T-cell acute lymphoblastic leukemia. Patients with bone marrow involvement have a very high incidence of CNS infiltration. B-cell lymphoblastic lymphoma is a very rare entity, with patients having a median age of 39 years.⁶¹ B-cell lymphoblastic lymphomas present without a mediastinal mass but instead involve lymph nodes and extranodal sites.

The treatment of precursor B-cell and T-cell lymphoblastic leukemia/lymphoma is detailed in Chapter 110.

Follicular Lymphoma

Introduction

FL is the second most common lymphoma diagnosed in the United States and western Europe, making up approximately 20% of all NHLs, and 70% of indolent lymphomas.⁶² The median age at diagnosis is 60 years, and there is a slight female predominance.^{63,64} The incidence is increased among relatives of persons with FL.⁶⁵

Pathology

FLs are malignant counterparts of normal germinal center B cells.⁴⁴ FL recapitulates the architecture of normal germinal centers (GC) of secondary lymphoid follicles.⁴⁴ The neoplastic cells consist of a mixture of centrocytes (small- to medium-sized cells with irregular or cleaved nuclei and scant cytoplasm) and centroblast (large cells with oval nuclei, several nucleoli, and moderate amounts of cytoplasm). The clinical aggressiveness of the tumor correlates with the number of centroblasts that are present. The WHO classification⁴⁴ adopted grading from 1 to 3 based on the number of centroblasts counted per high power field (hpf): Grade I, 0 to 5 centroblasts/hpf; Grade II, 6 to 15 centroblasts/hpf; Grade III, more than 15 centroblasts/hpf. Grade III has been subdivided into grade IIIa, in which centrocytes predominate, and grade IIIb, in which there are sheets of centroblasts.⁶⁶ Although the grading system remains in place, clinically, grade I and II and many cases of grade IIIa FLs are approached similarly. Akin to normal GCs, small numbers of T cells and follicular dendritic cells are present in the malignant follicles; however, tingible body macrophages, cells that have ingested apoptotic cells that are common in reactive GCs, are not observed. Involvement of the peripheral blood with malignant cells is commonly seen, and morphologically, these cells have notches and have been referred to as *buttock cells*. FL grade IIIb is an aggressive disease grouped with diffuse large B-cell lymphoma. Bone marrow involvement is exceedingly common in FL patients, usually taking the form of paratrabecular lymphoid aggregates.⁴⁴

Immunophenotype and Genetics

FL cells express monoclonal immunoglobulin light chain, CD19, CD20, CD10, and BCL6 and are negative for CD5 and CD23. In virtually all cases, FL cells overexpress BCL-2. Clonal Ig gene rearrangements are present and, in most cases, the Ig loci have extensive somatic mutations, further supporting a GC origin. Approximately 85% of FLs have the t(14;18), which drives overexpression of BCL-2, a member of a family of proteins that blocks apoptosis. However, multiple genetic events are required for the development of FL,

because the t(14;18) can be identified in a small fraction of normal B cells in most normal children and adults. Deep sequencing studies have established that the most common mutations in FL (90% of tumors) involve mixed-lineage leukemia 2 protein (*MLL2*), a gene encoding a histone H3 methylase.^{67,68} Less common recurrent mutations involve other genes involving epigenetic modifying genes, such as *EZH2*, *CREBBP*, and *EP300*, indicating that genetically determined alterations in the epigenome contribute to FL in ways that remain to be defined. Other recent studies suggest that reactive cells within the malignant microenvironment also contribute to the pathobiology of FL, based on evidence that immune signatures of T cell and macrophage infiltration defined by gene expression profiling are predictive of outcome.⁶⁹

Clinical Features

Patients with FL generally present with asymptomatic lymphadenopathy, which often waxes and wanes over the course of years. Bone marrow involvement is present in 70% of patients, whereas involvement of other nonlymphoid organs is uncommon. Less than 20% of patients present with B symptoms or an increased serum LDH. In a small subset of patients, the disease presents in the intestine; such patients usually have an early stage and a favorable prognosis.⁷⁰ Histologic transformation of FL to DLBCL occurs in 10% to 70% of patients over time, with a risk of about 2% to 3% per year⁷¹⁻⁷³ and is associated with the rapid progression of lymphadenopathy, extranodal disease (besides the marrow), B symptoms, elevated serum LDH, and calcium.

Prognosis

Measures of outcome include the FLIPI (see Table 103.7) and tumor grade.⁷⁴ A modified version of this score, the FLIPI2, evaluated five parameters, with some overlap of the FLIPI.⁷⁵ The utility of the FLIPI2 model remains uncertain. Since the incorporation of rituximab into the mainstream therapy of FL, the FLIPI has continued to be a useful prognostic model.⁷⁶

FL tumors are graded from 1 to 3 and this grade has some prognostic utility. There has generally been suboptimal consensus of pathologists on grading FL. There is no evidence to support a different treatment approach between grade I and grade II FL. Differences in molecular genetics as well as clinical behavior suggest that FL grade IIIa is more commonly an indolent disease, whereas grade IIIb is an aggressive disease.^{44,77}

The investigation of the cellular microenvironment of FL has provided interesting insights into prognosis.⁷⁸⁻⁸⁷ It has been suggested that FL is an immunologically functional disease in which an interaction between the tumor cells and the microenvironment modulates clinical behavior. These studies, which have observed an impact on the prognosis of reactive macrophages and T cells, need additional study in larger data sets and a prospective design with uniformly treated patient populations.

Treatment of Early Stage Disease

Less than 10% of patients with FL have stage I/II disease.⁸⁸ Radiation therapy is the treatment of choice for limited stage FL and results in a 5-, 10-, and 15-year freedom from treatment failure of 72%, 46%, and 39%, and an overall 5-, 10-, and 15-year survival rates of 93%, 75%, and 62%, respectively, with a median survival of approximately 19 years.⁸⁹ A dose of 24 to 30 Gy appears to be highly effective, with no evidence of benefit for higher doses.⁹⁰ However, most patients with stage I disease treated in the United States do not receive radiation therapy.⁸⁸ This is surprising given a large study of over 6,000 patients with stage I or stage II FL diagnosed from 1973 to 2004, 34% of whom were initially treated with RT, where patients who received initial radiation therapy (RT) had higher rates of disease-specific survival at 5 years (90% versus 81%), 10 years (79% versus 66%), 15 years (68% versus 57%), and 20 years (63% versus 51%).⁹¹

In pre-rituximab era studies, adjuvant chemotherapy probably does not add additional benefit after local RT.⁹² A recent retrospective analysis suggested an improved progression-free survival (PFS) outcome with chemoimmunotherapy or systemic therapy plus RT as compared to RT alone, with no impact on overall survival (OS).⁹³ This will require additional study. If significant morbidity is possible from RT based on the location of the disease area or if the patient chooses to not receive RT, observation may be a reasonable alternative, especially for stage II patients.⁹⁴ In this report, the median OS of selected untreated patients was 19 years. At a median follow-up of 7 years, 63% of patients had not required treatment.

Treatment of Advanced Stage Disease

The overwhelming majority of patients have advanced stage disease at diagnosis. Patients with asymptomatic FL do not require immediate treatment unless they have symptomatic nodal disease, compromised end organ function, B symptoms, symptomatic extranodal disease, or cytopenias. This approach is supported by randomized prospective trials of observation versus immediate treatment. One of the largest trials compared immediate treatment with chlorambucil to observation.⁹⁵ At a median follow-up of 16 years, no difference in OS and cause-specific survival was seen between the two approaches. Similar results have been noted in other prospective trials of initial treatment versus observation.⁹⁶

A major question is whether rituximab might change this approach in early treatment in asymptomatic patients. A retrospective analysis of good risk patients who were either observed or received single-agent rituximab⁹⁷ found no negative impact of watchful waiting. A prospective study compared observation to rituximab alone or rituximab followed by maintenance in previously untreated FL. The median time to next treatment was 34 months in the watch and wait patient but was not reached in the rituximab-treatment arm. The 3-year PFS was 33%, 80%, and 90% of the observed, rituximab, or rituximab followed by maintenance patients, respectively, with 95% OS in all three groups. The important issues of time to second therapy, quality of life, impact on histologic transformation, cost, toxicity, and future responses to rituximab are not yet addressed.⁹⁸

Rituximab has changed the paradigm of treating FL. The recent improvement in survival of patients with FL is largely due to the use of anti-CD20 monoclonal antibody-based therapy.⁹⁹ The benefit of adding rituximab to combination chemotherapy for the initial treatment has been demonstrated in multiple randomized trials of chemotherapy with or without rituximab (see Table 103.2).¹⁰⁰⁻¹⁰⁴ All of these trials have demonstrated improved response rates and time to progression in the rituximab plus chemotherapy arms, as well as improvement in OS. FDG-PET scanning has been employed to evaluate responses to CHOP-R in previously untreated patients. PET scanning was predictive when performed after four cycles and at the end of therapy. The 2-year PFS was significantly higher for PET-negative than PET-positive patients when employed as an interim or end of therapy scan. The 2-year OS was also significantly higher for PET-negative than PET-positive patients. This will require further study but may change management in the future.¹⁰⁵

Other chemotherapy drugs plus rituximab have also been used for the initial therapy of FL. Bendamustine plus rituximab (BR) has been compared to CHOP-R in a randomized phase III trial with bendamustine (90 mg/m² days 1 and 2) plus rituximab (375 mg/m² day 1) in 513 patients with advanced follicular, marginal zone, lymphoplasmacytic, and mantle cell lymphoma.¹⁰⁶ In this study, a superior median PFS in favor of BR versus CHOP-R was seen (69.5 versus 31.2 months) at 45 months. Moreover with BR, less toxicity, including lower rates of grade 3 and 4 neutropenia and leukopenia were observed. There was no difference in OS at a median follow-up of 45 months. Intensifying the schedule of CHOP-R from every 21 to every 14 days was also of no benefit.¹⁰⁷ Fludarabine plus

rituximab¹⁰⁸ and fludarabine, mitoxantrone, dexamethasone, and rituximab¹⁰⁹ both showed response rates of over 90% in previously untreated patients. However, significant neutropenia and opportunistic infections were observed with these regimens. A randomized phase III trial compared three regimens in previously untreated stage II to IV FL patients: CHOP-R; cyclophosphamide, vincristine, prednisone, and rituximab (CVP-R); or rituximab, fludarabine, and mitoxantrone (R-FM). Both R-FM and CHOP-R were superior to CVP-R in 3-year PFS and time to treatment failure (TTF), but there was no difference in OS.¹¹⁰ The current impact of this study is uncertain given the favorable results and lower toxicity seen with BR.

Rituximab alone has been used as the first therapy in patients with FL, with overall response rates of around 70% and complete response (CR) rates of over 30% reported.¹¹¹⁻¹¹³ The most favorable data of single-agent rituximab is the recent update of the swiss group for clinical cancer research (SAKK) trial.¹¹⁴ Patients received four weekly doses, and then patients with stable disease or better were randomized to observation or four doses of maintenance therapy, one dose every 2 months. In this study, 202 patients with previously untreated or relapsed/refractory FL administered four weekly doses of single-agent rituximab has been reported. The 151 patients with responding or stable disease at week 12 were randomized to no further treatment or prolonged rituximab maintenance every 2 months for four doses. At a median follow-up of 35 months, patients who received the prolonged rituximab maintenance had a twofold increase in event-free-survival (23 months versus 12 months). With a longer follow-up, 45% of newly diagnosed patients in this study were in remission at 8 years with the addition of maintenance rituximab.

Maintenance rituximab has also been shown to benefit patients who received chemotherapy without rituximab as part of the initial treatment. A randomized trial of maintenance rituximab versus observation after CVP with the majority having FL reported that patients who received maintenance rituximab had improved rates of 3-year PFS (68% versus 33%). Survival rates were similar between the two groups.¹¹⁵ With the current paradigm of treating patients with concurrent chemotherapy plus rituximab, this study has less applicability.

The use of maintenance rituximab after chemoimmunotherapy in patients with FL has been examined in a large randomized trial.¹¹⁶ Although maintenance rituximab appears to improve PFS rates, toxicities, albeit tolerable, are increased and the effect on OS is, to date, unclear. The Primary Rituximab and Maintenance (PRIMA) phase III intergroup trial randomly assigned 1,018 patients with previously untreated FL that responded to chemoimmunotherapy (CVP-R, CHOP-R, or fludarabine, cyclophosphamide, mitoxantrone, and rituximab [FCM-R]) maintenance with rituximab (375 mg/m² every 8 weeks for 24 months) or placebo.¹¹⁶ At a median follow-up of 36 months from randomization, patients assigned to rituximab maintenance had a higher rate of PFS (75% versus 58%). A higher percentage of patients in complete response/complete response, unconfirmed (CRu) at 24 months (72% versus 52%) was also seen 2 years postrandomization in patients receiving maintenance rituximab. There was a significantly higher percentage of patients with grade III/IV adverse events and infections in the rituximab maintenance group. At this time, OS is the same in both groups.

Radioimmunotherapy alone has been used as the initial treatment in a limited number of patients with FL.¹³¹ Itoisutimomab was given to 76 previously untreated patients with FL leading to overall and complete response rates of 95% and 75%, respectively, and, at 5-years, OS and PFS rates of 89% and 59%, respectively.¹¹⁷ ¹³¹I tositumomab is no longer commercially available. ⁹⁰Yttrium (⁹⁰Yi)-ibritumomab tiuxetan has also been studied as sole initial therapy with excellent results with limited follow-up.¹¹⁸

Radioimmunotherapy has also been used as consolidation following conventional chemotherapy induction in patients with FL. Both ⁹⁰Yi-ibritumomab tiuxetan and ¹³¹I-tositumomab have been studied. This approach has been associated with very high response rates, conversions of partial response (PR) to CR, and well-maintained responses.¹¹⁹⁻¹²¹ A phase III trial compared ⁹⁰Yi-ibritumomab tiuxetan

to observation following a CR or PR to induction chemotherapy for treatment-naïve patients with FL.¹²² Of note, the majority of patients did not receive rituximab along with the induction chemotherapy. At 8 years, both the PR and CR patients who received ⁹⁰Yi-ibritumomab tiuxetan had significantly longer median PFS with improvement of about 36 months. In contrast to this study, a randomized trial of CHOP plus rituximab to CHOP followed by ¹³¹Itoisutimomab did not see any differences in PFS between the two arms.¹²³

High-dose therapy and autologous stem cell transplantation (ASCT) has been used to consolidate first remission for patients with FL. These studies generally preceded the widespread use of rituximab. With ASCT in first remission, about 50% of patients are disease free at 10 years and beyond following ASCT, but an increased risk of second malignancies, including myelodysplastic syndrome (MDS), acute myelogenous leukemia (AML), and solid tumors, has been observed with long follow-ups of these patients. Several randomized trials have examined the role of ASCT in previously untreated patients with FL following an induction therapy.¹²⁴⁻¹²⁹ The majority of these studies have demonstrated a significant improvement in PFS, but no impact on OS.¹³⁰ One reason for the lack of impact on OS has been the excess number of second malignancies.

Although allogeneic stem cell transplantation (alloSCT) can potentially lead to a cure for patients with FL due to the significant treatment related mortality, this is largely reserved for patients with relapsed and more refractory disease.

Treatment of Relapsed FL

When patients with relapsed FL require treatment, there are many options, ranging from rituximab alone to combination chemotherapy plus rituximab, radioimmunotherapy, and for selected patients, stem cell transplantation.

A recent update of single-agent rituximab therapy in patients with relapsed FL is from the randomized SAKK trial.¹¹⁴ With a long follow-up, 35% of responders remain in remission at 8 years. However, in the context of current induction therapy that includes chemotherapy and rituximab in the majority of patients, it is uncertain if the response data to single-agent rituximab is as high or durable as in patients who received chemotherapy without rituximab as induction therapy. There is a evidence, however, that retreatment with rituximab in patients with relapsed, largely FL, who had previously responded to rituximab had a response rate of 40% with a median time to progression of 18 months following retreatment.¹³¹

The combination of chemotherapy and rituximab has enhanced the efficacy of treatment of relapsed FL. Probably the largest study treated selected patients with relapsed FL who were previously not treated with an anthracycline- or rituximab-containing regimen.¹³² Patients were randomized to CHOP or CHOP-R and responding patients were randomized to 2 years of maintenance rituximab or observation. The overall and CR rates were significantly improved in the CHOP-R group, and the median PFS was improved by approximately 12 months. An update of this study with a median follow-up of 6 years reported that maintenance rituximab also improved median PFS by 2.4 years. The OS at 5 years following maintenance was 74% versus 64% with observation alone. Given the current paradigm of chemoimmunotherapy and maintenance, the applicability of these data to presently treated patients is uncertain.

Another regimen in which a benefit for the addition of rituximab was seen for relapsed disease in a randomized trial employing FCM.¹³³ A number of phase 2 trials of other agents plus rituximab associated with quite high response rates included BR with 90% response rate (RR) and median PFS of 2 years.¹³⁴⁻¹³⁶ Single-agent bendamustine has an overall RR of 77% with a median response duration of 6.7 months.¹³⁴ With more widespread use of BR as initial therapy, BR will be employed less for recurrent disease. The regimen FCR has a similarly high response rate but with significant myelosuppression.¹³⁷ Phase 2 studies employing bortezomib and rituximab and bortezomib, rituximab, and bendamustine have reported RRs of approximately 50% and 93%, respectively.^{138,139}

The anti-CD20 radioimmunotherapy agents have been employed for treatment of patients with relapsed and refractory FL.¹⁴⁰ The RRs in this patient population are similar with both agents, with 60% to 80% of patients responding. The median PFS is about 12 months, although the approximately 20% to 37% of patients who achieve a CR have a median time to progression of approximately 4 years.^{141,142} A randomized trial compared single-agent rituximab to ⁹⁰Yi-ibritumomab in patients with relapsed indolent (predominantly FL).¹⁴³ The overall and CR rates were significantly higher with radioimmunotherapy (RIT), but no difference in time to progression or OS was observed. Retreatment with these agents remains controversial, with uncertainty of delivery of full dose and concerns of second malignancies.¹⁴⁴

FL is extremely responsive to RT; low-dose RT (e.g., total dose of 4 Gy, given as two consecutive daily 2-Gy fractions) can be used for the palliation of patients who have symptoms related to a single disease site, with CR rates of 57% and overall RRs of 82%.¹⁴⁵ Patients who go into CR have long, durable local control rates. There are no significant side effects of treatment, even in the head and neck region where higher doses would cause xerostomia and mucositis.

The use of either ASCT or alloSCT in FL is controversial and the subject of numerous clinical trials.¹⁴⁶ A large number of phase 2 studies prior to the availability of rituximab, involving high-dose therapy and autologous hematopoietic stem cell transplantation (HCT) have shown that approximately 40% of patients with good performance status and chemosensitive relapsed disease may experience prolonged PFS and OS.¹⁴⁷⁻¹⁵¹ Prior to the widespread use of rituximab for in vivo purging, many strategies were taken to render the autologous stem cell collections free of lymphoma cells. Although single institution studies suggested that reinfusion of tumor-free stem cells led to a decreased relapse rate, it remains controversial as to whether there is a benefit, particularly now with rituximab treatment. The only phase 3 randomized trial (the chemotherapy, unpurged stem cell transplantation, purged stem cell transplantation [CUP] trial) comparing ASCT to conventional chemotherapy in relapsed FL patients demonstrated a higher PFS and OS for ASCT, and no benefit for purging the stem cell graft.¹⁵² A retrospective analysis of patients undergoing ASCT following rituximab-based salvage therapy did not suggest a benefit of ASCT as compared to conventional therapy. Unfortunately, as has been seen in ASCT in first remission, second malignancies—both solid tumors and MDS and AML—are reported following ASCT.

Phase 2 studies have looked at the use of in vivo purging pre-ASCT and maintenance therapy with rituximab following ASCT in patients with relapsed FL. These suggest an improvement in PFS, similar to what has been seen following conventional chemotherapy and chemoimmunotherapy. A phase 3 trial in patients with relapsed FL has investigated the inclusion of rituximab for in vivo purging pre-ASCT and 2 years of maintenance post-ASCT.¹⁵³ There was an improvement in PFS for patients receiving rituximab for in vivo purging, maintenance, and the combination of both as compared to no rituximab, but no OS benefit.

AlloSCT has been investigated in patients with relapsed FL. Both myeloablative and reduced intensity conditioning (RIC) approaches have been employed. Unfortunately, myeloablative conditioning has a treatment related mortality of up to 40%; however, the relapse rate is less than 20%.¹⁵⁴ There is enthusiasm for RIC alloSCT because it has lower treatment-related mortality,¹⁵⁵⁻¹⁵⁷ but some reports suggest that the relapse rate may be higher than conventional myeloablative conditioning. The role of alloSCT versus ASCT for FL remains uncertain. A recent National Comprehensive Cancer Network (NCCN) database retrospective analysis found significantly higher 3-year OS for ASCT versus alloSCT (87% versus 61%).¹⁵⁸ Certainly, for younger patients with more resistant disease, alloSCT remains a potentially curative option for relapsed FL.

Histologic Transformation

Part of the natural history of any indolent B-cell NHLs is progression to a higher grade histologic subtype, most commonly DLBCL, but

much less commonly, BL or even HL can be seen.^{71,159} Histologic transformation (HT) is most commonly seen in FL, but is also seen in patients with MZL, lymphoplasmacytic lymphoma, and small lymphocytic lymphoma/CLL (where this is referred to as a Richter transformation), and a biopsy is critical in order to demonstrate transformation. HT occurs at a rate of approximately 2% to 3% per year.⁷² The clinical presentation of HT includes rapid growing masses, extranodal disease, B symptoms, hypercalcemia, and elevated serum LDH. *TP53* mutations and translocations or amplifications of *MYC* are the most common genetic abnormalities seen in HT.

Historically, HT to DLBCL has been associated with a very poor prognosis. In a series from Stanford, previously untreated patients and patients with limited disease and no prior therapy at transformation had improved prognoses.¹⁶⁰ Although the median survival for all patients with transformation was only 22 months, those who achieved a CR to combination chemotherapy had an actuarial survival of 75% at 5 years. More recent studies suggest that CHOP-R may improve OS for patients with transformed disease. Patients who have not previously received an anthracycline-containing regimen should be treated with CHOP-R and, assuming a CR is obtained, monitored. For previously treated patients, high-dose therapy and ASCT should be considered assuming the patient has chemosensitive disease. Patients with histologic transformation can have later relapses with indolent lymphoma.

Newer Agents

There are a multitude of new approaches that have been studied in patients with FL. This includes monoclonal antibodies, idiotype vaccines, immunomodulatory agents, and novel drugs such as kinase inhibitors.

Monoclonal antibodies directed against other B-cell-associated antigens as well as new anti-CD20 monoclonal antibodies (mAb) are being investigated in FL. These have included anti-CD80,^{161,162} anti-CD22 mAbs,^{163,164} and anti-CD40.¹⁶⁵ Several new anti-CD20 monoclonal antibodies are being evaluated in patients with FL who are refractory to rituximab. These include several humanized antibodies that are designed to have less infusion toxicity and a better antibody-dependent cell-mediated cytotoxicity effector function.¹⁶⁶⁻¹⁶⁸ The other mAb of interest is obinutuzumab, the first type II, glycoengineered, and humanized monoclonal anti-CD20 antibody.¹⁶⁹ In rituximab-refractory patients in the high-dose cohort, the RR was 55% with a median PFS of 11.9 months. Studies of obinutuzumab in combination with chemotherapy have shown 93% to 98% RRs in relapsed and refractory FL patients.¹⁷⁰

A number of immunostimulatory agents have been studied to enhance the activity of rituximab. These include cytokines such as IL-2 and immunostimulatory DNA sequences known as CpGs.¹⁷¹ To date, although having immunomodulatory effects, the impact on enhancing the therapeutic effect of rituximab has been limited. A phase 2 study of lenalidomide plus rituximab has reported high RRS, but a phase 3 study will be needed to demonstrate superiority over rituximab alone.¹⁷²

The other area of interest has been in active immunization, focusing largely on the idiotype protein as the antigen. To date, there have been three randomized studies employing idiotype proteins coupled to a protein called keyhole limpet hemocyanin (KLH) following the induction of remission in patients with FL. The Faville trial used rituximab for induction therapy. The median time to progression (TTP) was 9 months for the idiotype-KLH (Id-KLH) vaccinated patients and 12.6 months in the control group ($p = 0.019$).¹⁷³ However, this difference was attributed to more patients with high-risk FLIPI scores in the Id-KLH arm. The Biovax study reported showing a 14-month improvement in PFS for the Id-KLH vaccinated patients as compared to control; however, the induction chemotherapy was intense and remissions had to be sustained for 12 months prior to the initiation of vaccination.¹⁷⁴ The trial using the MyVax Id-KLH conjugate following CVP chemotherapy failed to show any PFS advantage. Based on

these studies, it is unlikely at the present time that idiotype vaccinations will be pursued in FL.

B-cell kinases are logical targets for therapy in FL. To date, three kinase inhibitors, idelalisib, ibrutinib, and fostamatinib, which target the phosphoinositide 3-kinase (PI3k) p110 δ , Bruton's tyrosine kinase (BTK), and spleen tyrosine kinase (SYK), respectively, have been tested. In relapsed and refractory FL patients, the response rates to idelalisib,¹⁷⁵ ibrutinib,¹⁷⁶ and fostamatinib¹⁷⁷ were 62% (including other indolent NHLs besides FL), 27%, and 10%, respectively. These agents are undergoing additional study, in combination with chemotherapy and as maintenance following remission induction, to better define their role.

Follicular Lymphoma Grade III

FL grade III has been historically referred to as follicular large cell lymphoma. It is histologically defined by the presence of more than 15 centroblasts per hpf. It is further subdivided into grade IIIa, where centrocytes are present, and grade IIIb, where there are sheets of centroblasts. These are further differentiated by the presence of *BCL6* rearrangements in a high fraction of grade IIIb cases. Because many studies likely include both grade IIIa and IIIb, this heterogeneity may affect an interpretation of the outcomes. Although the follicular architecture is intact, the clinical presentation, behavior, and outcome with treatment in many patients with FL grade IIIb more closely approximates that of DLBCL.¹⁷⁸⁻¹⁸⁰ In contrast to DLBCL, the relapse rate of FL grade IIIb is higher in some series, but survival is longer.¹⁸¹ A recent series suggested similar outcomes of grade IIIa and IIIb cases and no benefit for the inclusion of anthracyclines in the treatment regimen.¹⁸²

Small Lymphocytic Lymphoma/B-Cell Chronic Lymphocytic Leukemia

Introduction

Small lymphocytic lymphoma (SLL) is a mature (peripheral) B-cell malignancy. It is synonymous with CLL. The malignant cells in SLL and CLL are morphologically, immunophenotypically, and genetically identical. The difference between these two diagnoses is the clinical presentation, with a nonleukemic presentation in SLL. The diagnosis is made by an examination of involved tissue, such as the lymph node or bone marrow.

SLL represents less than 5% of all NHLs. CLL/SLL comprises 90% of chronic lymphocytic leukemias in Western countries. Less than 10% of patients present with only nodal involvement (i.e., SLL). However, most patients with SLL at presentation ultimately develop bone marrow and blood infiltration. The median age at diagnosis is 65 years.⁶³ At least 80% have stage IV disease due to bone marrow involvement at diagnosis.

Pathology

The cells within lymphoid tissues in CLL/SLL are small lymphocytes with condensed chromatin, round nuclei, and occasionally, a small nucleolus.⁴⁴ Larger lymphoid cells with prominent nucleoli and dispersed chromatin are also seen. These larger lymphoid cells are usually clustered together in so-called proliferation centers, which are pathognomonic. Roughly 60% of SLL/CLLs have Ig genes that show evidence of *significant* somatic mutation, defined as a rearranged Ig heavy-chain gene with a sequence that differs from germ-line position at 2% or more of the Ig V region nucleotides, which is taken as evidence of origin from an antigen-stimulated B cell.¹⁸³

Immunophenotype and Genetics

SLL/CLL cells express low-level monoclonal surface Ig, usually IgM or IgM and IgD. They also express human leukocyte antigen-DR (HLA-DR) and the B-cell antigens CD19, CD20, and CD23, and are characteristically CD5 positive. About 40% of cases express

CD38. Expression of the tyrosine kinase ZAP70 is also observed in a subset of cases and correlates with a more aggressive clinical course.¹⁸⁴

Immunoglobulin genes are clonally rearranged, with IgV region somatic mutations in up to 60% of patients. Cytogenetic abnormalities include trisomy 12, which is present in about 40% of cases, as well as 13q deletions (45% to 55% of cases), 11q deletions (17% to 20% of cases), and 17p deletions (7% to 10% of cases). Cases with 13q deletions have the most favorable prognosis, whereas those with del(11q) or del(17p) have an unfavorable prognosis.¹⁸⁵ The t(11;14) involving the cyclin D1 (*CCND1*) gene has been described, but many of these cases are believed to be leukemic variants of mantle cell lymphoma. Deep sequencing studies of CLL have revealed a number of recurrent mutations, the most common of which involve the *NOTCH1*, *MYD88*, and *SF3B1* genes.¹⁸⁶

Clinical Presentation

Most patients with SLL present with painless generalized lymphadenopathy, which has frequently been present for several years. B symptoms are rare. Hepatosplenomegaly is present in less than 50% of patients. The peripheral blood in patients with SLL may be normal or reveal only a mild lymphocytosis; by definition, patients with SLL have an absolute lymphocyte count of <5,000/ μ L at the time of diagnosis. A serum paraprotein is found in about 20% of cases, and hypogammaglobulinemia is present in about 40%. Both CLL and SLL patients may develop autoimmune hemolytic anemia, pure red cell aplasia, and autoimmune thrombocytopenia. Elevated serum LDH is uncommon, whereas increased levels of serum beta-2 microglobulin are more frequently seen and can be a marker disease burden. SLL/CLL can transform to DLBCL (Richter syndrome), an event that is associated with a short survival.¹⁸⁷ These patients present with rapidly growing masses, elevated serum LDH, and B symptoms. Rarely, transformation can be to B-cell prolymphocytic leukemia (B-PLL), which is characterized by high white cell counts and splenomegaly. It also has a poor prognosis.

Treatment of Small Lymphocytic Lymphoma

Patients with stage I SLL should be treated with involved field radiation, and not combined modality therapy or chemotherapy alone. In one limited series of 14 patients with stage I or II disease treated with 40 to 44 Gy, the 10-year freedom from relapse rates were 80% and 62% for stage I and stage II disease, respectively. Generally, patients with stage II or more advanced SLL are treated with chemotherapy regimens used for CLL (see Chapter 110). For patients with advanced stage disease who do not need systemic therapy but have one site causing symptoms, low-dose radiation (200 cGy for two fractions) can provide reasonable palliation, although the local control rates are not as high as seen with FL.¹⁴⁵

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma represents about 1% of all NHLs. In some cases, patients present with mixed cryoglobulinemia, possibly related to concurrent hepatitis C virus infection.^{188,189}

Pathology

Lymphoplasmacytic lymphoma is an indolent lymphoma composed of a diffuse proliferation comprised of a mixture of small lymphocytes, lymphoplasmacytic cells, and plasma cells.¹⁹⁰ Immunoglobulin inclusions in the cytoplasm (Russell bodies) or invaginating into the nucleus (Dutcher bodies) are commonly seen. Unlike multiple myeloma, amyloidosis is rare. Occasional cases may also contain frequent larger immunoblast-like cells.

Immunophenotype and Genetics

Monoclonal cytoplasmic immunoglobulin is seen within the plasmacytoid cells and plasma cells by immunohistochemistry. The

admixed lymphoid cells express B-cell antigens CD19, CD20, and surface IgM, and in general, do not express CD10 or CD23. A minor subset of cases is positive for CD5. Waldenström macroglobulinemia is an entity caused by high levels of monoclonal IgM that is generally associated with lymphoplasmacytic lymphoma (LPL). Deletions of 6q21 have been identified in 40% to 60% of patients with Waldenström macroglobulinemia. Activating mutations in MYD88, an adaptor protein that appears to function in signaling pathways downstream of the Ig receptor that lead to activation of the transcription factor nuclear factor kappa B (NF- κ B) activation, are highly associated with LPL, being present in close to 100% of cases. However, mutations of MYD88 are not specific for LPL, because they are also seen less commonly in DLBCL and other low-grade B-cell NHLs.

Clinical Presentation

Clinically, this disease is similar to small lymphocytic lymphoma. The median age is early 60s, and nearly all patients have stage IV disease by virtue of bone marrow involvement. B symptoms and elevated serum LDH are uncommon. Lymph node and splenic involvement are common. In the WHO clinical study, 5-year OS (58%) and failure-free survival (25%) were similar to SLL.

Treatment

At least 25% of patients with LPL/waldenström's macroglobulinemia (WM) have no indications for therapy at initial presentation. The indications for treatment include constitutional symptoms, cytopenias, or less commonly, symptomatic lymphadenopathy or splenomegaly. Other reasons for treatment are hyperviscosity related to the elevated serum IgM and paraneoplastic neuropathy.

Analogous to other indolent B-cell NHLs, rituximab plays a significant role in the therapy of LPL. Single-agent rituximab is indicated for minimally symptomatic patients. Approximately half of patients will have a partial response to single-agent rituximab.¹⁹¹ One can see transient increases in serum IgM levels after rituximab that can cause or exacerbate hyperviscosity.

Chemoimmunotherapy has largely replaced single agents for the treatment of LPL. Commonly used regimens include: dexamethasone, rituximab, cyclophosphamide (DRC)¹⁹²; bortezomib plus rituximab with or without dexamethasone (BRD)¹⁹³; or thalidomide plus rituximab.¹⁹⁴ The latter two have limitations due to neuropathy. For DRC, the overall and complete response rates were 83% and 7%, respectively, and 2-year OS and PFS rates were 81% and 67%, respectively. Bortezomib and rituximab and thalidomide-rituximab have similar response rates. Alkylating agents, including chlorambucil and bendamustine, have RRs in excess of 80%. Purine analogs are active agents; however, stem cell toxicity can be an issue with purine analogs as well as chlorambucil.¹⁹⁵ For recurrent disease, one can often utilize agents that were previously used. For patients with more refractory LPL, the mammalian target of rapamycin (mTOR) inhibitor everolimus, anti-CD52 mAb, and the oral Bruton's tyrosine-kinase inhibitor, ibrutinib, are active. Selected patients with relapsed disease are considered for high-dose therapy with ASCT or alloSCT. The results seen are similar to that of other indolent lymphomas.

There are rare patients who have stage IE disease with this histology (i.e., renal involvement). In this case, modest dose RT (12 to 18 Gy) within the organ tolerance can provide long-term control and, occasionally, a cure.

Marginal Zone Lymphomas

MZLs are indolent NHLs that include three diseases arising from post-GC marginal zone B cells: splenic marginal zone B-cell lymphoma (\pm villous lymphocytes); extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type (MALT-type lymphoma, or MALT lymphoma); and nodal marginal zone B-cell lymphoma.^{196,197}

Nodal MZL

Nodal MZLs constitute less than 1% of all NHLs. These lymphomas are primarily nodal diseases without evidence of extranodal involvement.

Pathology

Within lymph nodes, there are collections of B cells in a parafollicular, perivascular, and perisinusoidal distribution that often bear a monocytoid appearance, having folded nuclear contours and moderate abundant pale cytoplasm. These cells may surround reactive-appearing GCs and mantle zones. A subset of cases is also associated with variable degrees of plasmacytoid differentiation.

Immunophenotype and Genetics

Cells express monoclonal surface immunoglobulin (IgM > IgG > IgA) as well as CD19, CD20, CD79a, and are negative for CD10 and CD23. A minor subset of cases may be CD5 positive. Cases with plasmacytoid differentiation may show monoclonal expression of cytoplasmic kappa or lambda light chain by immunohistochemistry. Such cases may be associated with small monoclonal immunoglobulin spikes, but these are generally under 0.5 g/dL and are not associated with hyperviscosity. A subset of cases expresses surface IgD, analogous to splenic MZL. Immunoglobulin genes are rearranged with evidence of somatic mutation, implying a post-GC origin. There are no known chromosomal abnormalities specific to nodal MZL.

Clinical Features

Over 70% of patients present with stage III/IV disease, and the majority are asymptomatic. Bone marrow involvement is less common (45%) than in most indolent lymphomas. The 5-year survival for patients with nodal MZL is 55% to 79%. Similar to other indolent lymphomas, histologic transformation can occur with nodal MZL.

Treatment

The optimal therapy for patients with nodal MZL is not known. Patients are frequently treated with chemoimmunotherapy, typically either alkylating agents or purine analogs plus rituximab, which produce RRs in excess of 80%. A recent phase III study comparing CHOP-R to BR included 67 patients with MZL not otherwise specified.¹⁰⁶ There was no difference ($p < 0.32$) in median PFS between CHOP-R (47 months) and BR (57 months). For now, patients should be offered either clinical trials or treated with regimens used for FL.

Splenic Marginal Zone Lymphoma (\pm Villous Lymphocytes)

Splenic MZL (\pm villous lymphocytes) constitutes less than 1% of all NHLs, with a median age of 65 to 70 years and uncommon before the age of 50 years.⁶³ It is more common in Caucasians, with no gender predominance. Splenic MZL has been associated with viral infections, specifically hepatitis C and Kaposi's sarcoma-associated herpesvirus (KSHV). In one study, treatment of hepatitis C induced regression of the lymphoma.

Pathology

In splenic MZL, there is an expansion of marginal zones in the spleen. Plasma cell differentiation may be seen in a subset of cases, but as in nodal MZL, monoclonal spikes, if present, are less than 0.5 mg/dL. Bone marrow, lymph nodes, and peripheral blood involvement (referred to as splenic lymphoma with villous or nonvillous lymphocytes) can also be present. Generally, cells have small nuclei, but in the peripheral blood, they typically have abundant cytoplasm with "shaggy" or villous projections.

Immunophenotype and Genetics

Splenic MZL cells express monoclonal surface IgM, IgD, CD19, and CD20. The tumor cells generally lack CD5 and CD10, helping to distinguish this tumor from SLL/CLL, MCL, and FL. They also typically are negative for CD25, CD103, and annexin A1, which helps to distinguish splenic MZL from hairy cell leukemia. Ig genes have evidence for somatic hypermutation in about half the cases. In splenic MZL, trisomy 3 is present in 39% of cases, which is found in other MZLs. Abnormalities of chromosome 7q are also frequently seen. Deep sequencing identified recurrent somatic mutations in genes involved in the NOTCH, NF- κ B, and B-cell receptor pathways, as well as mutations in *TP53*.¹⁹⁸ *NOTCH2* mutations have been reported in 21% to 25% of cases, and were associated with a poor prognosis.

Clinical Features

Patients typically present with splenomegaly, lymphocytosis, and cytopenias, with lymphadenopathy being a much less common feature. B symptoms and elevated LDH are uncommon. Because of marrow and peripheral blood involvement, over 90% of cases have stage IV disease at diagnosis. IgM monoclonal gammopathies and mixed cryoglobulinemia can be seen, especially with a hepatitis C infection. Acquired C1 esterase deficiency seen in many B-cell lymphoproliferative disorders and can be a feature of splenic MZL.¹⁹⁹ The survival of patients is in excess of 70% at 10 years. A prognostic model based on three risk factors—hemoglobin less than 12 g/dL, LDH level greater than normal, and albumin level less than 3.5 g/dL—could identify patients with 5-year cause-specific survivals of 88% for patients with zero risk factors, 73% for patients with one factor, and 50% for patients with two or three factors.²⁰⁰

Therapy

Similar to other indolent NHLs, many patients with splenic MZL do not require immediate therapy. Asymptomatic patients without splenomegaly or cytopenias can be observed. Patients with symptomatic splenomegaly and or significant cytopenias merit treatment. Those uncommon patients who also have hepatitis C may benefit from treatment of the infection, suggesting that tumor growth and survival is promoted by factors or signals elaborated in response to hepatitis C antigens. Splenectomy is reasonable for selected patients with excellent relief of symptoms and cytopenias. Splenectomy was associated with an overall response rate of 85% and an estimated PFS and OS at 5 years of 58% and 77%, respectively. For patients who are not surgical candidates, splenic radiation has some utility. In general, 150 cGy is given to the entire spleen three times per week. The total dose must remain under renal tolerance because the left kidney is almost always in the field. Single-agent rituximab can improve splenomegaly and cytopenias in over 90% of patients.²⁰¹ In a study of induction with weekly rituximab followed by maintenance, the RR was 95%, with OS and PFS at 5 years of 92% and 73%, respectively.²⁰² Other options for therapy at relapse are similar to those used for FL, and include retreatment with rituximab, alkylating agents, and purine analogs in combination with rituximab.

Extranodal Marginal Zone Lymphoma

MALT lymphoma is a subtype of MZL involving extranodal tissues. The most common site is the stomach, but MALT lymphoma has been described in a number of different organs and tissues including the skin, salivary glands, the lung, the small bowel, ocular adnexa, the breasts, the bladder, the thyroid, the dura, and the synovium. It has been associated with a variety of chronic inflammatory and infectious conditions, including autoimmune diseases such as Sjögren's syndrome and Hashimoto's thyroiditis, and infections with *Helicobacter pylori* (*H. pylori*), *Borrelia burgdorferi*

(*B. burgdorferi*), *Chlamydomphila psittaci* (*C. psittaci*), *Campylobacter jejuni* (*C. jejuni*), and hepatitis C virus (HCV).^{203–206} MALT lymphoma behaves indolently and is principally observed until symptoms related to organ impairment become evident; however, in many cases, early stage disease treatment with radiation therapy or antibiotic therapy appears to be curative. There are few dedicated studies of MALT lymphoma outside of early stage disease and much of the management of advanced stage disease is extrapolated from the FL literature, which often includes a small number of MZL patients.

Epidemiology

MALT lymphomas account for approximately 5% to 8% of all NHLs, but represent 50% to 70% of all MZLs.^{63,207} It is the third most common subtype of NHL after DLBCL and FL. The median age at diagnosis is 60 years, with incidence nearly equal in men and women. Two-thirds of patients present with stage I/II disease, with a minority of patients having more advanced disease at diagnosis. B symptoms and bone marrow involvement are rare. MALT lymphomas can transform into a more aggressive lymphoma, but this occurs rarely. The most common transformation is into an activated B-cell-like DLBCL.²⁰⁸ Nearly half of all MALT lymphomas involve the gastric mucosa, where over 60% are associated with an *H. pylori* infection.

Pathology

MALT lymphomas are malignancies of antigen-stimulated B cells, which normally reside in lymph nodes within the marginal zone that is found outside the mantle zones of B-cell follicles.¹⁹⁷ Histologically, they are characterized by a monoclonal infiltrate of small- to medium-sized cells with abundant cytoplasm and irregular nuclear contours. Variable numbers of larger centroblast-like cells may also be present, and a subset of cases exhibit plasmacytic differentiation. An essential pathologic feature is the presence of lymphoepithelial lesions created by the invasion of mucosal glands and crypts by aggregates of lymphoma cells, producing an appearance that resembles the lymphocyte M-cell structures found in normal Peyer patches.

Immunophenotype and Genetics

MALT lymphomas are surface Ig positive, and are also positive for B-cell markers (CD19, CD20, CD79a, and CD22), and negative for CD5, CD10, CD23, and cyclin D1.⁴⁴ Uncommonly, MALT lymphomas are CD5 positive and this is associated with a worse prognosis; these lymphomas may have cytogenetic changes such as trisomy 3 and del7q.²⁰⁹ Distinguishing MALT lymphomas from benign reactive lymphoid infiltrates may be difficult; in this circumstance, light chain restriction by flow cytometry or immunoglobulin heavy chain gene rearrangement studies by PCR can be helpful.

Other cytogenetic abnormalities that have been reported in MALT lymphomas include t(11;18), t(14;18), t(1;14), t(3;14), and trisomy 8. The t(11;18) is the most common; it occurs in 18% to 53% of MALT lymphomas of any site and is associated with a low-grade histology.^{210,211} It produces the fusion of the apoptosis inhibitor 2 (*API2*) gene and the *MALT1* gene. The resulting fusion gene encodes a chimeric protein that stimulates the activation of NF- κ B, a transcription factor that turns on a number of genes that promote proliferation and inhibit apoptosis.²¹² The t(11;18) translocation predicts for a poor response to *H. pylori*-directed therapies in gastric MALT lymphoma.²¹³ A substantial proportion of malignant B cells in MALT lymphomas express B-cell receptors with strong homology to rheumatoid factors, and this appears to be mutually exclusive with the presence of the t(11;18) translocation.²¹⁴ This suggests that t(11;18)-negative MALT lymphomas are driven by the stimulation of high-affinity B-cell receptors by antibody-antigen immune complexes and activated T cells, whereas

t(11;18)-positive MALT lymphomas are not dependent on B-cell receptor signaling, but instead are driven by constitutive activation of NF- κ B. The t(14;18), which pairs the *MALT1* gene with the IgH gene and drives overexpression of MALT1 protein, is more common in nongastric MALT lymphomas.²¹⁵ The t(1;14), which results in the overexpression of BCL10, is rarer overall but more frequent in gastric and pulmonary MALT lymphomas. The t(3;14) translocation is present in 10% of thyroid, ocular adnexal, and cutaneous MALT lymphomas.²¹⁶ This translocation involves the IgH and *FOXP1* genes and drives overexpression of the FOXP1 transcription factor. Of note, overexpression of MALT1, BCL10, and FOXP1 are all believed to result in NF- κ B hyperactivation, making this a common feature of genetically diverse MALT lymphomas. MALT lymphomas are also more often associated with gains at chromosomes 3p, 6p, and 18p, and del(6q23) than the other subtypes of MZL.²¹⁷

Clinical Presentation

The clinical presentation of MALT lymphoma depends in large part on the site of disease. Gastric and intestinal MALT lymphomas may present with symptoms of dyspepsia and abdominal pain, sometimes with signs and symptoms of bowel obstruction, but rarely with bleeding. These lymphomas are diagnosed on endoscopy with biopsies from multiple areas of endoscopically abnormal tissue as well as random sampling of macroscopically uninvolved mucosa. Involvement of the salivary and lacrimal glands, on the other hand, can result in Sjögren's-like syndromes of dry eyes and mouth. MALT lymphomas involving the ocular adnexa typically present with painless conjunctival injection and photophobia, resembling allergic conjunctivitis. Patients with bronchus-associated lymphoid tissue (BALT) lymphomas typically are older men and can have symptoms including cough, fever, and/or weight loss.²¹⁸ Other sites of disease often present with an obstructing mass. Some patients are diagnosed incidentally, either because of imaging studies or an exam of the eye or GI track done for another reason or as part of an evaluation for a monoclonal gammopathy, which is present in approximately 25% to 35% of MALT lymphoma patients; this feature is generally associated with plasmacytoid differentiation.²¹⁹ B symptoms are rare in this disease.⁶³ Bone marrow involvement is present in a minority of patients; therefore, cytopenias are rare, as is disease in the peripheral blood.

In addition to the blood tests that are standard for patients with NHL at diagnosis, patients with MALT lymphomas should have a few additional tests. HCV testing should be performed given its association with MALT lymphoma; an HIV virus test is advised. Additional laboratory studies to consider include a β_2 -microglobulin, serum protein electrophoresis and immunofixation, and serum light chains. Staging is done with CT scans of the chest, abdomen, and pelvis, as well as imaging of the neck, including the parotids and salivary glands, and orbits with CT or MRI. A bone marrow biopsy should be considered for patients with multifocal disease, and an evaluation of the gastric mucosa is reasonable for all patients with nongastric MALT lymphoma given the documented high rate of gastric involvement in these patients.²²⁰

Treatment

Management of MALT lymphoma depends both on stage and site of disease. As an indolent lymphoma with a long OS, close observation at diagnosis until the development of signs, symptoms, or organ function impairment as a result of the disease is appropriate for patients with advanced stage disease. An exception is patients with advanced stage MALT lymphoma and concomitant HCV infection; a trial of anti-HCV antiviral therapy in these patients may result in regression of their lymphoma. For patients with early stage and localized disease, however, treatment with radiation therapy or treatment with antibiotics, such as for *H. pylori*-positive gastric MALT lymphoma, has been associated with high RRs and durable responses, many of which may represent cures.

Treatment of symptomatic or organ impairing relapsed, refractory, or advanced stage disease is similar to approaches used in FL with chemotherapy, immunotherapy, or chemoimmunotherapy.

Gastric MALT lymphoma represents a paradigm for treating early stage, localized MALT lymphomas. For those associated with an *H. pylori* infection that do not harbor a t(11;18) translocation, eradication of *H. pylori* is effective treatment and results in good long-term disease control and OS.^{221–223} In patients with *H. pylori*-negative lymphomas, MALT lymphomas with a t(11;18) translocation, or lymphomas that fail to respond to *H. pylori* therapy, RT is the preferred treatment modality.²²⁴ Chemotherapy, immunotherapy, or chemoimmunotherapy is active in this disease but is generally reserved for patients with relapsed or refractory disease to antibiotic therapy or RT, or patients with more advanced stage or aggressive disease.^{225,226} Similarly, MALT lymphoma of the ocular adnexa is primarily treated with RT.²²⁷ However, given the association described by some groups between *C. psittaci* infection and MALT lymphoma in this area, antibiotic therapy with doxycycline has been studied.²²⁸ The RR of single-agent doxycycline for MALT lymphoma of the ocular adnexa was 83%, with two-thirds of patients having partial responses. The 2-year PFS was 55%.

For relapsed or refractory disease or disease that is more extensive at presentation, agents that have been used and reported include single-agent therapy with alkylating agents such as chlorambucil or cyclophosphamide, purine analogs such as cladribine, bortezomib, and rituximab, and occasionally, multiagent anthracycline-based chemotherapy for younger patients with more aggressive disease. The use of single-agent, continuous, low-dose oral chlorambucil or cyclophosphamide in patients with early or advanced stage disease yielded CR rates of 75% and a relapse rate of 21% during the 8 year follow-up.²²⁹ Single-agent rituximab in patients with stage I through IV MALT lymphoma (15 gastric, 10 nongastric) who were either chemotherapy naïve or who had progressed following chemotherapy resulted in an overall response rate of 73% and was better for chemotherapy-naïve patients than for previously treated patients (87% versus 45%).²²⁵ Duration of response was short, however, with 36% of responders progressing at a median of 10.5 months. Combination chemoimmunotherapy with rituximab and fludarabine results in response rates of 85% to 100% and 2- to 3-year PFS of 80% to 100% at the expense, however, of significantly greater toxicity.²³⁰ MALT lymphoma is extremely sensitive to radiation therapy, and this modality has a role in the palliation of patients with advanced disease.

Mantle Cell Lymphoma

MCL is a malignancy of monomorphic small- to medium-sized B cells with the characteristic t(11;14) leading to overexpression of the cyclin D1 cell cycle regulator in the majority of cases.

Pathology

MCLs are neoplastic counterparts of naïve “mantle zone” B cells. Morphologically, MCL can have either diffuse architecture, or a vaguely nodular appearance, occasionally growing predominantly in expanded mantle zones around reactive GCs. Cytologically, in most cases, the neoplastic cells are small- to medium-sized and have irregular nuclei and scant cytoplasm. Some cases of MCL have a predominance of intermediate-size cells with more open “blastic” chromatin; such blastic variants are associated with a high mitotic rate. Other cases are comprised of a spectrum of cells, including large cells (pleomorphic variant).

Immunophenotype and Genetics

MCLs express B-cell antigens, surface IgM (usually together with surface IgD), CD5, and CD43 and usually lack CD10 and CD23. Overexpression of cyclin D1 further distinguishes these tumors from most other entities. IgH variable gene segments lack

a somatic mutation in 84% of cases (pre-GC), with the remainder being mutated.²³¹ By FISH, greater than 90% of MCLs have the t(11;14) associated with the rearrangement of the cyclin D1 gene (*CCND1*). The remaining cases do not overexpress cyclin D1, but instead usually overexpress cyclin D2, cyclin D3, or cyclin E due to the presence of translocations involving these genes and the IgH locus.²³² Cyclin D1-negative cases are similar clinically to cyclin D1-positive cases²³³ and have a similar gene expression profile. Deep sequencing²³⁴ has identified *NOTCH1* mutations in a minority of cases, which may be associated with a poor prognosis. *SOX11* overexpression is also associated with a worse prognosis.^{232,235}

Clinical Features. MCL constitutes about 7% of all NHLs. About 75% of patients are males, with a median age of 63 years. Approximately 70% of patients have stage IV disease, and B symptoms are observed in approximately one-third of patients. Typical sites of involvement are the lymph nodes, the spleen, the liver, Waldeyer's ring, and bone marrow. Peripheral blood involvement is present in 25% to 50% of patients at presentation. MCL can involve any region of the GI tract (88% lower tract, 43% upper tract by endoscopy), occasionally presenting as multiple intestinal polyps.²³⁶ CNS involvement is rare and is usually associated with a leukemic phase.

The median survival of patients with MCL is 4 to 5 years and improving. Approximately 10% to 15% of patients have a disease with a more indolent disease, with minimal lymphadenopathy, mild splenomegaly, and a proliferation index measured by Ki-67 staining of around 10%.²³⁷ These patients have a disease that behaves more like an indolent NHL, where a *watchful waiting* approach does not compromise response to therapy or survival. In contrast, patients with the blastic variant at diagnosis have a median survival of 18 months. Blastic transformation occurs in 35% of patients, with a risk of 42% at 4 years, and once occurring, the median survival is 3.8 months.²³⁸

Prognostic models have been employed for patients with MCL. The IPI developed for diffuse aggressive NHLs provides stratification of patients. Attempts to improve on the IPI include the mantle cell lymphoma International Prognostic Index (MIPI), which includes age, performance status (PS), LDH, and white blood cell count (WBC)⁵⁸ as prognostic factors, and several reports show that the MIPI is better than the IPI at stratifying patients.²³⁹ The proliferation index alone and also when incorporated into the MIPI provides additional predictive power.²⁴⁰ Gene expression profiling has been examined in MCL patients. In those studies, the proliferation signature and high expression of cyclin D1 were associated with an unfavorable prognosis.²⁴¹ Mutations and deletions of p53 are also associated with a worse prognosis.²⁴²

Treatment. The majority of patients with MCL have a disseminated disease requiring treatment. An indolent behaving disease is seen in 10% to 15% of patients, where a delay of initiation of treatment was not deleterious.²⁴¹ The treatment of MCL historically involved single alkylating agents as well as combination chemotherapy (CVP, CHOP) to which 30% to 50% of patients had a CR, with a median duration of 1 to 3 years.²⁴³ In a meta-analysis, single alkylating agents offered results similar to combination chemotherapy.²⁴⁴ A small number of patients with MCL will present with stage I to II disease. These patients are potentially curable with combined chemotherapy and involved field radiation (30 Gy). Chemoimmunotherapy has shown a significant impact in the treatment of MCL. A meta analysis of 638 patients with MCL showed that rituximab-containing regimens significantly increased median survival (37 versus 27 months)²⁴⁵ as compared to chemotherapy alone. One of the mainstays of chemoimmunotherapy for the initial treatment of MCL is CHOP-R. However, results of a randomized trial comparing CHOP-R to BR reported superior PFS with BR with less toxicity.¹⁰⁶ In patients with a median age of 70 years, the median PFS for BR was 35 months, compared to 22 months with

CHOP-R. One other randomized study compared CHOP-R to the fludarabine, cyclophosphamide, rituximab (FCR) regimen. In that study, for patients over age 60 years, CHOP-R and FCR had similar CR rates, but CHOP-R had less toxicity, and the OS at 4 years was 62% versus 47% in favor of CHOP-R.²⁴⁶ This study included a second randomization of maintenance with interferon- α or rituximab until progression. For the patients who received CHOP-R, a significant survival benefit from maintenance rituximab was observed, with an estimated 4-year OS rate of 87% versus 63%.

More aggressive approaches for the initial treatment of MCL have been the rituximab, hyperfractionated cyclophosphamide, vincristine, doxorubicin, dexamethasone (R-HyperCVAD) regimen or the consolidation of first remission following chemoimmunotherapy with high-dose therapy and ASCT. The most recent update from the M.D. Anderson Cancer Center of R-HyperCVAD reported a median OS not reached at 8 years, and a median time to failure of 4.6 years.²⁴⁷ A multi-institution SWOG phase 2 trial of R-HyperCVAD reported median PFS and OS of 4.8 and 6.8 years, respectively. However, 39% of patients were unable to complete the planned treatment.²⁴⁸ A similar issue was found in a report from academic centers in Italy, where, despite excellent disease control with R-HyperCVAD, with OS and FFS of 86% and 61%, respectively, 63% of patients were unable to complete the planned treatment course with the most common reason being treatment-related toxicity.²⁴⁹ There has been only one randomized trial comparing ASCT to conventional therapy, and this was in the pre-rituximab era. Autologous transplant for patients younger than 65 years, in first CR or PR, demonstrated improvements in PFS as compared to interferon- α maintenance, but a nonstatistically significant improvement in OS.²⁵⁰ Many phase 2 studies have intensified the induction therapy prior to ASCT in an attempt to improve outcomes. The Nordic regimen (CHOP-R + high-dose cytarabine [HiDAC] and ASCT for mantle cell lymphoma)²⁵¹ has yielded excellent results, with median OS and response duration longer than 10 years, and a median event-free survival (EFS) of 7.4 years. An analysis of outcome by MIPI score found that, at 10 years, 70% of patients with low-intermediate MIPI-B were alive, but only 23% of the patients were still alive with high MIPI-B.

The majority of patients with MCL relapse from primary therapy. Three agents are U.S. Food and Drug Administration (FDA) approved for relapsed MCL: bortezomib, lenalidomide, and ibrutinib. Bortezomib has a 29% overall RR, and a 5% CR/Cru with a median duration of 7 months.²⁵² Lenalidomide is FDA approved for bortezomib failures, with a 26% RR (CR, 7%), and a median duration of response of 17 months.^{253,254} Ibrutinib has a 68% RR, with a 21% CR, and a median duration of 17.5 months.²⁵⁵ Another oral kinase inhibitor targeting CDK4/6 is under investigation for relapsed patients.²⁵⁶ Conventional chemotherapy agents, including purine analogs and bendamustine, are active in relapsed patients.¹³⁵ For patients with localized progression, local RT can provide reasonable palliation.²⁵⁷ MCL is one of the most sensitive tumors to RT, and modest doses of radiation (20 Gy) can shrink even large masses and, therefore, should be considered in chemorefractory patients.

SCT for relapsed MCL patients has been of limited benefit. With long follow-ups, patients undergoing ASCT have a high relapse rate.²⁵⁸ There is interest in nonmyeloablative alloSCT for select patients with relapsed disease. The 3-year PFS and OS are 30% and 40%, respectively.²⁵⁹ Given the poor prognosis for patients with relapsed MCL, clinical trials should be explored for these patients.

Diffuse Large B-Cell Lymphoma

DLBCL constitutes 31% of all NHLs, and is the most common histologic subtype. Although, in the past, DLBCL was considered one disease, in the 2008 WHO classification, DLBCL is recognized to encompass many entities (see Table 103.4). Caucasian Americans

have a higher incidence of DLBCL than African Americans, Asian Americans, and Native or Alaskan Native Americans. There is a slight male predominance, and the median age is 64 years. There is a familial component in some cases, with about a 3.5-fold increased risk in relatives of probands with DLBCL. Patients with congenital or acquired immunodeficiency, patients on immunosuppression, and patients with autoimmune disorders have a higher risk of developing DLBCL, often EBV related. This implicated immune dysfunction is a risk factor for the disease. DLBCL can arise as a histologic transformation from any indolent B-cell NHL or CLL.

Pathology

DLBCLs consist of a diffuse proliferation of large cells that have a high mitotic rate. The only unifying feature is the large size of the tumor cells, which may have centroblastic, immunoblastic, plasmablastic, or anaplastic morphologies. In a subset of cases, classified as T-cell/histiocyte-rich large B-cell lymphoma, there are only scattered large tumor cells in a background of abundant small T cells and epithelioid histiocytes.²⁶⁰

Immunophenotype and Genetics

The normal cellular counterparts for DLBCL are GC and post-GC activated B cells. Tumor cells generally express B-cell antigens (CD19, CD20, CD79a), monoclonal IgM, and occasionally, other heavy chain isotypes. CD5-positive cases are uncommon and may have a worse prognosis.²⁶¹ CD10 and BCL6 expression typifies tumors of GC origin (GCB), whereas expression of MUM1 favors a non-GC, activated B-cell type origin (ABC). Of DLBCLs, 25% to 80% are reported to express BCL2, whereas approximately 70% express BCL6.^{44,262} CD30 positivity (14% of cases) is associated with better survival.²⁶³

Several chromosomal abnormalities have been observed in DLBCL. Rearrangements of BCL6 are found in a small proportion of FLs (6% to 13%), but occur in about 30% of DLBCLs.²⁶⁴ Many different BCL6 translocations have been described, all of which replace the BCL6 promoter with the promoter of another gene that is highly expressed in GC B cells, thus driving the overexpression of BCL6. Other tumors have point mutations in the BCL6 promoter that prevent BCL6 (a transcriptional repressor) from negatively regulating its own expression.²⁶⁵ BCL6 overexpression leads to increased proliferation and survival of GC B cells, and also blocks differentiation into plasma cells by interfering with the activity of the transcription factor PRDM1 (also known as BLIMP1).²⁶⁶ Another 20% to 30% of DLBCLs are associated with the t(14;18). Surprisingly, the t(14;18) is not always associated with BCL2 protein overexpression by immunohistochemistry.²⁶⁷ Ig genes consistently show somatic mutations in the Ig variable region genes.²⁶⁸ By GEP, the GCB type is often associated with the t(14;18) and amplifications of the REL oncogene on chromosome 2. In contrast, the ABC type is associated with a loss of 6q21 and trisomy 3, gains of 3q and 18q21-22, and mutations of EZH2.^{269,270} The involved area on 6q includes PRDM1 (BLIMP1), reinforcing the idea that PRDM1, a master regulator of plasma cell differentiation, functions as a tumor suppressor in B cells.²⁷¹ ABC cases also have a high level activation of NF- κ B, a transcription factor implicated in the B-cell receptor signaling pathway that supports B-cell proliferation and survival.²⁷² Recently, there has been great interest in the clinical implications of MYC rearrangements and overexpression in DLBCL. MYC is rearranged in 10% of DLBCLs, with the partner gene being one of the Ig genes in 60% of cases and some other gene in 40% of cases. Approximately 20% of MYC-rearranged cases have concurrent BCL2 or BCL6 rearrangements, a combination referred to as *double hit lymphoma*.²⁷³ Amplification and/or overexpression of MYC independent of rearrangements or amplification has also been described and is also associated with a poor prognosis.^{274,275} Deep sequencing of DLBCL samples have found extensive mutations, especially in the same

histone-modifying genes implicated in FL—the histone acetyltransferases EP300 and CREBP and the histone methyltransferase MLL2. Thus, like FL, epigenetic changes are likely to have a central pathogenic role in DLBCL.²⁷⁶

Clinical Features

Patients have a median of age 64 years, although younger in African Americans versus Caucasians.²⁷⁷ Patients present with rapidly enlarging masses, either nodal enlargement or extranodal disease. DLBCL presents as stage I or IE disease approximately 20% of the time. The disease is confined to one side of the diaphragm (stage I or II) in approximately 30% to 40% of patients. Stage IV disease is seen in approximately 40% of patients. B symptoms occur in 30% of patients, and serum LDH is elevated in over half the patients. Extranodal sites are common, occurring in 40% of cases, including the GI tract, the testis,²⁷⁸ the bone, the thyroid, the skin, the CNS, and bone marrow. DLBCL is highly invasive, with local compression of blood vessels, airways, involvement of peripheral nerves, and destruction of bone. Bone marrow involvement initially is found in only 10% to 20% of patients and has a strong correlation with the risk of spread to the CNS.²⁷⁹ Other sites of extranodal disease, specifically testicular, paranasal sinus, epidural, and the presence of multiple extranodal sites, are other risks for CNS dissemination.

Therapy of Early Stage Diffuse Large B-Cell Lymphoma

Less than 20% of patients with DLBCL have localized disease. The recommended treatment for localized disease outside of clinical trials is abbreviated, combination chemoimmunotherapy plus involved field radiotherapy, or combination chemoimmunotherapy alone. The benefit of adding radiotherapy to 6 to 8 cycles of chemotherapy remains unclear. The SWOG randomized trial from the pre-rituximab era in patients with localized diffuse aggressive lymphoma compared eight cycles of CHOP to three cycles of CHOP plus involved field radiotherapy.²⁸⁰ Patients treated with three cycles of CHOP plus radiotherapy had a significantly better 5-year PFS and OS than patients treated with eight cycles of CHOP (77% versus 64% for PFS, 82% versus 72% for OS). Overall life-threatening toxicity and cardiac toxicity were significantly higher in the patients receiving CHOP alone. The benefit of attenuated chemotherapy was largely found in patients over the age of 60 years. Although there is no analogous randomized trial that includes rituximab, there is a phase II trial of patients with early stage DLBCL employing three cycles of CHOP-R followed by involved field RT.²⁸¹ Patients had at least one adverse risk factor for early stage disease specifically: age >60 years, increased serum LDH, stage II disease, or performance status \geq 1. The PFS and OS at 2 and 4 years was 93% and 88%, and 95% and 92%, respectively.

In the pre-rituximab era, another randomized trial compared eight courses of CHOP with or without involved field radiotherapy in patients with previously untreated bulky or extranodal stage I or stage II diffuse aggressive NHL. The disease-free survival was greater for CR patients who received radiotherapy (73% versus 56%), although 10-year OS was similar in the two treatment arms (68% versus 65%).²⁸² The role of RT remains uncertain in patients with stage I or II disease. In patients aged 60 years or younger with low-risk disease, an aggressive regimen (rituximab, doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone [ACVBP]) was superior to CHOP plus radiation.²⁸³ Similarly, in patients over age 60 years, the addition of RT did not improve DFS or OS for patients who received four cycles of CHOP alone.²⁸⁴ A phase III study in patients age 60 years or under with IPI score of 0 or 1 compared six cycles of CHOP to CHOP-R, with all patients with bulk disease (masses greater than 7.5 cm) or extranodal sites receiving involved field radiation. If one looks at the patients with an IPI score of 0 with no bulk, which includes early stage patients, the 5-year EFS is approximately 90% with CHOP-R

alone. This supports the notion that chemoimmunotherapy alone is a reasonable option for early stage disease. However, in patients with bulk disease often defined as masses greater than 7.5 cm, the outcome is worse than for patients without bulk. In the randomized MabThera International Trial (MInT) trial of CHOP versus CHOP-R, all patients (IPI 0 or IPI 1) with masses >7.5 cm received 30 to 40 Gy of involved field radiation to those sites. Those patients with IPI of 0 and bulk disease had a 10% to 15% lower PFS than patients without bulk.²⁸⁵ A randomized trial of a similar patient population is examining whether involved field radiation impacts outcomes for patients with bulk disease or extranodal disease (the UNFOLDER trial). Early data in this trial suggests a benefit for RT after chemotherapy. Presently, the most appropriate management of patients with early stage DLBCL with bulk disease remains controversial.

Therapy of Advanced Stage Diffuse Large B-Cell Lymphoma

If a clinical trial is not available, the current recommendation for the treatment of advanced stage DLBCL is combination chemotherapy with CHOP-R for patients both under age 60 years as well as over age 60 years. Questions that have been addressed in trials has been the number of cycles, the interval for those cycles, and whether more intensive therapy including high-dose therapy and stem cell support has a significant impact on outcome.

In patients with DLBCL ages 60 to 80 years, the Groupe d'Etude des Lymphomes de l'Adulte (GELA) group reported that eight cycles of CHOP-R was superior to CHOP alone in terms of PFS, disease-free survival (DFS), and OS with no added toxicity.^{286,287} A U.S. Intergroup study compared in a similar population administering CHOP or CHOP-R given on a different schedule.²⁸⁸ Responding patients were randomly assigned to receive either rituximab maintenance therapy or no maintenance. A beneficial impact of rituximab added to CHOP chemotherapy on EFS and OS was observed; however, no benefit was seen for maintenance rituximab following CHOP-R induction. Similarly, in patients less than 60 years of age, with an IPI of 0 and 1, the addition of rituximab to CHOP improved time to treatment failure and OS compared to CHOP alone.²⁸⁵

The number of cycles of therapy has been examined in the rituximab with CHOP over age 60 years (RICOVER-60) trial, in patients over age 60 years. This study compared six to eight cycles of CHOP or CHOP-R administered every 14 days (CHOP-R 14). CHOP-R was superior to CHOP given for six or eight cycles (70% versus 57%), and there was no benefit of eight cycles of CHOP-R over six cycles (with two additional doses of rituximab).²⁸⁹ In another study, CHOP-R given every 21 days (CHOP-R 21) for eight cycles was compared to six cycles of CHOP-R 14.²⁹⁰ More grade III/IV neutropenia was seen in the CHOP-R 21 (57%/31%) treated patients, whereas more thrombocytopenia occurred in the CHOP-R 14-treated patients. With a median follow-up of 40 months, there was no difference in PFS or OS. Another study from the GELA trial did not find an improvement in outcome with CHOP-R 14. This supports the notion that CHOP-R 21 for six to eight cycles is the standard of care.

Attempts to intensify therapy have included alternative regimens and ASCT. The GELA group treated patients under age 60 years with IPI of 1 with the more aggressive regimen R-ACVBP followed by consolidation with methotrexate and leucovorin.²⁹¹ When compared to CHOP-R plus intrathecal methotrexate, R-ACVBP plus methotrexate and leucovorin led to higher PFS and OS. Several studies have examined the role of high-dose therapy and ASCT in first CR/PR for patients with aggressive NHL prior to the addition of rituximab to combination chemotherapy. In the pre-rituximab era, the overall benefit of ASCT in first remission for patients with DLBCL remains uncertain despite many randomized trials. A meta-analysis of 3,079 patients treated on 15 randomized trials with either conventional therapy or ASCT

in first CR, showed no difference in EFS, OS, or treatment-related mortality.²⁹² Two recent studies in the rituximab era have not resolved this issue of ASCT in first CR. R-CHOEP (rituximab, cyclophosphamide, adriamycin, vincristine, etoposide, and prednisone) was compared to R-MegaCHOEP, sequential high-dose therapy with stem cell support, for high-intermediate or high-risk age adjusted IPI score patients. There was more hematologic toxicity with R-MegaCHOEP. With a median follow-up of 42 months, no statistical difference was seen in 3-year EFS (70% versus 61%) or OS (74% versus 70%).²⁹³ More recently, a US intergroup trial treated patients with age-adjusted high-intermediate and high-risk IPI scores with at least a PR after five cycles of CHOP-based therapy (CHOP or CHOP-R), to a total of six cycles of CHOP-based therapy followed by ASCT versus a total of eight cycles of CHOP-based therapy alone.²⁹⁴ Patients who relapsed after chemotherapy alone could undergo ASCT as salvage therapy. After a median follow-up of 6.3 years, ASCT was associated with a higher PFS at 2 years (69 versus 55%; hazard ratio [HR] 1.72; 95% confidence interval [CI], 0.82 to 1.94) but no difference in OS (74 versus 71%; HR 1.26; 95% CI, 0.82 to 1.94). To date, the data do not support ASCT as a consolidation for first remission.

Treatment of Relapsed or Refractory Diffuse Large B-Cell Lymphoma

The majority of relapses from CHOP-R therapy are seen within the first 2 years after the completion of treatment. However, 18% of relapses occur greater than 5 years after the initial treatment.²⁹⁵ The failure of primary therapy to induce a CR or early relapse within the first few months of completing treatment is associated with a particularly poor prognosis. We generally recommend that patients who relapse after a CR be rebiopsied, because a subset will have FL.

Once relapse or refractory disease has been determined, the next issue to resolve is whether the goal is potential curative therapy or palliation. For patients with poor performance status, particularly elderly patients, the goal is often palliation. Local radiation can provide transient palliation. Other chemotherapy agents, including single agents such as cytarabine²⁹⁶ or bendamustine,²⁹⁷ are associated with overall RRs of 50% to 63%, a CR rate of 37%, and a median PFS of approximately 6 months.²⁹⁸ The all oral-agent regimen PEPC (prednisone, etoposide, cyclophosphamide, and procarbazine) can induce remission in over 50% of patients.²⁹⁹ Clinical trials may be an option for some of these patients depending on eligibility criteria.

The majority of patients with relapsed and refractory DLBCL receive combination chemotherapy, often with rituximab. Various combinations of drugs, including ifosfamide, carboplatin, etoposide, cytarabine, gemcitabine, and cisplatin, have been utilized for relapsed disease. The goal is to identify patients with chemosensitive disease who have the greatest likelihood of benefiting from high-dose therapy and ASCT, which leads to a higher long-term DFS and OS for relapsed DLBCL. A major question has been whether one second-line regimen is superior. The collaborative trial in relapsed aggressive lymphoma (CORAL) study compared R-ICE (rituximab, ifosfamide, carboplatin, and etoposide) to R-DHAP (rituximab, dexamethasone, high-dose cytarabine, and cisplatin), followed by ASCT.^{300,301} No difference in overall RR, EFS, or OS was seen between the two regimens, with approximately 60% of patients responding. A subset analysis suggested that patients with a GCB DLBCL may have a better treatment outcome with R-DHAP versus R-ICE. The ultimate goal of salvage therapy is to achieve disease control to proceed to ASCT. It has been known since 1987 that disease sensitivity is the best determinant of outcome with high-dose therapy and ASCT. Three patient groups were identified based on the response to most recent treatment. Patients with chemosensitive disease have 30% to 50% long-term DFS, those with chemorefractory disease have 10% to 15% long-term DFS and those with primary refractory disease have essentially no benefit from ASCT.³⁰² A major question was whether patients with chemosensitive disease benefit

from ASCT or simply continuing salvage chemotherapy. The Parma study addressed this question, where 109 patients who had relapsed after having achieved a CR and responded to two cycles of DHAP were randomized to high-dose therapy and ASCT or four additional cycles of DHAP. ASCT was associated with a superior failure-free survival (51% versus 12% at 5 years) and OS (53% versus 32% at 5 years).³⁰³ In the rituximab era, the long-term results of ASCT are less favorable than reported in the Parma trial, with about 30% long-term survivors in remission. Investigators have, to date, failed to improve on these results with the addition of maintenance therapy posttransplant with rituximab,³⁰⁴ an anti-CD19 immunotoxin, or the oral kinase inhibitor enzastaurin, or adding radioimmunotherapy to the conditioning regimen. For patients with relapsed or refractory DLBCL, high-dose therapy and ASCT remain the treatments of choice for patients with chemosensitive disease. If the recurrence is localized, adjuvant RT either before or after high-dose therapy and ASCT may be beneficial. For patients with chemorefractory disease, clinical trials or palliative therapy should be considered. Several new agents have shown some promise in patients with relapsed DLBCL, including ibrutinib, particularly in the ABC cell of origin subtype, lenalidomide,²⁵³ and everolimus.³⁰⁵

Allogeneic bone marrow transplantation is generally not the favored approach for relapsed DLBCL patients. Although highly selected patients can have prolonged remission, this is at the expense of a high treatment-related mortality. Overall, there is no advantage for alloSCT. Patients with recurrent disease following ASCT who have good performance status and chemosensitive disease are now considered for alloSCT usually with reduced intensity conditioning, rather than ablative alloSCT where morbidity and mortality are exceedingly high. Studies have reported a 40% to 60% year PFS with this approach, but with a treatment-related mortality of 20% for RIC alloSCT and up to 40% for myeloablative transplants.^{306,307}

Chimeric antigen receptor T (CAR-T) cells are another investigational immunotherapy approach to treating malignancies that have had some early success in CLL and B-cell acute lymphoblastic leukemia.³⁰⁸⁻³¹⁰ This strategy uses T cells collected from a patient that are genetically modified to express a receptor that will bind to a surface antigen expressed on the patient's own tumor cells. In the case of B-cell malignancies, this antigen has been CD19. After infusion, autologous CAR-T cells home to sites of disease and also persist over time. The CARs consist of an extracellular antigen recognition domain (typically a single chain Fv variable fragment from a monoclonal antibody) linked via a transmembrane domain to an intracellular signaling domain (usually the CD3 ζ endodomain), resulting in the redirection of T-cell specificity toward target antigen-positive cells, and one or more costimulatory domains including CD28, 4-1BB, or OX40 to enhance cytokine secretion and effector cell expansion, and prevent activation-induced apoptosis and immune suppression by tumor-related metabolites.³¹¹ Eight patients with DLBCL and/or primary mediastinal large B-cell lymphoma (PMLBCL) who have been treated with anti-CD19 CAR-T cells have been reported.³¹² Five of these patients had a CR (2) or PR (3) that persisted for up to 19 months following therapy.

Other Large B-Cell Lymphomas

Intravascular Large B-Cell Lymphoma

Intravascular large B-cell lymphoma (ILCL) is a rare subtype in which lymphoma cells proliferate within small blood vessels without producing a tumor mass or detectable circulating tumor cells.³¹³⁻³¹⁵ The tumor cells resemble centroblasts or immunoblasts, express B-cell-associated antigens, and are usually CD10 negative and MUM1 positive. Patients present with a variety of symptoms caused by the occlusion of small vessels. These include B symptoms, rapidly progressive neurologic signs (dementia, cerebral vascular accident, and/or peripheral neuropathy), and skin lesions imitating an inflammatory rash. Western and Asian subtypes have

been identified, with less frequent CNS and skin involvement in the former. Laboratory abnormalities include elevated serum LDH and anemia. The diagnosis is made by demonstrating large lymphoma cells within small to medium blood vessels. The diagnosis can be difficult, but if the disease is suspected, a *blind* biopsy of normal-appearing skin can be diagnostic. If this is not informative, a biopsy of other sites of suspected involvement may be necessary. The treatment of patients with ILBL includes both systemic chemoimmunotherapy and therapy for the CNS. Prior to rituximab, the prognosis for these patients was poor, with less than 10% long-term survivors. With an earlier diagnosis and therapy with CHOP-R, the 2-year PFS and OS have been reported to be 56% and 66%, respectively. CNS prophylaxis with either intrathecal or high-dose systemic methotrexate is recommended. Patients with secondary involvement of the brain or spinal cord at diagnosis, depending on the clinical situation, may need intrathecal chemotherapy, systemic high-dose methotrexate, and/or radiation to the sites of involvement.

T-Cell Histiocyte-Rich Large B-Cell Lymphoma

In this uncommon subtype of DLBCL, the majority of the tumor cell mass is comprised of nonneoplastic T cells and/or histiocytes, with malignant B cells making up less than 10% of the cellularity.³¹⁶ The lymphoma cells express CD20 but lack CD5, CD10, and CD138. An IPI of 2 or greater was reported in one series in a majority (77%) of patients, often with spleen, liver, and marrow involvement. The outcome of treatment is controversial, with one large series showing a less favorable prognosis, and a second suggesting a similar outcome to other forms of DLBCL when matched for risk factors.

EBV-Positive DLBCL of the Elderly. EBV-positive DLBCL of the elderly is a provisional entity in the 2008 WHO classification. It is seen in patients greater than age 50 years, without known immunodeficiency or prior lymphoma. In Asian countries, this accounts for 8% to 10% of DLBCL in patients without a known immunodeficiency.^{317,318} It is less common in Western countries. Patients often present with extranodal disease in addition to lymph nodes. Due to older age, frequent extranodal disease, and poor performance status, these patients often have a poor prognosis.

ALK-Positive Large B-Cell Lymphoma. These are rare variants of large B-cell lymphomas that express CD30 and ALK kinase, usually due to a t(2;17) that fuses *ALK* to the clathrin heavy chain 1 gene (*CTLC*). These tumors often have a plasmablastic appearance and have been reported to have a poor prognosis.³¹⁹

Special Situations

Testicular Diffuse Large B-Cell Lymphoma

DLBCL presenting in the testis is the most common malignant tumor in that site in men over 60 years of age, and constitute 1% of all lymphomas.^{278,320} Other less common histologies include BL in children and, rarely, FL. Historically, the long-term results of treatment are worse for these patients than predicted by the IPI. Despite therapy, patients are at risk for relapse systemically, in the CNS, and in the contralateral testis. Therefore, following orchiectomy, patients require systemic therapy, and strong consideration should be given to CNS prophylaxis with either systemic or intrathecal methotrexate, as well as prophylactic radiation to the contralateral testis. Much of the data for treating this condition is from small series without randomized trials to address management issues. A recent international prospective trial of 53 patients with untreated stage I or II primary testicular lymphoma treated with six to eight cycles of CHOP-R 21, four weekly doses of intrathecal methotrexate (12 mg), and RT to the contralateral testis (30 Gy) for all patients and (30 to 36 Gy) to regional nodes for patients with stage II disease.²⁷⁸ With a median follow-up of 65 months, the OS and

PFS at 5 years was 85% and 74%, respectively. Only three relapses were seen in the CNS. This study defines the current standard of care with chemoimmunotherapy, CNS prophylaxis, and radiation to the contralateral testis.

Treatment of the Aggressive Non-Hodgkin's Lymphoma in the Elderly

Lymphoma occurs at a higher incidence with increasing age.³²¹⁻³²³ Patients over age 60 years as shown in the IPI have a lower CR rate, PFS, and OS than patients 60 years of age or less. The reasons are probably a combination of increased treatment-related mortality and comorbidities. Biologically, the disease may also be different in older individuals, which may account, in part, for the higher IPI scores that have been reported in elderly patients. Dose reductions in these patients may also explain the less favorable outcome. The SWOG reported a CR rate of 37% in patients 65 years of age and older who received initial 50% dose reductions of cyclophosphamide and doxorubicin. Complete remission rates were 52%, a rate similar to those of younger patients, when full-dose chemotherapy was used.

Randomized trials have clearly demonstrated a significant survival benefit for the addition of rituximab to combination chemotherapy for DLBCL in patients over age 60 years.^{289,321-323,324} In light of the concerns of increased toxicity of treatment in elderly patients, several regimens have been reported with this in mind. A recent report of 149 patients age 80 years or older, employed reduced doses of cyclophosphamide, adriamycin, and vincristine at about 50% of standard dosing of CHOP-R (R-mini CHOP).³²⁵ Grade 3/4 neutropenia and thrombocytopenia was seen in 39% and 7% of patients, respectively, and 12 toxic deaths were seen. The 2-year OS and PFS were 59% and 47%, respectively. For patients who are not considered candidates for standard-dose or reduced-dose chemoimmunotherapy, regimens such as PEPC or BR³²⁶ can be useful for palliation in elderly patients, with over 50% RRs and a median PFS of over 6 months.

The approach toward elderly patients with aggressive lymphoma should be similar to patients age 60 years or younger, with curative intent. Supportive care measures with hematopoietic growth factors can be considered, albeit controversially, as well as prophylactic antibiotics. Analogous to younger patients, elderly patients should be considered for clinical trials if eligible and feasible.

Primary Mediastinal Large B-Cell Lymphoma

Within the category of DLBCL is a distinct clinical entity known as PMLBCL, representing 2.4% of all NHLs and 7% of all cases of DLBCL.³²⁷

Pathology

Histologically, the large tumor cells often have finer nuclear membranes and smaller nucleoli than other subtypes of DLBCL, sometimes making it difficult to distinguish the tumor cells from reactive macrophages in small biopsies. Not infrequently, a few multinucleated cells reminiscent of Reed-Sternberg variants may be admixed with more typical tumor cells. The tumor cells diffusely infiltrate the mediastinum and often elicit dense fibrosis, another feature that may render biopsies difficult to interpret.

Immunophenotype and Genetics

PMLBCLs express B-cell antigens CD19, CD20, CD22, TRAF1, and c-Rel, but lack slg and CD5.³²³ Unlike other DLBCLs, a low level expression of CD30 is seen in most cases, and a high fraction of tumors expresses TRAF1 and have nuclear REL. *BCL2* and *BCL6* rearrangements are absent. Translocations of the *CIITA* (major histocompatibility complex class II transactivator) gene are noted in about 40% of cases. Copy number gains in the region on chromosome 9p containing the genes for janus kinase 2 (*JAK2*) and programmed cell death ligand 1 and 2 (*PDL1* and *PDL2*) are

common. *PDL1* and *PDL2* are ligands for the programmed cell death receptor 1 (PD-1), which has a role in suppressing T-cell function.²⁶⁹ PMLBCL resembles classical Hodgkin's disease (HD) by GEP,³²⁹ because one-third of the most highly expressed genes in PMLBCLs are also expressed in the Reed-Sternberg cells of HL.

Clinical Features

PMLBCLs have a female predominance, with median age of 40 years. Over 70% of these patients present with stage I/II bulky disease involving the mediastinum, with pleural and pericardial effusions in about 50% of the patients. Superior vena cava syndrome is frequently seen in these patients. An elevated LDH (77%) and B symptoms (47%) are common. Relapses occur locally or in extranodal sites, including the liver, the GI tract, the kidneys, the ovaries, and the CNS.

Treatment

The general approach toward patients with PMLBCL has been similar to patients with localized DLBCL, with the majority of patients receiving combined modality therapy. The most recent results with chemoimmunotherapy demonstrate a 3-year OS of 89% with CHOP-R therapy. In the MInT trial, 87 patients with PMLBCL³³⁰ received six cycles of CHOP-R, 75% of whom also received RT; only 7% of patients who received radiation subsequently progressed or relapsed. A recent study of 51 patients treated with dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin (EPOCH) plus rituximab (DA-EPOCH-R), and no radiotherapy, reported an outstanding PFS (93%) and OS (100%). The two failures received radiation and were rendered disease free.³³¹ These studies suggest that six cycles of CHOP-R followed by RT, or six to eight cycles of DA-EPOCH-R and no RT gives excellent results in PMBCL.

Grey Zone Lymphoma

In 2008, the WHO created provisional diagnoses to capture B-cell lymphomas with features between two established diagnoses: BL and DLBCL, and classical Hodgkin's lymphoma (cHL) and DLBCL.³³² These lymphomas constitute the grey zone lymphomas.

B-Cell Lymphoma, Unclassifiable, with Features Intermediate Between B-Cell Lymphoma and Diffuse Large B-Cell Lymphoma

These lymphomas differ morphologically from DLBCL in that the neoplastic cells often range from intermediate to large in size, may have a very high Ki-67 index, and are uniformly CD10 positive. They differ from BL in that the cells are more variable in size, are often *BCL2* positive, may be *BCL6* negative, and may have a Ki-67 index lower than 100%. Although defined by morphologic features, GEP has, likewise, identified a group of lymphomas with a GEP between that of BL and DLBCL.³³³ This group is not synonymous with B-cell lymphoma, unclassifiable (B-UNC)/BL/DLBCL but the two overlap, suggesting B-UNC/BL/DLBCL is not a unique entity but rather a group of distinct lymphomas, including true BL, DLBCL, and unclassifiable lymphomas, which require further characterization.

Although potentially heterogeneous, these lymphomas carry a poor prognosis and are associated with high IPIs and frequent extranodal sites; this trend may be driven by inclusion of a subset of tumors with a particularly poor prognosis.^{334,335} Although the IPI remains the most powerful prognostic tool we have for DLBCL, certain genetic events are being recognized as indicators of particularly high-risk disease. Most notably, the presence of multiple concurrent chromosomal translocations, commonly involving *MYC* and *BCL2*, defines a group with an extraordinarily poor prognosis.²⁷³ This was first noted in Burkitt-like lymphoma, many of which were B-UNC/BL/DLBCL. No patients with these

double-hit lymphomas were alive at 1 year. In DLBCL, dual translocations are present in 12% to 14% of cases and are similarly associated with a poor prognosis.³³⁶ B-UNC/BL/DLBCL is enriched for these *double-hit* lymphomas, with 30% to 45% harboring both *MYC* and *BCL2* translocations. Although the majority of *double-hit* lymphomas fall into this diagnostic category, not all B-UNC/BL/DLBCLs are *double-hit* lymphomas. *Double-hit* lymphomas with this histology, however, appear to have a particularly poor prognosis, with a median OS of 4 months compared to 3 years in *double-hit* DLBCL with typical morphologic features.³³⁷

Although the prognosis for this group as a whole is poor, there has been no systematic investigation of the treatment of B-UNC/BL/DLBCL, and thus, no prospective evidence supporting the intensification of therapy over CHOP-R. However, three groups have retrospectively looked at the impact of intensified chemotherapy on outcomes for B-UNC/BL/DLBCL.^{343,338} These analyses are limited in that they are retrospective, small, and likely included patients without B-UNC/BL/DLBCL. However, each showed that intensive regimens such as a modified Magrath regimen with cyclophosphamide, vincristine, doxorubicin, methotrexate/ifosfamide, etoposide, cytarabine (CODox-M/IVAC), HyperCVAD, and DA-EPOCH-R had better outcomes over CHOP-R (overall response rate [ORR] 86% versus 57%, 4-year PFS approximately 50% to 65% versus 0% to 30%). Another group retrospectively examined the outcomes following intensive therapy compared with CHOP-R in 53 patients with aggressive B-cell lymphoma with high-grade features with or without an *MYC* translocation.³³⁵ Notably, patients in this study had a lower risk than is typical for B-UNC/BL/DLBCL. Amongst all patients, there was no improvement in OS with intensive regimens (4-year OS of 50% to 60%); this relatively good OS is widely different from previous reports and perhaps reflects the good risk profile of this cohort. However, among patients with an *MYC* translocation, intensive regimens resulted in a significantly longer PFS and a trend toward longer OS over CHOP-R, and, for *double-hit* lymphomas in this category, there was a nonsignificant trend toward a shorter PFS and OS compared with patients with an isolated *MYC* translocation. This suggests that perhaps it is the *double-hit* lymphomas within the category of B-UNC/BL/DLBCL that drives their poor prognosis, and these are patients that might benefit from intensive chemotherapy like modified Magrath or DA-EPOCH-R. Data from patients with *MYC* translocation-positive DLBCL treated with DA-EPOCH-R by the National Cancer Institute phase 2 studies are promising; nine patients (8%) harbored an *MYC* translocation and had a 4-year EFS of 83%.³³⁹ This regimen is currently being explored further in BL and *MYC* translocation-positive DLBCL in a multicenter trial.

At the present time, there is not sufficient evidence to suggest that all patients with B-UNC/BL/DLBCL should be treated with regimens more intense than CHOP-R. This is a heterogeneous group of patients with varied prognoses and natural histories, some of whom may do well with standard CHOP-R. However, for *double-hit* lymphomas, many of which are B-UNC/BL/DLBCL, CHOP-R is insufficient. These patients should be encouraged to participate in clinical trials. In the absence of a trial, intensified regimens of DA-EPOCH-R or modified Magrath, with or without an ASCT or alloSCT, can be considered. Agents that target *BCL2* and an *MYC*-driven protein, aurora A kinase, are currently in development and may prove useful in these lymphomas; these patients should be considered for clinical trials when available.

B-Cell Lymphoma, Unclassifiable, with Features Intermediate Between DLBCL and Classical Hodgkin's Lymphoma

An overlap between the clinical and pathologic features of PMLBCL and cHL has been recognized for some time. Both typically occur in younger female patients, involve contiguous nodal

stations, and on biopsy, demonstrate a variable number of malignant B cells within a fibrotic inflammatory infiltrate. In 2003, two groups explored GEPs of newly diagnosed PMLBCL, DLBCL, and cHL and found that the GEP of PMLBCL more closely resembled cHL than DLBCL.^{329,340} Specifically, PMLBCL had a low expression of genes involved in B-cell receptor signaling but a high expression of genes involved in IL-13 receptor signaling as well as immunomodulatory genes such as *PDL1* and *PDL2*. In addition, both cHL and PMLBCL are associated with amplification of 9p24.1, which contains the genes for *JAK2* and *PDL1*, and this correlated with increased PD-L1 expression.³⁴¹ The recognition of some lymphomas with features intermediate between PMLBCL and cHL, or B-UNC/cHL/DLBCL, further supports the pathologic relationship between these two malignancies.

Among patients with B-UNC/cHL/DLBCL, the majority are men, with presentations in the mediastinum. Histopathologically, one sees pleomorphic tumor cells resembling both the Hodgkin Reed-Sternberg (HRS) cell of cHL and the large, atypical B cell of DLBCL or PMLBCL. These cells appear in sheets, separated by fibrotic stroma with an associated inflammatory infiltrate. Immunohistochemical profiles of the malignant cells demonstrate frequent positivity for CD45, CD20, CD79a, and CD30, but are often CD15 negative; other B-cell markers like PAX5, organic cation transporter 2 (OCT-2), and BOB1 are often positive. Methylation profiling reveals a profile intermediate between that of PMLBCL and cHL, corroborating that it is distinct, perhaps on a continuum between the two.³⁴² Interestingly, patients can have composite lymphomas in which DLBCL and cHL present sequentially; whether these lymphomas relate to B-UNC/cHL/DLBCL is unknown. However, the methylation profiles of both components of a single case of a composite lymphoma were most similar to that of B-UNC/cHL/DLBCL, suggesting that they are related.

The prognosis is notably poorer in B-UNC/cHL/DLBCL than in cHL or PMLBCL.³⁴³ This is partly due to differences in pathobiology, but may also result from not knowing whether to treat with an NHL or a cHL regimen. There are no large prospective studies, but consensus has favored treating like NHL. There are single-arm studies demonstrating good activity of CHOP in HL, making CHOP-R an acceptable first-line therapy.^{344,345} More recently, 16 patients with B-UNC/cHL/DLBCL were treated with DA-EPOCH-R, and 4-year EFS and OS was only 45% and 75%, respectively.³³⁹ This regimen, however, was more effective in PMLBCL, where the 5-year EFS and OS were 93% and 97%, respectively.³³¹ Following combination chemotherapy, the role of involved field radiation therapy (IFRT) in both cHL and PMLBCL is debated. Despite frequently presenting with bulky mediastinal disease, patients with PMLBCL enjoy a favorable prognosis, with a 5-year OS >80% following CHOP-R and 97% following DA-EPOCH-R. Whether to radiate patients who achieve a complete metabolic response following CHOP-R is uncertain, but radiation was omitted in such cases in the DA-EPOCH-R series. The only published randomized trial of radiotherapy for this disease was stopped early due to increased relapses in the non-radiated group at the interim analysis; all patients on this study had a complete response to CHOP-R.³⁴⁶ A large randomized clinical trial is ongoing in Europe to decidedly answer this question. Despite the lack of evidence supporting RT in patients who have a complete response to chemotherapy with B-UNC/cHL/DLBCL, many are referred for radiation given their worse prognosis.

Burkitt's Lymphoma

Burkitt's lymphoma is a rare disease in adults, comprising less than 1% of adult NHLs, whereas BL constitutes 30% of nonendemic pediatric lymphomas.³⁴⁷

Pathology

BL cells resemble the small noncleaved cells within normal GCs of secondary lymphoid follicles. The mitotic rate is high, and

analogous to normal GCs, frequent tingible body macrophages are seen, producing the classical *starry sky* appearance. The fraction of Ki-67 positive (proliferating cells) in BL is typically 99% or greater.⁶⁴

Immunophenotype and Genetics

BL is a tumor of B-lineage derivation identified by the expression of CD19, CD20, sIgM, CD10, and BCL6, but not BCL2.³⁴⁸ Endemic BLs are EBV positive, whereas the majority of non-endemic BLs are EBV negative. BL is associated with a translocation involving *MYC* on chromosome 8q24 in over 95% of the cases. The most common partners are chromosomes 14, 2, or 22, rearrangements that produce fusions of *MYC* with either the *IgH* (80%), kappa (15%), or lambda (5%) light chain genes. The breakpoints in *MYC* and *IgH* differ in endemic versus sporadic BL. *MYC* translocation is absent in <5% of cases, so-called atypical BL.⁴⁴ These cases are otherwise typical of BL, and share a characteristic GEP with cases of BL that are associated with *MYC* rearrangements.^{333,349,350}

Clinical Features

BL is, in general, a pediatric tumor that has three major clinical presentations. The endemic (African) form presents as a jaw or facial bone tumor that spreads to extranodal sites, including the ovary, the testis, the kidney, the breast, and especially to the bone marrow and meninges. The nonendemic form has an abdominal presentation with massive disease, ascites, and renal, testis, and/or ovarian involvement, and, like the endemic form, also spreads to the bone marrow and CNS. Immunodeficiency-related cases more often involve lymph nodes and may present as acute leukemia. BL has a male predominance and is typically seen in patients less than 35 years of age.

Treatment

BL in adults has been similarly treated with regimens designed for pediatric populations. CHOP with intrathecal methotrexate should be considered insufficient treatment. Short, intensive therapy with CNS prophylaxis is the standard approach.^{338,351} The original Magrath regimen (CODOX-M/IVAC) had a 92% 2-year OS.³⁵² Other, more recent series with this regimen in older patients have reported a 2-year OS of 82% for low-risk patients and 70% for high-risk patients.^{353,354} Similar results have been seen with HyperCVAD rituximab-methotrexate-cytarabine.³⁵⁵ A recent study of DA-EPOCH-R for six to eight cycles (two cycles past complete response) reported outstanding results with freedom from progression (FFP) of 95% and OS of 100% at a median follow-up of 86 months.³⁵⁶ There is presently no evidence that first remission autologous transplant is indicated for adult BL.³⁵⁷ The outcome for relapsed patients is dismal, with adults rarely cured with ASCT.³⁵⁸

MATURE T-CELL AND NATURAL KILLER CELL NEOPLASMS

Mycosis Fungoides

For a discussion of mycosis fungoides, see Chapter 104.

Peripheral T-Cell Lymphomas, Not Otherwise Specified

Peripheral T-cell lymphomas (PTCL) includes a number of entities, which constitute 15% of all NHLs in adults.³⁵⁹ PTCL, not otherwise specified (NOS), comprising 6% of all NHLs, is the term used for cases that are not other entities defined in the WHO classification (e.g., ALCL).

Pathology

Features of PTCL, NOS vary widely and lack findings typical of other specific subtypes of PTCL. Lymph nodes are diffusely effaced by atypical lymphoid cells, which may include a spectrum of cell sizes or may be comprised mainly of large cells. The tumor cells may induce some degree of vascular proliferation and may be associated with varied stromal and host cell responses, sometimes including prominent infiltrates composed of eosinophils and/or macrophages. Mitoses, apoptosis, and geographic necrosis may also be seen.

Immunophenotype and Genetics

In contrast to B-cell lymphomas, the pattern of expression of T-cell surface antigens is variable. The normal cellular counterparts of PTCL NOS are mature peripheral T cells. T-cell-associated antigens are expressed (CD3+/-, CD2+/-).³⁶⁰ CD4 is more often more expressed than CD8 and tumors may be CD4-/CD8-. In most cases, one or more "mature" T-cell antigens are lost, such as CD5 or CD7. TCR genes are usually rearranged. The most common translocations are t(7;14), t(11;14), inv(14), and t(14;14)—translocations that involve TCR genes.

Clinical Features

Peripheral T-cell lymphoma NOS³²⁶ are aggressive NHLs, presenting with a median age of 65 years, with 69% of patients having stage III/IV disease. Both nodal and extranodal sites are common, including the skin, the liver, the spleen, and other viscera. B symptoms and pruritus are commonly seen. Laboratory abnormalities, including eosinophilia and hemophagocytic syndrome, are features of PTCL NOS.

Treatment

For PTCL NOS, most studies failed to show any advantage for regimens other than CHOP. A retrospective subset analysis of a phase 3 study in PTCL patients of CHOP versus CHOEP showed a significant improvement in EFS for PTCL patients younger than age 60 years with a normal LDH at diagnosis, but there was no difference in OS.³⁶¹ Various prognostic models for PTCL NOS have evolved, but generally, the IPI provides a reasonable stratification of outcome, with low-risk patients having a 55% 2-year OS and high-risk patients having a less than 15% 2-year OS.³⁶¹ ASCT has been applied to patients with PTCL NOS in first remission with approximately 50% 3- to 5-year PFS and OS. Given the generally unfavorable outcome for patients with PTCL NOS, clinical trials should be considered.

Recurrent disease is associated with very poor prognosis, with the median second PFS and OS after relapse of 4.6 and 6.7 months, respectively.³⁶² Conventional agents such as gemcitabine have limited activity.³⁶³ Several FDA-approved drugs for relapsed PTCL, including the antifolate agent pralatrexate and HDAC inhibitors romidepsin and belinostat, all of which have a 25% to 30% RR with median durations of response of less than 18 months.^{364,365} Nonmyeloablative alloSCT has a role for selected patients with 5-year OS and PFS of 50% and 40%, respectively, and nonrelapsed mortality of 12%.³⁶⁶

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma (AITL) constitutes 4% of all NHLs and about 20% all T-cell NHLs.

Pathology and Genetics

Lymph nodes are diffusely effaced by a polymorphous population of lymphocytes of varying size, shape, and immunoblasts. Stains for CD21, CD23, and CD35 reveal an expanded network of follicular dendritic cells, which often surround tumor cells with moderately abundant clear cytoplasm. The neoplastic cells resemble normal CD4-positive follicular T cells, and in addition to expression of

pan-T-cell markers such as CD3, often express CXCL13, PD-1, CD10, and BCL6. Immunoblasts in the background are often EBV-positive B cells, which expand in this disease and may give rise to secondary EBV-positive B-cell lymphomas. Trisomy 3 and/or 5 may occur.³⁶⁷ Deep sequencing has revealed mutations in about 50% of cases in ten-eleven translocation 2 (*TET2*), an epigenetic modifier previously implicated in myelodysplastic syndromes.³⁶⁸ Around 33% of PCTL NOS were also found to have *TET2* mutations in the same study; many of these tumors had some features reminiscent of AITL, suggesting that there is an overlap between these two disease categories.

Clinical Features

AITL presents in patients with a median age of 62 years. Often, there is acute onset of generalized lymphadenopathy, hepatomegaly, fever, B symptoms, skin rash with a lymphohistiocytic infiltrate, and autoimmune phenomenon, including polyarthritis, thyroid dysfunction, and hemolytic anemia. Laboratory study abnormalities include eosinophilia, polyclonal hypergammaglobulinemia, elevated serum LDH, anemia, and a positive Coombs test. Bone marrow involvement is common, with over 80% of patients having stage III or IV disease. The median survival ranges from 15 to 36 months, with patients dying of relapse, secondary EBV-positive DLBCL, or opportunistic infection.

Treatment

Up to one-third of patients with AITL can have spontaneous remissions or initial remissions to corticosteroids alone. AITL is approached similarly to PTCL NOS, with combination chemotherapy with 5-year OS and failure-free survival of 32% and 18%, respectively.³⁶⁹ ASCT in first remission is an option for younger patients based on phase 2 studies. For relapsed disease, the options are similar to PTCL NOS, except few responses to pralatrexate were seen.

Enteropathy-Associated T-Cell Lymphoma

Enteropathy-associated T-cell lymphoma (EATL) is a rare aggressive disease of intraepithelial T cells that is often associated with a history of gluten enteropathy.^{370,371} The more common type I is associated with clinical or serologic evidence of celiac disease and HLADQA1*0501, DQB1*0201 genotype.³⁷² Treatment of celiac disease with a gluten-free diet prevents the development of lymphoma.³⁷⁰ Type II EATL is not associated celiac disease and is now considered not to be an EATL.

Pathology

Two variants have been described: type I and type II. Type I EATL is grossly characterized by diffuse infiltration of the bowel wall by an atypical lymphoid infiltrate that often produces mucosal ulcerations, sometimes accompanied by tumorous masses. The morphology of the tumor cells varies, but often they are large and have anaplastic features. In cases associated with celiac sprue, adjacent mucosa may show a dense infiltrate of small intraepithelial lymphocytes associated with villous atrophy. These cells may have the same TCR rearrangement as the large tumor cell population, suggesting that they represent a precursor lesion to EATL that arises in the setting of long-standing celiac disease. Type II EATL is not associated with celiac disease and may represent a different entity.

Immunophenotype and Genetics

Type I EATL cells express CD3 and CD103, an integrin expressed on intestinal lymphocytes. The tumor cells may be CD4 positive (11%), CD8 positive (43%), or CD4/CD8 double negative, and some cases are CD30 positive as well. Type II EATL cells are positive for CD8 and CD56.³⁷³ Of type I and II cases, 50% to 60% have am-

plifications of the 9q31.3 region. A distinct feature of type II EATL is amplification of *MYC* due to copy gains of chromosome 8q24.

Clinical Features and Therapy

Patients with EATL present with intestinal obstruction, perforation, and bleeding. In some patients, there is a brief history of gluten sensitivity or worsening gluten enteropathy. Uncommonly, there is extraintestinal disease with dissemination to the lungs or skin. The small bowel is the most common site of disease, with the stomach or colon affected less often, whereas other viscera, the lung, the skin, or soft tissues may also be involved.³⁷¹ These patients have a very poor prognosis, with a median survival of 10 months. Surgery for limited-stage disease cures a small number of patients. Intensive induction with combination chemotherapy, including high-dose methotrexate, and autologous SCT in first remission, may yield better outcomes than chemotherapy alone.³⁷⁴

Anaplastic Large-Cell Lymphoma

ALCL constitutes 2% of all NHLs, but is the third most common T-cell NHL. ALCL is more frequent in children, representing 10% of all pediatric lymphomas. It is a heterogeneous disease category with several molecular and clinicopathologic subtypes. One of these unusual forms arises within the breast in association with breast implants.³⁷⁵

Pathology

Several morphologic variants of ALCL are recognized. The most common (80%) are cases composed of large cells with round or pleomorphic, often horseshoe-shaped or *embryoid* nuclei with multiple (or single) prominent nucleoli, which are referred to as *hallmark* cells. These cells have abundant cytoplasm, which gives them an epithelioid or histiocyte-like appearance. The remaining morphologies, which are most commonly seen in children, are the small-cell, lymphohistiocytic, and monomorphic variants. Tumor cells may preferentially localize within the sinuses of lymph nodes, producing an appearance that can be mistaken for metastatic solid tumors.

Immunophenotype and Genetics

Virtually all cases are CD30 positive. Over 60% of cases express CD3, CD25, CD43, or CD45RO, and many cases are CD4 positive. Unlike classical HL, ALCL cells usually lack CD15. A minority do not express B- or T-cell antigens, and up to 40% of cases may fail to express the common leukocyte antigen (CD45). TCR genes are clonally rearranged in most cases, but some tumors (particularly those that fail to express T-cell markers) apparently lack TCR rearrangements. Rearrangements involving the *ALK* gene are present in 40% to 60% of cases, more commonly in children and younger adults. The most common rearrangement is the t(2;5), which fuses a portion of the nucleolar protein nucleophosmin-1 (*NPM1*) gene on chromosome 5q35 to a portion of *ALK* on chromosome 2p23.³⁷⁶ The resulting fusion gene encodes a chimeric *NPM-ALK* fusion protein with constitutive tyrosine-kinase activity. Immunohistochemistry for *ALK* can be used to reliably identify cases associated with *ALK* gene rearrangements.

Clinical Features

ALCL encompasses at least three distinct clinicopathologic entities: primary systemic ALCL, *ALK* positive; primary systemic ALCL, *ALK* negative; and primary cutaneous ALCL. Systemic ALCL, regardless of *ALK* status, may present in lymph nodes or extranodal sites, including but not limited to the skin. Primary cutaneous ALCL is morphologically similar to systemic ALCL but lacks *ALK* expression or rearrangements, and is by definition restricted to the skin at diagnosis (see Chapter 104). ALCL has a male predominance, with a median age of 34 years for *ALK*-positive disease, and 58 years for *ALK*-negative disease.³⁷⁷ Except for age, there is

no difference in clinical presentations of ALK-positive and ALK-negative systemic disease. Patients with systemic disease often present with B symptoms, peripheral and retroperitoneal adenopathy, and skin involvement (25% of patients). Although marrow involvement is infrequent, 60% of patients have stage III or IV disease.

Treatment

Generally, ALCL has been treated with combination chemotherapy, largely CHOP. A subset analysis of the randomized CHOP versus CHOEP trial in patients less than age 60 years with normal LDH, found superior outcome with CHOEP (90% versus 55% OS).³⁶¹ Compared to other peripheral T-cell NHLs, ALCL has the highest 5-year OS, driven by the IPI score and the expression of ALK, with ALK-positive disease associated with a favorable prognosis,^{378,379} with 8-year OS of 82% versus only 49% in ALK disease. The major impact of ALK expression was seen in patients age 40 years or greater.³⁸⁰ For relapsed patients, options include SCT following reinduction therapy. The anti-CD30 antibody drug conjugate brentuximab vedotin (anti-CD30 monomethyl auristatin E [MMAE] antitubulin conjugate) is highly active,³⁸¹ with an overall RR of 86%, and a CR rate of 57%, with the median duration of CR of 13 months. Brentuximab is being examined in the initial treatment of ALCL. Crizotinib, an inhibitor of the ALK tyrosine kinase, has reported activity in relapsed disease.³⁸²

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma is an extremely rare disease of cytotoxic T cells.

Pathology

The tumor cells infiltrate the red pulp of the spleen and liver sinusoids as well as the bone marrow, although this can be subtle. Cells are medium sized with round nuclei, moderately condensed chromatin, and moderately abundant pale cytoplasm.

Immunophenotype and Genetics

The tumor cells are CD2+, CD3+, variably CD8+, CD7+, and CD56+. In contrast to most PTCL, which generally express the $\alpha\beta$ T-cell receptor, these tumors commonly express $\gamma\delta$ T-cell receptor. Isochromosome 7q and trisomy 8 have been reported in many cases, and these tumors are genetically distinct from other PTCL.³⁸³

Clinical Features and Treatment

Hepatosplenic T-cell lymphoma is an extremely rare disease presenting in adolescents and young adults, with a male predominance. Features include marked hepatosplenomegaly, often with marrow involvement, and occasionally, peripheral blood involvement and pancytopenia.^{384,385} Of patients, 10% to 20% occur in immunosuppressed, solid-organ allograft recipients and in patients with Crohn's disease on thiopurines.³⁸⁶ This is an aggressive disease, which usually relapses after the initial response to chemotherapy. The median survival is 1 to 2 years, with rare patients being long-term survivors after alloSCT.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma is a rare T-cell NHL of cytotoxic CD8+ T cells presenting with subcutaneous nodules.³⁸⁷ This entity represents less than 1% of all NHLs.

Pathology

The cellular infiltrates are found in the subcutaneous fat and generally spare the overlying skin. This consists of an infiltrate of

small, medium, and large atypical lymphocytes that infiltrate fat lobules, often forming rims around individual adipocytes. Cells express CD3 and CD8, and are usually negative for CD4 and CD56. Cytotoxic granules containing granzyme B, T cell intercellular antigen 1 (TIA-1) and perforin are also present. Most cases express $\alpha\beta$ TCRs, but a subset expresses $\gamma\delta$ TCRs instead. Like other PTCLs, there is often an aberrant immunophenotype marked by loss of one or more T-cell antigens (e.g., CD2, CD5, CD7). Clonal T-cell receptor rearrangements are present, but no specific cytogenetic abnormalities for this disease have been reported.

Clinical Features

This disease affects females more than males, with an age ranging from 40 to 60 years. The disease is localized to the skin with extremely uncommon involvement of other sites, including lymph nodes or bone marrow. The disease can wax and wane, and many patients' disease behaves like cutaneous T-cell NHLs, with a 5-year OS of 82%. Hemophagocytic lymphohistiocytosis (HLH) is reported in 17% of patients, and is associated with much lower 5-year survival (46 versus 91%). Patients with HLH merit combination chemotherapy and should be considered for SCT.

Extranodal Natural Killer/T-Cell Lymphomas, Nasal Type

Extranodal NK/T-cell lymphoma, nasal type, is an extranodal lymphoma usually presenting in the upper aerodigestive tract with occasional extranodal sites. This is a malignancy of NK cells that is generally EBV positive, with some cases of cytotoxic T-cell origin. This disease is rare in the United States and Europe, but is much more common in Asia (Hong Kong) and native populations in Peru.³⁸⁸

Pathology

Extranodal NK/T-cell lymphoma, nasal type, has widely varying cytologic features, but usually consists of a proliferation of a mixture of small and atypical lymphoid cells. The most characteristic features are prominent vascular invasion associated with fibrinoid necrosis of vessels walls and infarction of surrounding tissues.^{3,389} In touch preparations, cytoplasmic azurophilic granules may be seen in the neoplastic cells.

Immunophenotype and Genetics

The cells express CD2, CD56, and cytoplasmic CD3 and are generally negative for CD4, CD8, TCR, and surface CD3. The T-cell receptor and Ig genes are usually germ line. EBV genomes are present in virtually all cases. There is loss of heterozygosity at 6q and 13q, with frequent overexpression of p53 and/or TP53 mutations.

Clinical Features

The extranodal NK/T-cell lymphomas, nasal type are rare, typically presenting in males with an average age of 60 years. The vast majority of patients have localized disease with nasal obstruction and a destructive mass involving the nose sinuses and palate. Stage I disease is present in 81% of patients, and stage II disease in 17% of patients.³⁹⁰ B symptoms are uncommon. Although uncommon, other extranasal sites include: the intestines (37%), the skin (26%), the testis (17%), the lung (14%), the eye or soft tissue (9% each), the adrenal gland (6%), the brain (6%), and the breast or tongue (3% each). Patients with extranasal disease have higher stage, elevated LDH, bulky disease, and a poor performance status. Extranasal disease is associated with a worse prognosis than the nasal subtype for both early and late stage disease.³⁹⁰ A prognostic index for NK/T-cell lymphoma has been developed with the factors including B symptoms, stage III or IV disease, elevated LDH, and lymph node involvement.³⁹¹ CNS risk is increased in patients with three or four factors (10%) compared with less than 2% of those with one or two features.³⁹² The EBV viral load at diagnosis and end of therapy is predictive of PFS and OS.³⁹³

Treatment

Overall, patients with stage IE/IIIE have a 5-year DFS of 59%. The 5-year OS and PFS for patients with stage IE disease is 78% and 63%, respectively, and for stage IIE, the OS and PFS is 46% and 40%, respectively. In this series, there was no difference between combined modality and RT alone.^{390,395} For patients with stage IE/IIIE, early use of radiotherapy (50 to 55 Gy) is critical to optimal treatment. This is usually delivered with IMRT, a technique that allows for a reduction of dose to critical organs such as the eyes. This technique often uses treatment planning that fuses the MRI with the planning CT scan for optimal delineation of the tumor volume. Patients who received initial treatment with RT followed by chemotherapy had superior CR and OS rates as compared to patients who received chemotherapy before RT. Patients with stage II to IV disease generally have a very poor prognosis with relapses in other extranodal sites. More recent studies suggest that combined modality treatment may yield more favorable results. Phase 2 trials of concurrent RT and weekly cisplatin followed by three cycles of etoposide, ifosfamide, cisplatin, and dexamethasone reported overall RR of 83% and 3-year PFS and OS of 85% and 86%, respectively.³⁹⁶⁻³⁹⁹ For disseminated NK/T-cell lymphoma, only 30% of patients achieve a CR with CHOP chemotherapy with median OS of 4.3 months.³⁹⁰ Regimens with L-asparaginase have shown promising results in relapsed disease.^{400,401} The regimen SMILE (dexamethasone, methotrexate, ifosfamide, L-asparaginase, and etoposide) in disseminated disease has an ORR of 79%, with 45% CRs. The 1-year PFS and OS of 53% and 55%, respectively, have been reported.⁴⁰²

Adult T-Cell Leukemia/Lymphoma

ATLL is a highly aggressive disease that is associated with infection by the HTLV-1 in 100% of cases.⁴⁰³⁻⁴⁰⁵ This virus is endemic in southern Japan, the Caribbean basin, western Africa, the Southeastern United States and northeast Iran. The virus predominantly spreads by breast milk, and may be transmitted through sexual exposure and/or blood transfusion. The disease has a long clinical latency period, suggesting that HTLV-1 may not be sufficient for disease. The risk of developing ATLL following infection with HTLV-1 is estimated to be 4%. HTLV-1 causes an ATLL-like disease in severe combined immune deficiency (SCID) mice.⁴⁰⁶

Pathology

Lymph nodes are diffusely effaced by an atypical lymphoid infiltrate that preferentially involves T-cell zones and the medulla. The most characteristic morphologic feature is seen in the peripheral blood, where the circulating tumor cells often have multilobated nuclear contours, referred to as a *sunflower* or *starburst* appearance.

Immunophenotype and Genetics

ATLL is a tumor of CD4+ T cell, expressing CD2, CD3, CD5, CD25, but lacking CD7. The uniformly high levels of CD25 and variable expression of the transcription factor FOXP1 has led to the suggestion that this may be a tumor of Tregs. Deletions at 6q, trisomy 3, and monosomy X and Y are common, but key genetic events associated with ATLL development are largely unknown.

Clinical Features

The median age of ATLL patients is 60 years, with a male predominance.^{406,407} There are several variants of the disease: acute (60% of patients), lymphomatous (20% of patients), chronic (15% of patients), and smoldering (5% of patients), with median survivals of 6 months, 10 months, 24 months, and not yet reached, respectively.⁴⁰⁸ The chronic form can evolve into the acute type. Patients present with bone marrow and peripheral blood involvement, high white blood cell count, hypercalcemia (due to parathyroid hormone [PTH]-related protein, transforming growth factor beta

[TGF- β], and receptor activator of NF- κ B [RANK] ligand), lytic bone lesions, lymphadenopathy, hepatosplenomegaly, skin lesions resembling cutaneous T-cell lymphoma, and interstitial pulmonary infiltrates. Opportunistic infections can also accompany the clinical presentation, including pneumocystis, cryptococcus meningitis, strongyloides, and disseminated herpes zoster.⁴⁰⁹

Therapy

ATLL is generally approached with intensive multiagent chemotherapy regimens.^{410,411} Antiviral therapy with zidovudine and interferon- α should be considered upfront for the smoldering, chronic subtype. A retrospective analysis of 116 patients suggested an improved survival with interferon- α and zidovudine antiviral therapy for acute, chronic, and smoldering subtypes, whereas patients with the lymphomatous type experienced a better outcome with first-line chemotherapy.^{411,412} For the acute leukemia lymphoma type, a phase 3 randomized trial of 118 patients⁴¹³ reported that an intensive regimen vincristine, cyclophosphamide, doxorubicin, and prednisone, VCAP; doxorubicin, ranimustine, and prednisone, AMP; and vindesine, etoposide, carboplatin, and prednisone, VECP (VCAP-AMP-VECP) had a significantly higher CR rate but no difference in overall RR than CHOP-14 with intrathecal methotrexate. The 3-year OS was 24% with VCAP-AMP-VECP, but only 13% with CHOP. Based on expression of the CCR4 chemokine receptor on ATLL cells, mogamulizumab, an anti-CCR4 mAb is being investigated in combination with chemotherapy.⁴¹⁴ With the poor results of chemotherapy, both myeloablative and reduced intensity alloSCT has been applied to ATLL, with limited success.⁴¹⁵⁻⁴¹⁷

Primary Central Nervous System Lymphoma

Primary CNS lymphoma is the subject of Chapter 105.

Central Nervous System Prophylaxis for Aggressive Lymphomas

Prophylaxis for the development of CNS disease in DLBCL is highly controversial. Several sites of disease, including the testis, the ovary, bone marrow, the breast, the epidural space, and paranasal sinuses, have been reported to be associated with a high risk of CNS dissemination. A high-intermediate or high IPI score and multiple extranodal sites are also risk factors. Patients with BCLU-BL/DLBCL, as well as patients with *double-hit* cytogenetics, are at increased risk. In a retrospective analysis of aggressive NHLs, in the pre-rituximab era, the cumulative risk of CNS involvement was 2.8%. Intraparenchymal and intraspinal disease occurred in 66%, whereas isolated leptomeningeal disease was seen in only 26%. Eighty percent of CNS relapses occurred on or within 6 months of completing chemotherapy, suggesting a subclinical disease at diagnosis. In the current period of chemoimmunotherapy, it remains controversial if the addition of rituximab lowers the risk of CNS disease.⁴¹⁸ With the significant number of parenchymal relapses, intrathecal chemotherapy alone may be inadequate prophylaxis, making high-dose methotrexate a potentially more effective therapy. However, there is no compelling evidence that high-dose methotrexate is superior to the intrathecal route.

Lymphoma in Children

See Chapter 100 for a discussion of lymphomas in children.

Posttransplant Lymphoproliferative Disorders

Posttransplant lymphoproliferative disorders (PTLD) are a common and significant complication following solid organ transplantation,

occurring in up to 10% of adult patients.⁴¹⁹ PTLD is less commonly seen after alloSCT. They constitute a heterogeneous collection of diagnoses ranging from early lesions, with reactive plasmacytic hyperplasia, to polymorphic PTLD, with polyclonal or monoclonal expansion of atypical lymphoid cells, to monomorphic PTLD, with lymphoma histopathology and immunophenotype.³³² They differ from nontransplant-related adult lymphomas in that they tend to be extranodal, high grade, and have an aggressive clinical course with a mortality often exceeding 50%.

PTLD following hematopoietic SCT is usually a malignancy of donor lymphoid cells, whereas PTLD following solid organ transplantation is traditionally thought to be of recipient origin in the majority of cases, although donor-derived cases have been reported and typically involve the grafted organ. In both PTLD following hematopoietic and solid organ transplantation, over 80% of PTLDs are of B-cell origin.⁴²⁰ PTLD following solid organ transplantation can occur early, within the first year following transplant, or late, at 1 year or greater from transplantation. Early PTLD is much more common, with an incidence of 224 per 100,000 that falls to 54 per 100,000 by the second year. Over 90% of early onset B-cell PTLDs are EBV positive, whereas over 50% of late onset B-cell PTLD are EBV negative.⁴²¹ Immunosuppression following solid organ transplantation, however, results in a loss of EBV-specific cytotoxic T cells allowing for growth and acquisition of additional mutations in EBV-transformed B cells, such as alterations in *MYC*, *BCL6*, *TP53*, and DNA hypermethylation.⁴²²

EBV serologic status before transplant, as well as the degree and type of immunosuppression following transplant, are risks of developing PTLD. EBV-naïve patients pretransplant and younger patients have higher risk of PTLD.⁴²³ The nature of immunosuppression is also related to risk. The use of anti-T-cell mAbs, tacrolimus, and multiple immunosuppressive agents are associated with increased risk.

The incidence of PTLD varies with the type of organ being transplanted; in adult patients, this ranges from 1% to 3% of kidney and liver transplants, from 1% to 6% of heart transplants, from 2% to 6% of heart-lung transplants, from 4% to 10% of lung transplants, and up to 20% of small bowel transplants.⁴²⁴

Antiviral agents have been studied in both the treatment and prophylaxis settings. For treatment, no study has demonstrated a clear benefit, although they may have some efficacy in early or polymorphic disease.¹⁹ Antiviral therapy (ganciclovir) may decrease PTLD in high-risk EBV-seronegative patients.⁴²⁵ The other strategy for early intervention is to monitor EBV viral load. EBV viral load has been shown to be significantly increased in patients who develop PTLD.⁴²⁶ The use of a rising or increased viral load to alter clinical practice has been investigated following hematopoietic SCT, with a reduction in immunosuppression and/or preemptive therapy with rituximab or EBV cytotoxic T cells.⁴²⁷ But this has not yet translated into studies investigating preemptive changes in clinical management in the solid organ transplant setting.

Pathology

The histologic appearance of PTLD is highly variable. The WHO classification system includes the following categories: (1) early lesions, reactive plasmacytic hyperplasia, and infectious mononucleosis-like; (2) polymorphic PTLD, infectious mononucleosis-like appearance with architectural effacement and tissue destruction; (3) monomorphic PTLD (classified according to lymphoma classification schemes), including DLBCL, BL, multiple myeloma, plasmacytoma, PTCL NOS, other types of T-cell lymphoma; and HL and Hodgkin's-like lymphomas.⁴⁴

Clinical Presentation and Prognosis

PTLDs present as both nodal and extranodal disease. CNS involvement was reported in 22% of PTLDs. Other common extranodal sites include the lung and GI tract, which may be associated with a better prognosis. In solid organ transplants of the heart,

lung, and liver, the allograft is reported to be the site of disease in 22% of cases. Survival statistics in PTLD are variable, owing to the heterogeneity of the diagnosis, ranging from early lesions to monomorphic PTLD, and to advances in therapy. Median 1-year and 5-year survival are approximately 50% to 60% and 30% to 40%, respectively, depending on the type of organ transplanted. Reported median OS is 20 to 30 months.^{428,429} The IPI for aggressive NHLs has been applied to PTLD with limited utility. Other prognostic models for PTLD have been developed with risk factors being age ≥ 60 years, eastern cooperative oncology group (ECOG) PS ≥ 2 , and elevated LDH.⁴³⁰ Low (zero risk factors), intermediate (one risk factor), and high-risk (two to three risk factors) groups had 2-year OS rates of 88%, 50%, and 0%, respectively.

Therapy

There are no established treatment recommendations for PTLD given the heterogeneity of the diagnosis, from pathology to prognosis, and the general lack of prospective, randomized studies in the field. As we have learned more about the varied natural history of the different diseases and their risk and prognostic factors, therapy can now be better tailored to the individual patient. For instance, a stepwise approach to therapy is often indicated for patients with either early lesions or polymorphic disease, starting with a reduction in immunosuppression with or without the addition of antiviral therapy, to single-agent rituximab, to chemoimmunotherapy if indicated. This typically involves a 25% to 50% reduction in cyclosporine and tacrolimus and discontinuation of azathioprine and mycophenolate mofetil.⁴³¹

For patients with monomorphic disease, the initial reduction in immunosuppression is typically accompanied by the addition of rituximab with or without chemotherapy, depending on the aggressiveness and histopathology of the disease.⁴³² RRs to rituximab alone range from 44% to 79%.⁴³³ The PFS and OS at a follow-up of 27.5 months in these studies range from 42% to 47%, respectively. Patients with higher risk, more aggressive monomorphic disease are treated with sequentially dosed rituximab followed by CHOP with encouraging results with an overall RR of 90% (68% complete).^{434,435}

Antiviral therapy has been investigated in more resistant disease. The combination of arginine butyrate, an activator of latently infected lymphoma cells via the induction of EBV thymidine kinase, has been combined with ganciclovir with encouraging results in limited number of patients treated. SCT has anecdotal experience in refractory patients. EBV-specific allogeneic T-cell lines may also have a role in refractory disease.⁴³⁶

HIV-Associated Non-Hodgkin's Lymphoma

Aggressive NHLs are AIDS-defining malignancies. The diagnosis and management is detailed in Chapter 117. AIDS-related NHL occurs in three broad categories: systemic lymphoma, which represents about 85% of all lymphomas; primary CNS lymphoma, accounting for 15% of all lymphomas; and primary effusion or body cavity lymphomas, which are rare.⁴⁴ The breakdown of histologic subtypes includes DLBCL (75%); BL (20%); plasmablastic lymphoma (less than 5%); T-cell lymphoma (1% to 3%); and indolent B-cell lymphomas (less than 10%). About 30% of AIDS-related lymphomas have deregulation of the *bcl-6* gene and a similar number have *c-myc* abnormalities. Approximately 60% of cases have abnormalities of *p53*.⁴³⁷ The pathogenesis is analogous to PTLD, with EBV infection playing a major role in HIV-associated NHLs.⁴³⁸ An HHV-8 infection is associated with primary effusion lymphoma.⁵ The risk factors for developing lymphoma include depressed CD4 count, high HIV viral load, and a lack of effective antiretroviral therapy. Other risks include a lack of the *CCR5-32* deletion.

Systemic AIDS-related NHLs are generally highly aggressive diseases.⁴³⁹ Besides nodal disease, extranodal disease is exceedingly

common, with GI tract, skin and soft tissues, liver, lung, heart, as well as bone marrow and CNS involvement (in 5% to 20% of cases). B symptoms are also common presenting symptoms.

Plasmablastic lymphoma is a rare subtype of large B-cell NHL.⁴⁴⁰ The cells have plasmacytoid cytoplasmic features like plasma cells, but often have large nuclei with large single nucleoli. The malignant cells express plasma cell markers (e.g., CD38, CD138, MUM1) and often lack pan-B-cell markers (e.g., CD20, CD79a). This disease was originally described as oropharyngeal plasmablastic lymphomas that occur most frequently in HIV-positive individuals and are often EBV positive. An identical tumor can also occur in other immunodeficiency states. Plasmablastic lymphoma is a very aggressive disease with a poor prognosis.

Primary effusion lymphomas (PEL) present in fluid collections in the pleura, the peritoneum, or the pericardium, or, more rarely, in the CSF.⁴⁴¹ Solid tumor variants of PEL occur rarely in the GI tract. The PEL cells are large and pleomorphic, often lack CD20 and CD19, but may be CD79a+ and CD45+; they also often express CD30 and CD138. They are uniformly associated

with Kaposi's sarcoma herpesvirus/HHV-8, and most tumors are coinfecting with HHV-8 and EBV. Both plasmablastic lymphomas and PELs rarely occur in nonimmunocompromised hosts.

Presently, more than 50% of patients with AIDS-related lymphoma have long-term DFS. By histology, patients with HL have about a 70% long-term OS, patients with DLBCL and BL around 50%, and patients with primary CNS lymphoma the lowest at 20% to 25%.³⁵¹ Treatment for AIDS-related DLBCL with CD4 count that is 50 or greater should be CHOP-R. There is controversy concerning the inclusion of rituximab if the CD4 count is less than 50.⁴⁴² For plasmablastic lymphoma or if the Ki-67 staining is greater than 80%, we consider DA-EPOCH, adding rituximab if the patient is CD20 positive. Examination of the CSF is considered for all patients, as is prophylaxis against *Pneumocystis jirovecii* pneumonia, herpes zoster, and Candida as well as continuation of antiretroviral therapy, if tolerated. For BL histology, we consider CODOX-M/IVAC rather than CHOP-R.⁴⁴³ Based on a recent report in both patients who are HIV positive and patients who are HIV negative, DA-EPOCH-R is an alternative choice.³⁵⁶

104 Cutaneous Lymphomas

Francine M. Foss, Juliet F. Gibson, Richard L. Edelson,
and Lynn D. Wilson

INTRODUCTION

The cutaneous lymphomas comprise a heterogeneous group of malignancies of both T and B lymphocytes that localize to the skin. According to Surveillance, Epidemiology, and End Results (SEER) data, the skin is the second most common site of extranodal non-Hodgkin's lymphoma, with an estimated annual incidence of 1:100,000.¹ The Dutch and Austrian Cutaneous Lymphoma registries report that more than 70% of all cutaneous lymphomas are of T-cell origin, and 22% are of B-cell origin.² The term *cutaneous T-cell lymphoma* (CTCL) was formally adopted in 1979 at a conference sponsored by the National Cancer Institute (NCI) to describe a heterogeneous group of malignant T-cell lymphomas with primary manifestations in the skin. The World Health Organization and European Organization for Research and Treatment of Cancer (WHO-EORTC) classification of primary cutaneous lymphomas (Table 104.1, 104.2) defines three groups of cutaneous lymphomas: the cutaneous T-cell and natural killer (NK) lymphomas, the cutaneous B-cell lymphomas, and the precursor hematologic neoplasms.²

Further subgrouping based on clinical outcomes has been proposed for the cutaneous T-cell entities.^{2,3} The entities with indolent clinical behavior include mycosis fungoides (MF) and its variants, the cutaneous CD30+ entities, subcutaneous panniculitis-like T-cell lymphoma, and the primary cutaneous CD4+ small-/medium-sized pleomorphic T-cell lymphoma. Included in the aggressive group are Sézary syndrome (SS), the NK/T-cell disorders, gamma-delta positive disorders, CD8+ cutaneous diseases, and primary cutaneous peripheral T-cell lymphoma (PTCL). A similar classification for the cutaneous B-cell lymphomas has been proposed based on the histology (follicular or large cell type) and site of disease, with favorable outcomes seen in disease of the head or upper trunk and an unfavorable prognosis seen with either disseminated lesions or disease in the lower extremities (Table 104.3).

MYCOSIS FUNGOIDES AND THE SÉZARY SYNDROME

MF was first reported by Alibert in 1806 as a common epidermotropic lymphoma with an indolent evolution characterized by cutaneous lesions in the forms of patches, plaques, or skin tumors. In 1980, Bunn et al.⁴ reported the presence of Sézary cells in the blood of patients with MF, and the Sézary syndrome (diffuse erythroderma, circulating Sézary cells, and involvement of lymph nodes and bone marrow) was thus identified.⁵⁻⁷ The International Society of Cutaneous Lymphoma (ISCL) established criteria for the diagnosis of SS, which include an absolute Sézary count of at least 1,000 cells/mm³ in the blood, immunophenotypic abnormalities (expanded CD4+ populations and/or loss of antigens such as CD2, CD3, CD5, or CD4), or the presence of a T-cell clone in the blood.⁸

Epidemiology and Etiology

According to SEER data, the incidence of MF-CTCL had increased 3.2-fold between 1973 and 1984. The overall incidence rate is approximately 4 per 1 million, with an incidence of 1,500 cases per year. The actual incidence rate may be an order of magnitude higher, given possible underreporting and the difficulty and confusion in making the diagnosis. The incidence of MF rises with age such that the majority of patients are between 40 and 60 years. The disease is 2.2 times more common in men than in women, and incidence rates are somewhat higher in African Americans than in Caucasians.

One hypothesis regarding the etiology of MF/SS is that it may possibly represent a clonal evolution from a chronic antigenic stimulus. Associations with exposure to occupational chemicals or pesticides have been proposed but not definitely demonstrated in epidemiologic studies.^{5,6} In other studies, an association with a *Chlamydia* infection of keratinocytes has been proposed, but data demonstrating *Chlamydia* proteins in affected skin lesions are equivocal.^{9,10} The association between human T-cell leukemia virus (HTLV) type 1 infection and adult T-cell leukemia-lymphoma (ATLL) or Epstein-Barr virus in conjunction with nasal NK/T-cell lymphoma is not reflected in the epidemiology of MF-CTCL, but there are reports of the detection of HTLV-like viral particles in affected skin lesions and antibodies to HTLV-1 tax protein in patients with MF/SS.¹¹⁻¹⁴ These results suggest the association of perhaps a yet unknown retrovirus in some cases of MF/SS. Although there is no known geographical clustering and no evidence of maternal transmission of the disease, there are reports of multiple cases of MF/SS in a small number of families.

Pathobiology

The immunophenotypic profile of MF is one of clonal mature CD4+ CD45RO+ T cells with a marked homing capacity for the papillary dermis and epidermis. Some CTCL variants are CD8+ and different subtypes have distinct prognoses. Antigen loss is characteristic of the disease, with a loss of CD7, CD5, or CD2 and dim staining for CD3. Sézary cells express a TH2 phenotype, with secretion of interleukin (IL)-4, IL-5, IL-6, IL-10, and IL-13. The pruritus characteristic of the disease is related to secretion of IL-5 as well as other chemokines. One characteristic of the disease, even at its earliest stages, is profound immunosuppression with aberrant T-cell repertoires, cutaneous anergy, and increased susceptibility to bacterial and opportunistic infections.^{15,16}

The homing to skin by CTCL cells appears to be mediated in part by expression of the surface glycoprotein cutaneous lymphoid antigen (CLA), an antigen whose expression is low or absent on normal infiltrating T cells.^{17,18} CLA mediates binding to E-selectin on endothelial cells of cutaneous venules, thereby facilitating their exit from the circulation and into the skin. CLA is the physiologic ligand of endothelial cell E-selectin, a cell adhesion molecule

TABLE 104.1

World Health Organization–European Organisation for Research and Treatment of Cancer Classification of Cutaneous Lymphomas with Primary Cutaneous Manifestations

Cutaneous T-cell and NK-cell lymphomas
Mycosis fungoides
MF variants and subtypes
Folliculotropic MF
Pagetoid reticulosis
Granulomatous slack skin
Sézary syndrome
Adult T-cell leukemia/lymphoma
Primary cutaneous CD30+ lymphoproliferative disorders
Primary cutaneous anaplastic large cell lymphoma
Lymphomatoid papulosis
Subcutaneous panniculitis-like T-cell lymphoma
Extranodal NK/T-cell lymphoma, nasal type
Primary cutaneous peripheral T-cell lymphoma, unspecified
Primary cutaneous aggressive epidermotropic CD8+ T-cell lymphoma (provisional)
Cutaneous gamma/delta T-cell lymphoma (provisional)
Primary cutaneous CD4+ small-/medium-sized pleomorphic T-cell lymphoma (provisional)
Cutaneous B-cell lymphomas
Primary cutaneous marginal zone B-cell lymphoma
Primary cutaneous follicle center lymphoma
Primary cutaneous diffuse large B-cell lymphoma, leg type
Primary cutaneous diffuse large B-cell lymphoma, other
Intravascular large B-cell lymphoma
Precursor hematologic neoplasm
CD4+/CD56+ hematodermic neoplasm (blastic NK-cell lymphoma)

NK, natural killer; MF, mycosis fungoides.

ALCL, anaplastic large-cell lymphoma.

From Willemze R, Jaffe ES, Burg G, et al. WHO-EORTC classification for cutaneous lymphomas. *Blood* 2005;105:3768–3785; Willemze R, Meijer CJ. Classification of cutaneous T-cell lymphoma: from Alibert to WHO-EORTC. *J Cutan Pathol* 2006;33:18–26, with permission.

expressed on the surface of endothelial cells of cutaneous venules during chronic inflammation.¹⁹ Chemokine receptor CCR4 expressed by cells binds chemokine CCL17 that has adhered to the luminal side of the endothelium, facilitating T-cell leukocyte function antigen-1 binding to endothelial cell intracellular adhesion molecule-1 and fostering extravasation into the dermis.⁴

One of the most striking features of MF/SS is epidermotropism, or infiltration of the epidermis by malignant T cells.

The pathognomonic feature of MF is the Pautrier's microabscess, a collection of clonal malignant cells within the epidermis. The Pautrier's microabscesses may be a consequence of the expression of intracellular adhesion molecule-1 (ICAM-1) on keratinocytes. ICAM expression is induced by interferon (IFN), which is produced by infiltrating T cells and is a ligand for leukocyte function antigen-1.^{20,21} In advanced disease or SS, the keratinocytes lose the ability to express ICAM-1 due to low levels of IFN- γ production, resulting in loss of epidermotropism.²¹ Although specimens from early lesions of MF have lymphocytes in both the epidermis and dermis, clonality studies on dissected cells demonstrated that virtually all of the lymphocytes found in the epidermis belong to the malignant clone, whereas the dermis contains a predominance of inflammatory cells and nonmalignant lymphocytes.

Although there is no characteristic chromosomal translocation in patients with MF and SS, significant chromosomal instability is noted and losses on 1p, 10q, 13q, and 17p and gains of 4, 17q, and 18 are commonly observed.^{22,23} Genetic instability is also evidenced by significant copy number alterations even in early disease.²⁴ Recent studies have shown a high prevalence of deletions or translocations involving a gene, NAV3, at 12q2, which has helicase-like activity and might therefore contribute to genomic instability.²⁵ Chromosomal amplification of JunB at 19p12 has also been detected in MF/SS and is thought to be contributory to the TH2 cytokine profile characteristic of Sézary cells.²⁶ In Lin et al.,²⁴ 21 regions of amplification and 42 regions of deletion were identified, with significant amplifications of 8q (MYC) and 17q (signal transducer and activator of transcription 3 [STAT3]) and deletions of 17p (TP53) and 10 (phosphatase and tension homologue [PTEN], FAS).²⁴

DIAGNOSIS AND STAGING

The diagnosis of MF depends on both clinical and histopathologic criteria. The skin manifestations can be in the form of patches, plaques, erythroderma, cutaneous tumors, or ulcers. Early patch and plaque lesions may be indistinguishable from those of benign dermatoses, including psoriasis, eczema, large plaque parapsoriasis, or drug eruptions. The distribution of the lesions favors non-sun-exposed areas such as the *bathing trunk* distribution. An early diagnosis can be difficult and may rely on multiple biopsies obtained from different lesions over time. The ISCL has developed criteria for the diagnosis of early-stage MF that relies on clinical, histopathologic, immunopathologic, and molecular criteria²⁷ (Table 104.4). Of note, T-cell receptor clonality can be found in benign dermatoses and in lymphomatoid papulosis and pityriasis lichenoides (clonal dermatitis).^{28,29} Long-term follow-up of patients with clonal dermatitis reveals a significant risk of progression to overt MF, suggesting careful follow-up.

Early lesions of MF may be asymptomatic, such as scaling erythematous macular eruptions often in sun-shielded areas (Fig. 104.1). A patch is defined as a lesion that is not elevated or indurated and that may be hyper- or hypopigmented. A plaque is raised or indurated and may be associated with scaling, crusting, or ulceration. A tumor is a lesion that is more than 1 cm with evidence of depth or vertical growth. Erythroderma is defined as diffuse erythema involving more than 80% of the skin surface with or without scaling.⁸

Painful and/or pruritic erythroderma may arise de novo or during any of the earlier described phases and is not always associated with frank T-cell leukemia (as in SS). Infrequently, MF presents with cutaneous tumor nodules in the absence of patches or plaques (as in *tumor d'emblée*). Patients may also present with or progress to involvement of visceral organs.

The Sézary Syndrome

The diagnostic criteria for SS are dependent on the presence of a circulating Sézary cell count of at least 1,000 cells/mm³. The phenotype is typically that of a mature, memory CD4+ T

cell with a frequent loss of normal T-cell antigens (CD3, CD5, CD2, CD7, and CD26).⁸ The CD4/CD8 ratio is elevated, usually more than 10, and a T-cell clone is detected in the blood by polymerase chain reaction (PCR). The presence of more than 1,000 Sézary cells/mm³ is not absolutely diagnostic of SS in the absence of other clinical features of the disease, because these cells may be seen in about 5% of patients with benign dermatoses manifested by erythroderma.^{30,31} Histopathologic features in skin biopsies of patients with SS can be nonspecific, and there is a loss of epidermotropism in up to 70% of cases. Cytogenetic studies demonstrate unbalanced translocations and deletions, often involving 1p, 10q, 14q, and 15q, with evidence of clonal evolution and chromosomal instability over time.³² A differential diagnosis includes viral or drug-induced exanthems, atopic dermatitis, or psoriasis.

Clinical features of the SS include extensive skin involvement with erythroderma, which may progress to lichenification, palmoplantar hyperkeratosis, and diffuse exfoliation. Skin edema, hypoalbuminemia due to insensible fluid loss related to impaired skin integument, and intense pruritus are frequently observed in patients with advanced disease. Lymphadenopathy, histopathologically effaced nodes, and bone marrow involvement are common. Significant immunosuppression occurs related to impaired T-helper function as well as T-cell repertoire skewing, leading to a high incidence of infections, particularly related to indwelling intravenous catheters. The overall prognosis is poor, with a median survival of 2 to 4 years.³³

Staging and Prognosis of Mycosis Fungoides and the Sézary Syndrome

Staging systems for MF have been developed based on clinical features of skin involvement as well as infiltration of lymph nodes

Figure 104.1 Mycosis fungoides and the Sézary syndrome. **(A)** Mycosis fungoides cutaneous plaque. **(B)** Cutaneous tumor. **(C)** Folliculotropic mycosis fungoides. **(D)** Sézary syndrome with diffuse erythroderma. **(E)** Hyperkeratosis and involvement of palms with Sézary syndrome. **(F)** CD8+ cytotoxic T-cell lymphoma of the skin.

and viscera. Skin involvement is defined on the basis of the type of lesions and extent. T1 and T2 diseases are patches or plaques involving less than or more than 10% of the skin surface, respectively. T3 disease is the presence of at least one cutaneous tumor. T4 disease is erythroderma. Lymph node involvement has been classified based on the degree of infiltration with malignant cells. The dermatopathic node demonstrates typically many atypical lymphocytes in three to six cell clusters (LN2) or larger aggregates of atypical lymphocytes with nodal architecture preserved (LN3) clusters of T cells often with expansion of the parafollicular

zones. LN4 nodes are effaced by tumor cells, and typically such effacement is by atypical lymphocytes or neoplastic cells.⁵ T-cell receptor rearrangement (TCRR) is found in half of patients with LN3 nodes and rarely in those with LN2 histology.³⁴ Bone marrow involvement has been shown to have prognostic significance based on the degree of involvement, with cytologically atypical lymphoid aggregates and infiltrative disease associated with inferior survival.³⁵ In retrospective studies, bone marrow involvement was associated with blood involvement and advanced lymph node disease.^{7,36-38}

^a Data derived from Agar NS, Wedgeworth E, Crichton S, et al. Survival outcomes and prognostic factors in mycosis fungoides/Sézary syndrome: validation of the revised International Society for Cutaneous Lymphomas/European Organisation for Research and Treatment of Cancer staging proposal. *J Clin Oncol* 2010;28:4730–4739.

^b Proposed modifications to the staging system by the International Society of Cutaneous Lymphoma (ISCL).

Olsen E, Vonderheid E, Pimpinelli N, et al. Revisions to the staging and classification of mycosis fungoides and Sézary syndrome: a proposal of the International Society for Cutaneous Lymphomas (ISCL) and the cutaneous lymphoma task force of the European Organization of Research and Treatment of Cancer (EORTC). *Blood* 2007;110:1713.

The initial staging system for MF/SS was proposed by the MF Cooperative Group in 1979 and was based on skin involvement, palpable nodes, and visceral involvement.³⁹ More recently, the ISCL further stratifies patients based on the extent of blood involvement (Table 104.5).⁴⁰ In this new system, patients with significant blood involvement are identified in the erythroderma, or stage III group, and patients with stage IVA disease are further categorized based on the degree of lymph node and blood infiltration. Early stage (T1/T2) disease has been proposed to be divided into patch alone versus both patch and plaque disease. These changes have been validated by Agar et al.,⁴¹ who analyzed the outcome of 1,502 MF/SS patients at their institution.

Overall outcome in MF/SS is correlated with clinical stage, and retrospective studies have identified the extent of skin involvement as well as visceral disease as the most important prognostic factors.^{7,14,38} Patients with limited patch/plaque disease covering less than 10% of their skin surface have a prognosis indistinguishable from that of age-, sex-, and race-matched controls.⁴² The 10-year disease-specific survival for patients with more extensive skin involvement with patches or plaques is 83%, whereas those with tumors or histologically documented lymph node involvement had survivals of 42% or 20%, respectively.³⁸ Patients with effaced lymph nodes or the presence of large cell transformation had a uniformly poor prognosis.^{43,44} Other poor prognostic factors include blood involvement and loss of T-cell markers CD5 and CD7.⁴⁵ Even in patients with B0 disease, the presence of T-cell clonality has been shown to portend a worse prognosis.⁴¹

CLINICAL EVALUATION OF PATIENTS WITH CUTANEOUS LYMPHOMA

An initial evaluation should include a careful assessment of the number and distribution of each type of skin lesion. The Skin Weighted Assessment Tool divides the body surface into areas that

are assigned a value based on the percent of total body surface area represented.⁴⁶ The observer then estimates the percent of each body area involved with disease based on the estimation that the palm of the hand is 1%. The involvement is weighted based on whether the lesions are patch, plaque, or tumor. The sum is the skin score, which can be recorded and monitored during therapy.

Skin biopsies at multiple sites may be necessary to establish the diagnosis because lesion morphology varies even for different lesions from the same patient and the quality and quantity of infiltrating cells may be affected by topical therapies, including topical steroids. In addition, most of the cells in the underlying, often much more impressive dermal infiltrate are nonneoplastic reactive CD4+ and CD8+ T lymphocytes. Features of pleomorphism and the presence of large cells should be noted. Transformation to a large cell phenotype in patients with MF/SS is associated with a poor prognosis. Immunophenotyping and molecular studies for TCRR should be performed on skin biopsies.

Laboratory studies should include flow cytometry to detect circulating neoplastic cells. In investigational settings, it is possible to use monoclonal antibodies directed against TCR-V β families to detect and precisely quantitate the levels of circulating leukemia cells. In most instances, the level of circulating CTCL cells is actually much higher than estimated by less-sensitive techniques such as by evaluation of the peripheral smear for atypical cells.²¹ In many patients, the expansion of the neoplastic T-cell clone is accompanied by depression of normal T cells to levels comparable with those observed in advanced AIDS. Such a de facto T-cell deficiency may both explain the susceptibility of erythrodermic CTCL patients to infection by bacterial, viral, and fungal pathogens and contribute to the progression of the disease, which is often held in check by host immune mechanisms.⁴⁷

Flow cytometry should be performed with antibodies to the CD4, CD8, CD3, CD45R0, and CD26 antigens. The ratio of CD4+ to CD8+ cells is normally 0.5:3.5; elevations in this ratio correlate with total leukocyte count and with extent of skin disease in CTCL patients. An elevated ratio of CD4+ to CD8+

cells above 4.5:1.0 strongly suggests significant levels of circulating CTCL cells. Dual color staining with CD4 and other antigens can detect low or absent expression of CD3, CD7, or CD26 as a feature of Sézary cells.

Imaging studies (computed tomography scan or magnetic resonance imaging) are recommended at the initial evaluation, especially for those with advanced disease, as well as during follow-up, to detect enlargement of thoracic, abdominal, or pelvic nodes. Positron emission tomography has been performed for patients with CTCL, but there is not enough experience to reliably determine the sensitivity and specificity in cutaneous lymphoma.^{48,49} Pathologically enlarged lymph nodes should be biopsied at the initial staging and subsequently if enlargement is detected on the physical examination or imaging studies because a proportion of patients with CTCL may have other lymphomas (B or T cell; e.g., Hodgkin's) concurrently. A bone marrow biopsy should be obtained in patients with advanced disease, including those with SS, as well as in patients with compromised hematologic function. Biopsies of visceral organs such as the liver should be dictated based on clinical indication or to confirm findings on imaging studies.

PRINCIPLES OF THERAPY OF MYCOSIS FUNGOIDES AND THE SÉZARY SYNDROME

Treatment approaches for MF/SS depend on the clinical stage of disease. Early-stage disease that is localized to the skin (patch or plaque disease) has an excellent chance of cure or long-term control with therapies directed to the skin alone. In contrast, tumor stage disease, extensive plaque stage disease that is refractory to topical therapies, and nodal or visceral disease can be palliated but rarely cured. Over the past 15 years, a number of novel agents have shown activity in MF/SS (Table 104.6). Because MF/SS is immunosuppressive and an immunologically responsive disease, initial therapies for many patients involve cutaneous and biologic approaches, which act directly on CTCL cells (e.g., they are directly cytotoxic) but also have indirect effects (e.g., alter the cutaneous environment) that may play a role in disease control.⁵⁰

Skin-Directed Therapy

Skin-directed modalities include those for localized disease (radiotherapy, bexarotene, and carmustine) and those applicable to total skin therapy (topical chemotherapy with nitrogen mustard [NM], phototherapy, and total skin electron-beam therapy [TSEBT]; Table 104.6). All skin-directed therapies exert their primary effects on disease confined to the skin by inducing apoptosis of tumor cells and interfering with the local production of cytokines by epithelial and stromal cells necessary for neoplastic T-cell survival and proliferation.⁵¹

Approximately 7% of patients with stage I disease present with a solitary cutaneous lesion or several in proximity. Wilson et al.⁵² found that the rate of clinical remission after local external-beam radiotherapy is very high (approximately 95%) in these patients and may be the treatment of choice. In one study, a total of 21 patients were treated with electron-beam radiation to a median dose of 20 Gy. With a median follow-up of 36 months, the actuarial disease-free survival rates at 5 and 10 years were 75% and 64%, respectively, with a local control rate of 83% at 10 years.

Topical Chemotherapies

Topical NM is one of the first treatments for cutaneous manifestations of MF. The NM liquid can be applied to the skin as an aqueous solution of 10 mg/dL or applied in an ointment base. Long-term effects include induction of second cutaneous malignancies (e.g., squamous cell carcinomas) and hyperpigmentation

and hypopigmentation. Between 64% and 90% of NM-treated patients with T1 and T2 CTCL can achieve a complete response to therapy.

Topical Bexarotene Gel

Bexarotene (Targretin) is a novel RXR retinoid (retinoid X receptor) that has been shown to be effective both systemically and topically for patients with MF/SS. The overall response rate to topical bexarotene in clinical trials was 44%. The drug is not absorbed to any significant levels. The irritant dermatitis induced by the retinoid limits the use of the gel to patients with body surface area (BSA) of less than 15% because of discomfort. In many cases, topical bexarotene gel is used, alternating with topical steroids to minimize the irritant effect.

Phototherapy

Phototherapy has been effective for patients with MF/SS because keratinocytes are resistant to ultraviolet (UV) light-induced injuries, whereas lymphocytes are extremely sensitive to light in the form of either UVA (320 to 400 nm), UVB (290 to 320 nm), or narrow-band UVB (311 nm). Currently, narrow-band UVB is used most commonly because of the low risk of secondary skin neoplasms. Patients typically are treated three to four times per week for approximately 30 to 40 treatments to achieve a remission, and then treatment frequency is decreased to a maintenance schedule at weekly intervals. Broad-band UVB has the same treatment schedule.

Photochemotherapy with orally administered PUVA (ultraviolet A light with oral methoxypsoralen) has been an effective therapy for patients with patch and plaque stage MF. The intensity of the light and frequency of administration are titrated based on patient response and tolerability. Maintenance treatment is often necessary to prevent disease recurrence.

Combination Regimens Involving PUVA Photochemotherapy

Several well-conducted trials have assessed the role of PUVA in combination with various systemic agents, notably IFN- α and retinoids. Phase I and II studies of PUVA (three times weekly) combined with variable doses of IFN- α (maximum tolerated dose of 12 MU/m² three times weekly) in 39 patients with MF (all stages) and SS have reported an overall response rate of 100%.⁵³ The median duration of response (DOR) was 28 months, with a median survival of 62 months.

A randomized controlled trial compared PUVA (two to five times weekly) plus IFN- α (9 MU three times weekly) with IFN- α plus a retinoic acid receptor (RAR) retinoid, acitretin (25 to 50 mg per day), in 98 patients with a maximum duration of treatment in both groups of 48 weeks.⁵⁴ In 82 patients with stage I/II diseases, complete response rates were 70% in the PUVA/IFN group compared with 38% in the IFN/acitretin group. Time to response was 18.6 weeks in the PUVA/IFN group, compared with 21.8 weeks in the IFN/acitretin group.

Total Skin Electron-Beam Therapy

Total skin electron-beam therapy (TSEB) involves the use of electrons ranging in energy between 4 and 7 MeV applied homogeneously to the skin surface.⁵⁵ Structures below the deep dermis are relatively spared because most of the dose (80%) is typically administered within the first 10 mm of depth, and less than 5% beyond 20 mm depth. Generally, doses to skin target are in the range of 30 to 36 Gy. Blood and superficial lymph nodes may receive 20% to 40% of the skin surface dose, and this may be clinically important.

TSEBT may be administered as just one in a sequence of treatments for CTCL in a particular patient. For example, TSEBT

TABLE 104.6

is excellent treatment for patients with diffuse involvement with thick plaques or cutaneous tumors and is also suitable for patients with symptomatic erythroderma–T4 disease.⁵⁶ TSEBT is also an excellent alternative for patients with extensive patches or thin plaques refractory to PUVA or other skin-directed therapies.⁵⁷ Subsequently, TSEBT may be administered to a patient several times using a variety of dose schedules, as clinically required to help control progressive disease.

Clinical complete response rates for patients with T1 or T2 (patch or plaque) disease range from 71% to 98% and are higher in patients with less-extensive disease. Patients with T1 and T2 disease treated with TSEBT have disease-free and overall survivals of 50% to 65% and 80% to 90%, respectively, at 5 years, although patients with antecedent or coexisting lymphomatoid papulosis or alopecia mucinosa–follicular mucinosis appear to have a shorter disease-free survival after TSEBT than those who do not. Patients with more advanced T3 and T4 disease fare significantly worse, with 5-year disease-free and overall survivals of approximately 20% and 50%, respectively. However, those T3 patients with less than 10% of the total skin surface involved by CTCL have significantly better disease-free and overall survival after TSEBT than those with more extensive disease. For patients with erythrodermic MF (T4) who are managed with TSEBT alone (32 to 40 Gy), without concomitant or neoadjuvant therapy, the complete response rate is approximately 70%. The 5-year progression-free, cause-specific, and overall survivals are 26%, 52%, and 38%, respectively.⁵⁶ Based on data from Stanford lower dose TSEBT can also be considered. Overall response rates were in excess of 90% in those T2–T4 disease receiving 5–19 Gy. For those who received 1–<20 Gy and 20 to <30 Gy, overall response was in excess of 95%.⁵⁸

Palliation of adenopathy or visceral involvement in patients with N3 disease can be accomplished by the use of appropriate high-energy orthovoltage or megavoltage photons to doses of 20 to 30 Gy. Even 6 to 8 Gy in three fractions are sufficient (e.g., when combined with TSEBT). Combinations of TSEBT with total nodal radiation have been investigated. Although feasible, such combinations do not appear to prolong survival and may be associated with hematologic toxicities not observed with TSEBT alone.

TSEBT is well tolerated by most patients; acute sequelae either during or within the initial 6 months after treatment may include pruritus, desquamation, alopecia, epilation, hypohidrosis, xerosis, erythema, lower extremity edema, bullae of the feet, and onychoptosis. Chronic changes can include atrophy of the

skin, telangiectasia, alopecia, hypohidrosis, and xerosis. Second malignancies such as squamous and basal cell carcinomas, as well as malignant melanomas, have been observed in patients treated with TSEBT, particularly in patients exposed to multiple therapies that are themselves known to be mutagenic, such as PUVA and mechlorethamine.^{57,59}

For patients who suffer diffuse cutaneous recurrences after TSEBT not amenable to other skin-directed therapies, a second course of TSEBT is both feasible and worthwhile. At Yale University, a total of 14 patients have received two courses and 5 patients received three courses of TSEBT. The median total dose after these additional courses was 57 Gy, and 86% of the patients achieved a complete response after the second course, with a median disease-free interval of 11.5 months. The median dose was 36 Gy for the first course, 18 Gy for the second, and 12 Gy for the third.⁶⁰ A similar experience was reported from Stanford University, where 15 patients were identified who had been treated with a second course of TSEBT (median dose of 20 Gy), with a complete response rate of 40%.⁶¹ Nine of these patients had a partial response to therapy, and the median total dose for the entire group was 56 Gy. In both series, repeat courses were relatively well tolerated, and sequelae were similar to those observed during and after the first course of therapy.

Combined and Sequential Therapy

The adjuvant use of PUVA after TSEBT in patients with T1 and T2 disease significantly decreased cutaneous relapse. Patients treated with adjuvant PUVA after TSEBT had a 5-year disease-free survival of 85%, compared with 50% for those not receiving PUVA ($p < 0.02$). The median disease-free survival for the T1 patients receiving adjuvant PUVA was not reached at 103 months, versus 66 months for the non-PUVA group ($p < 0.01$). For those with T2 disease, the disease-free survival figures were 60 and 20 months, respectively ($p < 0.03$).⁶² Adjuvant topical NM also appears able to delay cutaneous recurrence after TSEBT. In 1999, Chinn et al.⁶³ from Stanford University showed that TSEBT with or without NM provided improved response rates compared with mustard alone for those patients with T2 and T3 level disease (76% versus 39%, $p < 0.03$ for T2; 44% versus 8%, $p < 0.05$ for T3).⁶³ For those with patch/plaque (T2), adjuvant mustard offered improved freedom from relapse after TSEBT compared with no adjuvant treatment. No significant survival differences were noted between the groups.

The combination of extracorporeal photochemotherapy (ECP) administered during and after TSEBT may improve survival ($p < 0.06$) for patients with T3 or T4 disease who have achieved a complete response to TSEBT; however, the group of treated patients was small, and the data are retrospective.⁶⁴ Wilson et al.⁶⁵ identified a significant improvement in cause-specific survival for erythrodermic patients (blood status both B0 and B1) treated with the combination of TSEBT and ECP compared with those not treated with ECP. The 2-year progression-free, cause-specific, and overall survivals for those receiving TSEBT/ECP were 66%, 100%, and 88%, respectively, compared with 36%, 69%, and 63%, respectively, for those not managed with the combination.

SYSTEMIC THERAPY FOR MYCOSIS FUNGOIDES AND THE SÉZARY SYNDROME

Biologic Therapies

IFN- α has been demonstrated in a number of studies to be a highly active agent in CTCL with response rates ranging from 40% to 80%.⁶⁶ Doses have ranged from 1 to 18 mIU administered subcutaneously on a number of schedules, the most common being three times a week. IFN- γ has also demonstrated activity but is not as widely used. Constitutional symptoms and bone marrow suppression have limited aggressive and long-term use of interferons for many patients. Early studies with high-dose IL-2 has demonstrated activity in relapsed CTCL but with significant toxicity. In a recent study of intermediate-dose IL-2, 11 patients (median age, 60 years) with advanced or refractory CTCL underwent 8-week cycles of daily subcutaneous injections of 11 mIU, 4 days per week for 6 weeks, followed by 2 weeks off of therapy. This dose was well tolerated, and there were four partial responses, three of which were sustained.⁶⁷ IL-12 has also demonstrated activity in early and advanced MF. A phase 2 study demonstrated responses in 43% of the patients, with response durations ranging from 3 to 45 weeks.⁶⁸

Extracorporeal Photochemotherapy

ECP, or photopheresis, involves a leukapheresis to isolate mononuclear cells that are exposed *ex vivo* to UVA in the presence of methoxypsoralen and then reinfused back into the patient. Methoxypsoralen incorporates into DNA and, in the presence of UV light, induces strand breaks and, subsequently, apoptosis. Circulating T cells and Sézary leukemia cells are more susceptible to UVA-induced apoptosis than are monocytes. The mechanism of action of ECP is believed to be related to the induction of apoptosis in clonal Sézary T cells, leading to uptake and processing of tumor antigens by immature dendritic cells generated from the effects of the ECP process on circulating monocytoid precursors.^{69,70} The process of ECP has been shown to induce a cell-mediated antitumor response. Clinical improvement with ECP has been demonstrated in both patients with SS and in patients with tumor and plaque-stage CTCL.

In a study of ECP in erythrodermic CTCL, Edelson et al. demonstrated an overall response rate of 83%. Since then, studies have reported a range of overall response rates from 31% to 86% and vary in their definition of response (50% clearing or 25% clearing).^{45,71-73} There is some evidence that ECP may be advantageous even in early stage disease (stage T1/T2) when there is any blood involvement.⁷⁴ Immune adjuvant therapies have been combined with ECP and have shortened the time to response.⁷⁵⁻⁷⁸ Duvic et al.⁷⁹ compared treatment of stage III and IV MF/SS patients with ECP alone or ECP in combination with IFN- α , bexarotene, or granulocyte monocyte colony-stimulating factor and found a 57% response rate in the group undergoing combination therapy as compared to 40% in those undergoing ECP alone.

Bexarotene (Retinoid Therapy)

Bexarotene (Targretin) is an oral RXR selective retinoid that has been shown to alter T-cell trafficking through downregulation of CCR4 and E-selectin.⁸¹ It is active both topically and orally. In a clinical trial of heavily pretreated refractory CTCL, oral monotherapy with bexarotene had a response rate of 54% in early-stage and 45% in advanced-stage CTCL patients. The median response duration was 299 days with continuous dosing at a dose of 300 mg/m² per day, and responses occurred in all groups of patients (57% at stage IIB, 32% at stage III, 44% at stage IVA, and 40% at stage IVB) including those with large-cell transformation. Pruritus decreased significantly in the treated patients and led to overall improvement in quality-of-life indices.⁸² The major toxicities of bexarotene included elevations in serum lipids and cholesterol and suppression of thyroid function.

Bexarotene combination therapy has been studied extensively but has yielded limited additional benefit. Straus et al.⁸³ demonstrated that bexarotene in combination with IFN- α 2b did not have an increased response rate as compared to bexarotene alone. In the EORTC task force's phase 3 randomized clinical trial investigating PUVA and bexarotene, there also was no significant difference between groups.⁸⁴ A phase 2 clinical trial (GEMBEX) of gemcitabine and bexarotene showed lower response rates than those for gemcitabine monotherapy. Another phase 2 trial investigating liposomal doxorubicin and bexarotene found no added benefit of bexarotene.⁸⁵ A clinical trial of pralatrexate and bexarotene is ongoing.

Histone Deacetylase Inhibitors

Histone deacetylase (HDAC) inhibitors modulate gene expression by inhibiting the deacetylation of histone proteins associated with DNA, thereby permitting expression of a number of genes. HDAC inhibition has been shown to induce histone acetylation, cell cycle arrest, and apoptosis in leukemia and lymphoma cell lines. The HDAC inhibitor romidepsin was tested in clinical trials at the NCI, and responses were seen in patients with T-cell lymphomas who received 14 mg/m² given intravenously on days 1, 8, and 15 of a 21-day cycle.⁸⁶ Two multicenter phase 2 trials of romidepsin have been completed and have led to U.S. Food and Drug Administration (FDA) approval for romidepsin in CTCL.^{86,87} In these trials, the overall response rate in 167 patients with advanced or refractory CTCL was 35%, with 6% achieving a clinical complete response. The median response duration was 11 and 14 months in the NCI and the sponsor phase 2 studies, respectively. The most frequent adverse events (all grades) were nausea, constitutional symptoms, thrombocytopenia, and reversible ST-T segment changes.

Vorinostat (Zolinza, suberoylanilide hydroxamic acid), an orally bioavailable HDAC inhibitor, was explored in a phase 1/2 study and showed activity in CTCL.⁸⁸ In a subsequent phase 2 study, vorinostat administered at 400 mg daily was associated with a 29% response rate in 74 patients with refractory CTCL, including 61 with stage IIB or higher disease. The response durations ranged from 34 to 441+ days.⁸⁹ Overall, 32% of patients had relief of pruritus. Panobinostat is an oral HDAC inhibitor that has been shown to have activity in CTCL. Of 139 patients enrolled in a phase 2 trial of panobinostat 20 mg three times a week, the response rate was 17.3%.⁹¹

Denileukin Diftitox

Denileukin diftitox is a fusion protein consisting of the *IL-2* gene joined to the active and membrane-translocating domains of diphtheria toxin. In the pivotal trial that led to FDA approval of denileukin diftitox, the drug was administered at a dose of either 9 mg per kilogram or 18 mg per kilogram, for 5 days every 21 days, in 71 patients with relapsed or refractory CTCL.⁹² The median number of prior therapies in this study was five. The overall response rate was similar for both dose groups and was 30% overall, with

10% complete responses (7 patients) and 20% partial responses (14 patients).⁹² The median response duration was 6.9 months. The major toxicities included a reversible elevation of hepatic transaminases, a hypersensitivity syndrome associated with drug infusion, and a mild vascular leak syndrome, all of which were alleviated in part by steroid pretreatment.⁹³

A randomized, placebo-controlled phase 3 trial has been completed comparing denileukin diftitox at doses of 9 and 18 µg per kilogram daily for 5 days on a 21 day schedule in patients with earlier stage CTCL who have had fewer prior therapies.⁹⁴ Of 144 patients treated, the overall response rates were 46%, 37%, and 15% for the 18 µg, 9 µg, and placebo arms, respectively. A combination study of bexarotene (75 to 300 mg) and denileukin diftitox (18 µg per kilogram for 3 days every 21 days)⁹⁵ reported an overall response rate of 70%, with four complete responses (35%) and four partial responses (35%). This study demonstrated that doses of bexarotene greater than 150 mg per day were capable of *in vivo* upregulation of CD25 (IL-2) expression and may enhance the efficacy of denileukin diftitox.

Monoclonal Antibodies

Alemtuzumab, a humanized monoclonal antibody that targets the CD52 antigen, has been shown to be active in relapsed or refractory T-cell lymphomas. Recent studies with lower doses of alemtuzumab (10 mg three times per week) have reported responses in 6 of 10 patients, including 2 complete responses and 4 partial responses, with minimal immunosuppression.^{96,97}

Zanolimumab a high-affinity, fully humanized monoclonal antibody that targets the CD4 receptor.⁹⁸ It has shown promising results in 49 patients with biopsy-proven CD4+ CTCL, including 23 patients with advanced-stage disease.⁹⁹ Partial remissions were reported in 16 of 36 (44%) evaluable patients overall, including 3 of 6 with advanced disease at 980 mg per week.

Mogamulizumab (KW-0761) is a humanized anti-CCR4 antibody that enhances antibody-dependent cellular cytotoxicity against malignant T cells. CCR4 has been shown to have increased expression in a subset of patients with MF.¹⁰⁰ The overall response rate in a phase 2 trial of mogamulizumab in relapsed/refractory CTCL patients was 37% (29% in MF, 47% in SS).¹⁰¹ Phase 2 studies are ongoing in CTCL, PTCL, and ATLL.

Brentuximab vedotin is a CD30-targeted antibody conjugated to an auristatin (monomethyl auristatin E [MMAE]), an antitubulin agent. After binding to CD30, the molecule is internalized and MMAE is released and binds to tubulin, leading to cell cycle arrest. In a phase 2 open label trial of 48 patients with CD30+ lymphoproliferative disorders including lymphomatoid papulosis (LyP) and primary cutaneous anaplastic large-cell lymphoma (pc-ALCL) or CD30+ MF, brentuximab demonstrated an overall response rate of 71% (34 out of 48), with 35% of patients achieving a complete remission (17 out of 48). Interestingly, it showed a 50% overall response rate in MF irrespective of the level of CD30 expression.¹⁰²

Cytotoxic Chemotherapy

Combination chemotherapy regimens have produced higher responses in patients with advanced refractory CTCL, but these responses have not been durable. A study of infusional EPOCH (etoposide, vincristine, doxorubicin, bolus cyclophosphamide, and oral prednisone) in advanced refractory CTCL demonstrated an overall response rate of 80% (12 patients), with 4 (27%) complete responses but a response duration of 8 months.¹⁰³ Treatment-related toxicity was significant, with 61% of the patients experiencing grade 3/4 myelosuppression. Because of the high risk of infection and myelosuppression and modest response durations with combination chemotherapy, single-agent therapies are preferred except in patients who are refractory or who present with extensive adenopathy and/or visceral involvement and require immediate palliation.

Purine Analogs

Response rates up to 70% have been reported for single-agent pentostatin in refractory patients. Investigators at the M.D. Anderson Cancer Center reported a response rate of 56% for dose-escalated pentostatin (3 to 5 mg/m² per day for 3 days on a 21-day schedule) in 42 patients with CTCL.¹⁰⁴ The failure-free survival was 2.1 months. Grade 3/4 neutropenia occurred in 21% of patients. The incidence of infectious complications with pentostatin was initially high but was subsequently reduced by prophylactic trimethoprim and antiviral therapies. In a combination study of pentostatin at 4 mg/m² per day for 3 days with intermediate-dose IFN-α, the overall response rate was similar, but the median progression-free survival was improved to 13.1 months.¹⁰⁵

Fludarabine and cladribine have demonstrated more modest single-agent activity in MF/SS. The combination of fludarabine with IFN-α had greater efficacy with an overall response rate of 51% (4 complete responses, 14 partial responses) with a median progression-free survival of 5.9 months and an overall survival of 19.6 months.¹⁰⁶ Similarly, a combination of fludarabine (18 mg/m²) and cyclophosphamide (250 mg/m²) for 3 days monthly was associated with a DOR of 10 months but with significant hematologic toxicity.¹⁰⁷

Gemcitabine has demonstrated impressive clinical activity in advanced and refractory CTCL. In a study of chemotherapy-naïve patients treated with 1,200 mg/m², the response rate was 75%, with 22% complete response rate.¹⁰⁸

Liposomal Doxorubicin

Pegylated liposomal doxorubicin is an active agent in Kaposi's sarcoma and has been shown to accumulate in involved skin lesions. In patients with advanced MF, response rates of 80% have been reported. In one small prospective multicenter study investigating liposomal doxorubicin monotherapy in 25 patients, 5 complete responses and 9 partial responses were reported.¹⁰⁹ In a larger phase 2 trial carried out at the EORTC of 49 patients with stage IIB, IVA, or IVB MF, 3 patients experienced a complete response and 17 experienced a partial response with a median duration of response of 6 months and a median time to progression of 7.4 months.¹¹⁰ With the exception of infusion related events, liposomal doxorubicin was well tolerated with no grade 3 or 4 adverse events (AEs).

Pralatrexate

Pralatrexate is a promising new folate antagonist with activity in patients with T-cell lymphoma that has been approved for patients with aggressive peripheral T-cell lymphoma and MF with large cell transformation. In preclinical studies, pralatrexate has been shown to be more potent than methotrexate.¹¹¹ In the PROPEL study, 111 patients with relapsed or refractory PTCL were treated with pralatrexate. The overall response rate was 29%, with a median duration of response of 10.1 months.¹¹² In an open label phase 1 clinical trial including 54 CTCL patients who failed at least one systemic therapy, pralatrexate was given at a dose of 15 mg/m² for 3 to 4 weeks, and the overall response rate was 41% (35% partial response, 6% complete response).¹¹³ Grade 3/4 adverse events were mucositis and leukopenia. In patients with transformed MF in the PROPEL study, the overall response rate was 25% (n = 3), demonstrating efficacy in a group that is largely refractory to therapy.

Autologous and Allogeneic Bone Marrow Transplantation

Results with autologous stem cell transplantation have not been promising in patients with MF/SS. One major issue in many studies is eradication of disease prior to transplant, and most patients have undergone extensive prior therapy. Molina et al.¹¹⁴ reported successful outcomes with donor transplants in six of eight

refractory CTCL patients. All achieved a complete remission; however, two died from transplant-related complications. Paralkar¹¹⁵ reported results using reduced intensity conditioning regimens in 12 refractory CTCL patients. Six patients (50%) achieved complete remission and the median duration of response was 22 months. In a retrospective analysis of allogeneic transplant for MF and SS, in a group of 60 patients where 44 underwent reduced intensity conditioning (RIC), patients with RIC had a 1- and 3-year overall survival of 73% and 63%, respectively, supporting a significant graft versus lymphoma effect.¹¹⁶

OTHER CUTANEOUS LYMPHOMAS

Primary CD30+ Lymphoproliferative Disorders

The primary CD30+ lymphomas comprise a spectrum of disease, with LyP being a clonal but nonmalignant variant and cutaneous ALCL (C-ALCL) resembling its systemic counterpart. Clinically and histopathologically, LyP and C-ALCL may be indistinguishable. The classic presentation of LyP is papular, papulonodular, or papulonecrotic skin lesions at different stages of development with a waxing and waning course. The lesions often disappear within 12 weeks and often leave a scar. The median patient age is 45 years, but the disease does occur in children; the male to female ratio is 1.5:1. Three histologic subtypes have been identified, all demonstrating large CD30+ cells with (type A) or without (type C) infiltrating inflammatory cells.¹¹⁷ In some cases (type B), there is infiltration of the epidermis, similar to MF. Up to 60% of cases demonstrate clonality for T-cell receptor (TCR), but the (2:5) (p23;q35) translocation characteristic of alk+ ALCL is not present. Up to 20% of cases may be preceded by or follow another lymphoma, including MF, ALCL, or Hodgkin's lymphoma. For most patients, the prognosis is excellent, and the disease is managed either with no treatment, low doses of oral methotrexate, or PUVA. In a series of 118 isolated cases of LyP, only 4% of patients developed systemic lymphoma.

C-ALCL is similar to systemic ALCL except for the cutaneous presentation and the absence of systemic disease. All patients with C-ALCL should undergo careful staging to rule out systemic involvement before being classified as C-ALCL. Most patients present with solitary nodules, tumors, or ulcerating lesions that may spontaneously regress, but multifocal disease has been observed in up to 20% of patients. The histopathologic features of the disease include the presence of large, anaplastic cells that express CD30 antigen in more than 70% of the tumor cells. The tumor cells demonstrate clonality for TCRR, an activated CD4 phenotype with loss of other T-cell antigens and frequent expression of cytotoxic proteins (granzyme B, T-cell intracellular antigen-1 [TIA-1], perforin). The (2:5) (p23;q35) alk translocation that is frequently seen in systemic ALCL is uncommonly observed in C-ALCL. In addition, the systemic ALCL expresses epithelial membrane antigen, which is absent in C-ALCL. The overall prognosis is excellent and most patients are treated by surgical excision and/or local radiotherapy to the lesions. For recurrent disease, low doses of methotrexate or other cytotoxic agents may be used. A new family of humanized anti-CD30 antibodies has been developed and has shown efficacy in both systemic and cutaneous ALCL.

Subcutaneous Panniculitis-like T-Cell Lymphoma and Cutaneous Peripheral T-Cell Lymphoma Unspecified

Subcutaneous panniculitis-like T-cell lymphoma (SPTL) and cutaneous peripheral T-cell lymphomas have distinct clinicopathologic features and outcomes. SPTCL is comprised of two subtypes, the alpha/beta and the gamma/delta, and both are characterized

by subcutaneous masses or flat plaques that mainly involve the legs but may be generalized. Often, patients present with B symptoms such as fever, fatigue, and weight loss. The WHO-EORTC classification has separated these phenotypes because of their disparate outcomes.² The alpha/beta SPTCL is characterized by subcutaneous infiltrates that spare the epidermis and dermis and rim individual fat cells. In early stages, the tumor cells may lack significant atypia and an inflammatory infiltrate may be present, leading to a diagnosis of inflammatory panniculitis. The phenotype of the malignant lymphocytes is CD3+, CD4-, and CD8+ with an expression of cytotoxic proteins. The outcome for the alpha/beta type of SPTCL is excellent, with an 80% 5-year survival. Treatments include corticosteroids, single-agent chemotherapy, and radiotherapy. The cutaneous gamma/delta T-cell lymphomas are characterized by disseminated disease with frequent mucosal and extranodal involvement. Hemophagocytic syndrome may occur. Histopathologic features include involvement of the dermis, epidermis, and fat with rimming of fat globules and angioinvasion. The phenotype of the cells is CD3+, CD2+/-, CD8+, and CD56+ beta F1- with a lack of expression of either CD4 or CD8. Most patients have a poor outcome despite aggressive chemotherapy, with a median survival of 15 months reported in one series of 33 patients.

Primary cutaneous PTCL unspecified is characterized by infiltration of the dermis by CD3+ CD4+ or CD3+ CD8+ pleomorphic small- and medium-sized cells, in many cases with an admixture of reactive lymphocytes. Most cases demonstrate a loss of T-cell markers and are CD30 negative and rarely CD56+. The clinical features are plaques or tumors, often on the face, neck, or upper trunk. The estimated 5-year survival of the CD4+ types is 80% and the preferred treatments are surgery, radiation, or single-agent chemotherapy. The CD8+ variants often express cytotoxic phenotypes (granzyme B+, perforin+, TIA-1+) and are characterized by ulcerative or necrotic tumor or plaques with frequent dissemination to visceral sites but rarely to lymph nodes. The median survival for this group of patients is 32 months despite aggressive systemic chemotherapy.

The Cutaneous Natural Killer Lymphomas

Extranodal NK/T-cell lymphoma is an Epstein-Barr virus-positive lymphoma with an NK or cytotoxic T-cell phenotype most commonly found in South America, South Asia, and Central America. The skin is the second most common site of involvement after the nasal cavity and sinuses. Skin manifestations include ulcerative or necrotic skin lesions characterized histopathologically by angiodestruction and extensive necrosis. The neoplastic cells express CD2, CD56, and cytotoxic proteins but lack surface CD3. The TCR is often germ line, and Epstein-Barr virus is almost always expressed. The median survival for disease presenting in the skin alone is 27 months, and 5 months for those presenting with other sites of disease.

Another variant of cutaneous NK lymphoma, the blastic NK lymphoma, has been recently reclassified by the WHO-EORTC as CD4+/CD56+ hematodermic neoplasm because recent studies have demonstrated a plasmacytoid dendritic cell derivation. This neoplasm commonly presents in the skin with solitary or multiple tumors or nodules. Most patients who present with skin involvement only rapidly develop widespread disease in multiple visceral sites. The infiltrates are CD4+ CD56+, and CD45RA+ cells, which lack CD3 and cytotoxic proteins and express CD123 and TCL 1, which are characteristic of plasmacytoid dendritic cells. The differential diagnosis is myelomonocytic or lymphocytic leukemia cutis, which can be distinguished by staining for myeloperoxidase and CD3, respectively. The skin biopsy is notable for a diffuse nonepidermotropic infiltration of the dermis by intermediate-sized blastlike cells with frequent mitoses. The prognosis is poor, with a median survival of 14 months. Initial therapy is often with acute myeloid leukemia type of regimens, which induce brief initial responses.

Cutaneous B-Cell Lymphoma

The primary cutaneous B-cell lymphomas (PCBCL) are 1.4 times more common in men than women, and more common in Caucasians.¹¹⁸ The etiology of PCBCL is also unclear, and the pathogenesis not well understood, but *Borrelia* has been identified in a small percentage of patients presenting with PCBCL. For PCBCL, nodal classification systems have been used, but given the different natural history of such lesions, specific classification and prognostic systems are necessary. In addition to the WHO–EORTC classification system for both T- and B-cell cutaneous lymphomas, other prognostic systems have been developed that take the location and histology of the lesion into account.¹¹⁹

Types of Primary Cutaneous B-Cell Lymphomas

The histologic subtypes of PCBCLs include marginal zone, follicular center cell type, and diffuse large cell (see Table 104.1). Mucosa-associated lymphoid tissue can be found in a variety of anatomic locations, and marginal zone lymphoma of the skin is the cutaneous counterpart. Small lymphocytes and reactive germinal centers are frequently appreciated in conjunction with marginal zone cells. The expression of CD20, CD79, and, commonly, bcl-2 but not bcl-6 has been identified in addition to the identification of the *IHG* and *MLT* genes of chromosomes 14 and 18, respectively. Follicle center cell cutaneous lymphomas often spare the epidermis and may consist of centrocytes, germinal centers, and reactive T cells. A follicular pattern is common and the expression of CD20 and CD79 is often noted. The expression of bcl-2 and MUM-1 is typically absent. The t(14:18) translocation, which is often seen in the nodal counterpart, is absent in the cutaneous presentation.

Cutaneous plasmacytoma consists of a cutaneous infiltrate of plasma cells without bone marrow involvement. This presentation

of PCBCL is quite rare and may present as papules, plaques, or tumors/nodules. Typically, the dermis is occupied by mononuclear cells, and amyloid deposition is often identified within the infiltrate. Immunoglobulins are often present, and cells may express CD38.

Diffuse large B-cell type is distinguished based on whether it occurs on the leg and whether it is intravascular type. Expression of CD20 and CD79 may be seen, and lesions identified on the lower extremity may express bcl-2, bcl-6, and MUM-1. Lesions that are found in other cutaneous locations may also express these markers, but more typically they are found on the lower extremities. Inactivation of p16 suppressor genes, additions for 18q and 7p, and loss of 6q may be noted with cutaneous diffuse large B-cell lymphoma.¹²⁰

Treatment for PCBCL depends on the histopathologic subtype. More indolent forms of PCBCL, such as marginal zone or follicle center cell, tend to be bothersome to the patient, but rarely follow an aggressive clinical course. Radiotherapy, surgical excision, and observation are options for such patients. Radiotherapy for PCBCL is very much the same as that described for MF–CTCL. The technical aspects of the treatment delivery are quite similar, as are the side effects. Patients who present with diffuse large cell leg-type histology are typically treated more aggressively, given the relatively poor outcomes with radiotherapy alone. Combined modality therapy is often considered for this group of patients, and therapeutic courses tend to follow those used in nodal lymphomas of similar histology. If the histology is diffuse large cell, but not of the leg type, consideration can be given to the use of radiotherapy alone as the sole therapeutic modality. Rituximab has been used in the management of patients with PCBCL and in those with widespread disease, but the evidence regarding efficacy and outcomes is anecdotal, and series are small. For patients with localized CBCL, the complete response rates approach 100%, with 5-year disease-free survivals of approximately 50%.^{118,121–125}

105 Primary Central Nervous System Lymphoma

Tracy T. Batchelor

EPIDEMIOLOGY

Primary central nervous system lymphoma (PCNSL) is an extranodal non-Hodgkin lymphoma (NHL) confined to the brain, leptomeninges, eyes, or spinal cord. PCNSL accounts for approximately 2% of all primary central nervous system (CNS) tumors, with a median age of 65 years at diagnosis.¹ The annual incidence rate is 0.47 cases per 100,000 person-years.^{1,2} Since 2000, there has been an increase in the overall incidence of PCNSL, especially in the elderly.

PATHOLOGY

Approximately 90% of PCNSL cases are diffuse large B-cell lymphomas (DLBCL), with the remainder consisting of T-cell lymphomas, poorly characterized low-grade lymphomas, or Burkitt lymphomas.³ Primary CNS DLBCL is composed of centroblasts or immunoblasts clustered in the perivascular space, with reactive lymphocytes, macrophages, and activated microglial cells intermixed with the tumor cells. Most tumors express pan-B-cell markers, including CD19, CD20, CD22, and CD79a. The molecular mechanisms underlying transformation and localization to the CNS are poorly understood.⁴ Limitations in molecular studies of PCNSL include the rarity of the disease and the limited availability of tissue because the diagnosis is most often made with stereotactic needle biopsy. Like systemic DLBCL, PCNSL harbors chromosomal translocations of the BCL6 gene, deletions in 6q, and aberrant somatic hypermutation in proto-oncogenes including MYC and PAX5. Inactivation of CDKN2A is also commonly observed in both entities. Also like DLBCL, PCNSL can be classified into three molecular subclasses by gene expression profiling: type 3 large B-cell lymphoma, germinal center B cell, and activated B-cell lymphoma. However, certain molecular features distinguish primary CNS DLBCL from systemic DLBCL. Gene expression profiles demonstrate that PCNSL is characterized by differential expression of genes related to adhesion and the extracellular matrix pathways, including MUM1, CXCL13, and CHI3L1. The ongoing somatic hypermutation with biased use of V_H gene segments that has been observed in PCNSL is suggestive of an antigen-dependent proliferation. These observations are consistent with the hypothesis that PCNSL is secondary to antigen-dependent activation of circulating B cells, which subsequently localize to the CNS by expression of various adhesion and extracellular matrix-related genes. However, further molecular studies to investigate the transforming events and the subsequent events responsible for CNS tropism in PCNSL are needed. Insights into the molecular pathogenesis of PCNSL may allow for the development of targeted therapeutic approaches for tumors.⁴

DIAGNOSIS AND PROGNOSTIC FACTORS

Neurocognitive symptoms are the most common presenting clinical features of PCNSL. The International PCNSL Collaborative

Group (IPCG) has developed guidelines to determine the extent of disease.⁵ A gadolinium-enhanced brain magnetic resonance imaging (MRI) scan is the most sensitive radiographic study for the detection of PCNSL (Fig. 105.1). Most PCNSL patients present with a single brain mass. The mass is typically isointense to hyperintense on T2-weighted MRI sequences and homogeneously enhancing on postcontrast images. The diagnosis of PCNSL is typically made by stereotactic brain biopsy, cerebrospinal fluid (CSF) analysis, or by analysis of vitreous aspirate in patients with ocular involvement. Given the possible delay in diagnosis and treatment with the latter two methods, prompt stereotactic biopsy is advised in almost all cases that are surgically accessible. Secondary CSF and ocular involvement occurs in approximately 15% to 20% and 5% to 20% of PCNSL patients, respectively. Presenting symptoms of ocular involvement include eye pain, blurred vision, and floaters.⁶ B symptoms such as weight loss, fevers, and night sweats are infrequent in PCNSL. A thorough diagnostic evaluation is needed to establish the extent of the lymphoma and to confirm localization to the CNS. Physical examination should consist of a lymph node examination, a testicular examination in men, and a comprehensive neurologic examination. A lumbar puncture should be performed if not contraindicated, and CSF should be assessed by flow cytometry, cytology, and immunoglobulin heavy-chain gene rearrangement. Because extraneural disease must be excluded to establish a diagnosis of primary CNS lymphoma, CT or CT/positron-emission tomography (PET) scans of the chest, abdomen, and pelvis, and a bone marrow biopsy and aspirate should be performed to exclude occult systemic disease. Involvement of the optic nerve, retina, or vitreous humor should be excluded with a comprehensive eye evaluation by an ophthalmologist that includes a slit-lamp examination. Blood tests should include a complete blood count, a basic metabolic panel, serum lactate dehydrogenase, and HIV serology.⁵

Two prognostic scoring systems have been developed specifically for PCNSL.^{7,8} In a retrospective review of 105 PCNSL patients, the International Extranodal Lymphoma Study Group (IELSG) identified age >60 years, Eastern Cooperative Oncology Group (ECOG) performance status >1, elevated serum lactate dehydrogenase (LDH) level, elevated CSF protein concentration, and involvement of deep regions of the brain as independent predictors of poor prognosis. In patients with 0 to 1 factors, 2 to 3 factors, and 4 to 5 factors, the 2-year survival proportions were 80%, 48%, and 15%, respectively. In another prognostic model, PCNSL patients were divided into three groups based on age and performance status: (1) <50 years old, (2) ≥50 years old with a Karnofsky Performance Scale (KPS) ≥70, and (3) ≥50 years old with a KPS <70. Based on these three divisions, significant differences in overall and failure-free survival were observed.

STAGING

There is no staging system that correlates with prognosis or response to treatment in PCNSL. However, because PCNSL is a

Figure 105.1 Magnetic resonance images from a patient with PCNSL. A T1-weighted, postcontrast, sequence (*left*) demonstrates intense, homogenous enhancement of the tumor in the region of the left caudate nucleus. A T2/fluid attenuated inversion recovery (FLAIR) sequence (*right*) demonstrates hyperintense signal surrounding the tumor, reflecting a vasogenic cerebral edema. (Courtesy of Priscilla Brastianos, MD.)

multicompartmental disease potentially involving the brain, spinal cord, eyes, and CSF, the IPCG recommends an extent of disease evaluation, as noted previously, which will enable clinicians to follow the response to therapy.⁷

TREATMENT

Defining a response to treatment in PCNSL requires an assessment of all sites involved by the disease. The IPCG has established response criteria that have been adopted into most prospective clinical trials (Table 105.1).⁵

Corticosteroids decrease tumor-associated edema and may result in partial radiographic regression of the tumor. An initial response to corticosteroids is associated with a favorable outcome in PCNSL.⁹ However, after an initial response to corticosteroids,

almost all patients quickly relapse. Corticosteroids should be avoided if possible prior to a biopsy, given the risk of disrupting cellular morphology, resulting in a nondiagnostic pathologic specimen.

Surgical resection is not part of the standard treatment approach for PCNSL given the multifocal nature of this tumor.¹⁰ The role of neurosurgery in PCNSL is to establish a diagnosis via a stereotactic biopsy.

Standardized induction and consolidation treatment for PCNSL has yet to be defined. Historically, PCNSL was treated only with whole brain radiation (WBRT) at doses ranging from 36 to 45 Gy, which resulted not only in a high proportion of radiographic responses, but also in rapid relapse. In a multicenter, phase II trial, 41 patients were treated with WBRT to 40 Gy plus a 20 Gy tumor boost and achieved a median overall survival (OS) of only 12 months.¹¹ Given the lack of durable responses to radiation and the risk of neurotoxicity associated with this modality of therapy, WBRT alone is no longer a recommended treatment for most patients with PCNSL. Moreover, because PCNSL is an infiltrative, multifocal disease, focal radiation or radiosurgery is not recommended. The most effective treatment for PCNSL is intravenous, high-dose methotrexate (HD-MTX) at variable doses (1 to 8 g/m²), typically utilized in combination with other chemotherapeutic agents and/or WBRT. However, there is no consensus on the optimal dose of HD-MTX or on the role of radiation in combination with methotrexate in the management of PCNSL. A number of randomized trials are ongoing to address these issues. Doses of methotrexate ≥ 3 g/m² result in therapeutic concentrations in the brain parenchyma and CSF, and when combined with WBRT, lead to more durable treatment responses.¹²⁻¹⁴ In a phase II trial, 79 PCNSL patients were randomized to receive either HD-MTX (3.5 g/m², day 1 or HD-MTX (3.5 g/m², day 1) + cytarabine (2 g/m² twice per day, days 2 to 3). Each chemotherapy cycle was 21 days. All patients underwent consolidative WBRT after induction chemotherapy. The HD-MTX + cytarabine arm had a higher proportion of complete radiographic responses and a superior 3-year OS.¹⁴ However, it is now widely recognized that there is a high incidence of neurotoxicity with combined modality treatment that includes WBRT.¹⁵ The latter observation prompted studies utilizing *lower doses* of WBRT. In a

TABLE 105.1

International PCNSL Collaborative Group Consensus Guidelines for the Assessment of Response in PCNSL

Response	Brain Imaging	Steroid Dose	Ophthalmologic Examination	Cerebrospinal Fluid Cytology
Complete response	No contrast enhancing disease	None	Normal	Negative
Unconfirmed complete response	No contrast enhancing disease	Any	Normal	Negative
	Minimal enhancing disease	Any	Minor RPE abnormality	Negative
Partial response	50% decrease in enhancement	N/A	Normal or minor RPE abnormality	Negative
	No contrast enhancing disease	N/A	Decrease in vitreous cells or retinal infiltrate	Persistent or suspicious
Progressive disease	25% increase in enhancing disease Any new site of disease	N/A	Recurrent or new disease	Recurrent or positive
Stable disease	All scenarios not covered by responses above			

RPE, retinal pigment epithelium.

Abrey LE, Batchelor TT, Ferreri AJ, et al. Report of an international workshop to standardize baseline evaluation and response criteria for primary CNS lymphoma. *J Clin Oncol* 2005;23:5034-5043.

multicenter, phase II study, no significant neurocognitive decline was observed after consolidative reduced dose WBRT (23.4 Gy) and cytarabine in patients who had achieved a complete response to induction chemotherapy including HD-MTX.¹⁶ However, further study and longer neuropsychological follow-up of these patients is necessary to definitively assess the safety of this regimen because numerous studies have demonstrated the delayed neurotoxic effects of WBRT in the PCNSL population and the reduced risk of neurotoxicity in regimens consisting of chemotherapy alone.^{17,18} Given the risk of clinical neurotoxicity, other studies have assessed whether WBRT can be *eliminated* from the initial management of PCNSL. In a multicenter, phase III trial, patients were randomized to receive HD-MTX–based chemotherapy with or without WBRT.¹⁹ Five hundred and fifty-one patients were enrolled, of whom 318 were treated per protocol. The intent to treat analysis revealed that patients treated in the combined modality arm (chemotherapy + WBRT) achieved prolonged progression-free survival (PFS) but no improvement in OS, demonstrating that the elimination of WBRT from the treatment regimen did not compromise OS. This has led to deferral of WBRT and chemotherapy-alone approaches for newly diagnosed PCNSL patients. These approaches are based on a foundation of HD-MTX. Variable doses and schedules of HD-MTX have been utilized, but in general, doses ≥ 3 g/m² delivered as an initial bolus followed by an infusion over 3 hours administered every 10 to 21 days is recommended for optimal outcomes and adequate CSF concentrations.²⁰ Multiple, phase II studies have demonstrated the safety, efficacy, and relatively preserved cognition of HD-MTX–based chemotherapy regimens.^{21,22} Moreover, longer duration of induction chemotherapy with HD-MTX (>six cycles) results in higher complete response proportions.^{16,21}

Several first-generation chemotherapy regimens for PCNSL included intrathecal chemotherapy. However, a number of non-randomized studies that included intrathecal chemotherapy did not improve outcomes in PCNSL relative to regimens that did not include intrathecal injections of chemotherapy.^{23,24} Moreover, the ability to consistently achieve micromolar concentrations of MTX in the CSF at a dose of 8 g/m² has led to the elimination of intrathecal chemotherapy from most of the chemotherapy regimens currently in use. However, the question regarding the role of intrathecal chemotherapy in the management of PCNSL should ultimately be addressed in a randomized trial.

Rituximab, a chimeric monoclonal antibody targeting the CD20 antigen on B lymphocytes, is being incorporated in combination regimens for PCNSL. When rituximab is administered intravenously at doses of 375 to 800 mg/m², CSF levels from 0.1% to 4.4% of serum levels are achieved. Despite limited CSF penetration, radiographic responses have been observed in relapsed PCNSL patients treated with rituximab monotherapy, and this antibody has been incorporated into contemporary regimens for PCNSL.²⁵ In a cooperative group, phase II study, 44 PCNSL patients were treated with induction chemotherapy consisting of HD-MTX at 8 g/m² (day 1), rituximab at 375 mg/m² (day 3), and temozolomide at 150 mg/m² (days 7 through 11), all of which are drugs with demonstrated efficacy as monotherapy in PCNSL.²² This induction chemotherapy was followed by consolidation chemotherapy consisting of intravenous etoposide 5 mg/kg as a continuous infusion over 96 hours and cytarabine at 2 g/m² every 12 hours for 8 doses. Of these patients, 68% achieved complete response, median PFS of the entire group was 4 years, and median OS was not observed at the time of publication. These results are comparable to any regimen that *includes* WBRT. It is noteworthy that PFS was shorter in PCNSL patients in whom chemotherapy was delayed >1 month after diagnosis compared to those patients who promptly initiated chemotherapy (3-year PFS of 20% versus 59%; $p = 0.05$). This observation highlights the importance of prompt biopsy and early initiation of chemotherapy in this patient population.

Given the limited durability of responses observed in many studies of PCNSL, there is increasing interest in high-dose chemotherapy (HDT) followed by autologous stem cell transplantation (ASCT) as first-line, consolidative therapy for PCNSL. Conditioning regimens including thioTEPA have demonstrated the most encouraging results. In a multicenter, phase II study, 79 patients were treated with induction HD-MTX, cytarabine, rituximab, and thioTEPA, followed by carmustine and thioTEPA conditioning prior to ASCT. The overall radiographic response (ORR) was 91%, 2-year OS was 87%, and treatment-related deaths occurred in <10% of enrolled patients. The toxicities, mostly cytopenias, were manageable.²⁶ There are three ongoing, multicenter, randomized trials comparing the efficacy of consolidative HDT/ASCT versus chemotherapy or WBRT for newly diagnosed PCNSL (Table 105.2).

Treatment in the Elderly

Elderly patients account for more than half of all the subjects diagnosed with PCNSL.²⁷ The risk of neurotoxicity is highest in this population and, in general, chemotherapy alone is the preferred option for this subgroup. The majority of PCNSL patients >60 years of age develop clinical neurotoxicity after treatment with a WBRT-containing regimen, and some of these patients die of treatment-related complications, rather than recurrent disease.²⁸ Several studies have indicated that HD-MTX at doses of 3.5 to 8 g/m² is well tolerated in elderly patients with manageable grade 3 or 4 renal and hematologic toxicity.^{29,30} In a multicenter, randomized, phase II trial of chemotherapy alone in elderly patients with PCNSL, 98 patients were randomized to receive three cycles of either MPV-A (methotrexate 3.5 g/m², days 1 and 15; procarbazine 100 mg/m², days 1 through 7; vincristine 1.4 mg/m², days 1 and 15) or MT (methotrexate 3.5 g/m², days 1 and 15; temozolomide 100 to 150 mg/m², days 1 through 5 and 15 through 19) with one additional cycle of cytarabine (3 g/m² per day for 2 consecutive days) in the MPV arm only. Although trends favored the MPV-A regimen over the simpler, less toxic MT regimen with respect to complete response rate, PFS, and OS, none of these differences reached statistical difference.³¹ Subsequent studies suggest that the addition of rituximab to both MPV and MT could increase the radiographic response rate. Both of these chemotherapy regimens are options in elderly PCNSL patients.

Salvage Treatment

Despite high initial response rates with HD-MTX–based induction therapy, most patients with PCNSL relapse. Moreover, there is a small subset of patients who have HD-MTX–refractory disease. Prognosis of progressive or relapsed PCNSL is poor, with a limited number of prospective, phase II studies for guidance on management. Rechallenge with HD-MTX has been shown to be effective in patients who had previously responded to this agent. In a multicenter, retrospective study of 22 relapsed PCNSL patients, 91% had a radiographic response to the first salvage treatment with HD-MTX, and 100% to second salvage. The median OS from the first salvage was 61.9 months.³² In a phase II trial of 43 patients with relapsed or refractory PCNSL, salvage therapy with high-dose cytarabine and etoposide was followed by HDT/ASCT with a conditioning regimen consisting of thioTEPA, busulfan, cyclophosphamide. There were 27 patients who ultimately proceeded to transplantation. Of 27 patients, 26 had a CR and the median PFS and OS in this group were 41.1 and 58.6 months, respectively.³³ In patients who were not initially treated with HDT/ASCT, this strategy remains an option. It is noteworthy that in a small series of patients with relapsed PCNSL after initial HDT/ASCT, a second autotransplantation was successful as salvage treatment.³⁴ Finally, WBRT in patients who have not received it as a part of their initial

treatment is an effective option in the relapsed PCNSL setting, although the risk of neurotoxicity remains.^{35,36} Many clinicians reserve WBRT for those patients with chemotherapy-refractory disease or at the time of relapse. In a series of 27 relapsed or refractory PCNSL patients treated with WBRT (median dose: 36 Gy), 74% achieved an ORR and the median OS was 10.6 months. Delayed neurotoxicity rates of 15% were noted at doses >36 Gy, even in the setting of short survival.³⁵ Novel therapeutics currently under study for systemic DLBCL have entered early phase clinical trials in primary CNS DLBCL and include bendamustine, lenalidomide, pomalidomide, everolimus, and pemetrexed.⁴

Neurotoxicity

The most frequent complication in long-term PCNSL survivors is delayed neurotoxicity. The exact incidence of delayed neurotoxicity is unclear, because earlier studies did not systematically assess neurocognitive function with serial neuropsychological testing. The elderly are at highest risk for this complication, with nearly

all patients over the age of 60 developing clinical neurotoxicity following combined modality therapy. Treatment with WBRT has been identified as the major risk factor for the development of late neurotoxicity. Common symptoms and signs include deficits in attention, memory, executive function, gait ataxia, and incontinence. These deficits have a detrimental impact on quality of life. Radiographic findings include periventricular white matter changes, ventricular enlargement, and cortical atrophy. Pathologic studies reveal demyelination, hippocampal neuronal loss, and large-vessel atherosclerosis.³⁷ Although the pathophysiology is unclear and likely multifactorial, damage to neural progenitor cells has been implicated to play an important role in radiation-related neurotoxicity.³⁸ Currently, there are no treatments to reverse these delayed neurotoxic effects. It is critical that serial neuropsychological assessments are incorporated into the management of patients with PCNSL, because cognitive outcome is a critical end point. The IPCG has developed an instrument for this purpose, which is composed of quality of life questionnaires and standardized neuropsychological tests that include an assessment of executive function, attention, memory, and psychomotor speed.¹⁵

106 Molecular Biology of Acute Leukemias

Glen D. Raffel and Jan Cerny

INTRODUCTION

Our understanding of the molecular genetics of acute leukemias has improved dramatically over the past decade. Fueled in part by the availability of the complete sequence of the human genome, more than 100 different mutations have been identified that can be causally implicated in the pathogenesis of acute leukemias (Table 106.1). At first glance, the plethora of mutations presents a discouraging prospect for the development of molecular-targeted therapies. However, far more mutations are identified than there are phenotypes of acute leukemia, and a theme is developed in this chapter that many of these mutations must target similar signal transduction or transcriptional pathways. Thus, it is plausible to consider therapeutic approaches that target these shared pathways of transformation. Although many mutations remain to be identified, those observed thus far have provided critical insights into the pathophysiology of leukemia and the development of novel therapeutic targets.

LEUKEMIC STEM CELL

An important emerging concept in the pathobiology of leukemia is the existence of a *leukemic stem cell*. In normal hematopoietic development, there is a rare population of hematopoietic stem cells that have self-renewal capacity and that give rise to multipotent hematopoietic progenitors. These multipotent myeloid or lymphoid progenitors do not have a self-renewal capacity but mature into normal terminally differentiated cells in the peripheral blood. It is hypothesized that there is a leukemic stem cell that has limitless self-renewal capacity and that gives rise to clonogenic leukemic progenitors that do not have self-renewal capacity but are incapable of normal hematopoietic differentiation. Hypothesized functional differences between the rare leukemic stem cells and the bulk of derived leukemic progeny such as increased quiescence or engagement within a protective niche are believed to provide an intrinsic chemoresistance.

The first convincing evidence in support of the existence of a leukemic stem cell was derived from experiments in which human leukemic cells were injected into immunodeficient non-obese diabetic mice with severe combined immunodeficiency disease (NOD-SCID) mice.^{1,2} These data show that the resultant leukemias are derived from as few as 1:1000 to 1:10,000 cells, indicating that there is a rare population of human leukemic cells that have self-renewal capacity in this assay. These cells have similar immunophenotypes to normal self-renewing hematopoietic progenitors and suggest that the leukemogenic mutation occurs in a hematopoietic stem cell. In support of this hypothesis, clonal cytogenetic abnormalities, such as the t(9;22), have been detected in primitive hematopoietic progenitors such as CD34+CD38- cells.³

However, this paradigm has been recently challenged and revised. First, new protocols that enhance engraftment of human leukemia in the xenotransplant setting have been described, suggesting the importance of homing and the role of the microenvironment.⁴ Data also show that it may be the leukemic oncogenes themselves that confer properties of self-renewal. In a murine system, transduction of the leukemia oncogenes mixed-lineage leukemia 1/eleven nineteen leukemia (*MLL/ENL*), monocytic leukemia zinc finger protein/transcriptional intermediary factor 2 (*MOZ/TIF2*) or *MLL/ALL1* fused gene from chromosome 9 protein (*AF9*) can confer properties of self-renewal to purified committed hematopoietic progenitors that have no capacity for self-renewal.^{5,6} *HOX* family and *NOTCH* genes, frequent mutational targets in acute leukemia as discussed later in this chapter, have been found to have significant roles in hematopoietic stem cell self-renewal.⁷ Secondary mutations may also enable activation of similar self-renewal pathways. For example, an analysis of cells from acute myeloid leukemia (AML) blast crisis in chronic myeloid leukemia (CML) shows a shift in the leukemic stem cell to an immunophenotype of a committed myeloid progenitor and concurrent nuclear localization of β -catenin, a process thought to increase stem cell self-renewal.⁸ One of the major goals is the identification of transcriptional programs, genes, and pathways that confer limitless self-renewal and may be targets for therapeutic intervention.

ELUCIDATION OF GENETIC EVENTS IN ACUTE LEUKEMIA

The search for causative mutations in acute leukemia has accelerated in recent years due to the availability of new means for evaluating genome integrity in leukemic cells. The bulk of known translocations and deletions were found by analyzing conventionally stained chromosomal banding patterns of karyotypes. The classical karyotypic analysis is able to identify lesions with a resolution of 5 to 10 Mb. These include balanced reciprocal chromosomal translocations, such as t(8;21)(q22;q22) or t(15;17)(q22;q21); internal deletions of single chromosomes, such as 5q- or 7q-; gain or loss of whole chromosomes (+8 or -7); or chromosome inversions, such as inv(3), inv(16), or inv(8). Array-based technologies such as comparative genomic hybridization (CGH) and single-nucleotide polymorphism (SNP) arrays allow detailed (<35 kb) mapping of unbalanced insertions or deletions.^{9,10} Array CGH determines DNA copy gain or loss by comparing the hybridization of sample DNA to a series of clones or oligonucleotides from regions throughout the genome bound to a chip with a normal reference DNA sample. SNP arrays differ in that oligomers of SNP sequences representing known alleles throughout the genome are used in the array to measure changes in expected genotype and copy number. Finally, low-cost high-throughput sequencing and

microarray-based resequencing techniques have allowed for the identification of new somatic mutations at the single-nucleotide level and are making enormous inroads into the pathogenesis, prognosis, and classification of leukemias with normal cytogenetics. Worldwide initiatives to sequence large numbers of cancer genomes, including leukemia subtypes, are being coordinated and cataloged through the International Cancer Genome Consortium (<http://www.icgc.org>) and the Cancer Genome Atlas (TCGA) (<https://tcga-data.nci.nih.gov/tcga>).¹²

Although intensive effort has focused on chromosomal translocations in leukemia, in part because of their high frequency in various kinds of leukemia, it has become increasingly clear that point mutations play an important role in a spectrum of leukemias. Ongoing high-throughput sequencing initiatives have identified numerous solitary and recurring somatic point mutations within the various leukemic subtypes. The interpretation of this sequencing data requires the identification of *driver* versus *passenger* mutations. *Driver* mutations cause genetic alterations contributing to leukemic pathophysiology, whereas *passenger* mutations occur in leukemia cells and are propagated but are not etiologic to the disease.¹³ It is, therefore, essential that newly discovered somatic mutations in leukemia undergo subsequent biologic validation through sequencing studies in an experimental model system.

MUTATIONS THAT TARGET CORE-BINDING FACTOR

Core-binding factor (CBF) is targeted by more than a dozen different chromosomal translocations in acute leukemias, including the t(8;21) or inv(16), observed in approximately 20% of AMLs,

and the t(12;21), present in approximately 25% of patients with pediatric B-lineage acute lymphoblastic leukemia (ALL).¹⁴ Adult patients with CBF leukemias have a favorable prognosis and the *translocation ETS leukemia (TEL)/AML1* fusion that is expressed as a consequence of t(12;21) in children confers a favorable prognosis among B-cell ALL.¹⁵ CBF is a heterodimeric transcription factor composed of the AML1 (also known as RUNX1 or CBF α 2) and CBF β proteins that is critical for normal hematopoietic development. Loss of function of either subunit results in a complete lack of definitive hematopoiesis.^{16,17} The AML1 subunit of CBF contacts DNA but only weakly transactivates target genes as a monomer. When bound to its heterodimeric partner CBF β , which does not itself contact DNA, transactivation of CBF target genes is dramatically enhanced.^{15,18,19} CBF transactivates a spectrum of target genes that are important in normal myeloid development, including transcription factors (e.g., *Pu.1*, *C/EBP α* and *GATA1*), cytokines (e.g., granulocyte-macrophage colony-stimulating factor [GM-CSF]) and cytokine receptors (such as macrophage-colony stimulating factor [M-CSF] receptor), as well as in lymphoid development, such as the T-cell receptor beta (TCR β) enhancer and the immunoglobulin (Ig) heavy-chain loci.^{18–21} Because CBF targets genes that are important for normal hematopoietic development, a mutation or gene rearrangement that resulted in loss of function of either AML1 or CBF β might be expected to impair hematopoietic differentiation.^{15,18,19}

In addition to frequent involvement of AML1 as a consequence of chromosomal translocations, it has been determined that loss-of-function mutations in AML1 are responsible for the inherited leukemia syndrome familial platelet disorder with propensity to develop AML (FPD/AML).^{22,23} Approximately 3% to 5% of sporadic cases of AML harbor loss-of-function mutations in AML1,^{22,24} with

a higher frequency in M0 AML (25%) and in AML or myelodysplastic syndrome (MDS) with trisomy 21. AML1 loss-of-function mutations are associated with poor rather than good prognosis subgroups such as acute myeloid leukemia 1/eight twenty-one (AML1/ETO); however, this may be a result of occurring in the context of myelodysplasia or mixed lineage leukemias.¹⁹

Compelling evidence has been shown that translocations that target CBF result in a loss of function through dominant negative inhibition. The AML1/ETO fusion associated with t(8;21) and the CBFβ/MYH11 (aka CBFβ/SMMHC) fusion associated with inv(16) are dominant negative inhibitors of CBF and impair hematopoietic differentiation. The expression of either the AML1/ETO or CBFβ/MYH11 fusion genes from their endogenous promoter in mice completely inhibits the function of the residual AML1 or CBFβ alleles, resulting in a lack of definitive hematopoiesis and resultant embryonic lethality.^{16,17} The phenotype observed is the same as that seen in AML1-/- or CBFβ-/- mice, indicating that the AML1/ETO or CBFβ/MYH11 fusions, respectively, act as potent dominant negative inhibitors of the native proteins.^{25,26} However, AML1/ETO and CBFβ/MYH11 have been shown to confer novel contributory gain-of-function effects beyond those involving CBF transcriptional targets. For example, AML1/ETO blocks the tumor suppressors p14ARF and nuclear factor 1 (NF1), whereas CBFβ/MYH11 blocks the expression of p15INK4B.^{27,28} AML1/ETO downregulates DNA-repair genes, perhaps enhancing genomic instability.²⁹ Histone deacetylases (HDAC) and DNA-methyltransferases (DNMT) associated with AML1/ETO alter the epigenetic profile of normal and leukemic cells to generate global changes in gene expression, which may be integral to leukemogenesis.^{30,31} Respective inhibitors such suberanilohydroxamic acid (SAHA) and azacytidine may, therefore, have therapeutic value in CBF leukemias.¹⁸

Although the expression of AML1/ETO leads to alterations of gene expression and hematopoietic cell proliferation leukemia and confers the ability to serially replat in methylcellulose culture (a measure of self-renewal potential), this does not result in the development of leukemia in an animal model. However, co-expression of an alternatively spliced isoform of the AML1/ETO transcript, AML1/ETO9a, which includes an extra exon, exon 9a, of the ETO gene (AML1/ETO9a encodes a C-terminally truncated AML1-ETO protein of 575 amino acids) leads to a rapid development of leukemia in a mouse retroviral transduction-transplantation model.³² The presence of AML1/ETO9a closely correlates with the presence of activating c-KIT mutations in humans, conferring a poor prognosis.³³ Similarly, the expression of CBFβ/MYH11 in adult hematopoietic cells results in leukemia only after a markedly prolonged latency; this latency can be shortened using mutagenesis strategies.²⁶ In summary, translocations that target CBF impair hematopoietic differentiation and confer certain properties of leukemic stem cells, such as the ability to serially replat, but are not sufficient to cause leukemia.

In pediatric B-ALL, 25% of cases have t(12;21)(p13;q13) in which the TEL (aka ETV6) gene translocates into AML1, thus allowing the production of a chimeric protein, TEL/AML1 (aka ETV6/RUNX1).^{34,35} TEL is a transcriptional repressor mediated through associated HDACs and, like AML1, has requirements in fetal and definitive hematopoiesis.^{30,34,36} TEL has 30 known fusion partners of different functional classes, including tyrosine kinases such as in TEL/platelet-derived growth factor receptor (PDGFR) and HOX genes such as in PAX5/TEL, although TEL/AML1 is the most common.³⁴ The fusion protein preserves the central repressor domain in TEL and contains almost the entire AML1 protein sequence. TEL/AML1 has the ability to bind to AML1 consensus sequences but now brings an HDAC-dependent repressor function to AML1-responsive promoter elements, thereby suppressing AML1 targets.³⁴ In addition, physiologic TEL function may be dysregulated by the fusion through heterodimerization via TEL helix-loop-helix domains.³⁴ TEL/AML1 is often found in conjunction with

deletions in the pre-B receptor, VPREG, and the tumor suppressor gene, CDKN2A.³⁷

CHROMOSOMAL TRANSLOCATIONS THAT TARGET THE RETINOIC ACID RECEPTOR ALPHA GENE

The empiric observation that all-*trans*-retinoic acid (ATRA) induces complete responses in patients with acute promyelocytic leukemia (APL) drove the subsequent cloning of the t(15;17) (q22;q21) fusion gene involving the RARα locus. Several groups demonstrated at approximately the same time that the RARα gene on chromosome 17 was fused to a novel partner that was eventually identified as the promyelocytic leukemia (PML) gene.³⁸⁻⁴⁰ Two reciprocal fusion RNA species are produced as a consequence of the translocation, RARα/PML and PML/RARα. The PML/RAR-α fusion protein contains the zinc finger of PML fused to the DNA- and protein-binding domains of RAR-α. Several other chromosomal translocations target the RARα locus and are associated with an APL phenotype. The best studied of these is the promyelocytic leukemia zinc finger (PLZF/RAR-α) fusion, which also aberrantly recruits the nuclear corepressor complex. However, in contrast with the PML/RAR-α fusion, ATRA is not able to relieve corepression mediated by the PLZF/RAR-α fusion and thus is not effective in patients who harbor the t(11;17) associated with this fusion gene.⁴¹

The PML gene has a broad, although incompletely understood role in the homeostasis of nuclear proteins as an organizing component of nuclear bodies (PML-NB) responsible for nuclear structure and shuttling.^{42,43} Recently, an important independent cytoplasmic role for PML as a tumor suppressor has been uncovered, whereby PML localized to the contact points between the endoplasmic reticulum and mitochondrial-associated membranes controls calcium transport and apoptosis.⁴⁴ PML is essential for maintaining self-renewal in hematopoietic stem cells (HSC) as shown by a mouse knockout model of PML, which demonstrated increased proliferation and premature exhaustion in the HSC compartment.⁴⁵ The PML region of PML-RARα was also identified as the target for arsenic trioxide therapy. The binding of arsenic increases PML oligomerization followed by SUMOylation, which in turn, causes PML/RARα degradation.⁴⁶

RARα possesses a DNA-binding domain, a hormone-binding domain, and a retinoid X receptor (RXR)-binding domain, all of which are included within the PML/RARα chimeric protein. RARα transactivates multiple genes involved in myeloid differentiation.⁴⁷ PML/RARα homodimers, enabled via a coiled coil domain in the PML portion, bind to RAR sites and repress genes important for granulocytic differentiation in part through HDAC and corepressor recruitment.⁴⁷ PML/RARα, however, does not have effects solely through dominant inhibition of RARα/RXR binding sites. PML/RARα was shown to have an extended repertoire of DNA consensus binding sites beyond those found for RARα.⁴⁸ PML/RARα appears to extensively modify histone-acetylation and methylation marks in expressing cells in an ATRA-dependent manner, likely through recruitment of HDACs and histone methyltransferases and demethylases within the PML-RARα complex.^{48,49} Drug targeting of PML/RARα-associated epigenetic modifying proteins may, therefore, provide effective adjuncts to ATRA-based therapies.

The transforming properties of the PML/RARα fusion gene have been tested in murine models. Expression of PML/RARα in transgenic mice from promoters that direct expression to the promyelocyte compartment result in an APL-like phenotype.⁵⁰⁻⁵² However, there is approximately a 6-month lag before the development of leukemia, incomplete penetrance of approximately 15% to 30%, and acquired karyotypic abnormalities, all suggesting that second mutations are required for induction of leukemia.

In at least some cases, activating mutations in *FLT3* may be the additional mutation required. ATRA is efficacious in leukemic animals expressing both *PML/RAR-α* and activated *FLT3*, and this model has allowed for the preclinical testing of newer agents such as arsenic trioxide.⁵³

MUTATIONS THAT TARGET HOX FAMILY MEMBERS

HOX genes are homeodomain-containing transcription factors important in patterning in vertebrate development and in hematopoietic development.^{54,55} *HOX* genes are clustered in four genomic loci *HOXA-D*, although additional *orphan HOX* genes occur elsewhere in the genome. Transactivation by *HOX* genes is potentiated by cofactors such as pre-B cell leukemia (*PBX1*) and myeloid ecotropic insertion site (*Meis1*). *NUP98*, a nuclear transport protein, is a fusion partner to at least eight different *HOX* genes in AML as well as numerous other genes.⁵⁶ *HOX* gene expression is tightly regulated during hematopoietic development. *HOXA9*, for example, is expressed in early hematopoietic progenitor cells but is downregulated during hematopoietic differentiation and is undetectable in terminally differentiated cells. The expression of *NUP98/HOXA9* results in derepression of *HOXA* cluster genes, several of which promote HSC self-renewal.^{54,56}

The contribution of the *NUP98* moiety to leukemic transformation is not fully understood. *NUP98* is normally a component of the nuclear pore complex and is constitutively and ubiquitously expressed. However, several lines of evidence suggest that *NUP98* contributes more than a constitutively activated promoter. For example, *NUP98* motifs known as *FG repeats* are essential for transformation and may serve to recruit transcriptional cofactors, such as *CBP/p300*, to *HOXA9* DNA-binding sites.⁵⁷ In murine models of leukemia, overexpression of *HOXA9* alone is not sufficient to cause AML, but coexpression of *HOXA9* with transcriptional cofactors, such as *MEIS1*, results in efficient induction of AML.⁵⁸ Thus, the *NUP98* moiety in the context of the *NUP98/HOXA9* fusion may serve multiple functions, including provision of an active promoter, and recruitment of transcriptional cofactors such as *CBP/p300* that subserve the function of other cofactors such as *MEIS1*. Epidemiologic evidence that the *NUP98* moiety contributes to leukemogenesis includes the observation that there are now a spectrum of fusion proteins involving components of the nuclear pore that are targeted by chromosomal translocations in acute leukemias. These include *NUP98* and *NUP214* fused to a diverse group of partners, including *HOXA9* and *HOXD13*, and the *DDX10*, *PMX1*, *DEK*, and *ABL1* genes, respectively.

Dysregulated *HOX* gene expression may be important in leukemias that do not directly target *HOX* family members. Several proteins that are upstream of *HOX* expression have been observed as fusion genes associated with AML, the most frequent of these are *MLL* gene rearrangements. More than 40 chromosomal translocations target *MLL* and result in fusions of *MLL* with a broad spectrum of partners. In addition, dysregulation of *HOX* genes by an enhancer effect, which occurs in *t(7;10)(q34;q24)*, where the *TCRβ* translocates into the *HOX11* locus, is an important contributor to T cell acute lymphoid leukemia (T-ALL) leukemogenesis.⁵⁹ However, a common biologic feature of all of these may be their ability to dysregulate *HOX* gene expression during hematopoietic development. For example, *t(12;13)* associated with AML results in the expression of high levels of *CDX2* from the *TEL* locus.⁶⁰ *CDX2* is a homeotic protein that regulates the expression of *HOX* family members in the colonic epithelium. As in hematopoietic development, *HOX* gene expression is highest in colonic stem cells in the colonic crypts and is downregulated with maturation. It has been shown that *CDX2* and *CDX4* can dysregulate *HOX* expression in hematopoietic progenitors and can result in leukemia.^{58,60} Evidence to support this includes the ability of *CDX2* to induce leukemia in murine retroviral transduction models.^{58,60}

Taken together, these data indicate that the *NUP98/HOXA9* fusion transforms hematopoietic progenitors in part through dysregulated overexpression and by transactivation mediated through the *NUP98* transactivation domain that recruits *CBP*. However, like other gene rearrangements involving hematopoietic transcription factors, expression of *NUP98/HOXA9* alone is not sufficient to cause leukemia. In murine bone marrow transplant models, *NUP98/HOXA9* induces AML only after markedly prolonged latencies indicative of a requirement for second mutation. Coexpression of *Meis1* or *FLT3ITD* with *NUP98/HOXA9* in mice significantly shortens the latency; however, these mutations are not present in all human cases, suggesting that additional cooperating pathways exist.^{61,62}

CHROMOSOMAL TRANSLOCATIONS THAT TARGET THE MLL GENE

The *MLL* locus is involved in more than 80 different chromosomal translocations with a remarkably diverse group of fusion partners^{63,64} and are associated with mostly French-American-British (FAB) subtype M4 or M5, and fewer with M2 AML. Patients who have received prior chemotherapy for cancer and develop AML (therapy-related MDS/therapy-related AML [t-AML]) often have abnormalities in 11q23, especially those patients treated with topoisomerase inhibitors such as etoposide or topotecan. Chromosomal translocations involving band 11q23 result in the expression of a fusion gene containing amino-terminal *MLL* sequences fused to a wide variety of partners. There has been no common functional motif or activity ascribed to all partners; however, specific fusions may be associated with specific leukemic phenotypes. The *MLL/AF4* fusion associated with *t(4;11)* is frequently observed in infant leukemias and is associated with an ALL phenotype in more than 90% of cases, whereas the *MLL/AF9* fusion associated with the *t(9;11)* is almost exclusively associated with AML. Certain *MLL* fusion genes also have prognostic significance. For example, patients with *t(9;11)(p22;q23)* have a better outcome than those with other translocations involving 11q23.

The *MLL* gene encodes a large, ubiquitously expressed protein. The *Drosophila* protein trithorax, a homolog of *MLL*, regulates patterning and *HOX* gene expression during development. It has been hypothesized, in part based on these observations, that *MLL* might be required for maintenance of *HOX* gene expression.⁶⁵ Mice that have homozygous deficiency for *MLL* have an embryonic lethal phenotype at postconception day 10.5. Even heterozygous animals have developmental anomalies in the axial skeleton and hematopoietic deficits, including anemia.⁶⁶ Thus, as for other genes targeted by chromosomal translocations, *MLL* is important for normal hematopoietic development.

Major advances have been made recently regarding the mechanisms underlying *MLL* and *MLL*-fusion gene function. *MLL* binds a broad cohort of epigenetic regulators including bromodomain-containing 3 and 4 (*BRD3* and *BRD4*); the H3K79 histone methyl transferase, *DOT1*; the lysine-specific demethylase, *KDM1A*; and the polycomb-repressive complex 2 (*PRC2*). Although *MLL* possesses a *Su(var)3-9*, enhancer-of-zeste and trithorax (*SET*) homology H3K4 histone methyl-transferase, it is not retained in *MLL*-fusion proteins. *MLL* and *MLL* fusions also require complex formation with menin (*MEN1*) and lens epithelium-derived growth factor (*LEDGF*) to be able to interact with DNA and activate target genes.^{67,68} *MLL* fusions have been shown to affect transcriptional *poising* at target genes as part of a larger super elongation complex (*SEC*).⁶⁹ The control of RNA polymerase II elongation after recruitment to promoter sites provides an additional layer of regulation to target genes such as *HOXA9*.^{69,70} *MLL* fusions also form a complex known as *DotCom*, which, via associated *DOT1* activity, yields H3K79 di/trimethylation marks, thus altering expression at affected genes.⁶⁹ *MLL*-fusion/*DotCom* interaction allows binding and transcription at target genes of the

Wnt/ β -catenin pathway via binding of nuclear-localized β -catenin. The Wnt pathway is essential for fetal HSC self-renewal, and aberrant activation of its downstream targets mediated by MLL-fusions is hypothesized to confer self-renewal properties to leukemic stem cells (LSCs).⁷¹

Although various MLL fusions have similar transforming properties *in vitro*, there are distinctive differences in disease penetrance and latency in the murine models depending on the fusion partner. It is possible that the MLL gene rearrangement may be critical for transformation, whereas the fusion partners confer properties related to disease phenotype. The long latency of disease in murine models supports the hypothesis that MLL fusions, like the PML/RAR- α and CBF-related fusion proteins, require second mutations to cause leukemia.

As noted previously in the section Leukemic Stem Cell, data indicate that certain MLL fusion genes may also confer properties of self-renewal to hematopoietic progenitors. MLL/ENL expression in common myeloid progenitors or granulocyte-monocyte progenitors in a murine system conferred properties of self-renewal, including the ability to serially replat in methylcellulose cultures and to engender a transplantable AML phenotype in recipient animals.⁵ Similarly, in a mouse model of MLL/AF9 oncogene-induced leukemia, up to a quarter of the leukemic cells exhibited stem cell behavior.⁷² Furthermore, the MLL/AF9-positive LSC are heterogeneous as they give rise to ALL when injected into immunodeficient mice. The same cells cause AML when injected into immunodeficient mice that are transgenic for the human genes stem cell factor (SCF), GM-CSF, and interleukin 3 (IL-3).⁷³ These data indicate that leukemogenic mutations may occur in cells that have no intrinsic self-renewal capacity and yet confer these properties by activation of specific transcriptional programs, which may be further modified by clues from the microenvironment.

MUTATION OF C/EBP α

C/EBP α is a 42-kDa hematopoietic transcription factor that is required for normal myeloid lineage differentiation and that inhibits proliferation.⁷⁴ C/EBP α is downregulated in 50% of AML, often through methylation of its promoter region.⁷⁵ Therefore, loss of C/EBP α function in leukemia likely impairs myeloid differentiation and removes a block on proliferation.⁷⁶ Two major types of C/EBP α point mutations have been described in AML—short frameshifting mutations in the region encoding the amino-terminus, causing the expression of a shortened 30-kDa protein with dominant negative activity, and in-frame insertions or deletions in the region of the carboxy-terminus, which alter the DNA-binding or dimerization domains, causing a loss of function.⁷⁷ Two-thirds of C/EBP α -mutated leukemias have both N- and C-terminal mutations on each allele.⁷⁶ Although the bulk of C/EBP α mutations occur in patients with normal cytogenetics, overall and progression-free survival is more favorable; therefore, C/EBP α status is an important prognostic determinant.⁷⁸ In contrast to AML, 2% of pre-B-ALL has been shown to have an upregulation of C/EBP α or family members through enhancer effects of IgH locus translocation into the C/EBP α locus as seen in t(14;19)(q32;q13).^{79,80}

MUTATION OF GATA-1

GATA-1 mutations are associated with a subset of acute megakaryocytic leukemias (AMKL) (FAB M7), in particular leukemias arising in patients with Down syndrome (constitutional trisomy 21).⁸¹ GATA-1 is a transcription factor promoting erythroid and megakaryocytic development.^{82,83} GATA-1 mutations result in the early termination of the full-length GATA-1 protein; however, translation of a short-form (GATA-1s) from an alternate initiation codon occurs. GATA-1s is theorized to function as either a hypomorphic

or dominant negative allele, and dysregulation of GATA-1 pathways are thought to contribute to leukemogenesis.^{84,85} GATA-1 mutations are often seen in a transient myeloproliferative disorder (TMD), which precedes Down syndrome-associated AMKL, suggesting that a GATA-1 mutation is an early event cooperating with germ-line trisomy 21.⁸⁴ GATA-1 mutations have been noted in Down syndrome fetal livers, and GATA-1s expression in a mouse model causes hyperproliferation of fetal liver megakaryocytes, supporting the hypothesis of an *in utero* origin of the disease.⁸⁶ Current efforts to identify the critical cooperating genes dysregulated in trisomy 21 are utilizing mouse models possessing trisomies syntenic with the 8.35-Mb Down syndrome critical region to identify candidate genes.⁸⁷

t(1;22) TRANSLOCATION ASSOCIATED WITH INFANT AMKL

The t(1;22)(p13;q13) is associated with the majority of non-Down syndrome AMKL in infants and results in the expression of the OTT1/MAL (aka RBM15/MKL1) fusion gene.^{88,89} OTT1 (RBM15) contains three amino-terminal RNA recognition motifs and a Spen paralog and ortholog C-terminal motif that is a transcriptional activator/repressor. *Ott1* deletion in mice reveals multiple hematopoietic roles, including megakaryocyte growth and hematopoietic stem cell function.^{90,91} The MAL (MKL1) gene is a Rho-GTPase-regulated cofactor for serum response factor (SRF) and controls megakaryocyte development.^{92,93} A knockin mouse model expressing OTT1/MAL is able to recapitulate AMKL and demonstrated constitutive transcriptional activation from recombination signal binding protein for immunoglobulin kappa J (RBPJ κ) binding sites, including Notch1 downstream targets, which is essential for its pathogenesis.⁹⁴

MUTATIONS OF EPIGENETIC MODIFIERS

Several translocations associated with leukemia involve transcriptional coactivators and chromatin modifying proteins that have no apparent DNA-binding specificity. These include the mixed-lineage leukemia/CREB-binding protein (MLL/CBP) and MOZ/CBP fusions that involve the transcriptional coactivator CBP and the MLL/p300 and MOZ/TIF2 fusions, which involve the coactivators p300 and TIF2, respectively.^{95,96} Although TIF2 itself is not known to have histone acetylase transferase (HAT) activity, a hallmark of the coactivators CBP and p300, it has a well-characterized CBP interaction domain that serves to recruit CBP into a complex with MOZ/TIF2.⁹⁷ Thus, recruitment of CBP/p300 is a shared theme among this group of fusion genes.

The transcriptional targets and transformation properties of this class of fusion proteins are not fully understood. Transduction of MLL/CBP into primary murine bone marrow cells followed by transplantation results in a long-latency AML, suggesting the need for secondary mutations.⁹⁸ MOZ/TIF2 also results in leukemia in a similar model system. MOZ is a HAT protein that contains a nucleosome-binding domain and an acetyl-coenzyme A-binding catalytic domain. A mutational analysis shows that leukemogenic activity requires MOZ nucleosome-binding activity and CBP recruitment activity, but the MOZ HAT activity is dispensable. These data would be consistent with a CBP gain-of-function in which CBP is recruited to MOZ nucleosome-binding sites.⁹⁷ However, it has also been hypothesized that the leukemogenic potential of this class of fusions may be related to dominant negative interference with CBP/p300 or that the translocation leads to simple loss of function of CBP expressed from one allele. In support of this hypothesis, loss of a single allele of CBP/p300 in the human Rubinstein-Taybi syndrome increases predisposition to malignancies, including colon cancer and mice that are heterozygous for CBP that develop hematopoietic tumors.⁹⁹

The *TET2* gene located on 4q24 belongs to the ten-eleven translocation (TET) family (*TET1*, *TET2*, *TET3*), which converts 5-methylcytosine (5-mC) to hydroxymethylcytosine (5-hmC), the initial step in DNA demethylation. Mutations of the *TET2* gene have been found in 8% to 27% of AML cases, in 20% to 25% of MDS cases, and in 4% to 13% of myeloproliferative neoplasms (MPN) cases. *TET2* mutations are mono-allelic loss of function in most cases, including missense, frameshift, and nonsense mutations. The presence of the mutant *TET2* is associated with superior survival in MDS and inferior survival in AML and chronic myelomonocytic leukemia (CMML).¹⁰⁰ *TET2* mutations are almost mutually exclusive with isocitrate dehydrogenase (*IDH1/2*) mutations, suggesting a similar epigenetic defect as *IDH1/2* mutations.¹⁰¹ In vivo, *TET2* inactivation induced both myeloid and also lymphoid malignancies. The precise mechanisms and downstream effects of *TET2* are as yet unknown.¹⁰²

Mutations in the gene encoding *IDH1/2* functionally overlap with *TET2* mutations, resulting in hypermethylation of leukemia cells, disruption of *TET2* function, and impaired hematopoietic differentiation. *IDH1* and *IDH2* are nicotinamide adenine dinucleotide phosphate (NADP)-dependent IDHs that catalyze isocitrate to alpha-ketoglutarate (α -KG) in the tricarboxylic acid (TCA) cycle.¹⁰³ *IDH1/2* mutations are detected in 15% to 33% of AML, mostly in normal karyotype AML, in 3.5% of MDS, in 2% to 5% of MPN, and also in glioma.¹⁰³ The mutations have been shown to exhibit a gain of function, leading to an aberrant accumulation of 2-hydroxyglutarate (2-HG). 2-HG is an oncometabolite, which inhibits an enzymatic activity of *TET2* and stimulates hypoxia-inducible factor 1-alpha (*HIF1 α*), leading to the initiation and promotion of cancer.¹⁰⁴ The impact of *IDH* mutations on the survival of AML patients is unclear. Some studies have observed no difference in outcome with respect to the *IDH* mutation status, whereas others have demonstrated a poor prognostic impact in certain AML subgroups.

Mammalian DNMTs catalyze the transfer of a methyl group onto the 5'-position of cytosine at CpG dinucleotides. DNMT3A and DNMT3B catalyze de novo DNA methylation, whereas DNMT1 is primarily responsible for maintenance methylation. Recurrent DNMT3A mutations at multiple sites were recently detected in a large cohort (22%) of patients with AML. Several different loss-of-function mutations have been found in all exons of DNMT3A, whereas a missense point mutation at amino acid R882, which decreases catalytic activity and DNA binding affinity, is most frequently identified.¹⁰⁵ DNMT3A-null hematopoietic stem cells have increased self-renewal capacity and lose their differentiation potential, which was accompanied by an aberrant methylation pattern implicated in leukemogenesis.¹⁰⁶ However, knockout of DNMT3A alone was not sufficient to initiate leukemia. DNMT3A mutations were reported to occur more frequently in AML with a normal karyotype and associated with FAB M5 morphology. The association with *NPM1* and *FLT3* mutations, unique DNA methylation and gene expression profiles, as well as unfavorable prognoses were observed in conjunction with DNMT3A mutations.¹⁰⁵

EZH2 is a H3K27 methyltransferase, which is one of the components of PRC2, required for silencing target genes and maintaining the *stemness* in stem cells. EZH2 augments leukemogenesis by the inhibition of differentiation programs in leukemic stem cells.¹⁰⁷ EZH2 mutations were found 6% of MDS cases and in 3% to 13% of MPN cases, but rarely in AML.¹⁰⁸

CHROMOSOMAL TRANSLOCATIONS THAT RESULT IN OVEREXPRESSION OF c-MYC

The chromosomal translocations described thus far result in the expression of aberrant fusion genes. Chromosomal translocations may also result in the overexpression of otherwise normal genes as a result of juxtaposition of a gene not normally expressed in adult hematopoietic tissues adjacent to an active promoter or

enhancer. Most of those identified thus far involve the Ig or TCR enhancer loci, and thus most of these are associated with lymphoid malignancies; however, alternative mechanisms resulting in MYC overexpression have been shown to be important in AML or CML blast crisis.¹⁰⁹

The prototypical example of juxtaposition of an Ig enhancer locus to an oncogene resulting in B-cell leukemia and lymphoma is the t(8;14)(q24;q32), resulting in overexpression of the MYC basic helix-loop-helix/basic region/leucine zipper (bHLH/bZIP) transcription factor on chromosome 8 due to juxtaposition to the Ig heavy-chain enhancer on chromosome 14.¹¹⁰ Similar phenotypes ensue from juxtaposition to other Ig enhancers in the human genome, such as the *Ig κ* locus on chromosome 2 or the *Ig λ* locus on chromosome 22, and are characterized as B-ALL or lymphoma. Overexpression of MYC from Ig enhancers in murine models results in B-cell leukemias and lymphomas, confirming a central role for MYC overexpression in transformation. MYC is fully active as a transcription factor when heterodimerized with MAX. MAX is normally a homodimer, or a heterodimer complexed with MAD, which represses transcription. Overexpression of MYC is thought to shift the equilibrium in favor of an MYC-MAX homodimer that transactivates a wide range of target genes, including those involved in metabolism, cell cycle, and apoptosis and those contributing to leukemogenesis.¹¹¹

CHROMOSOMAL TRANSLOCATIONS INVOLVING THE T-CELL RECEPTOR

T-cell leukemias are often associated with overexpression of a number of genes due to juxtaposition to the TCR enhancer loci (*TCR β* at chromosome 7q34 or *TCR α/δ* at chromosome 14q11). Overexpression is thus associated with T-cell phenotypes, including T-cell ALL and lymphoma. For example, T-cell ALL may be associated with overexpression of bHLH family members that include T-cell acute leukemia 1/stem cell leukemia (*TAL1/SCL*), *TAL2/SCL2*, *LYL1*, homeo-box 11 (*HOX11*), *HOX11L2*, *LIM only 2* (*LMO2*), *LMO1*, and MYC.^{110,112} In addition to the minority of T-ALL cases with gene rearrangements involving these loci, it has been demonstrated that many patients without evident cytogenetic abnormalities overexpress *TAL1*, *LMO2*, *HOX11*, or *HOX11L2*.

POINT MUTATIONS IN ACUTE LEUKEMIA

Oncogenic RAS Mutations

Activating mutations in RAS may be associated with AML, ALL, and MDS, typically at codons 12, 13, or 61 in N- or K-RAS. The reported incidence varies widely between studies from 25% to 44%, and RAS mutations may confer a worse prognosis.^{113,114} RAS mediates signals from upstream receptors through multiple downstream effectors including phosphoinositol 3' kinase (PI3K) and the rapidly accelerated fibrosarcoma/mitogen activated protein kinase/extracellular signal-regulated kinase (RAF/MEK/ERK) pathways.^{114,115} Considerable effort has been devoted to developing small-molecule inhibitors of RAS activation, with a focus on prenylation inhibitors, including farnesyl transferase and geranylgeranylation inhibitors that preclude appropriate targeting of activated RAS to the plasma membrane.^{115,116} Specifically targeting activated RAS mutants remains an attractive option, and prenylation inhibitors appear to have activity in AML. However, clinical activity is not correlated with the presence of activating mutations in RAS or even with inhibition of the target farnesyl transferase itself.^{116,117} Several possible interpretations can be made of these observations, including the possibility that

RAS is activated by mechanisms other than intrinsic point mutations (e.g., constitutively activated tyrosine kinases such as FLT3), that other proteins that are targets of prenylation are important in leukemia pathogenesis, or that farnesyl transferase inhibitors have off-target effects. Additional efforts have focused on inhibiting the downstream effectors instead including PI3K and RAF/MEK/MAPK.¹¹⁵

Activating Mutations in Tyrosine Kinases and Associated Receptors

The identification and characterization of activating mutations in hematopoietic tyrosine kinases has been one of the exciting developments in the pathogenesis of AML. Substantial evidence has been shown that chromosomal translocations that activate tyrosine kinases can contribute to the pathogenesis of CML and other MPNs. The most common of these is the *BCR/ABL* gene rearrangement, but other examples include the *TEL/ABL*, *TEL/PDGFR*, *TEL/Janus kinase 2 (JAK2)*, *H4/PDGFR*, *FIP1/PDGFR*, and *rabaptin/PDGFR* fusion proteins. However, these fusion genes are only rarely encountered in AMLs. Approximately 1% to 2% of cases of de novo AML have the *BCR/abelson (ABL)* gene rearrangement, whereas *BCR/ABL* gene rearrangement is present in 20% to 30% of adult ALL¹¹⁸ and in 2% to 3% of children with ALL.¹¹⁹ The Philadelphia chromosome¹²⁰ is a translocation between the *ABL1* oncogene on the long arm of chromosome 9 and a breakpoint cluster region (*BCR*) on the long arm of chromosome 22, t(9;22), resulting in a fusion gene,¹²¹ *BCR/ABL1*, that encodes an oncogenic protein with constitutively active tyrosine kinase activity. The molecular weight of this protein depends on the precise chromosome breakpoint. Most patients with ALL express a 190-kDa protein (p190), and the remainder express a 210-kDa oncoprotein (p210), which is also commonly found in CML. Although *BCR/ABL* may be necessary and sufficient for the development CML, this is not the case for Ph⁺ ALL. SRC kinases are required for the development of Ph⁺ ALL.¹²² There are many additional epigenetic changes, copy number abnormalities, and mutations downstream of *BCR-ABL* that contribute to the very aggressive clinical course. In addition, very rare cases of disease progression from CML to AML are associated with the acquisition of second mutations such as the *NUP98/HOXA9*, *AML1/ETO*, or *AML1/EV11* rearrangement.

Point mutations in the tyrosine kinase activation loop and juxta-membrane (JM) mutations that activate *FLT3* and *c-KIT*, receptor tyrosine kinases normally expressed on hematopoietic progenitors, have been identified in a significant proportion of AML cases. These findings may have important therapeutic implications with the demonstration of the efficacy of molecular targeting of the *ABL* kinase in *BCR/ABL*-positive CML and CML blast crisis with imatinib.¹²³ Activating mutations in *FLT3* have been reported in approximately 30% to 35% of cases of AML.¹²⁴ In 20% to 25% of cases, internal tandem duplications (ITD) within the JM domain result in constitutive activation of *FLT3*. These can range in size from a few to more than 50 amino acids and are always in frame. Because of the extensive variability in size and exact position of the repeats within the JM domain, it has been hypothesized that these mutations impair an autoinhibitory domain, resulting in constitutive kinase activation in the absence of ligand. In support of this, the crystallographic structure of *FLT3* demonstrates a seven amino acid extension of the JM domain that intercalates into the catalytic domain, thereby precluding kinase activation.¹²⁵ It is likely that ITD mutations in this region would disrupt the structure of the autoinhibitory domain, resulting in kinase activation.

Large studies have confirmed the frequency of these mutations in adult and pediatric AML populations and that mutations in *FLT3* appear to confer a poor prognosis.^{126–128} In an additional 5% to 10% of cases, so-called activating loop mutations occur near

position D835 in the tyrosine kinase.¹²⁹ When these mutations (D835 position) develop during treatment with a *FLT3* inhibitor, they confer resistance to this inhibitor.¹³⁰ High throughput sequencing of AML patient samples lacking known *FLT3* mutations revealed nine novel acquired mutations resulting in amino acid changes within the extracellular, JM, and activation domains; however, only four of the nine changes were *driver* mutations capable of kinase activation and conferring growth factor independence, thus emphasizing the need for biologic validation of sequencing data.¹³¹ *FLT3* mutations may occur in conjunction with known gene rearrangements, such as *AML1/ETO*, *PML/RAR α* , *CBF β /MYH11*, or *MLL*. Analogous activating loop mutations at position D816 have also been reported in *C-KIT* in approximately 5% of cases of AML. Activating mutations in the thrombopoietin receptor, *MPLW515L*, originally identified in myelofibrosis with myeloid metaplasia (MMM), and *MPLT487A* have been observed in both primary cases of AMKL and those secondary to MMM.^{132–134}

The JAK1 through 3 family of nonreceptor tyrosine kinases, in addition to involvement in translocation-derived fusions such as *TEL/JAK2*, have been found to contain activating point mutations. JAK kinases are important signaling intermediaries of multiple hematopoietic cytokine receptors and downstream effectors such as signal transducer and activator of transcription (STAT) proteins.¹³⁵ *JAKV617F*, originally identified as a causative mutation in *polycythemia vera*, is also seen in 8% de novo AML and up to 77% of AML cases transformed from MPN.^{136,137} Additional mutations in *JAK2* and *JAK3* have been isolated in AMKL.^{134,138} Mutations in *JAK1*, 2, or 3 are found in approximately 11% of *BCR/ABL*-negative childhood acute lymphoid leukemia and were often concurrent with deletion of the *IKAROS* lymphoid-specific transcription factor and the *CDKN2A/B* tumor suppressor.¹³⁹ Activating phosphorylation of *STAT3* and *STAT5a/b* has been reported in a substantial proportion (44% to 76%) of AML patients¹⁵⁶ and confers a poor prognosis.^{140,141}

A recently described subtype of precursor ALL is characterized by *cytokine receptor-like factor 2 (CRLF2)* alterations, which occur in about 5% to 7% of pediatric ALL, but in a significantly higher proportion of ALL with Down syndrome (~50%). Overexpression of *CRLF2* is associated with activation of the JAK-STAT pathway. The mechanism involves translocation of *CRLF2* and the *immunoglobulin heavy chain (IGH@)* locus or a deletion juxtaposing *CRLF2* with the *P2RY8* promoter. The *P2RY8/CRLF2* fusion appears to be the most relevant prognostic factor independent of *CRLF2* overexpression for poor outcome and high risk of relapse.¹⁴²

As sequencing efforts continue, it is likely that the list of activating kinase mutations will continue to increase. Because kinases are proving to be relatively amenable to targeted therapy, the opportunities for treatment tailored to these activated kinases should likewise expand.

MUTATIONS IN TUMOR SUPPRESSOR GENES

The Wilms tumor gene was originally described as a tumor suppressor gene in patients with Wilms tumor, aniridia, genitourinary anomalies, and mental retardation (WAGR).¹⁴³ *WT1* is found in adult tumors from different origins, and these tumors arise in tissues that normally do not express *WT1*; therefore, it has been suggested that the expression of *WT1* might play an oncogenic role in these tumors.¹⁴⁴ *WT1* is located at the chromosome 11p and encodes for a transcription factor with N-terminal transcriptional regulatory domain and C-terminal zinc finger domain (exon 7 to 10). The expression of *WT1* inversely correlates with the degree of differentiation in the hematopoietic system because it is present in CD34+ cells and absent in mature leukocytes.^{144,145} *WT1* functions as a potent transcription regulator of genes important

for cell survival and cell differentiation. The disruption of *WT1* function promotes stem cell proliferation and hampers differentiation.¹⁴⁴ Although the precise role of *WT1* in normal and malignant hematopoiesis remains to be further elucidated, it seems to have a dual role in leukemia.¹⁴⁶

The wild-type form of *WT1* is highly (75% to 100%) expressed in a variety of acute leukemias.¹⁴⁷ Consistent with the function of an oncogene is the pattern of *WT1* expression in CML, where low levels are found in the chronic phase, but are frequently increased in the accelerated and blast crisis phase.¹⁴⁸ High levels of *WT1* in patients after chemotherapy is associated with a poor prognosis.

WT1 can act as a tumor suppressor in mice.¹⁴⁹ Mutation of the *WT1* gene can be detected in approximately 10% of normal karyotype AMLs.^{150,151} Mutations that cluster to exon 7 (mostly frameshift mutations resulting from insertions and deletions) and exon 9 (mostly substitutions) are associated with a poor clinical outcome.¹⁵¹⁻¹⁵³ These data are examples of *WT1* as a tumor suppressor. On the other hand, a recent study analyzed mutations within the entire *WT1* coding sequence in a very large cohort of young adults with normal karyotype AML. Contrary to the previous observations,¹⁵¹⁻¹⁵³ *WT1* mutations had no prognostic impact.¹⁵⁴ The different results from these large studies could be explained by the variable biologic role of *WT1* in AML, possible differences in therapy, and other patient characteristics. Therefore, it is desirable that testing for *WT1* mutations becomes part of the risk assessment in future clinical trials to resolve these discrepancies.

TP53 is a tumor suppressor that induces cell-cycle arrest in a response to apoptotic cell death or DNA repair due to genotoxic substances, oncogenes, hypoxia, DNA damage, or ribonucleotide depletion.¹⁵⁵ Inactivation of *TP53* plays an important role during neoplastic transformation in solid tumors and also during progression of hematologic malignancies.¹⁵⁶⁻¹⁵⁸ Animal experiments suggest that the loss of one *TP53* allele could be sufficient for tumorigenesis.¹⁵⁹ This could be relevant for the development of leukemia in patients with a single *TP53* deletion. The loss of 17p in AML is often accompanied by a *TP53* mutation resulting in a loss of heterozygosity.^{160,161} Another possibility is the inactivation of downstream mediators of *TP53*, which affect not only cell-cycle arrest, but also DNA repair and apoptosis. Alternatively, overexpression of genes inhibiting or promoting degradation of *TP53* can be considered—for instance, *MDM2* gene amplifications have been detected in B-CLL.¹⁶² *TP53* deletion can be present as a loss of 17p as a part of a complex aberrant karyotype or as a single chromosomal aberration, both resulting in a poor clinical outcome.¹⁶³⁻¹⁶⁶ The incidence of *TP53* aberrations is high in AML with a complex aberrant karyotype (up to 70%),¹⁶³ but relatively rare in other AML groups (2% to 9%),^{128,163,167} and *TP53* mutations without cytogenetic alteration are a rare event.^{161,168} Low-risk AML t(8;21) or inv(16) are not associated with *TP53* deletion. There is significant positive association between *TP53* deletion and other high-risk chromosomal aberrations such as del(5q) and monosomy 5 and 7.^{20,166} Molecular risk factors *FLT3-ITD* and *NPM1* mutation do not seem to cluster with the *TP53* deletion in complex karyotype patients.¹⁶⁶ *TP53*-deleted cells have greater resistance to various conventional antileukemic drugs.¹⁶⁹ However, published data of multidrug-resistance gene expression showed a negative influence on therapy response in complex aberrant patients.¹⁷⁰ The association of *TP53* deletion and *MDR1* expression has been confirmed for CML, but not for AML.¹⁷¹ Hence, an independent mechanism of resistance needs to be considered.¹⁶⁶ Taken together, *TP53* deletion is a high-risk factor conveying a poor outcome, and further studies are necessary to provide and evaluate alternative therapies.

ACTIVATING MUTATIONS OF NOTCH

NOTCH1 is a component of an evolutionarily conserved pathway shown to direct T-cell lineage determination in early and late stages of lymphocyte development as well as play a role in hematopoietic

stem cell self-renewal.^{172,173} NOTCH1 is a heterodimeric transmembrane receptor. Ligand binding to NOTCH1 allows proteolytic cleavage of the heterodimerization domain (HD) by adamalysin (ADAM)-type protease and γ -secretase of the C-terminal intracellular domain (ICD), which then localizes to the nucleus to function as a transactivator. Involvement of NOTCH1 in T-ALL had been observed with the rare t(7;9)(q34;q34.3) in which translocation of TCR β locus into the *NOTCH1* gene results in the expression of the truncated, transcriptionally active ICD. A series of point mutations in NOTCH1 were identified in over half of all T-ALL cases.^{112,174} These mutations clustered in two primary locations, the HD and the proline-, glutamate-, serine-, and threonine-rich (PEST) domain. The missense mutations within the HD domain make NOTCH1 more amenable to γ -secretase-mediated cleavage, thus enhancing activation. The PEST domain controls the rate of degradation of the activated ICN. PEST domain mutants are primarily small insertions/deletions into the reading frame, causing a deletion of all or part of the domain and extending the half-life of the activated ICN. An alternative mechanism for NOTCH1 activation are inactivating mutations of the F Box protein, FBXW7, which is a component of the ubiquitin ligase complex that targets the NOTCH1 ICN as well as MYC for degradation and which occurs in ~15% of T-ALL.^{110,175}

Fortuitously, γ -secretase inhibitors (GSI) had already undergone significant clinical development due to the involvement of γ -secretase in processing the pathogenic β -amyloid peptide associated with Alzheimer's dementia. Initial clinical trials of GSIs in T-ALL have shown minimal effects on disease and significant gastrointestinal toxicity.¹⁷⁶ Use of GSIs in combination with agents affecting alternative pathways may provide synergism and improve efficacy. Treatment of a mouse model of T-ALL with GSIs and corticosteroids has demonstrated that GSIs are capable of abrogating corticosteroid resistance in established cell lines as well as limiting GSI-mediated gut toxicity.¹⁷⁷

MUTATIONS ALTERING LOCALIZATION OF NPM1

Nucleophosmin (NPM1) encodes a protein that acts as a molecular chaperone between the nucleus and cytoplasm. It is involved in multiple cellular processes, including the regulation of TP53/ARF pathways, ribosome biogenesis, and the duplication of centrosomes.¹⁷⁸ *NPM1* had been previously identified in acute leukemias as a translocation fusion partner with *RAR* and *MLF* as well as with *ALK* in anaplastic large cell lymphoma. Aberrant cytoplasmic localization of *NPM1* has been observed in 25% to 30% of adult AML and is associated with point mutations within exon 12, which are hypothesized to enhance a nuclear export motif within the expressed protein.¹⁷⁹ The mechanism by which mutated *NPM1* causes leukemia is not clear; however, the cytoplasmic localization of *NPM1* is thought to be intrinsic to its altered function.¹⁸⁰ *NPM1* mutations are found more frequently in AML with normal karyotypes (50% to 60%) and more apt to have *FLT3-ITD* mutations as well. Among normal cytogenetic AMLs, the presence of cytoplasmic *NPM1* in the absence of the *FLT3-ITD* is associated with a more favorable prognosis.¹⁸⁰

MUTATION OF LYMPHOID DEVELOPMENT GENES IN ACUTE LYMPHOID LEUKEMIA

An important mechanism underlying the pathogenesis of B-lineage ALL is the mutation of transcription factors essential for B-cell commitment and differentiation.¹⁸¹ Due to the requirement of these factors for normal early to late precursor B development, the immunophenotypic stage most closely related to the leukemias, it is hypothesized that the loss of normal expression levels leads to a block in differentiation, a critical step in leukemogenesis.¹⁸²

Although translocations involving these genes had been identified in a smaller percentage of B-cell ALLs, earlier, high-resolution SNP arrays and genomic sequencing of disease samples has actually demonstrated that frequent microdeletions and point mutations are extremely common.¹⁸¹ PAX5 is a master regulator of B-cell development at the pro- and pre-B-cell stage, the immunophenotypic stage most closely related to many B-ALLs.³⁷ PAX5 is a DNA-binding protein capable of interaction with corepressors, chromatin remodeling proteins, and other transcription factors such as erythroblastosis virus E26 oncogene homolog-1 (ETS1) and myeloblastosis (MYB).³⁷ The dual role of PAX5 is to simultaneously transactivate downstream factors promoting B-cell development and repress genes of alternative lineages such as *NOTCH1* and *CSFR1*.¹⁸³ Deletion of *Pax5* in mice yields early B cells that are not completely committed to B differentiation and can be transdifferentiated through the use of cytokines into other lineages.¹⁸³ Several rare translocations have been identified involving PAX5, including dic(9;12)(p13;p13), generating the PAX5/ETV6 fusion protein, which functions as a dominant negative.¹⁸⁴ In actuality, 30% of B-ALLs possess monoallelic loss-of-function mutations when examined by sequencing.¹⁸² How PAX5 haploinsufficiency contributes to B-ALL leukemogenesis is not entirely clear, and PAX5 mutational status does not appear to influence prognosis.¹⁸¹

IKAROS family members (IKZF1–3) are also frequently mutated in B-ALL.¹⁸⁵ IKZF1 is essential for hematopoietic stem cell function and lymphoid commitment.^{186,187} IKZF1 possesses zinc finger domains important for DNA-binding domains and homo/heterodimerization. Like PAX5, IKZF1 both activates lymphoid-specific genes such as IL-7R and represses genes, such as PU.1, required for alternative lineages. The function of IKZF1 as a transcriptional activator may be modulated through inherent mechanisms of chromatin remodeling and transcriptional elongation.¹⁸⁸ Approximately 15% of pediatric B-ALL patients have deletions or point mutations in IKZF1 leading to loss of function or dominant negative activity and correlating with a poor prognosis.¹⁸⁵ Interestingly, IKZF1 mutations are more frequently associated with mutations in tyrosine kinases such as BCR/ABL1 and JAK2 and cytokine receptors such as IL7R and CRLF2.³⁷ Furthermore, IKZF1 mutations appear in 20% of lymphoid blast crises evolving from chronic myelogenous leukemia.¹⁸⁹

Other recurrent mutations have been found, to a lesser frequency, in a large number of lymphoid-specific transcription factors, including, for example, E2A, encoded by the *transcription factor 3 (TCF3)* gene, EBF1, and LEF1. The most common mutation in TCF3 in B-ALL is the translocation, t(1;19)(q23;p13), encoding the fusion product, TCF3/PBX1, which is postulated to dysregulate both B-cell and HOX-associated pathways.¹⁹⁰ EBF1 has reported monoallelic loss-of-function mutations in B-ALL, whereas *LEF1* has been observed with mono- and biallelic deletions in both T- and B-ALL.¹⁸² The common feature of these genetic lesions are their requirement in normal lymphopoiesis, and deciphering the pathophysiologic effect of each mutation, particularly with regard to haploinsufficiency, will guide future therapeutic efforts.

MUTATIONAL COMPLEMENTATION GROUPS IN ACUTE LEUKEMIAS

Several lines of evidence indicate that more than one mutation is necessary for the pathogenesis of acute leukemia. First, there is evidence for the acquisition of additional cytogenetic abnormalities with disease progression from CML to AML (i.e., CML blast crisis). Published examples of progression in BCR/ABL-positive CML include the acquisition of t(3;21) *AML1/EV11*, t(8;21) *AML1/ETO*, or t(7;11) *NUP98/HOXA9* gene rearrangements. Progression of chronic myelomonocytic leukemia to AML in a patient with the *TEL/PDGFR* gene rearrangement was associated with acquisition of a t(8;21) *AML1/ETO* gene rearrangement.¹⁹¹ Second, expression of the *AML1/ETO* or *CBFβ/MYH11* fusion proteins in murine models is not sufficient to cause AML.^{26,192} Chemical mutagens

must be used in these contexts to generate second mutations that cause the AML phenotype. Third, evidence indicates that in some cases the *TEL/AML1* gene rearrangement associated with pediatric ALL may be acquired in utero, but ALL does not develop until years later, indicating a requirement for a second mutation.¹⁹³ Fourth, AML develops in transgenic mice that express the *PML/RAR-α* fusion protein only after a long latency of 3 to 6 months, with incomplete penetrance, indicating a need for a second mutation.^{50–52}

The genetic epidemiology of AML provides important clues to the nature of the collaborating mutations. One broad complementation group in AML is comprised of mutations that activate signal transduction pathways. These include activating mutations in *FLT3*, *RAS*, and *KIT*, and more rarely, the *BCR/ABL* and *TEL/PDGFR* fusion associated with disease progression in CML. These can be viewed as a complementation group because, although they are collectively present in approximately 50% of cases of AML, they rarely, if ever, occur together in the same patient.

A second complementation group, typified by translocations involving hematopoietic transcription factors, includes *AML1/ETO*, *CBFβ/SMMHC*, *PML/RARα*, *NUP98/HOXA9*, *MLL* gene rearrangements, and *MOZ/TIF2* and they are never observed together in the same leukemia. In general, this second class of mutations impair hematopoietic differentiation and may confer properties of self-renewal to the leukemic stem cell but are not sufficient to cause leukemia when expressed alone. However, one mutation from each of these two complementation groups often coexists in the same leukemia. For example, activating mutations in *FLT3* or *RAS* have been observed in association with virtually all of the fusion genes in the second class described earlier.¹⁹⁴

These findings suggest a hypothesis for pathogenesis of AML in which there are two broad classes of cooperating mutations (Fig. 106.1A).¹⁹⁴ One class, exemplified by activating mutations in *FLT3* or *RAS*, confers either a proliferative or survival advantage, or both, to hematopoietic progenitors but do not affect differentiation. These mutations do not confer self-renewal capacity as assessed in part by the ability to serially replat in culture or to serially transplant disease in murine models.^{195,196} A second class of mutations, exemplified by *AML1/ETO*, *CBFβ/SMMHC*, *PML/RARα*, *NUP98/HOXA9*, *MLL* gene rearrangements, and *MOZ/TIF2* serve primarily to impair hematopoietic differentiation and confer properties of self-renewal. Together, these cooperating mutations induce the AML phenotype characterized by enhanced proliferative and survival advantage, impaired differentiation, and limitless self-renewal capacity. Although the two class model holds for a limited number of mutational combinations, it likely broadly simplifies the interplay between genetic lesions, because many have dual pleiotropic effects on proliferation and differentiation.

Deeper insight into the cooperativity of different mutations has been aided by whole-genome or whole-exome sequencing of DNA samples. The Cancer Genome Atlas Consortium recently published the results of sequencing 200 individual AML samples along with matched epigenetic and RNA expression analysis.¹² Only an average of 13 coding mutations/genomes were uncovered, less than observed for most solid tumors. Mutations were grouped into the functional classes: transcription factor fusions, NPM1 related, tumor suppressors, DNA methylation related, signaling, chromatin modifying, myeloid transcription factor, cohesion complex, and spliceosome complex related. Certain mutational groups are mutually exclusive of each other, indicating possible convergent downstream pathways. For example, mutations in cohesion, spliceosome, signaling, and histone modification pathways do not usually occur in the same patient (Fig. 106.1B).^{12,197} Experimental validation of these novel individual mutations alone or in conjunction with suspected cooperating lesions is an important focus to identify driver versus passenger mutations and clinical significance. In addition, sequencing of a population, which allows for the quantification of mutational frequency in subclones in consecutive patient samples during the diagnosis, treatment, and relapse, identifies the mutations important for leukemia, initiation, progression, and resistance.¹⁹⁸

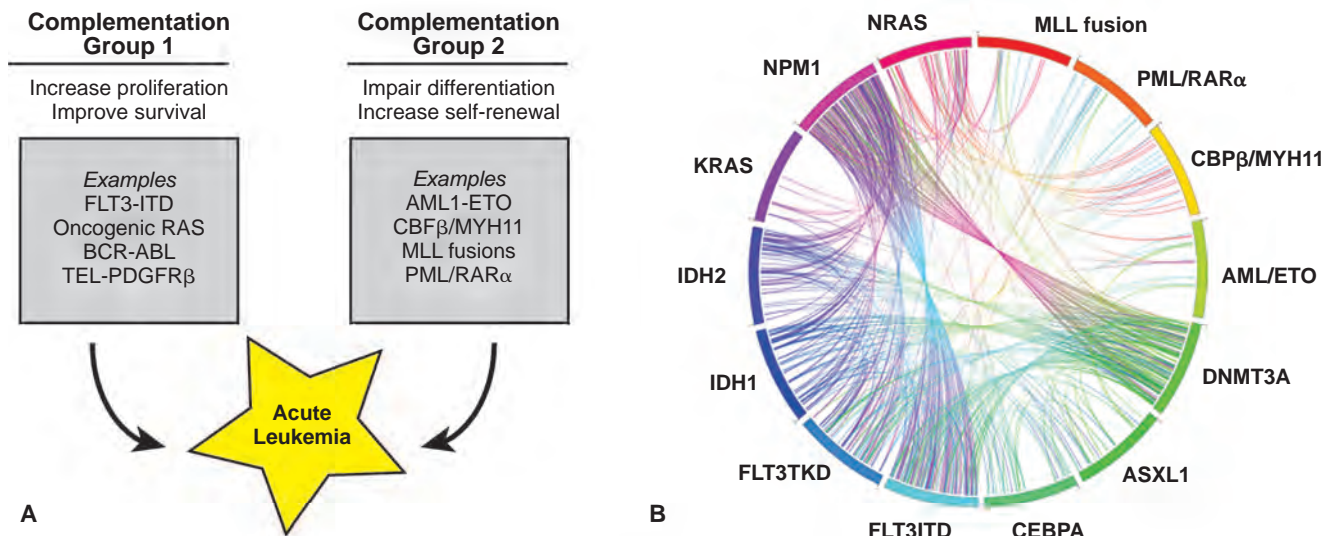

Figure 106.1 Cooperating mutations in acute leukemia. **A:** A classic model of leukemogenesis, composed of two broad complementation groups, is defined by a lack of concurrence of any two mutations in the same complementation group in the same patient. One group is characterized by activating mutations in signal transduction pathways. When expressed alone, these mutations confer a proliferative or survival advantage, or both, but do not affect differentiation. The second group is associated with impaired differentiation and the ability to confer properties of self-renewal to hematopoietic progenitors. Together, the complementation groups collaborate to engender the acute leukemia phenotype. **B:** Circos plot showing concurrent mutational groups in 498 cases of AML. Each connecting line represents simultaneous mutations in an AML sample and demonstrates the how high resolution analysis of AML genomes can establish complementation groups for recurrent mutations. (Modified from Sanders MA, Valk PJ. The evolving molecular genetic landscape in acute myeloid leukaemia. *Curr Opin Hematol* 2013;20:79–85.)

CONCLUSION

The quest to elucidate the essential pathophysiologic changes involved in leukemogenesis has been accelerated with the usage of newer technologies, such as high resolution mapping and high throughput sequencing. It is now possible to identify specific molecular pathways complementing known recurrent translocations as well as gaining insight into the mechanisms underlying normal karyotype leukemias. Not only can these novel mutations be used

for more accurate prognostication, but they can also provide an opportunity for drug development, targeting the essential pathways dysregulated in leukemia. As the availability of pathway-targeted therapeutics increases, interrogation of a patient's leukemia for alterations at the genomic level may allow for individualized therapy addressing the pathways responsible for leukemic cell survival, proliferation, and differentiation, which ideally would improve treatment efficacy and reduce therapy-related morbidity and mortality.

107 Management of Acute Leukemias

Partow Kebriaei, Marcos de Lima, Elihu H. Estey, and Richard Champlin

INTRODUCTION

Acute leukemias result from malignant transformation of immature hematopoietic cells followed by clonal proliferation and accumulation of the transformed cells. The pathogenesis of leukemia transformation is incompletely defined but is likely to be a multistep process.¹ Acute leukemias are characterized by aberrant differentiation and maturation of the malignant cells, with a maturation arrest and accumulation of leukemic blasts in the bone marrow. Acute leukemias are categorized according to their differentiation along the myeloid or lymphoid lineage. In 10% to 20% of patients, the leukemic cells have characteristics of both myeloid and lymphoid cells. Typically myeloid and lymphoid markers are found on the same cell. Less often, separate myeloid and lymphoid populations are present.

Hematopoietic cells are derived from stem cells and progenitors giving rise to the myeloid and lymphoid system. Stem cells have the fundamental properties of self-renewal and differentiation into distinct lineages. Hematopoietic stem cells and progenitors are resident in the bone marrow where they are supported and regulated through interactions with the local microenvironment. Leukemia likely develops after transformation of a hematopoietic stem cell or progenitor, which acquires stem cell–like properties of unlimited self-renewal.² The malignant stem cells represent a small fraction of the leukemia. The bulk of leukemic cells are the differentiated progeny that undergo limited maturation along the myeloid or lymphoid lineage. Leukemia chemotherapy must eradicate the disease while sparing normal hematopoietic stem cells. Treatments that eradicate the differentiated leukemia cells typically do not eradicate the malignant stem cells; consequently, relapse of the leukemia commonly occurs.³ High-dose, stem cell–toxic therapies may be used if followed by hematopoietic stem cell transplantation (HSCT) to restore normal hematopoiesis, and HSCT is an important modality of treatment for acute leukemias. However, a significant antileukemia effect mediated by donor T and natural killer (NK) cells also plays an important role in allogeneic transplantation, particularly for acute myelogenous leukemia (AML). A better understanding of the biology of normal and malignant stem cells and the marrow microenvironment is required for development of more effective therapies.

Although the cause of acute leukemias is unknown, malignant transformation is unlikely to be the result of a single event. Rather, it is likely caused by the culmination of multiple processes that produce genetic damage secondary to physical or chemical exposure in susceptible progenitor cells. Genomic analyses indicate that AML has fewer mutations than all solid tumors studied to date, with an average of 13 coding mutations per patient, of which only an average of 5 (and on occasion as few as 2) are recurrently mutated (*driver*) mutations; among the latter aberrations in DNA (cytosine-5)-methyltransferase 3A (*DNMT3a*), isocitrate dehydrogenase (*IDH*), tet methylcytosine dioxygenase 2 (*TET2*), or nucleophosmin (*NPM1*) contribute to the establishment of a founding AML clone and in FMS-like tyrosine kinase 3 (*FLT3*) to progression to the clinically apparent disease. The nonrecurrent *passenger*

mutations appear to represent mutations that occur during the life span of normal hematopoietic progenitors and are retained when a malignant mutation(s) occurs. Over time, subclones arise characterized by other mutations that contribute to resistance.^{4,5} Leukemia may occur following exposure to a number of carcinogens, such as benzene or radiation exposure. Acute leukemias may occur following chemotherapy, such as alkylators or topoisomerase II inhibitors, or radiation therapy given for another malignancy.^{6,7} These secondary leukemias typically have a high risk of cytogenetic abnormalities and have a poor prognosis. Other acquired factors include infectious agents and environmental toxins. Among infectious causes, the Epstein-Barr virus is associated with mature B-cell or Burkitt's acute lymphoblastic leukemia (ALL). Inherited genetic abnormalities that predispose to leukemia include ataxia telangiectasia, Down syndrome, and certain polymorphisms in Methylene tetrahydrofolate Reductase (*MTHFR*) (a gene involved in the folate metabolism).⁸

The presenting clinical symptoms are a result of bone marrow failure or the effects of tissue infiltration or circulating leukemia cells. Patients commonly complain of fatigue or spontaneous bleeding. Weight loss, fever, night sweats, and lethargy may also be present. Infections related to neutropenia may occur. Central nervous system (CNS) involvement is more common in ALL than AML. Bone and testicular involvement is also more commonly seen in ALL, and most commonly in children rather than adults.⁹ On physical examination, pallor and signs associated with thrombocytopenia may be present, such as gingival bleeding, epistaxis, petechiae, ecchymoses, or fundal hemorrhages. Less commonly, generalized lymphadenopathy, hepatosplenomegaly, or dermal involvement by leukemia cutis may be present. T-lineage ALL may commonly present with a mediastinal mass.

The diagnosis of acute leukemias requires morphologic identification of malignant blasts in the blood and bone marrow.¹⁰ This requires an evaluation of peripheral blood and bone marrow aspirate smears, phenotypic analysis of the blasts by cytochemical studies and flow cytometry, or immunohistochemistry with an appropriate panel of surface and cytoplasmic markers. Acute leukemias are classified according to their differentiation into the myeloid or lymphoid lineage, although some cases appear biphenotypic. The French–American–British Group (FAB) described a widely utilized classification system¹¹ that has been largely replaced by the World Health Organization's (WHO) classification system.¹² Cytospin slides made from cerebrospinal fluid (CSF) are used to diagnose CNS involvement. The current definition of CNS involvement used by the Children's Cancer Group (CCG) is greater than five white blood cells (WBC) per microliter of CSF plus unequivocal blasts identified on the cytospin.¹³ However, the risk for CNS relapse and the need for additional CNS-directed therapy is controversial when there are less than WBC per microliter of CSF, but blasts are present. Some studies suggest that the presence of blasts, even in the absence of pleocytosis, requires additional CNS-directed therapy,¹⁴ whereas others do not. A related concern is the prognostic significance of a traumatic lumbar puncture at diagnosis. Most studies concur that the presence of blasts in a traumatic lumbar puncture is associated with an inferior outcome.¹⁵

ACUTE MYELOGENOUS LEUKEMIA

AML is characterized by limited myeloid differentiation of the malignant cells. The malignant cells characteristically undergo maturation arrest at the level of the blast or promyelocyte, although varying proportions of mature hematopoietic cells are leukemia derived. The cells display myeloid specific markers, including Auer rods (aberrant primary granules), cytochemistry (Sudan black, myeloperoxidase, or nonspecific esterase), and cell surface antigens.¹¹ The WHO classification system's criterion for a diagnosis of AML is >20% blasts in marrow or blood, with patients having <20% blasts said most often to have a myelodysplastic syndrome (MDS). However, this distinction is purely arbitrary. And, indeed, the natural history of patients with 10% to 19% blasts (high-risk MDS) frequently bears more resemblance to that of AML than to that of patients with <10% blasts. Furthermore, the outcome of AML therapy is often similar in patients with high-risk MDS as in those with AML.

Management Options for Acute Myelogenous Leukemia

Broadly speaking, there are three management options for AML: supportive care only, supportive care plus standard anti-AML therapy, or supportive care plus investigational anti-AML therapy. When the disease was first systematically described 50 years ago, few patients lived more than 4 to 6 months after diagnosis. Today, with the advent of better antibiotics and transfusion practices, the natural history is almost certainly better, particularly in patients with WBC <25,000 to 50,000/ μ L. Nonetheless, it is safe to say that patients will, on average, lose >90% of their remaining life expectancy if given supportive care only. Furthermore, quality of life suffers dominated by time spent waiting for frequent transfusions and hospital admissions for infections, which ultimately lead to death. For these reasons, patients presenting to academic medical centers are generally interested in treatment beyond supportive care. This leads to a decision between standard and investigational therapies. The results of the latter are, by definition, unknown. It follows that the decision must rest on the likely outcome of standard therapy. The worse the outcome, the more likely appropriately informed patients select a clinical trial. Hence, the topic of prognostic factors with standard therapies is fundamental to the management of AML. Here, standard induction therapies will refer to (1) 3 days of an anthracycline, usually daunorubicin or idarubicin (days 1 through 3), plus 7 days of ara-C (100 to 200 mg/m² days 1 through 7), (2) decitabine or azacitidine, or (3) a lower dose of ara-C and standard postremission therapies of the previous, including ara-C at doses of 0.5 to 3.0 g/m².

Prognostic Factors in Acute Myelogenous Leukemia

There are two types of prognostic factors: those associated with treatment-related mortality (TRM) and those associated with resistance to therapy. Although there is considerable overlap between these two, TRM is often defined as death occurring within the first 28 days of initial therapy or occurring in patients in remission. Patients dying within the first 28 days appear to be a qualitatively distinct group. Resistance then may be considered as failure to enter remission despite not incurring TRM or as relapse from remission. Although considerable attention is often devoted to TRM and associated morbidity, there is little doubt that even in patients in their 70s, resistance is a more frequent cause of failure to enter complete remission (CR), and that relapse is at least threefold more common than death in CR.

Predictors of Treatment-Related Mortality

Although it is commonly believed that age is the principal covariate associated with TRM, Walter et al.¹⁶ found that performance status is more important than age and that both interact with lower albumin and platelet count, higher creatinine, WBC and percentage of blood blasts, and secondary AML. These were all used to compute a TRM score following the use of 3+7 as given in the Southwest Oncology Group (SWOG) or higher doses of ara-C as given at M. D. Anderson Cancer Center (MDACC). As such, they defined a group of patients who might be candidates for *less intense* therapies. However, this possibility needs to account for decreasing TRM rates, as noted by Othus et al.¹⁷ In SWOG, these declined from 18% in 1991 through 1995 to 3% in 2006 through 2009. Analogous figures at MDACC were 16% and 4%. The decline was independent of covariates such as those considered in the TRM score. The possibility that this reflected a tendency in recent years to give less intense drugs, such as azacitidine or decitabine rather than 3+7, to older patients at high risk of TRM who thus would be excluded from analyses seems unlikely because the same temporal trend in TRM was found in both younger and older patients; it seems improbable that the former were more likely to receive less intense therapy in recent years. Othus et al.'s data emphasize that the main problem in AML therapy is resistance. Hence, merely decreasing intensity is unlikely to result in improved outcomes unless efficacy is improved in parallel.

Predictors of Resistance to Standard Therapy

Cytogenetics. Various means to classify pretreatment AML cytogenetics have been proposed (Table 107.1 and 107.2), and generally separate patients into three to four distinct prognostic groups.

Favorable Group. The core binding factor (CBF)-related AMLs have the most favorable prognosis and constitute 10% to 15% of cases in patients under age 60 years.¹⁸ CBFs regulate the transcription of genes involved in the differentiation of normal blasts into mature progeny. CBFs contain a β unit (*CBFB*, located on the long arm of chromosome 16) and an α unit, one of which is known as *RUNX1* (formerly *AML1* and located on chromosome 21). The CBF AMLs result from translocations involving *RUNX1* or *CBFB*. Specifically, in t(8;21) *RUNX1* is fused with *RUNX1T1* (formerly *ETO*) located on chromosome 8, whereas in inv(16), *CBFB* is linked with the *MYH11* gene located on the short arm of chromosome 16. These abnormal CBFs exert a *dominant negative* effect over normal CBFs, leading to differentiation block and, in the presence of other genetic aberrations that promote survival of the affected stem cells, to AML. It is important to distinguish deletion of the long arm of chromosome 16 (del16q), which does not affect *CBFB*, from translocation between the two chromosome 16s, t(16;16), which is quite rare but does disrupt *CBFB* and, unlike del16q, behaves clinically like inv(16). Eighty-five percent of cases of inv(16) or t(8;21) AML are found in those under age 60 years. Although inv(16) is most frequently associated with the FAB subtype M4Eo, 40% of the 145 cases of inv(16) AML seen at MDACC over the past 25 years have had less than 5% eosinophils. Similarly, although t(8;21) AML is most often seen in the FAB subtype M2, 30% of the 124 cases at MDACC were seen in association with other FAB subtypes.

Inv(16) AML and t(8;21) AML differ in several ways. For example, t(8;21) tends to present with lower WBC counts and is frequently accompanied by the loss of a sex chromosome (particularly the Y) or a deletion (del) of the long arm (q) of chromosome 9 (del9q), whereas inv(16) is often accompanied by trisomy (+) 22 (+22), + (8), or + (21). Although both inv(16) and t(8;21) are distinguished by CR rates of approximately 90% and long remissions and survival, inv(16) AML is more apt to respond once relapse occurs; as a result, patients with inv(16) tend to live longer

TABLE 107.1

Acute Myeloid Leukemia Prognostic Index

Group	NCRI (formerly MRC)	SWOG/ECOG	CALGB
Best	inv(16); t(8;21)	inv(16); t(8;21) w/o del (9q) or complex changes	inv(16); t(8;21)
Intermediate	Normal; 11q abnormalities ^a ; +8; Others not in favorable or unfavorable groups	Normal; +8; Others not in favorable or unfavorable groups	Normal; t(9;11); +8 (for relapse); del(5q); Loss of 7q
Worst	-5/-7; Complex (≥ 5 chromosomes involved)	-5/-7; Complex (≥ 3 chromosomes involved); 11q abnormalities ^a ; inv(3q); del(20q); t(6;9); abnormal 17p	Complex (≥ 3 chromosomes involved); -7; +8 (for survival); inv(3)

NCRI, National Cancer Research Institute; MRC, Medical Research Center; SWOG, Southwest Oncology Group; ECOG, Eastern Cooperative Oncology Group; CALGB, Cancer and Leukemia Group B.

^a Patients with t(9;11) may fall into the intermediate group and patients with other 11q abnormalities into the unfavorable group.

than those with t(8;21). The prognosis of CBF AML is quite variable (although not as variable as normal karyotype AML). Thus, long-term remissions occur in only 25% to 30% of patients aged >65 years or with high levels of mutant tyrosine-protein kinase (*C-KIT*) alleles.¹⁹

Worst Group. There is some debate as to the placement of patients with other abnormal karyotypes. Thus, for example, both the Medical Research Council (MRC) and SWOG cytogenetic classification systems include patients with +8,-Y in an *intermediate* prognostic group together with normal cytogenetic (NC)-AML (see Table 107.1). However, although the MRC considers del20q or t(6;9) AML in its intermediate group, the SWOG places these in its *worst* group, and other differences exist (see Table 107.1). However, there is very little debate about the great bulk of patients

in the *worst* group: those with monosomy of chromosome 5 (-5), and/or 7 (-7), deletions (del) of the long arms of chromosomes 5 (del 5q) or 7 (del 7q) and with abnormalities of 3q. Particularly poor prognoses have been associated with *complex* abnormalities involving at least three to four distinct changes. In the last 5 years, some of the prognostic import of complex cytogenetics has been attributed to an association with a *monosomal karyotype* (MK+) defined by the presence of two or more autosomal monosomies (i.e., not involving the X or Y chromosome) or by the presence of one autosomal monosomy and a structural change, which is a translocation but no addition. MK+ patients are largely incurable with standard therapy, with median survivals of approximately 6 months. Now it appears that alterations in the tumor suppressor gene TP53, located on the short arm(p) of chromosome 17, underlie the prognostic effect of MK.

TABLE 107.2

European Leukemia Net Classification System

Prognostic Group	Proportion of De Novo Patients in Group by Age <60 years, Age ≥ 60 years	Subsets
Favorable	41%, 20%	Inv (16), t(16;16), t(8;21) NC with NPM mutation (NPM+) but no FLT3 ITD (ITD-) NC with mutated CEBPA
Intermediate 1	18%, 19%	NPM- ITD- NPM+ ITD+ NPM- ITD+
Intermediate 2	19%, 30%	Cytogenetic abnormalities (including t9;11) not considered best or worst
Adverse	22%, 31%	3q abnormalities, t(6;9), -7,-5, del 5q, abnormal 11q (other than t9;11), abnormal 17p, complex abnormalities

NC, normal cytogenetics; FLT3, FMS-like tyrosine kinase 3; ITD, internal tandem duplication; NPM, nucleophosmin; CEBPA, CCAAT enhancer binding protein alpha.

Intermediate Group. Criteria for intermediate cytogenetics differ (see Table 107.1). However, there is agreement that patients with NC-AML are the lynchpin of this group. NC-AML occurs in 25% to 40% of patients depending on age (less frequent with increasing age) and type of AML (less frequent with therapy related AML [t-AML]). As might be expected from the term *intermediate cytogenetics* and the frequency of NC-AML, NC-AML is associated with greater variation in outcome than any other single cytogenetic group.

NPM, FLT3 ITD, and CEBPA. Recent years have shown the ability of molecular biology to dissect this heterogeneity. Today, patients with NC-AML should routinely be tested for internal tandem duplications (ITD) in the *FLT3* gene, mutations in the nucleophosmin gene (*NPM1*), and in the CCAAT enhancer-binding protein alpha (*CEBPA*) gene. Most cost effectively, this would be done once a diagnosis of NC-AML is established (the prognostic relevance of *NPM*, *FLT3*, and *CEBPA* being less in other patients than in those with NC-AML), and *CEBPA* testing would only be carried out in patients who were negative for *FLT3*, *ITD*, and *NPM1*. NC-AML patients with *NPM1* mutations but without *FLT3* ITDs and patients with a double *CEBPA* mutation have a prognosis with standard therapy essentially equivalent to patients with best cytogenetics. In contrast, patients with *FLT3* ITDs have a prognosis more closely resembling that of patients with the worst cytogenetics. This has been codified in the widely employed four-group European Leukemia Net (ELN) Classification system (see Table 107.2). The system has been tested in patients with de novo AML that did not contribute to its development; treatment was standard. Each of the four groups were relevant in patients age <60 years, whereas the two intermediate groups were difficult to distinguish prognostically in older patients.

Secondary AML. Although many studies detailing effects of various molecular markers include only patients with de novo AML, there is little doubt that t-AML or AML following a documented abnormality in blood count for 1 to 3 months before the diagnosis of AML, often called an antecedent hematologic disorder (AHD), is associated with resistance. T-AML and AML after an AHD are collectively known as secondary AML. The association between resistance and secondary AML is independent of the tendency of patients with secondary AML to have the worst group cytogenetics (see previously). The relative effects of an AHD and t-AML remain to be established, although it has been suggested that the latter is more important.

Age. Although much of the association between older age and resistance reflects an association with the worst group cytogenetics (see previously) and/or with secondary AML, age per se probably predisposes to resistance.

Mutations Other than *NPM*, *FLT3* ITD, and *CEBPA*. The ability of cytogenetics, *NPM*, and *FLT3* ITD, along with older age and secondary AML to predict resistance has been studied using areas under receiver operating characteristic curves (AUC). An AUC of 1.0 indicates perfect prediction, an AUC of 0.5 is a coin flip (sensitivity = specificity), and an AUC of 0.6 to 0.69, 0.70 to 0.79, and 0.80 to 0.89 is often taken as denoting poor, fair, and good predictive ability, respectively. Walter et al.¹⁶ defined resistance in several ways: (1) no CR despite no death within 28 days of starting therapy (TRM), (2) as in 1 plus relapse within 3 months, (3) as in 1 plus relapse within 6 months, and (4) as in 1 plus relapse within 1 year. They used data from 4,565 patients treated on trials of the national cooperative groups of the UK (MRC/National Cancer Research Institute [NCRI]) and the Netherlands (HOVON) and on trials of the SWOG and MDACC in the United States. Age, performance status, WBC count, secondary disease, cytogenetic risk, and *FLT3*-ITD/*NPM1* mutation status were each independently associated with failure to achieve

CR despite no early death (*primary refractoriness*). However, the AUC of a bootstrap-corrected multivariate model predicting this outcome was only 0.78, indicating fair predictive ability. Removal of *FLT3*-ITD and *NPM1* information slightly decreased the AUC (0.76). The prediction of therapeutic resistance, defined as primary refractoriness or early treatment failure as indicated by short relapse-free survival (RFS), was more difficult, with AUCs for models predicting primary refractory disease or RFS of ≤ 3 , ≤ 6 , or ≤ 12 months of 0.75/0.73 (with/without inclusion of *FLT3*-ITD/*NPM1* data), 0.76/0.73, and 0.75/0.71, respectively.¹⁶ These data indicate that our ability to forecast resistance based on routinely available clinical covariates is limited and argues for the integration of additional disease characteristics to optimize outcome projection in AML.

Minimal Residual Disease

Although the incorporation of the pretreatment molecular information described previously will likely improve prognostic accuracy, the information obtained posttreatment will almost certainly also be relevant. Of particular note are assessments of minimal residual disease (MRD) in patients in CR by standard criteria. Given that AML relapses in most patients, such patients presumably have residual AML (MRD) even in CR. Quantification of MRD would allow broad recommendations for postremission therapy. In particular, patients with low levels of MRD that remain stable or decrease might continue on their initial therapy. In contrast, therapy might be changed in patients with high or rising MRD levels, in an effort to possibly avert subsequent hematologic relapse. Because relapse can only be diagnosed when more than 5% blasts are present in the marrow, the sensitivity of morphologic examination of the marrow for the detection of relapse is only 1 in 20. In contrast, if 30 metaphases are examined, a cytogenetic examination has a sensitivity of 1 in 30, whereas fluorescence in situ hybridization (FISH) typically has a sensitivity of 1 in 500.

MRD can be determined by polymerase chain reaction (PCR) to detect (1) leukemia fusion genes (such as those characteristic of inv 16, t(8;21), or t(15;17)); (2) mutations (e.g., in *NPM1*); or (3) overexpression of genes such as Wilms tumor 1 (*WT1*). PCR techniques generally have sensitivities of 1 in 10⁽⁻⁴⁾. An MRD can also be examined by multiparameter flow cytometry (MPFC), which relies on the identification of patterns of cell surface antigens characteristic of the patient's AML. The sensitivity is 1 in 10⁽⁻³⁾–10⁽⁻⁴⁾. Buccisano et al.²⁰ have shown that patients with good (inv 16, t8;21) or intermediate karyotypes who have MRD detected by MPFC (MRD+) at the end of postremission therapy have outcomes resembling those in patients with *FLT3* ITD+ or unfavorable karyotype AML. In turn, patients who are *FLT3* ITD+ but without MRD fare better than those who are *FLT3* ITD+ with MRD. In patients where both MPFC and PCR are applicable, data suggest PCR is more sensitive and specific. It remains to be established whether blood can be used rather than bone marrow, whether MRD should be assessed at multiple time points (e.g., CR, immediately after completion of post remission therapy and beyond), what levels of MRD should motivate a change in therapy and whether these levels are reproducible at different centers, and critically, whether a reduction in MRD will lead to better relapse-free or overall survival rather than MRD merely being a surrogate of refractory AML.

Treatment of Newly Diagnosed Acute Myelogenous Leukemia

Treatment of AML begins with induction chemotherapy, with the goal of achieving CR with a resolution of morphologically detectable disease and the restoration of normal blood counts. This is followed by postremission therapy to eradicate MRD. Both

chemotherapy and HSCT have been utilized, and each approach has a major role in the treatment of this disease. An AML cure occurs in only a minority of patients with available forms of chemotherapy. HSCT has a greater antileukemia effect but is associated with higher TRM.

Regardless of a patient's age, the initial goal in treating AML is to produce a CR, defined as a marrow with less than 5% myeloblasts, a neutrophil count greater than 1,000/ μL , and a platelet count greater than 100,000/ μL .^{21,22} When successful, induction therapy preferentially targets AML blasts, thus allowing normal blasts to resume control of hematopoiesis. Obtaining CR is critical because, at least in the past, only patients who do so have a chance of potential cure. An operational definition of potential cure is a remission lasting 2 to 3 years, after which the risk of relapse declines sharply to less than 10%.²³ Responses less than CR are now recognized: CRp for which the criteria are the same as CR except that the platelet count can be <100,000/ μL , although platelet transfusions are not being given,²¹ and CRi for which no blood count minima are specified, however, the marrow must be reasonably cellular (e.g., least 200 cells must be counted)²¹ because if such were not the case, a CRi could be produced in any patient by simply rendering the marrow hypoplastic with high doses of cytotoxic chemotherapy. It remains unclear whether CRp or CRi will prolong survival to the same extent as CR.²⁴ It is known that CRp and CRi are more likely to be associated with MRD than CR.²⁵ However, following treatments where CR is perhaps more likely to be associated with MRD (e.g., after use of lower intensity treatments such as azacitidine or decitabine), there may be less value to obtaining a CR.²⁵

Prolongation of the initial response has traditionally entailed further chemotherapy, typically two to four courses of *consolidation* with or without subsequent prolonged lower dose *maintenance*. However, several randomized studies suggest that maintenance chemotherapy, although occasionally prolonging remissions, does not lengthen survival.²⁶ These results have spurred interest in development of new approaches. In particular, recent years have seen the advent of targeted therapy. Although, as described previously, successful chemotherapy is itself selectively toxic to AML blasts, targeted therapy is taken to mean therapy that, although perhaps less toxic to AML blasts than chemotherapy, is much less toxic than chemotherapy to normal blasts and to gastrointestinal epithelium, damage to which can lead to sepsis and death. However, as noted previously, the main problem in AML is overcoming resistance, even in patients in their 70s.^{27,28} It is axiomatic that therapy depends on the prognosis. Accordingly, we will discuss induction and postremission therapy according to the patient's prognostic group with standard therapy, as determined by the ELN classification system (see Table 107.2) and within each group note modifications that might be made for patients whose prognosis might differ from that of the group as a whole (e.g., older patients). The focus will be on the choice between standard therapy, now including decitabine and azacitidine, which are widely used in the treatment of older patients, and investigational treatment.

European Leukemia Net Favorable Prognosis Patients

Remission induction should typically consist of 3 days (days 1 through 3) of drugs, such as daunorubicin or idarubicin, that interact with the enzyme topoisomerase 2 (topo II) and 7 days (days 1 through 7) of the pyrimidine analog cytarabine (ara-C) at 100 mg/m² daily; such combinations are called 3+7. A bone marrow aspiration is typically obtained approximately 14 days after the initiation of 3+7. If the marrow shows less than 10% blasts or is hypocellular, marrows are repeated, usually weekly, until it is clear that either a CR has occurred or that there has been a reappearance of AML, often best assessed using MPFC, which can distinguish an excess of normal blasts often seen during marrow recovery from chemotherapy from an excess of AML blasts.

Retreatment usually takes the form of either another course of 3+7, the administration of high-dose ara-C, or of an investigational salvage regimen. SWOG data indicate a CR rate of 40% with a second course of 3+7, which competes favorably with previous investigational *salvage* regimens.^{29,30} Furthermore, the SWOG analysis could not identify patients more or less likely to respond to a second 3+7 course.^{29,30}

Two randomized trials have shown that a daily daunorubicin dose of 90 mg/m² in 3+7 is superior to a daily dose of 45 mg/m² in patients up to age 65 years, particularly in patients with CBF AML.^{31,32} A French retrospective study suggested that 90 mg/m² might be superior to 60 mg/m² in patients with CBF AML.³³ The MRC/NCRI in the United Kingdom is currently randomizing patients between these two doses. Although a French trial suggests that idarubicin at 12 mg/m² daily for 3 days is superior to daunorubicin at 80 mg/m² daily for 3 days,³⁴ there have often been greater differences between separate randomized trials examining this issue than between daunorubicin and idarubicin in a given study. As a result, there is a consensus that these drugs are interchangeable in 3+7, with idarubicin (12 mg/m² daily, days 1 through 3) and daunorubicin (60 mg/m² daily, days 1 through 3) used most frequently.

The ara-C dose to be used during induction has also been the subject of debate.³⁵ The HOVON/SACK group randomized 431 adults age <60 years to ara-C at a daily dose 200 mg/m² for 7 days (previously shown equivalent to 100 mg/m² daily for 7 days³⁶) during cycle 1 of induction therapy and 1 g/m² twice daily on days 1 through 5 during cycle 2 of induction therapy and 429 similar patients to 1 g/m² every 12 hours on days 1 through 6 in cycle 1 and 2 g/m² twice daily on days 1, 2, 4, and 6 in cycle 2. Idarubicin 12 mg/m² daily for 3 days was given during cycle 1 and amsacrine, analogous to idarubicin/daunorubicin, was given during cycle 2.⁵ Subsequently, patients with CBF AML in remission received 1 cycle of mitoxantrone + etoposide, whereas patients with other cytogenetic findings received an autologous or allogeneic transplant. With a median follow-up of 5 years, there was no difference between the two regimens in CR rate (80% to 82%) and, at 5 years, the cumulative incidences of relapse, relapse-free survival, event-free survival (34% to 35%), and overall survival (40% to 42%) were similar between the two regimens. Furthermore, there was no suggestion that any cytogenetic group benefited more from the higher dose ara-C regimen; in particular, 5-year survival rates were 64% to 67% in patients with CBF AML. The latter results seem equivalent to those using ara-C doses of 3 g/m² twice daily on days 1, 3, and 5 during postremission therapy as is often done in the United States. Othus et al. have recently not found an advantage in patients with NC-AML who were *NPM+/FLT3* ITD negative according to whether they received during induction standard 3+7 (in SWOG) or idarubicin + ara-C at 1.5 g/m² daily for 3 to 4 days (at MDACC). Both groups received intermediate (1 g/m² per dose) and high (2 to 3 g/m² per dose) doses during postremission therapy.³⁷ The HOVON and SWOG/M. D. Anderson results seem to indicate that there is no benefit for intermediate- or high-dose ara-C during induction. However, as indicated by a randomized Cancer and Leukemia Group B (CALGB) study, there is a benefit for higher doses of ara-C during postremission therapy after 3+7 induction in CBF AML (3 g/m² twice daily on days 1, 3, and 5 versus 400 mg/m² or, particularly, 100 mg/m² daily for 5 days) or in NC-AML (with the 3 g/m² and 400 mg/m² doses being equivalent and both superior to the 100 mg/m²),³⁸ although as noted in MRC's AML 15 trial, the 3 g/m² dose can be replaced by 1.5 g/m².³⁹

The duration of postremission therapy is also uncertain, although it seems that between two (based on HOVON data⁵) and four cycles (based on MRC/NCRI data³⁹) are sufficient. It is likely that determinations of MRD (e.g., using PCR in CBF and *NPM+/FLT3* ITD-negative AML^{40,41}) will be important here. For example, in patients with CBF, AML MRC/NCRI randomized data suggest that a fifth cycle might be useful in patients who

are MRD negative after the fourth cycle, but not in patients who are MRD positive after the fourth cycle. Patients who are MRD positive after the completion of planned postremission therapy might be candidates for further therapy. Given their low risk of relapse relative to the risk of nonrelapse mortality following allogeneic HSCT, a general consensus is that the average patient with CBF, *NPM1*+/*FLT3* ITD–negative AML, or *CEBPA*+ AML is not a candidate for HSCT in CR1,⁴² although recent data suggest that HSCT is indicated in patients with double *CEBPA* mutations.⁴³

There are clearly patients in the best prognosis group who have worse prognoses than the averages reported on trials. These include CBF AML patients age 60 to 65 years,¹⁹ and those with high levels of mutant *CKIT* alleles.¹⁹ Reduced-intensity HSCT is an alternative in the former. A randomized American–German trial is examining dasatinib in CBF AML based on the drug's ability to inhibit *CKIT*, which is mutated in 20% to 25% of these patients and overexpressed in others.⁴⁴ Finally, meta-analyses of several trials randomizing patients to 3+7+/- gemtuzumab ozogamicin (GO) 3 to 6 mg/m² once during remission induction have indicated unequivocal survival benefit due to a lower incidence of relapse in patients with CBF (and many with NC-AML) leading to attempts to reintroduce this drug into clinical practice.^{45,46} Fludarabine as given in FLAG-ida therapy also appears to be useful as induction and postremission therapy in CBF AML.³⁹

European Leukemia Net Intermediate 2 and Worst Prognosis Groups

Even patients age <60 years in the intermediate 2 group have 5-year survival rates of only 20% to 25% and median survivals of less than 2 years, recalling that the ELN prognostic system does not account for the unfavorable effect of secondary AML.²² Hence, these patients, particularly those in the worst group, are considered prime candidates for clinical trials.²² Although it is not unreasonable to use 3+7 for induction and to begin the trial once in CR, it is noteworthy that differences in induction therapy can affect relapse⁴⁵⁻⁴⁷ and, accordingly, survival rates; furthermore, CR rates in the worst groups are generally <50%.²⁷ Here, we will describe therapies that, although not likely better than standard, are in common clinical use.

Dose Intensification

Generally, intensification of an ara-C dose (e.g., to 3 g/m² every 12 hours on days 1, 3, and 5) during postremission therapy has not improved outcomes in intermediate 2 or the worst patients,³⁸ or if improving it “statistically,” it has improved it only minimally (e.g., $p = 0.02$, but from zero to only 13% 5-year survival in the HOVON trial).⁵

Clofarabine, Cladribine, and Fludarabine

The MRC/NCRI group has conducted two randomized trials involving clofarabine. Older patients considered fit for intensive therapy had similar outcomes whether given clofarabine + daunorubicin or daunorubicin + 10 days of standard dose ara-C.⁴⁸ Older patients not considered fit for intensive therapy had higher CR rates but similar survival when given clofarabine rather than low-dose ara-C.⁴⁹ A multicenter trial randomizing patients with relapsed AML also found higher CR rates but similar survival with clofarabine + high-dose ara-C compared with high-dose ara-C alone, largely due to more TRM in the clofarabine arm.⁵⁰ The Polish Acute Leukemia Group reported longer survival in adults age <60 years with either de novo or secondary AML randomized to daunorubicin, ara-C (DA) + cladribine (DAC) rather than to standard induction DA.⁴ In contrast, a randomized MRC/NCRI trial in adult patients age <60 years found that FLAG-ida given for induction and one postremission course was associated with longer event-free survival

and fewer relapses than daunorubicin + ara-C, although survival was similar due to more deaths in CR with FLAG-ida.³⁹

Azacitidine and Decitabine

The majority of patients in the intermediate 2 and worst prognostic groups are aged >65 years. It is in these groups that azacitidine and decitabine have found greatest use. It is becoming apparent that results with these drugs used alone rival those with *more intense* therapies, at least in older patients. For example, Quintas-Cardama et al.⁵¹ found similar overall survival (OS) among 557 patients aged >65 years given regimens generally containing ara-C at 1 to 2 g/m² daily and idarubicin or fludarabine +/- other agents and 114 patients given decitabine (n = 67) or azacitidine (n = 57) despite higher CR rates with the more intense therapies.⁵¹ An international study randomizing 485 patients age >65 years, one-third of whom had the worst prognosis cytogenetics and one-third of whom had secondary AML, found median survivals of 7.7 months for decitabine at 20 mg/m² daily for 5 days versus 5.0 months for standard treatment (88% low-dose ara-C, 12% supportive care only).⁵² A focus on whether the difference is *statistically significant* ($p = 0.037$) loses sight of the unsatisfactory results in both arms, with patients losing >90% of their normally remaining life expectancy. An analogous trial involving azacitidine leads to the same conclusion.⁵³ Thus, a fundamental question is whether results with either drug can be improved. One possibility is identifying patients more likely to respond either based on molecular characteristics or less active disease. Examples of the latter are patients in CR, although use of decitabine to delay relapse appears to have been unsuccessful,⁵⁴ or patients with MRD after HSCT.⁵⁵ A second possibility is a combination with other active drugs. A combination of decitabine with deoxyguanosine (SGI-110) increases exposure to decitabine but has not obviously improved outcomes to date.⁵⁶ More fundamentally, it remains unclear whether azacitidine or decitabine, although known as hypomethylating agents, actually exert their effects via hypomethylation.⁵⁷

Gemtuzumab Ozogamicin

In contrast to its utility in patients with CBF AML, meta-analyses have not indicated a role for this drug in combination in ELN intermediate 2 and the worst prognosis patients.⁴⁵

Hematopoietic Stem Cell Transplantation

It is generally recommended that patients in ELN intermediate 2 or the worst prognosis groups receive HSCT in CR1 as detailed in the transplant section that follows.

ELN Intermediate 1 Prognosis Group

Here, the decision between the relatively standard approaches discussed for the favorable group and the emphasis on clinical trials stressed in the last section is more difficult. It is perhaps, at times, best to defer this decision to the patient; experience suggests that given the same prognostic data following use of standard therapies, some patients will prefer these, whereas others prefer a trial. Here, the need for new prognostic information is most acute and there might be great use in incorporating posttreatment information into the decision; examples include time or courses to CR,⁵⁸ achievement of CRp/CRi rather than CR,²⁴ or MRD measured by MPFC²⁰ or PCR for *NPM1*⁴¹ or *WT1*.⁵⁹ The use of FLAG-ida might be considered because its ability to decrease high relapse rates relative to CBF AML might justify the increased incidence of death in CR associated with its use.³⁹ Transplantation in CR1 is often suggested, although it is possible that, provided CR rates after relapse are in the 50% range (much more likely than in the ELN intermediate 2 and the worst groups), a strategy of delaying HSCT until the second CR may be reasonable.⁶⁰

Although their prognosis is, on average, worse than others in the ELN intermediate 1 group, patients with *FLT3* ITDs are currently included in this group (see Table 107.2). They often present with a high WBC count, usually have NC-AML, although t(6;9) AML is very specific for *FLT3* ITDs, and, although having CR rates similar to others with NC-AML, are prone to relapse.⁶¹ The abnormal tyrosine kinase activity associated with *FLT3* ITDs can be inhibited by various drugs (tyrosine-kinase inhibitors [TKI]). Used alone, *FLT3* inhibitors have limited activity in relapsed/refractory AML, with quizartinib being the most effective, producing *composite CR* rates of about 50%, with >90% of the responses being CRi rather than CR or CRp. However, this response rate has allowed 25% to 35% of patients given quizartinib to subsequently receive HSCT.⁶² It is uncertain whether the failure of count recovery, and hence, the lack of CRs reflects concomitant quizartinib-induced inhibition of *CKIT* or the presence of other aberrations in the blasts that are not affected by *FLT3* inhibitors. However, the latter possibility has motivated the addition of chemotherapy to quizartinib.⁶³ Sorafenib, a commercially available *FLT3* inhibitor, has been combined with 3+7 and compared with 3+7 alone in two randomized studies. In patients aged >60 years the combination produced only increased toxicity,⁶⁴ but in younger patients, it was associated with longer event-free but not overall survival. In neither study were effects different in patients with or without *FLT3* ITDs,⁶⁵ indicating that sorafenib's relevant mechanism of action may be independent of *FLT3* inhibition and perhaps prefiguring a more general use of chemotherapy–sorafenib combinations. Even quizartinib, presumed to be a much more selective *FLT3* inhibitor than sorafenib, may also have activity in patients without *FLT3* ITDs.⁶² As predicted by various genomic studies, resistance to quizartinib is associated with the emergence of new subclones: In the case of quizartinib these contain *FLT3* point mutations whose abnormal TK activity might be decreased by crenolanib, another *FLT3* inhibitor.⁶⁶ Although it is generally accepted that patients with *FLT3* ITDs should receive HSCT in CR1, *FLT3* ITDs predict for relapse even after HSCT. Accordingly, another potential role for quizartinib, and by extension other targeted agents, is the prevention of relapse after HSCT or even in patients who cannot receive HSCT.

Summary of Treatment Recommendations

Patients with favorable prognoses as specified by the ELN²² can be treated with standard therapy emphasizing higher doses of ara-C post-CR (HiDAC), although it remains unknown if the same is true in patients considered at best risk based on *NPM1* +/- *FLT3* ITD–status rather than cytogenetics. Older patients with CBF

AML and CBF patients with multiple alleles affected by *CKIT* mutations have worse prognoses than average CBF and thus might be candidates for (reduced intensity) HSCT or for clinical trials with dasatinib. The choice of 3+7 rather than a clinical trial for induction in the ELN intermediate 1 group depends on whether patients see their prognosis with the former as good enough to be reluctant to undertake a clinical trial, which might produce a worse outcome. FLAG-ida might be useful as induction and post-remission therapy in the intermediate 1 and CBF groups and the availability of gemtuzumab ozogamicin (GO) as part of induction therapy would be useful because the drug clearly prolongs survival in CBF and in many intermediate 1 patients.⁴⁶ In contrast, CR rates are often <50% in the ELN intermediate 2 and adverse groups with standard therapy making a clinical trial particularly important, recalling that the choice of induction therapy can affect the relapse rate. The general consensus is that patients in the intermediate 1, 2, and adverse groups should receive HSCT in the first CR. Results with HSCT are still sufficiently poor that clinical trials involving new transplant preparative regimens or the means to prevent post-HSCT relapse should be considered in these groups, as discussed later in this chapter. Given that many older patients will fall into the intermediate 2 or the worst ELN prognostic categories and have particularly poor outcomes with standard therapy, most such patients are candidates for clinical trials, as suggested by both ELN²² and National Comprehensive Cancer Network (NCCN)⁶⁷ guidelines. It is important to recall that the major cause of treatment failure in older patients is resistance to therapy, not TRM. Thus, the use of less intense therapy is appropriate only if the chosen therapy is plausibly more effective, and not merely less toxic, than standard therapy. These recommendations are summarized in Table 107.3. Regardless of specific recommendations, any choice of therapy in older patients must refer to the observations of Sekeres et al.⁶⁸ that 74% of older patients estimated that their chances of cure with 3+7 were at least 50%; in contrast, 85% of their physicians estimated this chance to be less than 10%. Although the most plausible cause of this discrepancy is a patient's natural tendency to hope for a favorable outcome, there may also be gaps in communication between physicians and patients.

Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APL) has a unique pathophysiology and requires special considerations for treatment. In more than 95% of cases, APL results from a chromosomal translocation, t(15;17). This translocation results in a fusion protein

TABLE 107.3

Treatment Recommendations According to European Leukemia Net Prognostic Group

ELN Group (see Table 107.2)	Induction	Postremission	Other Considerations
Best	3+7; consider FLAG-ida if CBF	1 cycle of idarubicin + ara-C 1g/m ² BID × 5 days; then 1–3 cycles with ara-C as above; consider 1 cycle FLAG-ida particularly if CBF	(a) Dose reductions if treatment-related mortality (TRM) scores > 10–20 and clinical trials if TRM scores > 20; (b) Reduced-intensity HSCT for older CBF patients or those with high levels of <i>CKIT</i> mutation; (c) Trials of dasatinib for the latter
Intermediate 1	3+7, FLAG-ida, or clinical trial	If high level <i>FLT3</i> ITD HSCT in CR1 using related donor or unrelated donor; if not, using related donor or postremission therapy as in ELN best group	If high level <i>FLT3</i> ITD (a) clinical trial combining 3+7 and newer <i>FLT3</i> inhibitors quizartinib, crenolanib, or (b) 3+7 + sorafenib if age <60 years
Intermediate 2 or worst	Clinical trial	HSCT in CR1 using related or unrelated donors	(a) Trials testing means to decrease relapse post-HSCT (b) Supportive care only if TRM score > 20–30

PML/retinoic acid receptor alpha (RAR α), the gene for PML being located on chromosome 15 and the gene for RAR α on chromosome 17. The PML-RAR α protein, an aberrant form of the normal RAR, recruits corepressor complexes that inhibit transcription of genes involved in promyelocytic differentiation.⁶⁹ Predictors of APL in patients with AML are younger age, Hispanic ethnicity, and obesity.⁷⁰ Although it typically has a distinctive morphology characterized by abnormal granules and multiple Auer rods, a microgranular variant exists. The possibility of this variant must be borne in mind in patients who present without morphologically typical APL but with the coagulopathy that is the clinical hallmark of the disease. The diagnosis of APL requires proof of the PML-RAR α rearrangement. Although this can be obtained by demonstration of the presence of t(15;17), at least 2 to 3 days are required for test results. Immediate confirmation of the diagnosis can be made by using immunohistochemistry to demonstrate an abnormal pattern of anti-PML antibody nuclear staining consequent to the formation of PML-RAR α (the PML oncogenic domains test). If doubt remains about the diagnosis, all-transretinoic acid (ATRA) should be added to 3+7.⁶⁹

APL is very sensitive to daunorubicin or idarubicin and is uniquely sensitive to ATRA and arsenic trioxide. The responsiveness to the anthracyclines may reflect the absence of multidrug resistance gene (*MDR1*) in APL cells,⁷¹ whereas pharmacologic doses of ATRA release corepressor complexes and lead to degradation of PML-RAR α .⁶⁹ For many years, the initial treatment of APL has consisted of idarubicin 12 mg/m² daily for 4 to 5 days and ATRA 45 mg/m² until CR (AIDA regimen).⁶⁹ Use of transfusions to maintain the platelet count above 30,000/ μ L, serum fibrinogen above 150 mg/mL, and the international normalized ratio (INR) below 1.5 is mandatory. Ten percent to 25% of patients will develop the APL differentiation syndrome (APLDS) characterized by fever, weight gain/edema, pleural effusions, and pulmonary infiltrates; the WBC is often elevated. Steroids (e.g., methylprednisolone 45 mg intravenous (IV) daily with subsequent tapering) are effective for the treatment of APLDS. The principal prognostic factor in untreated APL is initial WBC. Patients with WBC less than 10,000/ μ L will have CR rates greater than 90% with idarubicin plus ATRA, whereas patients with higher WBC counts will have CR rates of 80% to 85%. Almost all patients who fail to achieve CR die, which is usually related to bleeding in the brain or lung before treatment begins or in the first few days thereafter. Once in CR, patients typically receive three courses of consolidation with idarubicin 12 mg/m² daily for 3 days and ATRA 45 mg/m² daily on a 2-week on, 2-week off basis. With this treatment, at least 90% of patients should test negative using PCR to detect residual PML-RAR α transcripts after completion of consolidation therapy; patients who are not have a 50% chance of relapse versus 5% for patients who are PCR negative. The former should receive arsenic trioxide (ATO) with or without GO⁷² and an allogeneic stem cell transplant if these measures do not produce PCR negativity. Although many protocols omit ara-C, allowing for the administration of higher doses of idarubicin or daunorubicin, a French trial found superior results in patients randomized to receive ara-C in addition to ATRA and daunorubicin.⁷³ It has been suggested, however, that this outcome reflected the use of relatively low doses of daunorubicin.

Recent developments have highlighted the use of ATO for newly diagnosed rather than purely for relapsed APL. The use of ATO during consolidation in patients treated with AIDA has largely obviated the need for maintenance therapy.⁷⁴ After demonstration by Estey et al.⁷⁵ that ATRA + ATO could be used without the addition of chemotherapy to cure patients presenting with WBC <10,000/ μ L, LoCoco et al.⁷⁵ randomized patients age less than 70 years old with WBC <10,000/ μ L between ATRA/idarubicin (AIDA) as conventionally given and ATO/ATRA as described by Estey et al.⁷⁵ With a median follow-up of 34 months, 2-year event-free survival was 87% with AIDA and 96% with ATO + ATRA ($p = 0.02$ for superiority) and 2-year survival was

also better with ATO + ATRA ($p = 0.02$).⁷⁶ Fever, prolonged myelosuppression, and early deaths were more common with AIDA and clinically insignificant hepatotoxicity with ATO + ATRA. It is likely that ATO + ATRA will become the new standard for treatment of APL with WBC <10,000/ μ L. The relapse rate appears so low that there is probably no need to routinely monitor patients with PCR testing. Similarly, Australasian Leukemia Study Group data suggest that the addition of ATO to AIDA induction will improve outcomes in patients presenting with WBC >10,000/ μ L.⁷⁷ In these patients, however, PCR monitoring in CR probably remains necessary for 2 years. Attention in APL currently focuses on the discrepancy between results, such as those described previously, in academic centers and the poorer results noted in population-based studies⁷⁸; it has been proposed that the initiation of ATRA upon suspicion of a diagnosis of APL might reduce this discrepancy.⁷⁸

Salvage Therapy

Salvage therapy refers to treatment given for relapsed AML or AML that has never gone into CR (primary refractory). As usual, it is critical to assess a patient's chance for success following the administration of standard salvage therapy, using regimens such as FLAG + ida or mitoxantrone + etoposide + ara-C (2 g/m² daily for 5 days) (MEC). A principal predictor of response to first salvage therapy is the duration of first remission; this has been true even when the therapy used for salvage contained no drugs used initially. As is often the case, consideration of several covariates to assess prognosis is useful.⁷⁹ Data presented in the section on transplantation suggest that HSCT should be the first option for such patients, although the possibility of selection bias contributing to results with HSCT needs to be kept in mind. There is also uncertainty as to whether those patients in whom a donor is available should receive investigational chemotherapy before HSCT. If HSCT is unavailable or while a search for a donor is ongoing, patients should receive investigational treatments, including or not including conventional agents.

Hematopoietic Stem Cell Transplantation for Acute Myelogenous Leukemia

Stem cell transplantation provides the possibility of cure for a significant fraction of patients with AML. The approach utilizes a preparative regimen of chemotherapy or radiation with the goal of eradicating the leukemia and providing sufficient immunosuppression of the recipient to prevent rejection of the transplant. There is also an allogeneic graft-versus-leukemia (GVL) effect in which donor T and NK cells act to eradicate malignant cells that survive the preparative regimen.⁸⁰ Autologous transplants can be done. Patients initially have their own hematopoietic cells collected and cryopreserved; these cells are then reinfused after high-dose therapy to restore hematopoiesis. Improvements in supportive care, histocompatibility, and tissue matching and development of less toxic preparative regimens have all increased the likelihood of success with autologous or allogeneic transplantation. This section reviews the role of HSCT in the treatment of AML in adults.

Prognostic Factors and Indications for Transplant

Outcomes of HSCT are improved if the transplant is performed earlier in the disease course, preferably in CR, due to less chemo-refractoriness and the lower likelihood of infectious or chemotherapy-related side effects. The major prognosticator is disease status at transplant (Fig. 107.1). Prognostics of patients in CR are significantly better than for those with active disease at the time of HSCT. Similarly, most of the covariates discussed in the previous paragraphs retain their influence in the setting of HSCT, such as cytogenetics and FLT3 mutational status (Fig. 107.2).⁸¹ Secondary

Figure 107.1 Disease status at transplantation is the major determinant of survival after allogeneic hematopoietic stem cell transplantation (HSCT) for acute myelogenous leukemia (AML). Leukemia-free survival (LFS) of 773 AML patients (379 were in first complete remission and 394 had active disease at HSCT) who underwent first allogeneic HSCT using matched related, matched unrelated, and mismatched donors between 2001 through 2012. Three-year LFS were 52.2% and 15.6% for CR1 and active disease patients, respectively. (Data courtesy of Dr. Betul Oran.)

Figure 107.2 The influence of FLT3-ITD mutational status on survival is illustrated here. Leukemia-free survival of 227 AML patients that underwent first allogeneic hematopoietic stem cell transplantation (HSCT) in first complete remission and FLT3-ITD mutation at diagnosis were evaluable. Donors included matched related, matched unrelated, and mismatched. Three-year LFS after HSCT were 56.9% and 42.6% for patient with FLT3-ITD wild and FLT3-ITD mut at diagnosis, respectively. (Data courtesy of Dr. Betul Oran.)

AMLs are considered high risk and the outcome without allogeneic HSCT is generally poor.⁸² The presence of MRD is also a negative prognosticator prior to HSCT.^{83–85} A large retrospective registry study investigated outcomes of AML patients transplanted with active disease. The authors found that five adverse pretransplant variables significantly influenced survival: the presence of circulating blasts, the first CR duration less than 6 months, the use of a donor other than a human leukocyte antigen (HLA)-identical sibling, a Karnofsky score less than 90, and poor risk cytogenetics.⁸⁶ It is generally accepted that fit patients with disease that is primarily refractory to chemotherapy or that has relapsed are eligible for

allogeneic or autologous HSCT, as will be discussed. There is, however, controversy surrounding HSCT in first CR. Table 107.4 lists indications for allogeneic HSCT in AML.

Preparative Regimens and Regimen Intensity

The preparative regimen (chemotherapy with or without radiation therapy that precedes the infusion of hematopoietic progenitor cells) provides treatment for AML and the necessary immunosuppression to prevent graft rejection of an allogeneic transplant. Preparative regimens may be chemotherapy or total body irradiation.

TABLE 107.4

Indications for Allogeneic Transplant in Acute Myelogenous Leukemia

Disease Stage	Cytogenetics ^a	Mutations
First remission	Diploid: presence of mutations may dictate decision to transplant	FLT3 ITD FLT3 TKD NPM with FLT3 or ERG mutation MLL PTD Overexpression of BAALC Overexpression of ERG
First remission	Complex; del 5, del 7	
First remission, age > 50–55 years	Diploid cytogenetics: controversial	
First remission, therapy-related or secondary disease ^b	All eligible	All eligible
Primary induction failure	All eligible	All eligible
Second or subsequent remission	All eligible	All eligible
Relapsed, active disease	All eligible	All eligible

ITD, internal tandem duplication; NPM, nucleophosmin; ETS-related gene; FLT3, FMS-like tyrosine kinase 3; TKD, tyrosine-kinase domain.

^a There is variability in the definition of high-risk cytogenetics depending on the classification used. There is also some controversy surrounding the influence of chromosomal abnormalities involving the *MLL* gene located at 11q23, such as in t(9;11), t(6;11), and t(11;19). Some authors will classify patients with these abnormalities as intermediate-risk disease, as opposed to granting them high-risk status. Presence of 9q and 11q abnormalities may also place patients in first complete remission in a higher than desired risk of relapse.

^b Secondary disease: preceding myelodysplastic syndrome or chemo- or radiation-therapy induced.

diation (TBI) based. A myeloablative regimen generally causes cessation of normal marrow function to a degree that requires autologous or allogeneic hematopoietic cell transplant. Hematopoietic transplantation allows for the use of stem cell toxic agents, which eradicate both normal and leukemic stem cells; hematopoiesis is restored by normal stem cells present in the transplant. Reduced intensity regimens were developed to decrease regimen related toxicity; this approach relies on the immune GVL effect to eradicate residual disease that would survive the preparative regimen. Conditioning utilizes either a lower dose of alkylating agents or low doses of radiation. The advent of these reduced intensity preparative regimens has allowed for the use of hematopoietic transplantation in older patients and in those with comorbidities, which would make them ineligible for myeloablative therapy. This has been an important advance, because the peak incidence of AML is in the 6th and 7th decades of life. Still, there is controversy regarding which patients should receive myeloablative versus reduced-intensity preparative regimens. The safety of myeloablative regimens is improving, and their use for *fit* patients aged 55 to 65 years is now an attainable goal. Randomized clinical trials will be necessary to resolve this question of regimen choice and intensity. It is recommended that older patients with AML be treated within clinical trials.

Myeloablative Regimens. The most commonly used myeloablative regimens are cyclophosphamide-TBI (Cy-TBI),⁸⁷ busulfan-cyclophosphamide (BuCy),⁸⁸ and, more recently, busulfan and fludarabine.⁸⁹ The development of BuCy as an alternative to TBI-containing regimens led to ongoing debates as to which conditioning regimen is the best for the treatment of myeloid leukemias with HSCT. Two randomized studies were performed. The Nordic group compared Cy-TBI to BuCy in a heterogeneous group of patients with AML, lymphoid malignancies, and CML receiving allogeneic HSCT.⁹⁰ Results indicated improved Disease free survival (DFS) among advanced stage disease patients treated with Cy-TBI, along with an increased rate of long-term complications for recipients of BuCy. Similarly, Blaise et al.⁹¹ studied young patients with AML in first CRs and concluded that Cy-TBI and allogeneic HSCT produced better disease-free and overall survival than BuCy. The major pitfall of these reports is the use of the oral busulfan formulation, which results in unpredictable plasma levels. The Center for International Bone Marrow Transplant Research (CIBMTR) compared the use of oral or intravenous (IV) BuCy and Cy-TBI in 1,230 AML patients who received allogeneic transplantation in first remission. There was less nonrelapse mortality and relapse 1 year after transplant, and improved leukemia free survival (LFS) in recipients of IV busulfan compared to TBI regimens.⁹² A prospective cohort study tested the hypothesis of noninferiority of survival after IV busulfan ablative regimens, compared to TBI-based regimens for myeloid leukemia patients ($n = 1,025$ versus $n = 458$, respectively). Two-year probability of survival was better after IV busulfan treatment (56% versus 48%; $p = 0.03$).⁹³ Another retrospective registry analysis performed with the European Cooperative Group for Bone Marrow Transplantation (EBMT) database found IV BuCy to lead to similar outcomes to CyTBI for the treatment of AML in first CRs.⁹⁴ Exchanging cyclophosphamide for the nucleoside analog fludarabine may increase the safety margin of the regimen.⁹⁵ Fludarabine appears to increase alkylator-induced cell killing by inhibiting DNA-damage repair and is highly immunosuppressive. A preparative regimen using fludarabine and single daily dosing of IV busulfan has been studied in multiple centers and appears to be effective and potentially less toxic than the commonly used BuCy regimen.

Reduced Intensity Conditioning Regimens. Given the relative insensitivity of AML to the GVL effect, chemotherapy or radiation intensity is an important component of HSCT. There is a trade-off between nonrelapse mortality (NRM) and dose intensity, which may negate the decrease in relapse rates associated

with higher dose regimens. The CIBMTR collects information on most transplants performed in North America. The most commonly used reduced-intensity regimens (for all indications) as reported to the CIBMTR are fludarabine combined with low-dose TBI,⁹⁶ cyclophosphamide,⁹⁷ busulfan,⁹⁸ melphalan,⁹⁹ or other drugs. Antithymocyte globulin or alemtuzumab are commonly added to the regimen for in vivo depletion of T cells in order to reduce the risk of graft versus host disease (GVHD). The use of in vitro or in vivo T-cell depletion remains controversial in the setting of myeloablative and reduced-intensity conditioning, but the perceived increased risk of leukemia relapse¹⁰⁰ is challenged by reports indicating similar or improved outcomes with ex vivo T-cell depletion.¹⁰¹ The fludarabine-melphalan reduced-intensity regimen has been used at the MDACC for approximately 15 years, and long-term follow-up demonstrates its ability to induce durable disease control in a significant fraction of AML patients.¹⁰² Likewise, the Seattle group experience of treating AML in first CRs (median age of 59 years) with a nonmyeloablative, low-dose TBI-based regimen achieved a low TRM rate.¹⁰³

Transplants for AML in First Complete Remission. Although multiple phase 2 studies have indicated that both allogeneic and autologous transplants benefit subsets of patients with AML in first CRs, the conclusions from randomized trials are less clear.¹⁰⁴⁻¹⁰⁷ The majority of studies indicate that allogeneic and autologous transplants are associated with lower relapse rates but also with higher mortality rates in CR (especially allogeneic HSCT). Nonrelapse mortality (death of all causes for patients in CRs) traditionally has reduced the benefit of less relapses after allogeneic HSCT, and most randomized studies did not show statistically significant advantage in survival (Table 107.5). The debate is far from resolved, given that newer preparative regimens (as discussed previously) and improvements in supportive care are reducing nonrelapse mortality significantly. A common feature of these large clinical trials is the fact that, although most patients assigned to chemotherapy will complete the intended treatment, a significant minority of those assigned will not receive an allogeneic or autologous HSCT.

Most studies indicate that the use of consolidation chemotherapy prior to myeloablative or reduced intensity allogeneic HSCT in first remission does not influence survival after transplant.¹⁰⁸ In the autologous HSCT setting, however, another retrospective registry analysis concluded that consolidation may improve transplant outcomes. Leukemia-free and overall survival rates were improved for those who received consolidation, but the number of consolidation cycles (one versus two) and the cytarabine dose did not significantly affect transplantation outcomes.¹⁰⁹

The European Organization of Research and Treatment of Cancer—Leukemia Group/ Gruppo Italiano Malattie EMatologiche dell'Adulto (EORTC-LG/GIMEMA) AML-10 trial set out to compare autologous and allogeneic HSCT for patients in first CRs.¹⁰⁷ After one course of consolidation chemotherapy, patients younger than 46 years with an HLA-identical sibling donor were assigned to undergo allogeneic HSCT, whereas all others were to undergo autologous HSCT. In the donor group, 68.9% received an allogeneic HSCT, whereas in the no-donor subset, an autologous transplant was performed in 55.8% of those eligible. DFS was improved in the former group, whereas the death rate in first CR was decreased in the latter (17.4% versus 5.3%). OS was similar, but DFS was improved for patients with poor prognosis cytogenetics after allogeneic HSCT, especially for patients aged 15 to 35 years. Instead, however, the MRC study indicated an advantage in survival for allogeneic transplanted recipients with intermediate-risk disease.¹⁰⁵ In both the EORTC/GIMEMA AML-8 and the MRC AML-10 trials, the relapse-free survival was improved with autologous HSCT when compared to chemotherapy alone, without an OS benefit. The likelihood of achieving another remission after relapse was higher in the chemotherapy arms, which led to the similar survival.

Dutch-Belgian Hemato-Oncology Cooperative Group (HOVON) and the Swiss Group for Cancer Research (SAKK) Retrospective analysis of three prospective studies conducted from 1987 to 2004. Genetic randomization ¹¹¹	N = 1,032 patients in CR after two chemotherapy cycles Consolidation: either third cycle of chemotherapy, auto or allo-HSCT Age <55 years Median follow-up from diagnosis is 63 months	Donor n = 326 patients (32%) No donor n = 706 (68%)	82% (n = 268) (allogeneic HSCT) 28% (n = 165) (autologous HSCT) No donor group: 8% received allogeneic HSCT from other donors, 65% went to receive a 3rd chemo cycle	Donor vs. no donor 32% vs. 59% (p < 0.001) Reduction in risk of relapse was observed in all cytogenetics categories, but was only significant in the intermediate and poor risk groups including poor risk group	Donor vs. no donor 48% vs. 27%, HR 0.7, 95% CI, 0.59–0.84 (p < 0.001) Improved DFS was observed in all cytogenetics categories, but was only significant in the intermediate and poor risk groups Age <40 years (HR 0.59, 95% CI, 0.46–0.77; p < 0.001) Age <40 years: HR 0.83, 95% CI, 0.64–1.07; p = NS)	BuCy	Death in CR1: Donor X no donor 21% X 4% (p < 0.001)	Donor X no donor 4-year survival 54% X 46% (HR 0.85, CI 0.70–1.03; p = 0.09)

NS, not statistically significant; HR, hazard ratio; CI, confidence interval; CR, complete remission; DFS, disease-free survival; HSCT, hematopoietic stem cell transplant; Cy-TBI, cyclophosphamide and total-body irradiation; BuCy, busulfan and cyclophosphamide.

^aTwo patients died after unrelated donor transplant.

Jourdan et al.¹¹⁰ reported the long-term follow-up results of four studies investigating postremission consolidation strategies conducted by the Bordeaux Grenoble Marseille Toulouse (BGMT) cooperative group in Europe. The donor group (i.e., with the HLA-identical sibling) comprised 182 patients (38% of those who had achieved a first CR); allogeneic HSCT was performed in 171 patients (94%). The no-donor group had 290 patients, of which 62% received an autologous HSCT. The intent-to-treat analysis (donor versus no donor) showed a statistically nonsignificant advantage in overall 10-year survival probability of 51% versus 43% for the donor group. Patients were stratified using the covariates WBC count at diagnosis, the FAB subtype, the cytogenetic risk, and the number of induction courses to achieve a CR. An intermediate risk group benefited from allogeneic HSCT, with longer survival, whereas small numbers precluded definitive conclusions in other subgroups.

Cornelissen et al.¹¹¹ updated the follow-up and consolidated the results of three consecutive studies sponsored by the Dutch-Belgian Hemato-Oncology Cooperative Group (HOVON) and the Swiss Group for Cancer Research (SAKK) between 1987 and 2004. These studies investigated myeloablative allogeneic HSCT for young patients with AML in first CR, comparing results in patients with a transplant donor identified versus those with no donor who received conventional chemotherapy. Subsets of patients in the no-donor subgroup were eligible to receive autologous HSCT. The initial sample size was 2,287 patients. Patients younger than 55 years, without FAB M3 disease, who achieved a first CR after a maximum of two cycles of chemotherapy and then received consolidation treatment were considered eligible for allogeneic HSCT (n = 1,032, 45% of the cohort). The donor group comprised 326 patients (32%), and the no-donor group comprised 599 patients (58%). In the donor group, 82% went on to an allogeneic transplant. Patients in the donor group had fewer relapses and longer DFS. Patients with a donor younger than 40 years of age and with an intermediate- or poor-risk profile had statistically significantly improved DFS.

It is likely that some subsets of patients in first CR will benefit more from HSCT than others. Patients older than 55 years have an extremely poor outcome with conventional chemotherapy. Historically, they have not been eligible for myeloablative allogeneic transplantation because of concern for toxicities, but this group may benefit from nonmyeloablative allogeneic HSCT. A feasibility study demonstrated a marked improvement in relapse-free survival with nonablative allogeneic transplants in elderly patients with AML in first CR compared to patients without a donor who received standard chemotherapy.¹¹² The incorporation of comorbidity indexes to estimate NRM risk have contributed to patient selection as well, and the proportion of patients ultimately receiving allogeneic HSCT is increasing, especially in reference centers.^{113,114}

High-dose ara-C-containing chemotherapy regimens, on the other hand, have improved the outcome of young patients, particularly for patients with good risk cytogenetics (t[8;21] and inv16); the consensus is to not perform allogeneic HSCT in these patients while in first CR. An HLA-compatible family donor (an HLA-identical sibling or a one-antigen mismatch relative) is available in less than 35% of the cases. Unrelated donor transplants that are HLA matched using high resolution methods for the HLA-A, -B, -C, and -DR loci fare comparably with matched sibling donors.¹¹⁵ Interestingly, in the unrelated donor setting, it is possible that donor-derived NK cell reactivity could reduce relapse rates. A study of 1,277 patients with AML that received unrelated donor HSCT indicated that the activating KIR2DS1 gene provided an HLA-C-dependent prevention of relapse, whereas the donor KIR3DS1 gene was correlated with reduced mortality. This information may guide donor choice aiming at relapse prevention.¹¹⁶

Autologous HSCT has been proposed and extensively investigated as an option for first CR consolidation (see Table 107.5). The role of autologous HSCT in first CR, however, remains controversial. Phase 2 and 3 studies demonstrate that some subgroups

of AML patients may benefit from autologous HSCT, with a reduction in relapse and improvement in leukemia-free survival. Patients with unfavorable cytogenetics do not appear to benefit, and allogeneic transplant is their preferred option. AML patients, however, are very often poor mobilizers of stem cells, possibly due to AML and treatment-related changes on the normal stem cell pool. Reinfusion of leukemia stem cells contained in the autologous graft is a possibility, and gene marking studies have demonstrated that malignant cells contained in the autograft may contribute to systemic relapse.¹¹⁷ *Purging* describes the various ex vivo procedures that have been used to eliminate these residual leukemic cells from the graft.¹¹⁸ Preclinical studies have suggested that this strategy significantly reduces the number of clonogenic progenitors. Chemotherapeutic agents have been extensively used for ex vivo purging, but none of the purging techniques have been tested in a randomized fashion, and conclusive evidence of a benefit for purged grafts is lacking.

Most studies of autologous HSCT enrolled patients younger than 50 years old. However, autologous HSCT transplants have also been investigated for patients older than 60 years. The EORTC-GIMEMA AML-13 trial proposed the collection of peripheral blood stem cells after induction therapy with mitoxantrone, cytarabine, and etoposide (MICE) with or without G-CSF, and consolidation chemotherapy with idarubicin, cytarabine, and etoposide (mini-ICE). Patients aged 61 to 70 years with good performance status were eligible. Of 61 patients, 54 (88%) had peripheral blood stem cells harvested, but only 35 patients received autologous HSCT (57%). The 3-year disease-free and overall survival rates were 21% and 32%, respectively. The authors considered this a negative study that exemplified the limitations of dose intensification for patients with AML in this age range.¹¹⁹ An updated analysis of the multicenter European AML96 trial (n = 586 patients) suggested a role for autologous transplants for AML in first CR. Patients were to be consolidated with allogeneic or autologous transplantation, or with chemotherapy. Patient risk was estimated based on age, percentage of CD34-positive blasts, FLT3-ITD mutant-to-wild-type ratio, cytogenetic risk, and de novo or secondary AML. Allogeneic improved survival in the favorable subgroup, and autologous transplants improved survival in the intermediate-risk group.¹²⁰ It is possible that new molecularly defined subgroups of AML patients in first CR might benefit from autologous transplantation, but clear recommendations will have to await analysis of larger patient cohorts and/or historic databases and correlative samples.⁴³

A meta-analysis of 24 trials comparing chemotherapy to autologous and allogeneic HSCT that involved 6,007 patients (3,638 patients with cytogenetics information), remission-free survival benefit was observed for poor-risk (hazard ratio [HR], 0.69; 95% confidence interval [CI], 0.57 to 0.84) and intermediate-risk AML (HR, 0.76; 95% CI, 0.68 to 0.85) but not for good-risk disease (HR 1.06; 95% CI, 0.80 to 1.42). Similar results were obtained in the OS analysis. Allogeneic HSCT improved survival for poor-risk (HR 0.73; 95% CI, 0.59 to 0.90) and intermediate-risk AML (HR 0.83; 95% CI, 0.74 to 0.93) but not for good-risk AML (HR 1.07; 95% CI, 0.83 to 1.38). The use of autologous HSCT was not associated with improved outcomes.¹²¹ Therefore, considering that TRM has decreased substantially in the context of allogeneic HSCT, this approach is considered in all adult patients up to age 75 years in first CR who do not have good risk cytogenetics if a sibling or a molecularly matched unrelated donor (HLA-A, -B, -C, -DRB1, -DQB1) is available (see Table 107.5). The decision to proceed to HSCT in first CR should take into account disease and patient-related factors, as well as donor source and expected TRM. It has been proposed that allogeneic HSCT should be considered in situations where DFS is expected to be improved by at least 10%.¹²²

Transplantation for Acute Myelogenous Leukemia in Relapse and Primary Induction Failure. Outcomes of relapsing AML patients are influenced to a large extent by the duration

of the first CR. First remissions shorter than 6 months and failure to achieve a CR with initial therapy (primary induction failure) are associated with a likelihood of CR of less than 10% to 20%. Patients relapsing within the first year of remission that fail to respond to the first salvage attempt are, for practical purposes, incurable with standard chemotherapy regimens. Autologous HSCT has been used to treat relapsed and refractory patients, but with poor results. Allogeneic HSCT is considered the treatment of choice for AML in primary induction failure or beyond the first CR, resulting in long-term disease-free survival in 20% to 40% of patients.¹²³ Results of allogeneic and autologous HSCT are generally better if performed in the second CR as opposed to during an active relapse. However, results were comparable in patients in early relapse versus second remission if one can proceed promptly with HSCT.¹²⁴

Armistead et al.¹²⁵ performed a retrospective review to evaluate all relapsed AML patients treated at MDACC between 1995 and 2004. Median age was 58 years, and 59% of the patients had poor risk cytogenetics. After removing patients who died from their initial salvage therapy or who received a stem cell transplant as their first salvage regimen, the survival outcomes from 490 patients (130 of whom were transplanted) were analyzed. This cohort was divided into the 113 patients who achieved a second CR and the 377 who did not. In both groups, the patients who underwent allogeneic HSCT had a statistically significant survival benefit compared to those who did not. In patients who achieved a second CR, 2-year overall survival was 45% versus 20% for patients who did not undergo transplant after achieving a second CR ($p = 0.005$). For the relapsed refractory group, 2-year OS in the transplant cohort was 13% versus zero for the nontransplanted patients ($p < 0.001$).¹²⁵

The value of salvage chemotherapy prior to transplant is controversial. As indicated previously, patients in second CR have a better prognosis after HSCT than those transplanted in relapse in most studies. On the other hand, early and more indolent relapses should probably be treated with allogeneic transplantation as soon as possible, assuming that an acceptable donor is readily available. A patient who had a remission duration of 6 months or less is unlikely to enter second remission with chemotherapy, which may be needed, however, given the speed of progression or other problems that may preclude allogeneic HSCT in a timely fashion. Patients transplanted in second CR will have long-term disease control in 20% to 60% of the cases with HSCT, whereas patients transplanted in primary induction failure will benefit in 10% to 30% of the cases. The cure rate for patients in first and subsequent relapses is in the 10% to 30% range and, as expected, refractory relapses comprise the worse subgroup.

Alternative Donor Transplantation. As discussed previously, many patients lack an HLA-compatible related or unrelated donor. It is often necessary to proceed to transplantation urgently, and unrelated donor searches typically require several months to identify a donor. Therefore, alternative approaches have been studied, including unrelated umbilical cord blood (CB) transplants or related haploidentical grafts.

Cord blood is a rich source of hematopoietic stem cells for transplantation. The number of cells is approximately 1 log fewer than in a typical bone marrow harvest, but CB transplants are associated with less severe GVHD. This has allowed for the successful use of cord blood transplants from donors mismatched for up to two of the HLA-A and -B (intermediate resolution) and -DR loci (high-resolution typing). As the number of transplants reported to the international registries increases, the importance of high-resolution typing for class I HLA genes is also becoming clearer.¹²⁶ Given the lower cell dose, cord blood transplants are associated with slower engraftment, particularly in adults. Results of retrospective studies are similar to those with unrelated donor bone marrow transplants in selected patient populations.^{127,128} Although outcomes are better in pediatric patients, cord blood transplants have been used successfully in patients in the 6th and 7th decades of life.^{129,130}

A variety of approaches are under investigation aiming at expediting CB engraftment in adults, including ex vivo expansion.^{131,132}

Individuals inherit one HLA haplotype from each parent, so almost all patients will have a haploidentical relative available. Haploidentical transplants are associated with a high risk of graft rejection and GVHD. The *classic* approach utilized extensive ex vivo T-lymphocyte depletion in order to prevent GVHD. Engraftment is enhanced by transplantation of large numbers of CD34+ cells. This labor-intensive approach is linked to delayed immune recovery posttransplant.¹³³ Another approach is the use of T-cell replete hematopoietic stem cell grafts followed by two doses of posttransplant cyclophosphamide, with or without additional immunosuppression.¹³⁴ There is increasing preclinical and clinical evidence that NK cells mediate a potent antileukemia effect. Donor versus host NK-cell reactivity can thus be predicted by KIR gene expression in the donor and the absence of inhibitory KIR ligands in the recipient (HLA BW4 and C alleles). AML patients who receive haploidentical HSCT in which donor NK cells were predicted to be alloreactive had significantly lower relapse rates and improved leukemia-free survival.¹³⁵

Treatment and Prevention of Relapse after Allogeneic Transplantation. AML recurrence is a major cause of treatment failure. A reduction of early TRM, leading to higher overall survivorship rates, and transplantation of patients at high risk for relapse have led to an increase in the number of recurrences after allogeneic HSCT. There is no homogeneity or consensus regarding treatment of this difficult clinical scenario. Donor lymphocyte infusion, second transplant, chemotherapy, and immunosuppression withdrawal are commonly used with low success rates. CR duration after HSCT is a major determinant of salvage success, as is response to treatment of relapse.¹³⁶ The biology of disease relapse is complex, and this is an area of active basic and clinical research.^{137,138} The prevention of relapse may include immunologic or pharmacologic interventions, such as the use of leukemia-specific cytotoxic T lymphocytes or the maintenance of remission with 5-azacitidine or other drugs, such as FLT3 inhibitors for patients harboring the mutation. Low-dose azacitidine maintenance of remission is currently under investigation in a randomized trial.^{55,139-143}

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL is a heterogeneous disease with distinct biologic and prognostic groupings. Considerable progress has been made in understanding the biology of ALL, which has led to more precise disease prognostication and treatment strategies tailored to specific disease subgroups. This has resulted in dramatic improvements in the outcomes of children with ALL, with cure rates up to 80%. The therapeutic approach for adult ALL is modeled on pediatric regimens, and although initial remission rates range between 80% to 90%, only 25% to 50% of adults achieve long-term disease-free survival. This stark difference in outcome for adults as compared to children has been variously attributed to the greater incidence of adverse cytogenetic subgroups found in adults and possibly poorer tolerance and compliance of adults with intensive therapies required for the successful treatment of ALL. Continued research into the biology of this heterogeneous disease and further development of targeted therapies used in a risk-stratified manner will hopefully lead to comparable survival rates in the near future.

Epidemiology

ALL accounts for approximately 20% of acute leukemias in adults, with increasing incidence above 50 years of age. The incidence of ALL is more common in Caucasians compared with African Americans, with an age-adjusted overall incidence in the United States

of 1.5 per 100,000 in Caucasians and 0.8 per 100,000 in African Americans.¹⁴⁴ A higher incidence of ALL has been reported in industrialized countries and urban areas. Finally, ALL is slightly more common among men than among women (1.3 to 1.0).

Diagnosis and Evaluation

Historically, the FAB classification system distinguished three subtypes of ALL based on cell morphology.¹¹ L1 lymphoblasts, which were small to intermediate in size, were the most common, followed by L2, which defined slightly larger sized blasts, and finally L3, which defined large blasts, described as having a *starry sky* appearance, which were seen in Burkitt's leukemia or lymphoma. This classification system has been replaced by the WHO system, which is based on immunophenotypic, cytogenetic, and molecular information, and consequently provides more precise and clinically relevant disease subgroupings.¹²

Of all cases of ALL, 85% are of B-cell lineage, and the most common form is the precursor B phenotype (also called common precursor-B ALL or early precursor-B ALL); these cells express a B-cell immunophenotype (CD19, CD22), TdT, cytoplasmic CD79A, CD34, CD10 (CALLA), and lack cytoplasmic μ and surface immunoglobulin (sIg). It is found frequently in patients with the Philadelphia chromosome, t(9;22)(q34;q11). A less common type, termed pro-B ALL, lacks CD10 expression and may represent an earlier level of B-cell maturation. Mature B-cell lineage ALL has the immunophenotype of mature B cells with sIg expression and is seen with Burkitt's leukemia or lymphoma. T-lineage ALL accounts for 15% to 20% of cases. This *common thymocyte* type expresses pan T-cell markers, CD2, cytoplasmic CD3 (cCD3), CD7, CD5, and distinctively shows coexpression of CD4 and CD8 and expression of CD1a. A more primitive type called *prothymocyte* or *immature thymocyte* type has TdT, cCD3, and variable expression of CD5, CD2, and CD7, but lacks CD4, CD8, and CD1a.

More recently, using molecular profiling, a distinct subset within the immature thymocyte group has been identified as early T-cell precursor (ETP) with very poor prognosis.¹⁴⁵ These leukemias express one or more myeloid or stem cell markers (CD117, CD34, HLA-DR, CD13, CD33, CD11b, or CD65) in addition to the immature thymocyte markers.¹⁴⁵ The mature T-lineage phenotype expresses the pan T-cell markers, variable TdT, but lacks CD1a.

Cytogenetic and Molecular Abnormalities

Specific and well-characterized recurring chromosomal abnormalities facilitate diagnosis, confirm subtype classification, and have major prognostic value for treatment planning. Abnormalities in chromosome number or structure are found in approximately 90% of children and 70% of adult ALL patients.¹⁴⁶⁻¹⁵⁰ Differences in the frequency at which good- and poor-risk prognosis cytogenetic abnormalities occur in children versus adults may partially explain the differences in treatment outcomes between childhood and adult ALL. These cytogenetic abnormalities are acquired somatic mutations that frequently result from translocations of chromosomal DNA and lead to new aberrant protein products presumed to be responsible for the cellular dysregulation that leads to the malignant state. Deletions or loss of DNA may eliminate genes that have tumor suppressor functions. Gains of additional chromosomes may lead to gene dosage effects that provide transformed cells with survival advantages. As in AML, cytogenetic abnormalities in ALL define unique prognostic groups, as listed in Table 107.6.

Molecular methods are increasingly used to better understand the genetic consequences of these cytogenetic abnormalities intrinsic to the pathophysiology of ALL, as well as to refine prognosis and identify novel therapeutic targets in ALL. Quantitative reverse transcription polymerase chain reaction technology (RT-PCR) allows for quantification of MRD, which is an independent

TABLE 107.6

Common Karyotypic Abnormalities in Pediatric and Acute Lymphoblastic Leukemia

Phenotype	Karyotype	Genes Involved	Function of Fusion Protein	Frequency (%) in ALL		Overall Survival (%) at 3–5 Years

prognostic factor in both pediatric and adult ALL.^{151,152} High-resolution genomic profiling has revealed distinct gene-expression patterns in subtypes of ALL, which may be used to yield insights into the biology of ALL and identify new therapeutic targets¹⁵³⁻¹⁵⁹ as well as further refine disease-risk stratification^{160,161} and identify genetic markers associated with drug sensitivity and resistance pathways.¹⁶² For example, alterations in the lymphoid transcription factor gene IKZF1 (IKAROS), are present in 70% of patients with BCR-ABL ALL, and some patients without the BCR-ABL translocation; both the BCR-ABL-positive and BCR-ABL-negative patients behave similarly with poor outcome.¹⁶³ Importantly, patients with the IKAROS gene profile harbor novel kinase-activating mutations¹⁶⁴ and xenograft models show evidence for response to TKIs.¹⁶⁵ Additionally, activating *NOTCH1* mutations are present in up to 50% of T-ALL cases, and the signaling pathways and target genes responsible for Notch1-induced neoplastic transformation are currently under investigation; the nuclear factor kappa B (NF- κ B) pathway appears to be one of the major mediators, suggesting that the use of gamma-secretase inhibitors used in combination with NF- κ B inhibitors, such as bortezomib, may have synergistic effects.¹⁶⁶

Mechanisms for drug resistance are also affected by pharmacogenomics, which is the study of how genetic variation among individuals contributes to interindividual differences in efficacy and toxicity of drugs.^{167,168,169} For example, hyperdiploid cells accumulate more methotrexate polyglutamates because they possess extra copies of the gene-encoding reduced folate carrier, an active transporter of methotrexate.¹⁷⁰ Associations also have been identified between germ-line genetic characteristics (genes that encode drug-metabolizing enzymes, transporters, and drug targets) and drug metabolism and sensitivity to chemotherapy. Rocha et al.¹⁷¹ studied 16 genetic polymorphisms that affected the pharmacodynamics of antileukemic agents and observed that, among 130 children with high-risk disease, the glutathione S-transferase μ 1 (*GSTM1*) nonnull genotype was associated with a higher risk of recurrence, which was increased further by the thymidylate synthetase (*TYMS*) 3/3 genotype.

Finally, epigenetic changes, including hypermethylation of tumor-suppressor genes or microRNA genes, and hypomethylation of oncogenes have been identified in up to 80% of patients with ALL,^{172,173} and insights into these mechanisms provide another area for therapeutic development.¹⁷⁴

Therapy for Acute Lymphoblastic Leukemia

Treatment for adult ALL is modeled on therapy developed for childhood ALL and consists of remission induction, consolidation, and maintenance therapy and CNS prophylaxis, using a risk-stratified approach. Selecting therapy based on patient- and disease-specific prognostic factors has led to a significant improvement in outcomes for childhood ALL, and the adoption of this approach for adults has had a similarly favorable impact.

Prognostic Factors and Risk Assessment

Classic evaluations of prognostic features in adult ALL have led to five widely accepted features: age, WBC count, leukemic cell immunophenotype, cytogenetic subtype, and time to achieve CR.¹⁷⁵ The presence of recurring molecular abnormalities and detection of MRD are more recently used prognostic features based on increasing data supporting their predictive value (Table 107.7).¹⁷⁶ The presence of any of these features portends a high risk for relapse following standard ALL therapy, and the remaining patients are considered standard risk. Up to 75% of adults with ALL are considered to be poor-risk patients, with an expected DFS rate of 25%, and 25% of adults with ALL constitute standard-risk patients, with a projected DFS rate of greater than 50%.¹⁷⁷ Age, WBC count, and treatment response during induction therapy remain classic prognostic features.

TABLE 107.7

Unfavorable Prognostic Features in Adult Acute Lymphoblastic Leukemia

Characteristic	High-Risk Factor(s)
<i>Clinical Factors</i>	
Age	>35 years
Leukocytosis	>30 × 10 ⁹ /L (B lineage); >100 × 10 ⁹ /L (T lineage)
Immunophenotype	Early T-cell precursor
Karyotype	t(9;22)(q24;q11.2), t(4;11)(q21;q23), t(8;14)(q24.1;q32), complex, low hypodiploidy
Molecular profile	IKZF1, CRLF2, TP53, LYL1
<i>Treatment Related</i>	
Therapy response	Time to morphologic CR >4 weeks
	Persistent MRD

CR, complete response; MRD, minimal residual disease.

Age is a continuous variable with OS, decreasing with increasing age; OS ranges from 34% to 57% for patients younger than 30 years compared with only 15% to 17% for patients older than 50 years.¹⁷⁸ A high WBC count is also a continuous variable; generally, a WBC count greater than 30,000/ μ L or 50,000/ μ L for B-lineage ALL and greater than 100,000/ μ L for T-lineage ALL predict for poor prognosis. Of note, while an increased WBC count holds prognostic significance independently as a measure of tumor burden, a high WBC count may be also associated with increased risk of complications during induction therapy, increased risk of CNS relapse, and association with poor-risk cytogenetic subgroups (e.g., t[4;11] and t[9;22]). Finally, the achievement of CR and time to CR after induction therapy carry significant prognostic implications, with patients who require more than 4 weeks to achieve a CR having a lower likelihood of being cured. The emergence of MRD monitoring provides an even more accurate assessment of disease response. In contrast to children, a decrease in MRD burden occurs more slowly in adults.¹⁵¹ In general, the presence of MRD, defined as 10⁻⁴ at any time after the start of consolidation is associated with an increased relapse risk, and the predictive value increases at later time points.¹⁵¹ Patel et al.¹⁵² prospectively analyzed MRD samples following induction, consolidation, and maintenance of 161 patients with non-T-lineage, Ph negative, ALL treated on the international MRC UKALL XII/ECOG 2993 trial. MRD status best discriminated outcome after 10 weeks of therapy, when the relative risk of relapse was 8.95-fold higher in MRD-positive patients and the 5-year relapse-free survival was 15% compared to 71% in MRD-negative patients. The predictive value of MRD depends on the technical quality of the assay and the frequency of monitoring. There is not yet consensus on the clinically relevant time points to measure MRD or the standard methodology to measure MRD.

Specific cytogenetic abnormalities have a major impact on prognosis. The presence of the Ph chromosome and t(4;11)(q21;q23) has been associated with inferior survival in multiple large series.^{150,177,179} Additionally, the presence of the t(8;14)(q24.1;q32) complex karyotype, defined as five or more chromosomal abnormalities or low hypodiploidy or near triploidy, was noted to result in poor survival in the analysis of patients treated on the UKALL XII/ECOG 2993 trial; in contrast, the presence of hyperdiploidy or del(9p) indicated a good prognosis.¹⁷⁹ Of note, the t(8;14) associated with a mature B ALL phenotype has a poor prognosis when treated with standard ALL regimens. However, modified ALL regimens, incorporating

CD20-targeted therapy, now result in significantly better survival for this group.¹⁸⁰ Similarly, although the Ph chromosome has traditionally been considered a marker of high-risk disease, the outcome for this subset of patients has greatly changed with the incorporation of TKIs into classic ALL therapy. Reports from studies incorporating TKI into their regimens show a greater proportion achieving CR and MRD negativity, and thus suggesting a better prognosis.^{181–183} Finally, patients with early T-cell precursor ALL form a distinct subset of patients with T lineage with inferior CR rates and increased rates of relapse.¹⁴⁵

Remission Induction

In the remission-induction phase of therapy, the goals are to eradicate 99% of the initial tumor burden and to restore normal hematopoiesis and performance status. Current induction regimens for adults consist of at least a glucocorticoid (prednisone, prednisolone, or dexamethasone), vincristine, and an anthracycline, with expected remission rates of 72% to 92% and a median remission duration of 18 months (Table 107.8). Dexamethasone has replaced prednisone based on better *in vitro* antileukemic activity and higher drug levels in the CSF.¹⁸⁴ The German multicenter study group for ALL (GMALL) noted decreased early mortality when dexamethasone was given in an interrupted schedule rather than continuously.¹⁸⁵ The most commonly used anthracycline is daunorubicin, and attempts have been made to increase the dosage, with no clear benefit noted, possibly due to the increased hematologic toxicity.¹⁸⁶ Intensification of the induction regimen has been attempted with the addition of cyclophosphamide, asparaginase, or cytarabine. Although no clear improvement in CR rates have been noted,^{187,188} remission duration may be improved in some ALL subtypes (e.g., cytarabine in T-ALL, cyclophosphamide in mature B ALL). Additionally, treatment intensification specifically for patients in the adolescent age range (e.g., 15 to 20 years old) appears to result in better outcomes with survival rates nearing those of pediatric patients.¹⁸⁹ The use of targeted therapies during induction (e.g., rituximab for mature B ALL and imatinib for Ph + ALL) has improved CR rates for these subtypes of ALL. Finally, supportive care is of great importance during this period. Treatment-related early deaths occur in up to 10% of patients,

and significant comorbidities, such as fungal infections, occur as a consequence of prolonged cytopenia. The use of growth factors lessens the regimen-induced myelosuppression and may allow for the timely administration of treatment. In a randomized trial, the use of G-CSF during induction was associated with faster recovery of neutrophils and decreased hospital stay.¹⁹⁰ In the G-CSF treated group, the CR rate was higher (90% versus 81%; $p = 0.10$), and the rate of induction deaths was lower (4% versus 11%; $p = 0.04$).

Consolidation Therapy

Once in remission, the consolidation is administered at a relatively higher level of intensity in efforts to further reduce the leukemic burden and decrease the likelihood of relapse. Consolidation may include rotational consolidation programs, modified induction regimens, or HSCT. Most regimens include methotrexate, cytarabine, cyclophosphamide, and asparaginase. But it is difficult to compare regimens as the number and schedule of the chemotherapy agents used vary. Results from the UKALL XA, GIMEMA ALL 0288, and PÉTHEMA (Programa para el Estudio de la Terapéutica en Hemopatía Maligna) ALL-89 multicenter randomized trials failed to demonstrate a benefit for intensification in terms of prolonging OS and DFS.^{186,191,192} However, more recent nonrandomized studies and regimens using a risk-adapted strategy indicate that intensive consolidation may improve outcome.

In the CALGB 8811 study, the induction course consisted of a five-drug combination and was followed by early and late intensification courses with eight drugs.¹⁹³ This regimen improved the median duration of CR and median survival to 29 and 36 months, respectively—considerably better than results with earlier trials.¹⁹³ A dose-intense regimen of hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone (hyper-CVAD), alternating with high doses of cytarabine and methotrexate, led to significantly higher CR rates and survival ($p < 0.01$)¹⁸⁷ when compared to the less-intense vincristine, doxorubicin, dexamethasone (VAD) regimen,¹⁹⁴ with an OS of 38% at 5 years.

Finally, the GMALL 05/93 study intensified consolidation in a subtype-specific manner. High-dose methotrexate was used in standard-risk B-lineage ALL, high-dose methotrexate, and

high-dose cytarabine in high-risk B-lineage ALL, and cyclophosphamide and cytarabine in T-lineage ALL. The CR rate was 87% in standard-risk patients, with a 5-year OS of 55%.¹⁹⁵ Intensified induction and consolidation improved the CR and DFS rates in a subset of high-risk patients with the pro-B ALL immunophenotype, in whom a continuous CR rate of 41% was achieved as compared to 19% for the others.¹⁹⁵

Hematopoietic Stem Cell Transplantation for Acute Lymphoblastic Leukemia in First Remission

Allogeneic hematopoietic transplantation has a major role in the treatment of ALL, particularly in patients who have recurrent disease or high-risk features (NCCN guidelines). The role of allogeneic HSCT for ALL patients in first CR is controversial. A review of a number of small, phase 2 trials in high-risk adult ALL who underwent allogeneic HSCT in first CR suggests a higher DFS when compared with historic controls based on conventional chemotherapy, ranging broadly from 21% to 71%.¹⁹⁶ Several multicenter, randomized, prospective studies have been conducted (see Table 107.8). To minimize patient selection bias, these trials employed a “genetic” randomization method, offering allogeneic HSCT in first CR to all patients with a sibling donor and chemotherapy or autologous HSCT to patients without a donor. Results were then analyzed using intent-to-treat methods that compared patients with or without donors.

The multicenter French study group Leucemie Aigue Lymphoblastique de l'Adulte completed two large studies between 1986 and 1991 (LALA-87)¹⁹⁷ and 1994 and 2002 (LALA-94).¹⁹⁸ Using an intent-to-treat analysis, a significant DFS and OS benefit was observed for allogeneic HSCT in high-risk patients in both trials. High-risk was defined as having one or more of the following factors: presence of the Ph chromosome, null ALL, age older than 35 years, WBC count greater than $30 \times 10^9/L$, or time to CR greater than 4 weeks. The international MRC UKALL XII/ECOG E2993 trial also noted significantly improved survival (53% versus 45%) for patients who received an allogeneic HSCT in first CR as compared to chemotherapy or autologous HSCT.¹⁹⁹ However, in contrast to the LALA studies, this advantage was confined to the standard-risk patient subset (OS 63% versus 51%) due to the high TRM observed in the high-risk group (39%) as compared to the standard-risk group (20%). Of note, high risk in this study was defined as age older than 35 years or a high WBC (greater than 30,000 for B-lineage or greater than 100,000 for T-ALL); Ph+ patients were excluded in this analysis. Similarly, the advantage of SCT was confined to standard-risk ALL in a similar study by the Dutch Cooperative Trials group.²⁰⁰ In contrast to these studies, no survival advantage was noted for allogeneic HSCT in first CR in three other multicenter, prospective studies.^{201–203} In the EORTC ALL-3 trial, although the donor group had a lower relapse rate (38% versus 56%; $p = 0.001$), it also had a higher cumulative incidence of death in CR (23% versus 7%; $p = 0.0004$), resulting in similar survival rates (41% versus 39%).²⁰² Finally, no survival advantage has ever been shown for autologous HSCT as compared to chemotherapy for patients who do not have a matched related donor.^{197–199,202,203}

In addition to the transplant donor, the transplant preparative regimen, source of stem cells, and immunosuppression prophylaxis all impact treatment outcome. TBI remains the standard backbone for myeloablative ALL transplant preparative regimens. The most widely used regimen remains the combination of TBI and cyclophosphamide, although a retrospective analysis of registry data from the CIBMTR suggests that the combination of TBI and etoposide may afford better survival for patients in second CR when compared to cyclophosphamide and TBI.²⁰⁴ Nonradiation-containing regimens, most commonly busulfan and cyclophosphamide, have been investigated in hopes of decreasing radiation-related complications, with no significant differences noted in outcome.^{205,206}

As illustrated in the MRC UKALL XII/ECOG 2993 study, an increasing TRM rate with age compromises the antileukemia benefit for older patients.¹⁹⁹ Because the incidence of ALL increases in adults over age 50 years, transplant approaches with reduced TRM are needed. Reduced-intensity preparative regimens are under evaluation with a goal to reduce toxicity.

The EBMT reported results from the largest series of 97 adult patients with ALL treated with reduced-intensity conditioning (RIC) HSCT and confirmed the benefit of RIC for patients in remission, with a 2-year OS of 52% versus 27% for patients transplanted with advanced disease.²⁰⁷ Smaller studies have corroborated the benefit for RIC transplantation for older patients with early stage ALL.^{208–210} Marks et al.²⁰⁶ compared transplant conditioning regimen intensity, myeloablative versus RIC, within the limitations of a retrospective analysis in patients with Ph-ALL receiving an allogeneic HSCT in first CR and second CR. Although regimen intensity did not impact TRM or relapse risk in a multivariate analysis, a significantly older patient population was able to tolerate RIC versus myeloablative conditioning (median age 45 years versus 28 years; $p < 0.001$). Thus, RIC merits further investigation in prospective studies.

Maintenance Therapy

Maintenance therapy is administered to patients in remission after consolidation therapy at a low level of intensity, but for a protracted period of time. It has experienced the least modification over time. It consists of a backbone of daily 6-mercaptopurine, weekly methotrexate, and monthly pulses of vincristine and prednisone, generally administered for 2 to 3 years.²¹¹ Attempts to omit maintenance, or shorten its duration to 12 to 18 months, have led to inferior results.¹⁷⁵ However, maintenance therapy is not necessary in mature B ALL, in which a high cure rate is achieved with short-term, dose-intense regimens. The best maintenance regimen for Ph+ patients is not clear but should include a TKI, and is also recommended after transplant,²¹² although the duration post-SCT is not clear. Many investigators recommend maintaining the WBC count below $3,000/\mu L$ during maintenance. Transaminitis is commonly observed during this period and appears to be caused by the methylated metabolites of mercaptopurine. It is not necessary to alter the regimen because of liver enzyme elevation, because the transaminitis promptly resolves with completion of therapy.

Central Nervous System Prophylaxis

CNS prophylaxis can consist of intrathecal (IT) chemotherapy (methotrexate, cytarabine, corticosteroids), high-dose systemic chemotherapy (methotrexate, cytarabine, L-asparaginase), and CNS irradiation. Despite aggressive systemic therapy, the CNS remains a sanctuary site, and without specific meningeal-directed therapy, CNS disease will develop in up to 50% of adult patients.¹⁴ Risk factors for CNS disease include elevated WBC or lactate dehydrogenase (LDH) at diagnosis, traumatic lumbar puncture, and T-lineage ALL phenotypes. Although some trials still rely on CNS irradiation, most treatment regimens are adopting a risk-adapted approach²¹³ and attempting to omit CNS irradiation¹⁷⁵ due to its many acute and late complications, including endocrinopathy, neurocognitive deficits, and secondary cancers.

Treatment of Specific Acute Lymphoblastic Leukemia Subgroups

Philadelphia Chromosome–Positive Acute Lymphoblastic Leukemia

Historically, patients with Ph+ ALL have had a poor prognosis, with long-term DFS rates of 10% to 20%.²¹⁴ Allogeneic

transplantation from a related or unrelated donor was widely used for consolidation, with 30% to 65% long-term survival for patients receiving HSCT in first CR.²¹⁵⁻²¹⁷ Beyond first remission, HSCT was curative in only a small fraction of patients, with DFS ranging between 5% and 17%.²¹⁸

However, the development of potent TKI of the tyrosine kinase activity of the BCR-ABL fusion product, resulting from the Philadelphia chromosome translocation, has revolutionized therapy for Ph-associated leukemias. Imatinib mesylate was the first TKI to demonstrate significant activity in patients with CML and Ph+ ALL,²¹⁹ although response duration in Ph+ ALL was short, with a median time to progression and median OS of 2.2 and 4.9 months, respectively. However, synergistic effects have been observed *in vitro* when imatinib has been combined with commonly used chemotherapy agents, and a number of studies have investigated the benefit of concurrent or sequential administration of imatinib with chemotherapy. Results from these trials suggest that the incorporation of imatinib into standard ALL therapy results in significantly improved remission induction rates, more patients being able to receive transplant in first remission, and ultimately, better OS rates ranging from 52% to 78%.^{181-183,220} Whether consolidation with HSCT in first CR will remain the standard of care for these patients will depend on the durability of the remission inductions, which is currently under investigation. Long-term follow-up of the GRAAPH-2003 study, which incorporated imatinib into its remission and consolidation treatment, resulted in a 50% 4-year OS for patients receiving allogeneic SCT compared with 33% at for those not transplanted.²²¹ A national multicenter trial is currently in progress in which patients with Ph+ ALL were prospectively randomized to continued chemotherapy or allogeneic transplants in an effort to determine the best route of consolidation for these patients.

The role of imatinib in the treatment of elderly patients with Ph+ ALL is of particular interest. This is a group with a historically poor outcome due to poor tolerance of the standard chemotherapy regimens and disease resistance. Several trials have examined various approaches in this population. Use of imatinib and methylprednisolone alternated with chemotherapy improved the CR rate and OS at 1 year in 30 patients older than 55 years as compared to historical controls (72% versus 29% and 66% versus 44%, respectively).²²² More impressive was a 100% CR noted among 29 patients, with median age 60 years, ranging from 61 to 83 years, who were treated with a combination of imatinib and prednisone only. The median survival from diagnosis was 20 months.²²³ Finally, Ottmann et al.²²⁴ conducted a randomized trial of imatinib monotherapy versus standard induction therapy followed by imatinib plus standard consolidation chemotherapy for all patients. Fifty-five patients with a median age of 67 years were treated. The imatinib-treated arm had a significantly higher CR rate (96% versus 50%) with less regimen-related toxicity as compared to the standard induction arm; however, there was no significant difference in OS between the two arms (42% at 2 years).

The development of resistance to imatinib has led to the search for alternative, second-generation TKI such as dasatinib and nilotinib.^{225,226} Dasatinib is a dual Src and Abl kinase inhibitor that has shown significant activity in patients with imatinib-resistant disease.²²⁷⁻²²⁹ The significant activity of dasatinib has prompted investigation of its use in front-line regimens. Early response rates suggest a higher and faster rate of molecular remissions when compared to imatinib.^{230,231}

Mature B-Lineage Acute Lymphoblastic Leukemia

Treatment of Burkitt's leukemia or lymphoma with the conventional ALL regimens have been disappointing. Short-duration, intensive regimens that maintain serum drug concentrations and minimize treatment delays have demonstrated the greatest

efficacy in this disease, mainly due to its high-growth fraction.²³² These regimens incorporate strategies such as the use of fractionated cyclophosphamide, alternation of non-cross-resistant cytotoxic agents between treatment cycles, and aggressive CNS prophylaxis.²³³ More recently, the addition of the anti-CD20 monoclonal antibody rituximab has further improved the outcome of patients with Burkitt's leukemia or lymphoma. Thomas et al.²³⁴ administered rituximab in addition to the hyper-CVAD regimen and reported a CR rate of 86%, with 3-year OS of 89%. This was significantly better than the 19% 3-year survival reported for hyper-CVAD alone.

T-Cell Acute Lymphoblastic Leukemia and T-Lymphoblastic Lymphoma

The survival of patients with T-cell ALL and T-lymphoblastic lymphoma (T-LBL) has improved significantly using the regimens designed for ALL, with OS ranging from 50% to 70%.²³⁵ Use of mediastinal radiation given after chemotherapy appears to reduce mediastinal relapse. A proportion of patients with relapsed disease can achieve a second CR and long-term survival with allogeneic stem cell transplant. Compared to patients with B-lineage ALL, the spectrum of genetic abnormalities in T-cell ALL is less well characterized; FISH or PCR testing is required to detect the higher rate of cryptic chromosomal translocations and gene mutations in T-cell ALL. Subset analysis of T-cell ALL patients treated on the MRC/UKALL trial revealed complex cytogenetics, CD13 positivity, and CD1a negativity to be associated with poorer outcome.²³⁶ Greater understanding of the molecular pathogenesis of this subset of ALL has led to the development of novel therapies, such as nelarabine and forodesine,²³⁷ developed specifically towards neoplastic T cells, and gamma-secretase and TKIs developed specifically toward aberrant pathways.^{156,158} In CALBG study 19801, 26 patients with relapsed T-cell ALL received nelarabine at 1.5 g/m² per day on days 1, 3, and 5 repeated every 22 days, with a median number of two courses administered.²³⁸ A relatively high CR rate of 31% was noted in this heavily treated group of patients, suggesting that nelarabine induces cytotoxicity through therapeutic pathways different from that of currently used standard drugs. Furthermore, the median DFS was 20 weeks, which should allow sufficient time for a select group of patients with a preserved performance status to proceed to transplant (approximately one-third of patients progressed to transplant in this study). These findings were corroborated in a recent German study in which 126 patients with relapsed/refractory T-ALL or LBL received single-agent nelarabine and 36% of patients achieved CR. Eighty percent of the patients in CR subsequently received SCT, with a 3-year OS of 31% for the transplanted patients.²³⁹ The most common nonhematologic toxicity noted in the study was reversible peripheral sensory and motor neuropathy.²³⁸ Nelarabine is also being combined with standard combination chemotherapy to improve long-term outcome in higher risk T-ALL.²⁴⁰ Unfortunately, many of the commonly used agents for ALL therapy, such as vincristine and methotrexate, also have neuropathic toxicities, so nelarabine use remains limited. Newer strategies, including long continuous infusions of nelarabine, are currently being explored to reduce dose-limiting neurotoxicity.

Treatment of Primary Refractory or Relapsed Adult Acute Lymphoblastic Leukemia

Most current induction regimens obtain complete responses in 72% to 92% of newly diagnosed patients. Early deaths account for some of the induction failures, but in most studies, 5% to 10% of patients have disease that is resistant to the remission induction regimen. These patients often have poor prognostic factors at presentation, and additional attempts at induction chemotherapy

may be unsuccessful. Several studies suggest that patients with an HLA-identical sibling benefit if they proceed directly to allogeneic transplantation without undergoing a second attempt at induction therapy.^{123,241} In the largest of these studies, approximately 35% of these patients with primary refractory disease became long-term disease-free survivors.²⁴²

In addition to primary refractory patients, 60% to 70% of patients who achieve a complete response eventually relapse. Numerous regimens have been reported in the setting of relapsed ALL. These can be divided into two main groups: those that repeat the regimens used for newly diagnosed patients and those that involve high-dose, typically cytarabine-based regimens, with no superior reinduction therapy identified. Cytarabine has been used in combination with L-asparaginase, anthracyclines, or mitoxantrone, with responses as high as 72%.^{243,244} However, these are transient, short-lived responses, and allogeneic HSCT remains the most effective modality for achieving durable remissions for patients in or beyond second CR. Two large multicenter trials have best characterized prognosis and outcome following relapse. The outcome of 609 adults with relapsed ALL, all of whom were previously treated on the MRC UKALL12/ECOG 2993 study, was investigated.²⁴⁵ The survival at 5 years after relapse was 7%. Factors predicting a good outcome after salvage therapy were young age (OS 12% for patients older than 20 years versus 3% for patients older than 50 years) and duration of first remission greater than 2 years (OS 11% versus 5%). When survival was evaluated based on treatment strategy, survival following HSCT ranged from 15% to 23% depending on donor type (15% for autograft, 16% for matched unrelated donor, 23% for matched related donor), and was significantly better than chemotherapy only at 4% ($p < 0.00005$).²⁴⁵ Oriol et al.²⁴⁶ reported on the outcome of 263 adults with relapsed ALL, all of whom were previously treated on four consecutive PETHEMA trials with similar induction therapies. OS at 5 years was 10%. Factors predicting a good outcome were identical to the prior study: age less than 30 years (OS 21% versus 10%) and duration of first remission greater than 2 years (OS 36% versus 17%). Forty-five percent of patients achieved a second remission, with better outcomes noted in the group who then proceeded to transplant. The best outcome was noted for patients younger than 30 years old with a long first remission duration transplanted in second CR, with an OS of 38% at 5 years. TRM was higher for patients who had received a prior transplant during first remission (TRM 45% versus 23%), but there was no difference in OS. Similar long-term leukemia-free survival rates of 14% to 43% have been

reported from other small series for patients who received HSCT in second CR. As expected, the primary cause of failure is relapse (greater than 50%).

CNS relapse occurs in approximately 2% to 10% of patients who have received appropriate prophylaxis. In the majority of patients, concurrent bone marrow relapse can be documented. Occasionally, CNS relapse may occur without demonstrable systemic relapse; however, this event almost always predicts subsequent bone marrow relapse, and patients with isolated CNS relapse should first receive CNS-directed therapy and then systemic reinduction chemotherapy. Long-term outcome is poor, with zero to 6% OS at 4 years.²⁴⁵ Intensive treatment, with a combination of intrathecal or radiotherapy and systemic chemotherapy, followed by consolidation with HSCT may improve results.

Several new agents are being investigated in the treatment of acute lymphoblastic leukemia. Among the more successful approaches has been the use of novel monoclonal antibodies alone and in combination with chemotherapy. The anti-CD20 monoclonal antibody rituximab has already been successfully implemented in the treatment of CD20+ and Burkitt's leukemia. A new anti-CD20 antibody, ofatumumab is currently under investigation. Inotuzumab ozogamicin, a novel anti-CD22 antibody conjugated to calicheamicin is also being developed in the treatment of B-ALL and has shown promise. In a phase 2 study of 49 patients with relapsed and refractory B-ALL with a median age of 36 years, the OR rate was 57%.²⁴⁷ Further single-agent and combination studies are ongoing. A novel T-cell engaging CD19/CD3 bispecific antibody, blinatumomab, has also shown impressive activity in patients with previously treated ALL. In a phase 2 trial of blinatumomab in patients with MRD or persistent disease after induction/consolidation for B-ALL, 16 out of 21 (76%) patients became MRD negative, with a relapse-free survival of 78% at a median of 405 days.²⁴⁸ Further studies of blinatumomab in the relapsed setting are ongoing. Further investigation into the genetic basis of ALL continues to uncover pathogenic driver mutations and activated signaling pathways that could potentially be therapeutically targeted.²⁴⁹ Finally, cellular therapy in the form of T-cell therapy is showing great promise in patients with advanced ALL. Patients with multiply-relapsed ALL are showing dramatic responses to treatment with chimeric antigen receptor–modified, CD19-directed T-cell therapy.²⁵⁰ This approach is being used as a bridge to transplant,²⁵¹ and has been evaluated in the adjuvant setting in the form of a preemptive donor lymphocyte infusion (DLI).²⁵²

108 Molecular Biology of Chronic Leukemias

James S. Blachly*, Christopher A. Eide*, John C. Byrd, and Anupriya Agarwal

INTRODUCTION

Chronic myeloid leukemia (CML) and chronic lymphocytic leukemia (CLL) are very different diseases and yet share important clinical features. Both are usually diagnosed in an indolent stage characterized by the expansion of differentiating cells that can last for several, sometimes many years. In both, the acquisition of additional mutations promotes progression to advanced therapy-refractory disease and both are incurable with currently available drug therapy. In this chapter, we will discuss the key pathogenetic mechanisms of CML and CLL, with an emphasis on recent data and potential therapeutic implications.

CHRONIC MYELOID LEUKEMIA

CML is caused by the constitutively active tyrosine kinase BCR-ABL1 generated as the result of a reciprocal translocation between chromosomes 9 and 22. The annual incidence of CML is 1.3 to 1.5 per 10^5 , with a slight male preponderance, but no significant differences across ethnicities. The only established CML risk factor is exposure to ionizing radiation, evident from studies in survivors of the nuclear explosions in Japan and patients exposed to Thorotrast or radiotherapy. During the initial chronic phase (CP), cellular differentiation and function are largely maintained, therapy is effective, and mortality is low. Without effective treatment, the disease invariably progresses to a rapidly fatal blastic phase (BP) of myeloid or lymphoid nature.

Pathogenesis

The first cases of what was probably CML were described by Bennett and Virchow in the mid 1840s. In 1960, Philadelphia cytogeneticists Nowell and Hungerford¹ described a “minute” chromosome 22 in CML cells that became known as the Philadelphia (Ph) chromosome. In 1973, the work of another cytogeneticist, Janet Rowley,² revealed that this abnormality is, in fact, the result of a reciprocal translocation between chromosomes 9 and 22 (t[9;22] [q34;q11]). The genes juxtaposed by the translocation were subsequently identified as *ABL1* (Abelson) on 9q34 and breakpoint cluster region (*BCR*) on chromosome 22q11 (Fig. 108.1A). As a result of the (9;22) translocation, the *BCR-ABL1* fusion gene is formed on the derivative of chromosome 22 (22q-, Ph), whereas the reciprocal *ABL1-BCR* resides on the derivative of 9q+. A series of seminal studies demonstrated that the constitutive tyrosine kinase activity of BCR-ABL1 is required for cellular transformation and that the clinical disease was reproducible in a murine model.³ According to the World Health Organization, the presence of *BCR-ABL1* in the context of a myeloproliferative neoplasm is diagnostic of CML, although the translocation is also found in a subset of patients with acute lymphoblastic leukemia (ALL) and rare cases of acute myeloid leukemia (AML).

*Share equal contribution.

Molecular Anatomy of the BCR-ABL1 Junction

The breakpoints within *ABL1* occur upstream of exon 1b, downstream of exon 1a, or more frequently, between the two. Regardless of the exact breakpoint location, splicing of the primary transcript yields an mRNA in which *BCR* sequences are fused to *ABL1* exon a2. Breakpoints within *BCR* localize to one of three breakpoint cluster regions. More than 90% of CML patients and one-third of Ph+ ALL patients express the 210-kDa isoform of BCR-ABL1, in which the break occurs in the 5.8-kb major breakpoint cluster region (*M-bcr*), which spans exons e12-e16 (formerly exons b1-b5). Alternative splicing gives rise to either b2a2 (e13a2) or b3a2 (e14a2) transcripts,⁴ which are mutually exclusive and present in 36% and 64% of patients, respectively. Patients with b3a2 rearrangements are, on average, older than patients with b2a2 transcripts and have elevated platelet levels.⁵ The remainder of Ph+ ALL patients and rare CML cases harbor breakpoints further upstream in the 54.4-kb minor breakpoint cluster region (*m-bcr*), generating an e1a2 transcript that is translated into p190^{BCR-ABL1}.⁶ A third breakpoint downstream of exon 19 in the micro breakpoint cluster region (*μ-bcr*) gives rise to an e19a2 *BCR-ABL1* mRNA and p230^{BCR-ABL1} and is associated with neutrophilia. The reciprocal *ABL1-BCR* transcript, although detectable in approximately two-thirds of patients, does not seem to play any significant role in pathogenesis.⁷

Functional Domains of BCR-ABL1 and Kinase Activation

p210^{BCR-ABL1} contains several distinct domains (Fig. 108.1B).⁸ The N-terminal coiled-coil domain of BCR allows BCR-ABL1 dimerization, which is critical for kinase activation. The p210^{BCR-ABL1} protein also retains the serine/threonine kinase and Rho guanine nucleotide exchange factor homology (Rho-GEF) domains of BCR, which are deleted in p190^{BCR-ABL1}, which may explain differences in disease phenotype associated with the two variants. In contrast to BCR, the *ABL1* sequence is almost completely retained, including SRC homology domains 2 and 3, the tyrosine-kinase domain, a proline-rich sequence, and a large C terminus with nuclear localization signal, DNA-binding, and actin-binding domains. The N-terminal “cap” region of *ABL1*, which is lost in the BCR-ABL1 fusion, negatively regulates kinase activity by binding to a hydrophobic pocket at the base of the kinase domain, which, in the 1b isoform, is mediated by N-terminal myristoylation.

Signal Transduction

Numerous substrates and binding partners of BCR-ABL1 have been identified (see Fig. 108.1B) that contribute to increased proliferation, decreased apoptosis, defective adhesion to bone marrow stroma, and genetic instability.⁹ Because a comprehensive review of the multiple implicated pathways is beyond the scope of this chapter, we will focus on those for which strong evidence supports a rate-limiting role in disease pathogenesis.

Figure 108.1 (A) A Schematic representation of the t(9;22)(q34;q11) translocation that creates the Philadelphia (Ph) chromosome. The *ABL1* and *BCR* genes reside on the long arms of chromosome 9 and 22, respectively. As a result of the (9;22) translocation, the *BCR-ABL1* gene is formed on the derivative of chromosome of 22 (22q-, Ph chromosome), whereas the reciprocal *ABL1-BCR* resides on the derivative of 9q+ . **(B)** The BCR-ABL1 domain structure and simplified representation of molecular signaling pathways activated in CML cells. Following dimerization of BCR-ABL1, autophosphorylation generates docking sites on BCR-ABL1 that facilitate interaction with intermediary adapter proteins (purple) such as GRB2. CRKL and CBL are also direct substrates of BCR-ABL1 that are part of a multimeric complex. These BCR-ABL1-dependent signaling complexes in turn lead to activation of multiple pathways whose net result is enhanced survival, inhibition of apoptosis, and perturbation of cell adhesion and migration. A subset of these pathways and their constituent transcription factors (blue), serine/threonine-specific kinases (green), and apoptosis-related proteins (red) are shown. Also included are a few pathways that have been more recently implicated in CML stem cell maintenance and BCR-ABL1-mediated disease transformation (orange). However, it is important to note that this is a simplified diagram and that many more associations between BCR-ABL1 and signaling proteins have been reported. DBL, diffuse poorly-differentiated B-cell lymphoma; SH3, Src homology 3; SH2, Src homology 2; GRB2, growth factor receptor-bound protein 2; SOS, son of sevenless; PI3K, phosphatidylinositol-3 kinase; JAK2, janus kinase; RAS-GTP, rat sarcoma-guanosine triphosphate; RAS-GDP, rat sarcoma-guanosine diphosphate; hnRNP E2, heterogeneous nuclear ribonucleoprotein E2; AKT, RAC-alpha serine/threonine-protein kinase; mTOR, mammalian target of rapamycin; STAT5, signal transducer and activator of transcription 5; MEK1/2, mitogen-activated protein kinase 1/2; CEBP α , CCAAT/enhancer binding protein alpha; PP2A, protein phosphatase 2A; ERK, extracellular signal-regulated kinase; FOXO3, forhead O transcription factor; SKP2, S-phase kinase-associated protein 2; BAD, BCL2-associated agonist of cell death.

Phosphatidylinositol-3 Kinase

Phosphatidylinositol-3 kinase (PI3K) is activated by autophosphorylation of tyrosine 177, which generates a high-affinity docking site for the GRB2 adapter, which in turn recruits GAB2 into a complex that activates PI3K. Consistent with a critical role of the Y177/GRB2/GAB2 axis, a mutation of this critical tyrosine to phenylalanine or a lack of GAB2 abrogates myeloid leukemia.¹⁰ An alternative pathway of PI3K activation is a complex formation between its p85 regulatory subunit, CBL, and CrkL, which bind to the SH2 and proline-rich domains of BCR-ABL1.¹¹ PI3K activates the serine/threonine kinase AKT, which suppresses the activity of the forkhead O transcription factors (FOXO), thereby promoting survival.¹² Additionally, PI3K enhances cell proliferation by promoting proteasomal degradation of p27 through upregulation of S-phase kinase-associated protein 2 (SKP2), the F-Box recognition protein of the SCF^{SKP2} E3 ubiquitin ligase.¹³ Another important outlet of PI3K signaling is the AKT-dependent activation of mammalian target of rapamycin (mTOR), which enhances protein translation and cell proliferation.¹⁴

Rat Sarcoma/Mitogen-Activated Protein Kinase Pathways

GRB2-mediated recruitment and activation of son of sevenless (SOS) promotes exchange of guanosine triphosphate (GTP) for GDP on rat sarcoma (RAS).¹⁵ GTP-RAS activates mitogen-activated protein kinase (MAPK), promoting proliferation. Signaling from RAS to MAPK involves the serine/threonine kinase RAF-1¹⁶ and ras-related C3 botulinum toxin substrate (RAC), another GTP-GDP exchange factor.¹⁷ A crucial role for the latter is supported by the fact that a lack of RAC1/2 delays BCR-ABL1-driven leukemia in a murine model.

Janus Kinase/Signal Transducer and Activator of Transcription Pathway

BCR-ABL1 activates signal transducer and activator of transcription 5 (STAT5) through direct phosphorylation or indirectly through phosphorylation by hematopoietic cell kinase (HCK), a SRC family kinase, or janus kinase 2 (JAK2).¹⁸ Active STAT5 induces the transcription of antiapoptotic proteins like myeloid cell leukemia 1 (MCL-1) and B-cell lymphoma-extra large (Bcl-xL).¹⁹ JAK2 has been shown to play a central role in the cytokine signaling machinery that enables survival of CML stem cells in the presence of BCR-ABL1 tyrosine kinase inhibitors. Recent studies have also shown that the complete lack of STAT5 abrogates both myeloid and lymphoid leukemogenesis, implicating it as a potential target for the elimination leukemic stem cells.²⁰⁻²²

Cytoskeletal Proteins

BCR-ABL1 phosphorylates several proteins involved in adhesion and migration, including focal adhesion kinase (FAK), paxillin, p130 Crk-associated substrate (p130CAS), and human enhancer of filamentation 1 (HEF1). This and the activation of RAS²³ are thought to impair integrin-mediated adhesion of CML progenitors to stroma and the extracellular matrix, causing premature circulation as well as abnormal proliferation of Ph⁺ progenitors.²⁴ A novel adaptor protein pathway in which BCR-ABL1 interaction with Grb2-related adaptor downstream of Shc (GADS)/SH2 domain containing leukocyte protein of 76kDa (SLP-76)/non-catalytic region of tyrosine kinase adaptor protein 1 (NCK1) regulates the actin cytoskeleton and nonapoptotic membrane blebbing was also recently described.²⁵

DNA Repair

BCR-ABL1 impairs DNA damage surveillance by various mechanisms. For example, BCR-ABL1 has been shown to suppress checkpoint kinase 1 (CHK1) through the inhibition of

ataxia telangiectasia and Rad3-related protein (ATR)²⁶ or the downregulation of breast cancer 1, early onset (BRCA1), a substrate of ataxia telangiectasia mutated (ATM).²⁷ Nonhomologous end joining and homologous recombination, both critical double-strand break repair pathways, are defective in CML. BCR-ABL1 also upregulates RAD51, inducing rapid but low-fidelity double-strand break repairs on challenge with cytotoxic agents and inducing reactive oxygen species (ROS) that promote chronic oxidative DNA damage, double-strand breaks, and point mutations. It has been demonstrated that BCR-ABL1 kinase inhibits the activity of uracil-DNA glycosylase (UNG2), which leads to the accumulation of uracil derivatives in genomic DNA and contributes to increased point mutations.²⁸ Lastly, telomere length decreases with disease progression from CP to BP.²⁹

Although significant progress has been made to understand the extraordinary complexity of CML biology, a complete picture is still elusive. To overcome the limitations of investigating single pathways, quantitative proteomics³⁰ and whole transcriptome analyses³¹ are being used to establish a comprehensive picture of BCR-ABL1 signaling. These results suggest that cellular processes in CML, rather than relying on a single pathway, use integrated networks to fully realize their leukemogenic potential.

Murine Models of Chronic Myeloid Leukemia

The most commonly used murine model of CML is the retroviral expression of BCR-ABL1 in bone marrow followed by transplantation into lethally irradiated syngeneic recipients, which develop a CML-like myeloproliferative neoplasm.³² Recently, an inducible transgenic mouse model has been developed, in which conditional BCR-ABL1 expression is under the control of the three enhancers of the murine stem cell leukemia (SCL) gene. This model serves as a promising new tool for studying leukemogenic mechanisms in hematopoietic stem cells during disease initiation and progression.³³ Lastly, xenograft models use various strains of immunodeficient mice for engraftment of primary CML cells.³⁴ A limitation of xenograft models is low engraftment of CML CP cells, probably because of their compromised interactions with the microenvironment as a result of species differences in cytokines and adhesion molecules. Promising results have been obtained by injecting CML cells directly into the livers of newborn mice.³⁵

Chronic Myeloid Leukemia Stem Cells

The origin of CML in a pluripotent hematopoietic stem cell (HSC) was elegantly demonstrated in the late 1970s.³⁶ BCR-ABL1 does not confer self-renewal, implying that it must be acquired by an HSC already endowed with this capacity.³⁷ For unknown reasons, the main cellular expansion occurs in the progenitor cell compartment, while, at least initially, the majority of HSCs are Ph negative.³⁸ Serial xenograft studies have shown that CML leukemia stem cells (LSC) reside within the quiescent CD34+38- fraction of bone marrow cells. Significant progress has recently been made by the identification of the interleukin 1 (IL-1) receptor-associated protein (IL-1RAP) as a surface marker specifically expressed on CD34+38- CML LSC.³⁹ Several genes were shown to have a critical role for LSC maintenance in CML, including promyelocytic leukemia (PML),⁴⁰ Rac2 GTPase,⁴¹ smoothened (SMO)/hedgehog (Hh),⁴² Wnt/ β -catenin,^{43,44} phosphatase and tensin homolog (PTEN),⁴⁵ hypoxia-inducible factor 1 (HIF-1),⁴⁶ B lymphoid kinase (BLK),⁴⁷ stearoyl-CoA desaturase1 (SCD1),⁴⁸ transforming growth factor beta (TGF- β), and FOXO3a.¹² Additionally, BCL6 was reported to be required for the maintenance of LSCs in CML and contribute to drug resistance.⁴⁹ BCL6 expression in these cells is regulated in a PTEN/AKT/FOXO-dependent manner. Recently, an interesting new role of lipid metabolism has emerged in CML stem cell maintenance due to the increased expression

of arachidonate 5-lipoxygenase (ALOX5). Alox5 knockout mice fail to develop CML, suggesting a critical role of ALOX5 in CML leukemogenesis.⁵⁰ Sirtuin 1 (SIRT1), a nicotinamide adenine dinucleotide-dependent protein deacetylase that promotes cell survival under metabolic, oxidative, and genotoxic stresses through deacetylation of multiple substrates including p53, Ku70, and FOXO, is also transcriptionally activated by BCR-ABL1. SIRT1 knockdown or inhibition by a small-molecule inhibitor effectively suppresses the development of CML-like myeloproliferative disease in mice.⁵¹ Importantly, it has been shown that CML stem cell survival may be independent of BCR-ABL1 kinase activity.⁵² A number of studies further suggest that the bone marrow microenvironment provides survival signals to LSCs by involving a number of mechanisms such as chemokine (C-X-C motif) receptor 4 (CXCR4)/stromal cell-derived factor 1 (SDF-1),^{53,54} N-cadherin, and Wnt/ β -catenin.⁵⁵ However, the fact that many of these genes are also critical for maintenance and self-renewal of normal HSCs may be an obstacle to exploiting them as therapeutic targets.

Progression to Blastic Phase

Disease progression is believed to be due to the accumulation of molecular abnormalities that lead to a loss of terminal differentiation capacity of the leukemic clone, which continues to depend on BCR-ABL1 activity. BCR-ABL1 mRNA and protein levels are higher in CML-BP than in CP cells, including CD34+ granulocyte macrophage progenitors (GMP), which are expanded in BP.⁵⁶ One of the mechanisms that enhances BCR-ABL1 activity in BP is inactivation of the phosphatase protein phosphatase 2A (PP2A) through upregulation of SET.^{57,58} Constitutive BCR-ABL1 activity has also been shown to perturb the CML transcriptome,⁵⁹ resulting in altered expression of genes implicated in BP (e.g., preferentially expressed antigen in melanoma [PRAME], myeloid zinc finger 1 [MZF1], ecotropic virus integration site 1 [EVI-1], Wilms tumor 1 [WT1], and JUN-B). Interestingly, a six-gene signature (NIN1/RPN12 binding protein 1 homolog [*S. cerevisiae*] [NOB1], DEAD [Asp-Glu-Ala-Asp] box polypeptide 47 [DDX47], immunoglobulin superfamily member 2 [IGSF2], lymphotoxin beta receptor 4 [LTBR4], scavenger receptor class B, member 1 [SCARB1], and solute carrier family 25 member A [SLC25A3]) was recently found to accurately discriminate early from late CP, CP from AP, and CP from BP⁶⁰; however, the biologic role of these genes in disease progression is still unknown.

CML-BP patients also harbor various additional genetic lesions such as additional chromosomes, gene insertions and deletions, and/or point mutations. A deep-sequencing study of a small cohort of CML-BP patients detected mutations in 76.9% of cases.⁶¹ The most common mutations (other than those in the BCR-ABL1 kinase domain) occur at the loci of the runt-related transcription factor (*RUNX1*),⁶² the additional sex combs like 1 (*ASXL1*), *WT1*, and the tumor suppressor gene *TP53*⁶³ in myeloid BP and in cyclin-dependent kinase inhibitor 2A/2B (*CDKN2A/B*), and the Ikaros transcription factor (*IKZF1*) in lymphoid BP.⁶⁴

The most striking feature of BP, the loss of differentiation capacity, suggests that the function of key myeloid transcription factors must be compromised. Occasionally, the differentiation block can be ascribed to mutations that result in the formation of dominant-negative transcription factors such as runt-related transcription factor 1- ecotropic virus integration site 1 (*AML1-EVI-1*) or nucleoporin 98kDa-homeobox A9 (*NUP98-HOXA9*), which block differentiation or favor preferential growth of immature precursors.^{65,66} Isolated cases of myeloid transformation have been associated with the acquisition of core binding factor mutations typical of AML. A more universal mechanism appears to be the BCR-ABL1-induced downregulation of CCAAT/enhancer binding protein- α (*CEBP α*) through the stabilization of the translational regulator heterogeneous nuclear ribonucleoprotein E2 (*hnRNP E2*), which is low or undetectable in CP but readily detectable in CML-BP.⁶⁷

Aberrant Wnt/ β -catenin activation cooperates with interferon-regulatory factor 8 (*Irf8*)⁶⁸ to contribute to CML progression by conferring self-renewal capacity to GMPs.⁶⁹ The acquisition of self-renewal by GMPs is expected to greatly increase the pool of LSCs in BP. Recently, a crucial role of the RNA-binding protein Musashi2 (*MSI2*) was shown in CML progression to BP, where *MSI2* represses the expression of *Numb*, a protein that impairs the development and propagation of BP.⁷⁰ Interestingly, expression microarray studies have implicated a few genes such as β -catenin not only in disease progression, but also in resistance to tyrosine-kinase inhibitors, supporting the view that drug resistance and disease progression share a common genetic basis.⁷¹ This has implications for prognostication as well as for the development of strategies to prevent progression and overcome resistance.

Conclusions

BCR-ABL1 orchestrates an integrated network of signaling pathways that upend the physiologic control of proliferation, cell death, DNA repair, and microenvironment interaction and lead to the clinical phenotype of CML. Cooperation with additional genetic events that accumulate over time inevitably leads to BP and drug resistance. Although significant progress has been made toward understanding transformation and disease progression, much remains to be learned. Efforts toward determining the molecular pathways critical for the maintenance of these cells, and to develop better and faster techniques to differentiate the LSC from the normal HSC, have been intensified in the last decade. The availability of genomewide scanning tools has undoubtedly accelerated this process. This knowledge has been used to design new strategies to target LSCs and hopefully lead to the discovery of new therapeutic targets to eliminate CML stem cells, overcome drug resistance unless effective therapy is initiated early on, and improve the prognosis of patients whose disease has progressed on therapy.

CHRONIC LYMPHOCYtic LEUKEMIA

CLL is one of the most common leukemias in adults and has a relatively consistent immunophenotype, including dim surface immunoglobulin expression, CD19, CD20, CD23, along with the pan T-cell marker CD5.⁷² The impact on overall survival in both young and elderly patients with CLL is substantial: patients diagnosed under the age of 50 have a median expected life span of 12.3 years, compared to 31.2 years in an age-matched control group.⁷³ Although younger patients have poor outcomes and shortened survival with CLL, several studies have also identified elderly patients as a high-risk group for poor survival following treatment.⁷⁴⁻⁷⁷ A subset of CLL patients have indolent disease for many years and do not require therapy. Improving our understanding of the origin, biology, and progression of CLL will improve risk stratification and will help identify new treatments for this disease.

Origin of Chronic Lymphocytic Leukemia

The identification of a normal B-cell counterpart remains controversial.⁷⁸⁻⁸⁰ Unlike most other B-cell lymphomas and leukemias (with the notable exception of mantle cell lymphoma), CLL co-expresses typical mature B-cell markers with CD5. This prompted many to hypothesize that CLL may be derived from CD5+ B cells whose immunoglobulin (Ig) V_H is unmutated. However, the overall phenotype of CLL with expression of CD5, CD23, and CD19, and low levels of surface IgM or IgD is not observed in any normal B-cell counterpart. Additionally, investigators identified that approximately 40% of CLL cases have an unmutated *IGHV* locus,

whereas the remainder are mutated.^{81,82} These two groups were also shown to have distinct clinical features, prompting the hypothesis that CLL may represent two distinct diseases.^{81,82}

In contrast, two seminal articles examining gene expression profiling in CLL and normal B cells provided findings suggesting that CLL is in fact one disease with a common CLL gene signature.^{83,84} The first, by Klein et al.,⁸³ examined mRNA profiles derived from *IGHV* unmutated, *IGHV* mutated, and normal B cells from different stages of differentiation. An unsupervised analysis of gene expression profiles demonstrated that *IGHV* mutated and unmutated CLL cases were not distinguished in any manner among a common profile typical of CLL. This CLL profile in the majority of samples most resembled postgerminal center memory B cells and lacked any similarity to naïve B cells, CD5+ B cells, or germinal center centroblasts. A supervised analysis of *IGHV*-unmutated and -mutated CLL did, however, demonstrate distinct genes that could separate these two clinical subsets of CLL.

A second article, published concurrently by Rosenwald et al.,⁸⁴ demonstrated similar findings of a common CLL profile described by Klein et al., as compared with other normal B cells and B-cell malignancies. In particular, the CLL gene phenotype was not shared by CD5+ normal B cells, thereby providing corroborating evidence that this is likely not the CLL cell of origin. In an unsupervised analysis of CLL samples, *IGHV*-unmutated and -mutated samples were intermingled. However, a supervised analysis of *IGHV*-unmutated and -mutated CLL again identified a number of genes differentially expressed in the former group related to B-cell receptor signaling and proliferation. In particular, *ZAP70* (zeta-chain associated protein kinase) was overexpressed in *IGHV*-unmutated CLL as compared with *IGHV*-mutated CLL.^{85–88}

Subsequent studies have suggested that *ZAP-70* expression may partly explain why *IGHV*-unmutated CLL patients show more B-cell receptor signaling activity upon ligation of the B-cell receptor.^{89–91} Multiple studies confirming both the clinical prognostic significance of *IGHV* mutational status and/or *ZAP-70* expression have subsequently been reported. *IGHV* status and/or *ZAP70* represent very strong independent variables in predicting early disease progression, treatment remission duration, and survival of CLL patients. The variability in direct measurement of *ZAP-70* among investigators has limited the application of this biomarker clinically, but more recently, *ZAP70* methylation status has been demonstrated to be a clinically relevant surrogate.⁹² In the future, the assessment of methylation may supplant the direct measurement of *ZAP-70*.

Chromosomal Abnormalities in the Pathogenesis of Chronic Lymphocytic Leukemia

In CLL, conventional metaphase cytogenetics can identify chromosomal aberrations in only 20% to 50% of cases because of the low in vitro mitotic activity of CLL tumor cells.⁹³ Early unstimulated metaphase karyotype studies of CLL demonstrated abnormalities, including trisomy 12, deletions at 13q14, structural aberrations of 14q32, and deletions of 11q, 17p, and 6q in descending frequency of occurrence.⁹⁴ In addition, complex karyotype (three or more abnormalities) occurs in approximately 15% of patients and was noted in these early studies to predict for rapid disease progression, Richter's transformation, and inferior survival.^{95–97} A stimulated metaphase analysis has also been reported with the identification of translocations in 33 of 96 patients (34%) that were both balanced and unbalanced, which is associated with significantly shorter median time from diagnosis to requiring therapy and overall survival.⁹⁸ Subsequent comparative genomic hybridization (CGH) and global single nucleotide polymorphism (SNP) array studies in CLL have confirmed these and other chromosomal deletions in CLL.^{99–101} Increasing aberrations in these same studies of CGH or SNP arrays have been associated with more aggressive disease.

Given the limitation of standard or stimulated karyotype analysis, interphase cytogenetics of known abnormalities are used to identify common, clinically significant aberrations in CLL. The largest study of interphase cytogenetics resulted in improved sensitivity to detect partial trisomies (12q12, 3q27, 8q24), deletions (13q14, 11q22-23, 6q21, 6q27, 17p13), and translocations (band 14q32) in more than 80% of all cases. In a large study of 325 patients by Döhner et al.,¹⁰² a hierarchical model consisting of five genetic subgroups was constructed on the basis of regression analysis of CLL patients with chromosomal aberrations. The patients with a 17p deletion had a median survival time of 32 months and the shortest treatment-free interval (TFI) of 9 months, whereas patients with an 11q deletion followed closely with 79 months and 13 months, respectively.¹⁰² The favorable 13q14 deletion group had a long TFI of 92 months and a median survival of 133 months, whereas the group without detectable chromosomal anomalies and those with trisomy 12 fell into the intermediate group with median survival of 111 and 114 months, respectively. Their TFI was 33 and 49 months, respectively. Based on this pivotal study, CLL patients are prioritized in a hierarchical order (deletion 17p13 > deletion 11q22-q23 > trisomy 12 > no aberration > deletion 13q14).¹⁰² Interestingly, patients with high-risk interphase cytogenetics or other complex abnormalities almost always have *IGHV* unmutated or *ZAP-70*-positive CLL.¹⁰³

The frequency of recurrent deletions in CLL suggests the possibility of unique tumor suppressor genes in these lost regions. In particular, attention to coding genes within the 13q14 region failed to identify a viable tumor suppressor gene candidate for many years of investigation to the frustration of multiple investigators. However, in 2002, Croce and colleagues¹⁰⁴ identified miR-15 and miR-16, two noncoding microRNAs, in the deleted region of 13q14. MicroRNAs range in size from 21 to 25 nucleotides and represent a newly recognized class of gene products whose function is to silence genes through binding to the 3'-untranslated region of specific genes to inhibit translation. When near compatible hybridization of the noncoding RNA exists, RNA transcription can also be antagonized. This same group later showed that miR-16 regulates the expression of *bcl-2*, which is overexpressed in CLL and other B-cell lymphoproliferative disorders.¹⁰⁵ Multiple different studies have associated specific miR expression with rapid disease progression, fludarabine resistance, and poor prognosis. In addition, miR-34a has been directly related to the adverse outcome associated with p53 dysfunction.^{106,107} At the time of writing this chapter, several reports are coming forth in CLL and other types of cancer about the role of miRs in cell-to-cell communication via exosomes. Further study of miRs in CLL is under way to elucidate their full role in the pathogenesis and progression of CLL. In addition, other conserved, larger noncoding RNAs with different siRNA and epigenetic silencing roles have been recently identified to have a significant role in CLL.

Recurrent Mutations in Chronic Lymphocytic Leukemia

Several groups have recently used next-generation sequencing to demonstrate a number of recurrent mutations in CLL, including known and novel mutations in over two dozen genes with functions as diverse as cell cycle control (*ATM*, *TP53*), histones (*HISTH1E*), inflammation (*MYD88*, *DDX3X*, *MAPK1*), Notch signaling (*FBXW7*, *NOTCH1*), general signal transduction (*BRAF*, *KRAS*, *PRKD3*), gene transcription (*SMARCA2*, *NFKB1E*), and RNA processing (*SF3B1*, *XPO1*).^{108–111} These mutations are seen in select genetic subtypes—for instance, *NOTCH1* in patients with trisomy 12,¹¹² *MyD88* among *IGHV*-mutated patients,¹¹⁰ and *SF3B1* in del(11q22.3) patients.¹⁰⁸ Although the disease potential of alterations in, for example, *TP53*, *ATM*, or even the very rare *BRAF* mutation may be clear, the pathogenesis of most of these recurrently mutated genes or pathways remain yet to be worked out

and is a promising area for investigation, particularly if experimental therapeutics could be targeted to patients according to their specific genomic alterations. Additionally, several of these genes, including NOTCH1^{110,113} and SF3B1,¹⁰⁸ also appear to impact the prognosis of CLL, providing justification for potentially assessing mutational status to predict disease outcome.

Progression of Chronic Lymphocytic Leukemia: The Role of Genomic Instability and Clonal Evolution

Several studies have been examined for features associated with clonal evolution and have noted this to be more frequent in patients with *IGHV*-unmutated status¹¹⁴ or those expressing the surrogate marker for *IGHV*-mutational status, ZAP-70.¹¹⁵ In another study, patients with long telomere length were more likely to have *IGHV*-mutated disease and del(13q14), whereas those with del(11q22.3), del(17p13.1), complex karyotype (more than abnormalities), and *IGHV*-unmutated disease were likely to have extended telomeres.¹¹⁶ Furthermore, one small study suggested long telomere length among patients with *IGHV*-unmutated disease could identify patients with an expected extended progression-free survival.¹¹⁷ More recently, Landau et al.¹¹⁸ examined the role of intratumoral heterogeneity and the presence of subclonal driver mutations in the progression of CLL. Using sequencing and copy number analysis at multiple time points, early events (del(13q), +12, *MYD88* mutation) could be delineated from later events (e.g., *SF3B1*, *TP53* mutation), and the development of mutations or expansion in preexisting subclones could be related to the administration of chemotherapy. In addition, the presence of subclonal driver mutations early in the disease was an independent adverse prognostic factor. The contributions of telomere length, global hypomethylation, and subclonal driver mutations' clonal expansion to CLL progression still require further study.

Chronic Lymphocytic Leukemia and Proliferation

For decades, CLL was viewed as a nonproliferating leukemia driven solely by disrupted apoptosis and extended tumor cell survival. This paradigm was, in part, perpetuated based on the nonproliferating blood compartment. However, it has been recognized that, as with normal B cells, CLL cell proliferation likely occurs in sites where microenvironment stimulation can occur, such as the lymph node and bone marrow. In such sites, proliferation centers are observed with a high proportion of dividing CLL cells that are often surrounded by either T cells or accessory stromal cells capable of providing cytokine costimulation.^{119,120} In patients, all body compartments can now be accurately measured with the oral intake of heavy water, and the birth rate of CLL tumor cells can thereby be assessed in vivo.¹²¹ These studies have demonstrated a broad range of proliferation of CLL cells, varying by disease state and *IGHV*-mutational status.^{122,123} As one might expect, this proliferation rate identified through heavy water studies in CLL was shown to be predictive of disease progression. Collectively, these studies have at least partially discredited the theory that CLL is purely an accumulative disease and have focused the study on specific body compartments that have very different biologic features of proliferation.

Chronic Lymphocytic Leukemia and Disrupted Apoptosis

Because the normal counterpart to CLL is unknown, it is quite difficult to directly compare differences in spontaneous apoptosis. However, several studies derived from CLL do provide evidence that apoptosis is disrupted. Despite the rarity of *BCL2*

gene rearrangement in CLL, overexpression of *BCL2* mRNA and Bcl-2 protein is common and has been shown to contribute to both disrupted spontaneous apoptosis and also ex vivo drug resistance.¹²⁴⁻¹²⁸ Similarly, other antiapoptotic Bcl-2 family member proteins including MCL-1, A1, and Bcl-xL have also been shown to be elevated either in resting CLL or in CLL cells exposed to soluble and contact factors present in the microenvironment; these factors also contribute to drug resistance.¹²⁹⁻¹³¹

Finally, a host of transcription factors involving the nuclear factor kappa B (NF- κ B),¹³² WNT,¹³³ Hedgehog,¹³⁴ and JAK/STAT¹³⁵ signaling pathway have been shown to be constitutively active and also to contribute to disrupted apoptosis and drug resistance in CLL. In particular, differential activation of NF- κ B in CLL¹³⁶⁻¹⁴⁰ versus normal resting B cells, its prognostic significance¹⁴¹⁻¹⁴⁵ with respect to predicting outcome, and also its positive role in regulating many of the antiapoptotic genes upregulated in CLL has generated particular interest.

B-Cell Receptor Signaling in Chronic Lymphocytic Leukemia

The identification of the divergent natural history of CLL based on *IGHV*-mutational status, ZAP-70 expression, and associated enhanced B-cell receptor signaling has raised interest in this pathway's role in the pathogenesis of CLL.^{89-91,144} Why the BCR is constitutively active in CLL is not yet clear, but current theories include stimulation by self- or ubiquitous environmental antigens as well as tonic BCR self-transactivation. Downstream, activation of the proximal lyn and syk kinases, and Bruton's tyrosine kinase (BTK), in turn, has been demonstrated in CLL.¹⁴⁵⁻¹⁴⁹ Additionally, increased activity of the PI3K pathway has been reported.¹⁵⁰⁻¹⁵² Complementing this, a study demonstrated that mature memory B-cell development was, in great part, dependent on the PI3K pathway.¹⁵² A study of the isoform-specific inhibitor of PI3K- δ demonstrated that much of the survival protection generated by the microenvironment from stromal cells, cytokines (CD40L, IL-6, tumor necrosis factor alpha [TNF- α]), and fibronectin contact is mediated via PI3K- δ isoform signaling.¹⁵³ Moving inhibitors of B-cell receptor kinase pathway inhibitors into clinical trials has been of great interest. Here, syk, PI3K- δ isoform inhibitors, and BTK inhibitors have demonstrated dramatic and often rapid clinical responses with relatively favorable toxicity profile in CLL patients.¹⁵⁴ The success of such therapeutics further emphasizes the importance of BCR signaling in the pathogenesis of CLL.

Conclusion

Data concerning the pathogenesis of CLL continue to accumulate. Emerging from such work is the importance of epigenetics in the progression of CLL from normal B cells, the presence of recurrent genetic mutations, and the critical role of enhanced B-cell receptor signaling. Mouse models have demonstrated the importance of NF- κ B, Bcl-2, Tcl1, and loss of miR-15, miR-16, and *DLEU2* in the pathogenesis of CLL. The application of these principles (e.g., ibrutinib to quench tonic BCR signaling) in human trials is already yielding dramatic changes in the treatment of patients with CLL.¹⁵⁴ It is likely that current investigations, combined with whole-transcriptome sequencing, global proteomic assessment, and miR profiling, will lead to further advances in risk stratification and treatments for CLL.

109 Chronic Myelogenous Leukemia

Brian J. Druker and David Marin

INTRODUCTION

Chronic myelogenous leukemia (CML; also called *chronic myeloid leukemia*) is a clonal hematopoietic disorder caused by an acquired genetic defect in a pluripotent stem cell. CML is a bi- or triphasic illness, with most patients diagnosed in a relatively indolent chronic or stable phase that is characterized by excessive numbers of myeloid lineage cells that fully mature. The disease has the capacity to progress to a more aggressive leukemia as a malignant clone loses the capacity for terminal differentiation. This more aggressive or advanced phase can be further subdivided into an accelerated phase and a blastic phase, with the blastic phase being akin to an acute leukemia and having a dismal prognosis.¹

CML has become a paradigm for targeted drug development based on an understanding of the molecular pathogenesis of a disease. A series of discoveries led to the recognition that the BCR-ABL protein, which results from a reciprocal translocation involving chromosomes 9 and 22, has a central role in the pathogenesis of CML. The BCR-ABL protein functions as a constitutively activated tyrosine kinase and this knowledge led to the development of imatinib (Gleevec, Glivec), a drug that specifically inhibits the BCR-ABL tyrosine kinase.² Other tyrosine-kinase inhibitors (TKI) with improved potency have been developed, and BCR-ABL TKIs are now the standard therapy for newly diagnosed patients with CML. Allogeneic hematopoietic cell transplantation (HCT), which was the preferred therapy prior the advent of targeted therapy, is now reserved for patients with resistance to TKIs or for patients with advanced phase disease.

EPIDEMIOLOGY

CML accounts for approximately 15% of all leukemias, with 4,000 to 5,000 new cases diagnosed in the United States annually. The incidence of CML is 1.6 to 2.0 cases per 100,000 persons per year, and the incidence is similar in all countries worldwide.³ Although CML occurs in all age groups, its incidence increases with each decade of life, making it mainly a disease of adults. According to the Surveillance, Epidemiology, and End Results (SEER) program, the median age at diagnosis is 66 years, which is much higher than that reported in single-institutional series and clinical trials.³ The disease has a slight male predominance (2.2:1.3).³

The only known risk factor for the development of CML is exposure to radiation at high doses. This is evident from studies of survivors of the atom bomb explosions in Japan in 1945 and from follow-ups of patients treated with radiation for ankylosing spondylitis and cervical cancer.⁴⁻⁶ No known association has been found between CML and infectious agents or chemical exposures, and no familial predisposition has been implicated in CML.

PATHOGENESIS

The discovery of the Philadelphia (Ph) chromosome in 1960 made CML the first human neoplasm to be characterized by a consistent cytogenetic marker.⁷ In 1973, the Ph chromosome, a shortened chromosome 22 (22q-), was shown to be the result of a balanced, reciprocal translocation between the long arms of chromosomes 9 and 22, t(9;22)(q34;q11) (Fig. 109.1).⁸ In the 1980s, the BCR-ABL chimeric gene and protein formed as a result of the (9;22) translocation was characterized and its central role in the pathogenesis of CML was established.^{9,10} The Ph chromosome and BCR-ABL are found in cells of the myeloid, erythroid, and megakaryocytic lineages, some B cells, and a small proportion of T cells, but not in other cells of the body, establishing CML as a clonal disorder that originates in a pluripotent hematopoietic stem cell.

The (9;22) translocation transposes the ABL (Abelson) proto-oncogene from chromosome 9 into a relatively small, 5.8-kb genomic region on chromosome 22 named the *breakpoint cluster region* (*bcrl*).¹¹ Although the genomic breakpoints in the ABL gene are highly variable, they almost always occur upstream of the second exon (a2), resulting in translocation of all but exon 1 of ABL. Two slightly different chimeric BCR-ABL genes are present in most patients with CML, depending on the precise location of the breakpoint in the BCR gene. Breaks can occur between exon e13 (also known as b2) and exon e14 (b3), yielding an e13a2 fusion messenger RNA (mRNA), whereas a break occurring between exons 14 and 15 produces an e14a2 fusion mRNA (Fig. 109.2).⁹ In the majority of patients, either e13a2 or e14a2 transcripts are present, but occasionally, patients have both transcripts in their leukemia cells. Although the e14a2 mRNA encodes a BCR-ABL protein that is 25 amino acids larger than that encoded by the e13a2 transcript, both are referred to as *p210BCR-ABL*. Patients with e13a2 or e14a2 transcripts have similar prognoses. In 5% of the patients, the breakpoint occurs in other regions of the BCR gene resulting in the so-called *rare transcripts*; these transcripts have the same biological activity as the more common ones.^{1,9} It is important, however, to identify patients harboring these rare transcripts because molecular monitoring may otherwise prove impossible.

The BCR-ABL fusion protein resides in the cytoplasm and has constitutive tyrosine kinase activity compared to the tightly regulated activity of the normal ABL product (p145).^{12,13} The BCR-ABL tyrosine kinase binds to and phosphorylates numerous intracellular proteins. The net effect of this is to induce all of the phenotypic abnormalities observed in patients with CML.⁹ These include increased proliferation or decreased apoptosis of hematopoietic stem or progenitor cells leading to a massive increase in myeloid cell numbers and the premature release of immature myeloid cells into the circulation, postulated to be due to a defect in adherence of myeloid progenitors to marrow stroma and genetic instability resulting in disease progression. Despite the complexity of BCR-ABL signal transduction, all of the transforming functions of BCR-ABL depend on its tyrosine kinase activity, making this disease an ideal candidate for therapy directed against this activity.

Figure 109.1 Diagrammatic representation of the formation of the Philadelphia (Ph) chromosome. The normal chromosomes 9 and 22 are shown, along with the derivative chromosomes 9q+ and 22q- (Ph). The approximate positions of the normal *ABL* gene at 9q34 and *BCR* at 22q11 and the *BCR-ABL* fusion gene formed as a result of the translocation are shown.

DIAGNOSIS

Clinical Manifestations

Of patients with CML, 90% are diagnosed in the chronic or stable phase. Of patients in older studies, 10% to 20% and as many as 50% in more recent series present without symptoms and are diagnosed as a result of finding an elevated white blood count on routine blood sampling. The most common presenting symptoms of CML are related to anemia, splenomegaly, and increased cell turnover. These symptoms include fatigue, left upper quadrant

pain, abdominal distention or discomfort, early satiety, weight loss, and night sweats.¹⁴

Occasionally, patients may present with a hyperviscosity syndrome, which requires leukapheresis, with manifestations such as stroke, priapism, stupor, or visual changes caused by retinal hemorrhage. The most common physical finding is splenomegaly, its magnitude correlating with the degree of leukocytosis. Ecchymoses are frequently observed, but spontaneous bleeding is uncommon. A lymphadenopathy is not usually seen in the chronic phase.

Laboratory Tests

Peripheral Blood and Bone Marrow

The diagnosis of CML is frequently suspected from an examination of the peripheral blood and bone marrow. The white blood cell (WBC) count in the chronic phase of CML usually exceeds $50 \times 10^9/L$ at the time of diagnosis and can range up to $800 \times 10^9/L$. During the chronic phase, leukemic WBCs differentiate and function normally. The peripheral blood smear shows a full spectrum of myeloid cells from blasts to neutrophils, with blasts comprising less than 15% and usually less than 5% of the WBC differential. Basophilia is invariably present, and its absence should prompt consideration of other myeloproliferative disorders. Eosinophilia is also commonly present. The majority of patients have thrombocytosis and, on occasion, the platelet count may be more than $1000 \times 10^9/L$. Most patients with CML have a normochromic, normocytic anemia that is inversely proportional to the degree of leukocytosis.

The bone marrow in patients with chronic phase CML is markedly hypercellular, with a predominance of myeloid cells with full maturation. Blasts are fewer than 15% and most commonly fewer than 5%, and basophilia is also present. Megakaryocytes are usually increased in number, are characteristically small, are hypo- or monolobated, and have a tendency to cluster. Erythroid hypoplasia is frequently present and may seem exaggerated because of the increased myeloid-to-erythroid ratio. Erythroid precursors are otherwise morphologically unremarkable. Reticulin fibrosis is usually absent or mild but may become more prominent with disease progression.¹⁵

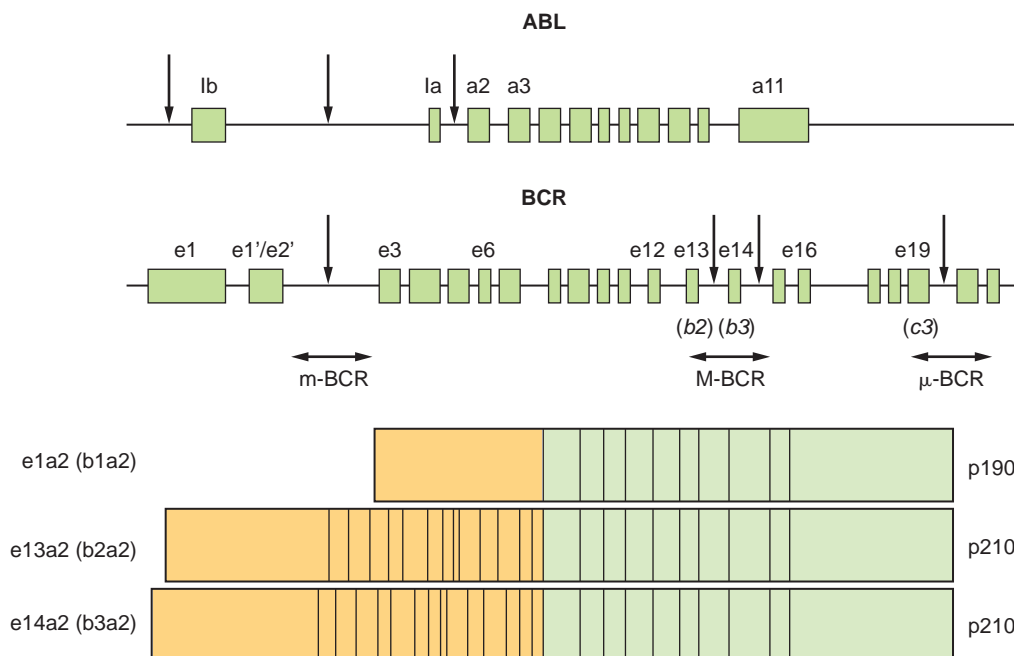

Figure 109.2 Schematic representation of the genomic structure of the normal *ABL* and *BCR* genes (top) and various fusion transcripts generated by the different *BCR-ABL* fusion genes (bottom). The b2a2 or the b3a2 transcript is found in the majority of patients with chronic myelogenous leukemia. See text for details.

Cytogenetics

A cytogenetic analysis of 20 bone marrow metaphases has been the standard method to detect the Ph chromosome, which is present in the majority of cells at diagnosis. Although most patients have a typical $t(9;22)(q34;q11)$, approximately 5% have variant translocations that have no impact on prognosis.¹⁶ These variant translocations may be simple, involving chromosome 22 and a chromosome other than chromosome 9, or they may be complex, involving one or more other chromosomes in addition to chromosomes 9 and 22.¹⁷ Clonal cytogenetic abnormalities in addition to the Ph chromosome are present at diagnosis in approximately 5% of patients diagnosed in chronic phase.^{18,19} The most common are duplication of the Ph chromosome and trisomy 8, iso-17q, and trisomy 19.^{18,19} These abnormalities have only a small adverse prognostic impact when identified at diagnosis.¹⁹

Molecular Testing

The diagnosis of CML requires the presence of *BCR-ABL*. In 95% of patients, its presence can be inferred by the detection of the Ph chromosome using standard cytogenetics. Another 5% of patients with a hematologic picture resembling CML who lack a detectable Ph chromosome will have a *BCR-ABL* fusion gene detectable by fluorescence in situ hybridization (FISH) or reverse transcription-polymerase chain reaction (RT-PCR). These Ph chromosome-negative, *BCR-ABL*-positive patients have a clinical course that is indistinguishable from that of Ph chromosome-positive, *BCR-ABL*-positive patients.²⁰ Patients with a hematologic picture resembling CML, but who are Ph chromosome negative and *BCR-ABL* negative, are classified within the myeloproliferative neoplasm group.²¹ Some of these patients have mutations in the *SETBP1*²² or *CSF3R*²³ genes, whereas others remain genetically unclassified.

FISH detects the colocalization of large, fluorescently labeled genomic probes specific to the *BCR* and *ABL* genes. FISH can be performed on metaphase or interphase cells and on peripheral blood. At diagnosis, when typically 90% of cells are *BCR-ABL* positive, FISH is a highly accurate diagnostic test, because false-negative results are uncommon.²⁴ However, because of the random colocalization of the signals from the *BCR* and *ABL* probes, 8% to 10% of normal cells score positive, making FISH less useful at low disease burdens. A lower false-positive rate can be obtained with *dual-FISH* (D-FISH), which uses probes that span the breakpoint region.²⁵

RT-PCR to amplify the unique sequences created by the fusion of *BCR* and *ABL* is a highly sensitive technique that is ideal for the detection of minimal residual disease.²⁴ PCR testing can either be qualitative, providing information as to the presence or absence of the *BCR-ABL* transcript, or quantitative, assessing the amount of *BCR-ABL* message. Quantitative RT-PCR is preferred for monitoring and may allow for the early detection of resistance to therapy.²⁶ False-positive and false-negative results are both possible with RT-PCR, and rigorous controls are required to detect these instances. False-negative results can be due to poor quality RNA, failure of the reaction or failure of the PCR primers to detect rare transcripts, whereas false-positive results are usually due to contamination of the sample.

Differential Diagnosis

The diagnosis of CML is relatively straight forward. The presence of a WBC count over $50 \times 10^9/L$ with a peripheral blood smear showing a full spectrum of myeloid lineage cells plus basophilia should raise the suspicion of CML. The diagnosis of chronic phase CML can be confirmed by the presence of the *BCR-ABL* gene as described in the Cytogenetics section and the Molecular Testing section and by the absence of advanced phase features described later in Advanced Phase Disease.

The main differential diagnosis includes a leukemoid reaction and other myeloproliferative neoplasms. In patients with a

leukemoid reaction, which is typically seen in patients with underlying infections, the WBC count is usually less than $50 \times 10^9/L$ and the peripheral blood smear consists predominantly of segmented neutrophils and bands, often with toxic granulations. Less mature myeloid cells are rarely seen; there is no basophilia; and the Ph chromosome and *BCR-ABL* are absent. Approximately 5% of patients with CML present with extreme thrombocytosis and a minimally elevated WBC count, resembling essential thrombocytosis, but are distinguished by the presence of the *BCR-ABL* gene. The differential diagnosis with other myeloproliferative neoplasm is relatively easy because the latter frequently lack the basophilia that is seen with CML and lack the *BCR-ABL* gene, but may have other molecular abnormalities such as *SETBP1* or *CSF3R* mutations.

PROGNOSTIC FACTORS

Historically, the progression of CML to blast crisis occurred in 5% to 10% of patients in the first 2 years after diagnosis and, thereafter, the annual progression rate increased from 20% to 25%. The Sokal score was developed to predict the probability of disease progression, but this and a variety of other factors are now being used to predict the probability of optimal response to therapy. The Sokal score was developed to predict the probability of disease progression.²⁷ Despite it being developed in a pre-TKI era and as a predictor for disease progression, it has been found useful to predict the probability of achieving an optimal response to imatinib.^{28,29}; however, it has been less useful for predicting responses to newer TKIs.^{30,31} The Sokal score is a numerical value that is calculated from a complex equation that takes into account four factors at diagnosis: the percentage of blasts in peripheral blood, platelet count, spleen size (centimeters below the costal margin) and age of the patient.²⁷ Patients then were divided according to their individual numerical value into three risk groups: low, intermediate, and high, risk of progression, with median survivals of 5, 4, and 3 years, respectively. Many of these patients received therapies not currently in use, such as busulfan and hydroxyurea; however, the Sokal score remains useful to predict the response of patients treated with imatinib, but less so with newer TKIs.^{28,31} Other variables closely related with the Sokal score such as hemoglobin and white blood count at diagnosis also have prognostic value.^{29,32,33}

THERAPY

Assessment of Response

Response to therapy in patients with CML is assessed by the monitoring of blood counts, cytogenetics, and real-time quantitative polymerase chain reaction (RQ-PCR). A complete hematologic response (CHR) indicates the normalization of the complete blood count (CBC), spleen size, and resolution of symptoms related to the CML. A partial cytogenetic response corresponds to 1% to 35% of Ph-positive metaphases and a complete cytogenetic response (CCyR) is the absence of the Ph chromosome on conventional cytogenetic analysis; a major cytogenetic response (MCyR) is the combination of partial and CCyR.

RQ-PCR has emerged as the most effective and efficient manner to assess leukemic burden because it can easily be done on peripheral blood. At diagnosis, an untreated patient may have in excess of 10^{12} cells. With a CHR, this falls to approximately 10^{11} cells and, with a CCyR, to approximately 10^{10} cells. Because the majority of newly diagnosed CML patients treated with TKIs obtain a CCyR, RQ-PCR is particularly useful for monitoring minimal residual disease because its dynamic range extends two-logs or more below a CCyR. RQ-PCR measure *BCR-ABL* transcripts in relation to a control gene such as normal *ABL* or *GUSB*, and can be expressed as the absolute ratio or as log reductions from the 100% value. In an attempt to introduce some level of uniformity,

many laboratories are using the International Scale (IS), whereby values are *corrected* to those obtained in a reference laboratory.³⁴ It is generally accepted that CCyR corresponds to an approximately 2-log reduction in transcript levels or 1% IS.³⁵ Major molecular response (MR3) is defined as a 3-log reduction in transcript levels or 0.1% IS, and this should correspond to a leukemia burden of approximately 10^9 cells. Similarly, MR4 is defined as a 4-log reduction (0.01% IS, or 10^8 leukemic cells). A complete molecular response (CMR) is generally defined as the absence of detectable BCR-ABL transcripts, a status that depends on the technology and criteria for negativity employed, with the limits of technology being somewhere between MR4 and MR5.

Treatment of Chronic Phase Disease

BCR-ABL TKIs are the standard frontline therapy for newly diagnosed patients with chronic phase CML. Hydroxyurea, a well-tolerated oral agent that inhibits DNA synthesis by inhibiting ribonucleotide reductase, remains in use as an initial therapy to control blood counts pending definitive diagnosis and therapy. Allogeneic HCT, although curative, is typically reserved for patients with resistance to TKI therapy or in the management of advanced phase disease due to its morbidity and mortality. Interferon- α , a previous mainstay of therapy, has been supplanted by TKIs, and has been used with variable results in clinical trials attempting to improve molecular responses to TKIs.

BCR-ABL Tyrosine-Kinase Inhibitors

BCR-ABL TKIs inhibit the BCR-ABL tyrosine kinase by competing with ATP binding to the kinase. The first drug of this class was imatinib, which rapidly became the treatment of choice for patients with chronic phase CML after it was approved by the U.S. Food and Drug Administration (FDA) in 2001.² Today, imatinib, nilotinib, dasatinib, bosutinib and ponatinib are licensed for use in CML. They differ in their respective affinity for the ABL-binding pocket—for example, imatinib has a BCR-ABL IC₅₀ of 221 nM, whereas ponatinib has an IC₅₀ of 0.37 nM and respective half-lives, ranging from 13 hours for imatinib to 4 hours for dasatinib. They also differ in their ability to inhibit other tyrosine kinases, with ponatinib, dasatinib, and bosutinib being the most promiscuous, whereas imatinib and nilotinib are the most specific. Other kinases inhibited by imatinib and nilotinib include the platelet-derived growth factor receptors KIT, and ARG (*ABL*-related gene), whereas the other drugs inhibit SRC family members amongst many others. These differences explain, at least in part, the different toxicity profiles of the various drugs.^{36–40} Despite that, it is possible to define a drug class side effect profile that includes myelosuppression, fatigue, gastrointestinal disturbances, hepatotoxicity, myalgias, arthralgias, and skin rashes.⁴¹ All five drugs can cause these side effects, but the relative frequency of the individual side effect differs for each drug. Common toxicities observed are listed in Table 109.1.

TABLE 109.1

Comparison of Side Effects (All Grades) Reported in More Than 10% of the Patients Between Imatinib 400 mg Per Day, Nilotinib 300 mg Twice Per Day, Dasatinib 100 mg Per Day, and Bosutinib 500 mg Per Day

Imatinib

With over 15 years of experience and hundreds of thousands of patients using imatinib as first-line therapy, the side effects are well understood and there are no apparent long-term safety concerns. Approximately 70% of patients that receive imatinib as first-line therapy will achieve CCyR by 12 months, and 80% will have done so by 5 years.^{28,29} The 8-year survival for 553 patients treated with imatinib as part of a randomized trial comparing imatinib to interferon plus Ara-C was 85%, or 93% if only CML-related deaths were considered. This high survival rate has been confirmed in additional single-center studies.⁴² Imatinib is given once daily, normally with food (in order to prevent nausea). The current standard dose of imatinib is 400 mg per day. Several randomized studies comparing 400 mg per day to 800 mg per day in newly diagnosed patients revealed more rapid responses with the higher doses; however, one-third of patients required dose reduction due to greater toxicity. With longer follow-up, the response rates to 400 mg per day and higher doses are similar. Progression-free survival (PFS) was not impacted by the higher doses, although a recent study from Germany has suggested that deeper molecular remissions that are more frequently obtained with higher doses of imatinib may translate into a trend toward improved PFS.⁴³⁻⁴⁵

Nilotinib

Nilotinib is a BCR-ABL inhibitor that was rationally designed to be more potent and selective than imatinib. Until recently, it had been used as a second-line agent at a dose of 400 mg twice daily. At this dose, it induces CCyR in 30% to 40% of the patients who are resistant to imatinib, and most interestingly, there is no cross-intolerance with imatinib.⁴⁶⁻⁴⁸ Nilotinib obtained a license for first-line use in 2010. The first-line dose is 300 mg twice daily. Nilotinib is administered twice daily in a fasting state because food increases absorption and may lead to increased side effects, particularly the prolongation of Qtc intervals. Overall, nilotinib is well tolerated and causes less nausea, myalgia, arthralgia, and fluid retention than imatinib. On the other hand, it produces skin rashes or pruritus in the majority of patients; in most cases, these can be easily controlled with antihistamines. Nilotinib induces hyperglycemia in approximately 40% of patients; it also causes increases in cholesterol and triglyceride levels. Hepatotoxicity is frequent, although this is normally limited to mild increases in transaminases that do not require action. A severe toxic hepatitis occurs rarely. Similarly, nilotinib causes an increase in the bilirubin level in the majority of patients, but this seldom necessitates any modification of therapy. Nilotinib has also been associated with progressive peripheral arterial occlusive disease,⁴⁹ although the incidence of this complication is not yet clear.

Dasatinib

Dasatinib is a multitarget kinase inhibitor that is more than 300 times more potent than imatinib in inhibiting the BCR-ABL oncoprotein in vitro.^{50,51} As with nilotinib, most of the experience to date has been using dasatinib in patients who are resistant to imatinib. Initially, dasatinib was used at a dose of 70 mg twice daily due to its short half-life, but a large randomized study comparing several schedules of dasatinib in patients with imatinib resistance showed that 100 mg once daily was equally efficacious to the 70 mg twice daily or 140 mg once daily schedules, but with significantly less toxicity for chronic phase patients.⁵² Dasatinib induces CCyR in 30% to 40% of patients with imatinib resistance.^{48,53,54} Dasatinib was also approved for first-line use in chronic phase CML patients at a dose of 100 mg per day. Dasatinib is generally well tolerated. Pleural effusions are the main complication of dasatinib therapy. Most

studies report an incidence below 25%, although rates as high as 54% have been reported.^{51,55-58} Pleural effusions can occur at any time during therapy and often recur despite a dose reduction. Diagnostic thoracentesis is not usually required and, in practice, the effusion nearly always resolves on discontinuing the drug. Resolution of the pleural effusion can be accelerated by using 0.5 mg per kilogram of prednisolone for 1 or 2 weeks. Dasatinib has been associated with pulmonary hypertension. The incidence of this complication is not clearly established, and it may be at least partially reversible on discontinuation of the drug.⁵⁹

Bosutinib

Bosutinib is a dual SRC and ABL TKI, which is currently licensed only for second-line use. Similarly to nilotinib and dasatinib, bosutinib induces CCyR in 30% to 40% of the patients who are resistant to at least one prior TKI therapy.⁶⁰ Bosutinib has also been evaluated in newly diagnosed patients, but it did not meet its primary endpoint of improved rates of CCyR at 1 year.⁶¹ The drug is well tolerated. Its main side effect is diarrhea, which can easily be managed symptomatically.⁶⁰⁻⁶² Bosutinib has also been found to cause pleural effusions and pulmonary hypertension, although the incidence of both complications appears to be lower than with dasatinib.

Ponatinib

Ponatinib is the latest addition to the TKI armamentarium. It has been licensed for the management of patients who are resistant to at least two prior TKIs or who harbor the kinase domain mutation T315I. This mutation confers resistance to all the other TKIs discussed in this chapter. The peculiar chemical structure of ponatinib allows it to overcome the steric hindrance caused by the substitution of a threonine by isoleucine in position 315 of the kinase domain.⁶³ The efficacy of ponatinib has been explored in the PACE study where approximately 200 chronic phase patients who were resistant or intolerant to either dasatinib or nilotinib (the majority of these patients had failed at least three prior TKI lines) and 64 chronic phase patients with the T315I mutation were treated with 45 mg daily. The CCyR rate was 46% with a higher response rate in patients with the T315I mutation.⁶⁴⁻⁶⁶ The main side effects are skin rash, pancreatitis, and hepatotoxicity. Various cardiac, cerebral, and peripheral vascular thrombotic events have been reported in patients on ponatinib. These have occurred in up to 27% of patients treated with ponatinib and have included fatal myocardial infarction and stroke. These vascular side effects led to the early termination of the phase 3 trial comparing ponatinib with imatinib as frontline therapy and a recommendation that lower doses of ponatinib be used—30 mg in patients initially and 15 mg after patients achieve a MR3. To date, strategies combining ponatinib with antithrombotic agents have not been formally reported.

Choice of Initial Therapy for the Newly Diagnosed Patient in Chronic Phase

Imatinib, nilotinib, and dasatinib are licensed for first-line use. Four randomized studies have been conducted comparing imatinib to newer TKIs, one each comparing imatinib to nilotinib or bosutinib, and two comparing imatinib to dasatinib. Data from these studies are summarized in Table 109.2. A few generalities emerge from these studies. All therapies are extremely effective with excellent PFS. The newer, more potent TKIs induce faster cytogenetic and molecular responses, but in only the imatinib versus nilotinib study has this translated into a significant difference in PFS at 3 years. In the other studies, there was either

TABLE 109.2

Comparison of the Efficacy Profiles of Imatinib, Nilotinib, Dasatinib, and Bosutinib as Front-line Therapy for Chronic Phase Patients Using Results of the Randomized Trials Comparing Nilotinib 300 mg Twice Daily Versus Imatinib 400 mg Daily (Enestnd),^{110,111} Dasatinib 100 mg Once Daily Versus Imatinib 400 mg Daily (Dasision),^{50,51} Dasatinib 100 mg Daily Versus Imatinib 400 mg Daily (North America Cooperative Group),¹¹² and Bosutinib 500 mg Once Daily Versus Imatinib 400 mg Once Daily (Bela)⁶¹

	ENESTnd		DASISION		North America Cooperative Group		BELA	
	Imatinib	Nilotinib	Imatinib	Dasatinib	Imatinib	Dasatinib	Imatinib	Bosutinib
Number	283	282	260	259	123	123		
CCyR at 12 months	65% *	80% *	73% *	85% *	72%	83%	68%	70%
CCyR at 24 months	77% *	87% *	82%	85%			81% *	87% *
MR3 at 12 months	27% *	55% *	28% *	46% *	33%	47%	27% *	41% *
MR3 at 24 months	44% *	71% *	46% *	64% *			52% *	67% *
MR4.5 at 24 months	9% *	25% *	8%	17%				
PFS at 24 months	95.2%	98.0%	92.1%	93.7%				
OS at 24 months	96.3	97.4%	95.2%	95.3%	97% (at 3 years)	97% (at 3 years)	95%	97%
Patients still on therapy at 24 months	67%	74%	75%	77%			71% *	63% *

The rates of response (CCyR, MR3, and MR4.5) are given as cumulative incidences. Progression free-survival (PFS) and overall survival (OS) are expressed as 2-year probabilities. Patients still on therapy at 24 months are expressed as proportions. Asterisks indicate that the difference is statistically significant ($p < 0.05$).

no difference or a trend to improved PFS, but no studies have shown a significant difference in overall survival (OS). With most relapses on imatinib occurring in the first 3 years, it is unlikely that additional follow-up will lead to significant changes in this data.

Imatinib is still the first-line TKI for many clinicians because its long-term side effect profile is well understood. Further, in most health systems, it is significantly cheaper than dasatinib or nilotinib. The main arguments in favor of using nilotinib or dasatinib as first-line therapies are that they induce deep molecular responses in a higher proportion of patients and that this may impact PFS. With optimal responses to imatinib being highly dependent on the Sokal score, it would be reasonable to choose nilotinib or dasatinib for patients with higher risk Sokal scores.

Another consideration for the selection of initial therapy is comorbid conditions based on the side effect profiles described in Table 109.1. For example, nilotinib can increase the glucose level and serum lipids in a significant proportion of patients; therefore, clinicians may want to avoid nilotinib when treating a patient with diabetes or a dyslipidemia. Similarly, it has been suggested that patients with cardiovascular risk factors should not receive nilotinib because of the risk of developing peripheral arterial occlusive disease. It also should be avoided in patients with a history of pancreatitis. Dasatinib has been shown to inhibit platelet function and has been associated with hemorrhages, so one would favor the use of other TKIs in patients with platelet or clotting disorders. Patients of advanced age and patients with a history of autoimmune disease have a higher risk of developing pleural effusions on dasatinib. Other patients with preexisting pulmonary disease should not receive dasatinib because of the risk of developing pleural effusions, although there is no evidence that patients with pulmonary disease are more likely to develop pleural effusions. The major limitation of this strategy is that it only can be used in the proportion of patients with the relevant comorbidities. In addition, there are no specific

circumstances where imatinib should be avoided in preference to other TKIs.

Management of Chronic Phase Patients on Tyrosine Kinase Inhibitor Therapy

TKI therapy can be started as soon as the definitive diagnosis of CML is made. Hydroxyurea may be used to control the peripheral counts while awaiting the results of diagnostic testing. Hydroxyurea can be stopped as soon as patients start on TKI therapy or may be continued for 1 or 2 weeks in cases where the WBC or platelet count is very high. Concomitant therapy with allopurinol is recommended until the WBC is consistently in the normal range. Tumor lysis syndrome is exceedingly rare even in patients with advanced phase disease. After initiating therapy, the WBC count should begin to fall within the first 2 weeks and usually normalizes within 6 weeks. The normalization of the platelet count is commonly delayed by 1 to 3 weeks.^{28,67} Myelosuppression occurs in about 10% to 25% of patients. It may occur at any time, but it is more frequent within the first 2 to 6 weeks. Patients should have complete blood counts checked weekly to every other week during the first 2 months of therapy. In the absence of significant myelosuppression, the frequency of hematologic monitoring can be reduced. It is advisable to monitor electrolytes, calcium, magnesium levels, and hepatic and renal function at the same time as the CBC because liver toxicity, hypocalcemia, hypomagnesemia, and changes in electrolytes levels are relatively common. Nonhematologic toxicity is normally managed with supportive measures or by interrupting the TKI therapy until resolution of side effects and then by the reintroduction the TKI at the same or at a reduced dose depending on the nature and the severity of the specific side effects. Because there is very little cross-intolerance between the various TKIs, it is advisable to switch TKIs for potentially dangerous or recurrent side effects with the exception of myelosuppression, which is more likely related to the underlying disease.

Bone marrow cytogenetics should be monitored every 6 months until a complete cytogenetic response CCyR is obtained. Some advocate for a marrow at 3 months, but the prognostic significance of this is less clear. With the wider availability of RQ-PCR standardized to the IS, RQ-PCR may replace the necessity of performing marrows. RQ-PCR for BCR-ABL transcripts should be performed every 3 months on peripheral blood for at least the first 2 years on therapy and, depending on response and stability, may be monitored every 4 to 6 months.

Relapse on therapy is defined as a loss of a previously obtained response, such as a loss of CHR, loss of CCyR, or increase in RQ-PCR transcript level. Relapses can be due to a number of factors such as the development of resistance or poor adherence to therapy. Adherence to therapy should be discussed with all patients on a regular basis.³³ Increases in the BCR-ABL transcript level are not always easy to interpret because the accuracy of the test varies substantially depending on the depth of response. It is important to confirm an increase in the transcript level with a second test before altering TKI therapy. Small increases in the transcript numbers are frequent. In general, increases by a factor of two or three on the IS are common and can be ignored because they seldom reflect resistance. At lower transcript levels, increases greater than 5-fold are common and in most cases can be dismissed. The magnitude of the increases is more critical than the loss of MR3, MR4, or CMR, which do not have clinical relevance. Repeated increases beyond interassay variability or confirmed increases consistent with loss of CCyR are should be taken seriously.

Prognostic Landmarks on Therapy

Patient responses are normally assessed at 3, 6, and 12 months. Failure to achieve a CHR at 3 months is rare, and these patients have a poor prognosis.⁶⁸ Cytogenetic and molecular response have been evaluated for prognostic significance. One of the most widely accepted landmarks is the achievement of a CCyR at 12 months,^{28,29,48,69-72} and many other parameters are based on the likelihood of obtaining this response. For example, for patients who do not achieve an MCyR by 6 months, the chances of obtaining a CCyR at 12 months is 50% or less.^{29,68}

Another parameter that is gaining acceptance as having prognostic significance is the BCR-ABL transcript ratio at 3 months. Several studies have shown that patients with a BCR-ABL transcript ratio greater than 10% on the IS have a significantly higher PFS and lower cumulative incidence of CCyR and deep molecular responses (MR3 or higher).^{42,73} Similar results have been obtained

for patients treated with dasatinib or nilotinib.⁴⁸ One possible limitation to the use of this parameter is the lack of availability of standardized molecular testing.

A third parameter that has been analyzed for prognostic significance is the achievement of a MR3. An analysis of the phase 3 randomized clinical trial comparing imatinib to interferon- α plus Ara-C reported that patients who had achieved MR3 by 12 months had a superior PFS than the patients who were in CCyR but not in MR3.⁷⁴ These results were not confirmed by a subsequent analysis.²⁸ Other groups have also failed to confirm a PFS or OS benefit in patients who achieve MR3,^{68,75} whereas a recent update from a German CML study suggested that OS is improved in patients who achieve a MR3 at 12 months. Others have suggested that achieving MR3 represents a safe haven with a low risk of disease progression or relapse. Patients in CCyR who have not achieved MR3 were shown in one study to be more likely to lose their CCyR,⁶⁸ but this has not been confirmed in subsequent studies. In most patients who achieve a CCyR, the BCR-ABL transcript level declines over time, which means that a sizable proportion of patients who have failed to achieve MR3 will still do so at a later time without further intervention. Whether achieving even deeper responses will impact PFS, OS, or allow treatment to be discontinued is the focus of future investigations.

Management of Hematologic Toxicity on Tyrosine Kinase Inhibitors

Grade 3 or 4 myelosuppression is relatively common at the onset of TKI therapy and probably reflects the elimination of hematopoiesis from Ph chromosome-positive stem cells before Ph-negative hematopoiesis can be adequately expanded. In the randomized studies comparing imatinib to nilotinib and imatinib to dasatinib, it appears that dasatinib is the most myelosuppressive, followed by imatinib, with nilotinib at 300 mg twice daily being the least myelosuppressive (Table 109.3). Even with nilotinib at 300 mg twice per day, 10% of patients will develop grade 3 or 4 myelosuppression. Although dasatinib may suppress normal hematopoiesis, the suppression of normal hematopoiesis by imatinib and nilotinib is relatively minimal; thus, dose reductions of imatinib and nilotinib are unlikely to expedite the recovery of normal blood counts. In the case of imatinib, doses lower than 300 mg per day may allow for the emergence of resistant leukemic clones, but the minimum adequate doses of dasatinib and nilotinib have not been established. For chronic phase patients, treatment should only be interrupted for an absolute neutrophil count of less than $1.0 \times 10^9/L$ and a platelet count less than $50 \times 10^9/L$. These parameters can

TABLE 109.3

Comparison of Grade 3/4 Myelosuppression Between Imatinib 400 mg Per Day, Nilotinib 300 mg Twice Per Day, Dasatinib 100 mg Per Day, and Bosutinib 500 mg Per Day

	Percentage (%)		Clinical Trial
	Imatinib	Alternative TKI	
Anemia	5	3	ENESTnd (Nilotinib)
	8	11	DASISION (Dasatinib)
	7	6	BELA (Bosutinib)
Neutropenia	20	12	ENESTnd (Nilotinib)
	21	24	DASISION (Dasatinib)
	24	11	BELA (Bosutinib)

	11	19	DASISION (Dasatinib)
	14	14	BELA (Bosutinib)

Based on data from the ENESTnd, DASISION, and BELA trials.^{50,51,61,111,112}

be modified for patients with more advanced disease. The use of myeloid or erythroid growth factors while continuing therapy with imatinib appears to be safe. For patients with recurrent myelosuppression, the ability to obtain optimal responses may be compromised; thus, these patients may be candidates for more aggressive therapy. Recurrent pancytopenia is associated with primary cytogenetic resistance in spite of dose reduction or change of TKI therapy. This cohort of patients has a poor prognosis. One possible explanation for this phenomena is that hematologic toxicity is linked to a lack of an expandable Ph-negative stem cell population that can restore effective Ph-negative hematopoiesis, and; therefore, these patients are intrinsically unable to respond adequately to TKI therapy.^{29,30}

Management of Primary Treatment Resistance or Relapse

A loss of disease control in the first 5 years of therapy occurs in approximately 15% of chronic phase patients treated with imatinib. Point mutations in the BCR-ABL kinase domain that render the kinase less sensitive to imatinib are observed in approximately 40% of patients who relapse on therapy, but only in a minority of patients with primary resistance (defined as an inability to reach the landmarks defined in Prognostic Landmarks on Therapy). Regardless, all patients being considered for a change in therapy should have the ABL kinase domain sequenced because this may influence the choice of therapy. The point mutations that mediate resistance are scattered throughout the ABL kinase domain and disrupt critical contact points between imatinib and the BCR-ABL protein or induce structural alterations that prevent TKI binding.^{2,76} Other mechanisms of resistance include BCR-ABL amplification, drug efflux, and BCR-ABL-independent mechanisms, such as clonal evolution.⁷⁷

Given that the majority of patients who relapse have disease that remains dependent on the BCR-ABL kinase, it was logical to develop novel agents that inhibit imatinib-resistant mutations. As noted previously, dasatinib, nilotinib, bosutinib, and ponatinib were initially developed for patients with imatinib resistance or intolerance. All of these compounds inhibit the majority of imatinib-resistant mutations other than T315I, which is only inhibited by ponatinib.^{36,37,78,79} The potency of the various drugs against kinase mutations varies. Some mutations are less sensitive to nilotinib (Y253H, E255K/V, and F359V/C), whereas others are less sensitive to dasatinib (F317L and V299L), bosutinib (F317L and V299L), or ponatinib (E255V).⁸⁰ T315I is the most common mutation that emerges in patients with resistance to dasatinib, bosutinib, and nilotinib, but this is rare (<2%) in patients not exposed to these drugs. Highly drug resistant compound mutations have been seen on occasion.⁸¹

If a patient becomes resistant or intolerant to a first-line therapy, second-line therapy should be started without delay. Patients who require second-line therapy because of nonhematologic toxicity and those with secondary cytogenetic resistance (loss of CCyR) to first-line TKI therapy have a 50% to 90% probability of achieving stable CCyR on second-line therapy.^{31,48} Patients with primary cytogenetic resistance, particularly when associated with recurrent pancytopenia, constitute a poor risk group.^{42,48} There are no randomized studies comparing the efficacy of the various drugs, and the various single-arm phase 2 studies report similar efficacy for all the drugs. Importantly, most of the published experience is based on the use of nilotinib, dasatinib, and bosutinib in patients who have failed imatinib. Limited data exists on the efficacy of these drugs on patients who have failed nilotinib or dasatinib. None exists on the use of imatinib after failure of other TKIs. The choice of second-line therapy may be guided by mutational analysis or potential toxicities. Once the new therapy is started, patients receiving second-line therapy should be managed and assessed for response as described in the first-line section. Responses

to second-line TKIs are as durable as first-line responses; therefore, responding patients do not necessarily need to be considered for allogeneic HCT.⁴⁸

Hematopoietic Cell Transplantation

Until 1999, CML was the leading indication for allogeneic HCT, but with the widespread availability of imatinib and the other TKIs, HCT rates for CML have fallen.⁸² However, the proportion of patients with advanced stage CML who proceed to HCT has increased.⁸³ HCT remains an effective therapy for patients who are resistant to TKIs and remain in chronic phase and for patients with advanced phase disease whose leukemia can be restored to the chronic phase.

If transplantation is performed with myeloablative conditioning during chronic phase using an HLA-identical sibling donor, 5-year survival rates are 60% to 80%, with a 10-year disease-free survival of 50% to 60%, and a 20-year survival of 38%.⁸⁴ Survival estimates roughly halve as the disease progresses from chronic phase to accelerated phase to blast crisis. For younger patients, HCT performed using unrelated donors yields results similar to those obtained with HLA-matched siblings.⁸⁵

Reduced-intensity conditioning regimens, otherwise known as *nonmyeloablative regimens*, emphasize immunosuppression rather than myeloablation to facilitate engraftment, and can be performed in the outpatient setting. The cure relies on immune reconstitution from the donor, with or without additional lymphocyte infusions, to eradicate residual disease. Common preparative regimens include combinations of fludarabine, busulfan, low-dose total body irradiation, T-cell antibodies, and other immunosuppressive drugs. The reduced-intensity conditioning regimens avoid the high early mortality associated with myeloablative conditioning and prolonged neutropenia. Reduced intensity conditioning have shown to be superior to myeloablative HCT in patients over 60 years of age.⁸⁶ However, infections and acute and chronic graft versus host disease remain significant problems. Disease-free survival ranges from 40% to 85% at 3 to 5 years.^{87,88} Imatinib has been used after HCT for prophylaxis against relapse. Small studies suggest that imatinib can be safely administered from the time of engraftment through the first post-HCT year in patients at high risk of post-transplant relapse.^{89,90} Dasatinib and nilotinib post-HCT have also been used in a small number of patients.⁹¹ These small numbers do not allow for an assessment of the effectiveness of this approach in increasing long-term disease-free survival rates.

Relapse after HCT is a common problem, particularly if T-cell depletion is used. Imatinib as the initial treatment for patients who relapse into the chronic phase after allogeneic HCT restores CMR in 83% of patients in molecular relapse and 58% of those in cytogenetic relapse.⁹² Approximately 10% to 25% of patients attaining complete molecular remissions are able to discontinue imatinib after 6 to 24 months and remain in remission, whereas the others require either reinstitution of imatinib or donor lymphocyte infusions.⁹³ Lower and less durable responses to imatinib are seen in patients relapsing into the accelerated phase or blast crisis.⁹⁴ Early studies with dasatinib and nilotinib confirm their efficacy in this situation, but the number of patients studied is too small to draw firm conclusions.^{91,95} Patients who relapse cytogenetically or hematologically into the chronic phase can also be treated with donor lymphocyte infusions, with 60% to 80% achieving durable remissions and a 5-year disease-free survival rate of approximately 50%.⁹⁶⁻⁹⁸ In contrast, patients in the accelerated phase and blast crisis are much less responsive to immune manipulations. The risks of donor lymphocyte infusions are significant and result in a treatment-related mortality of 8% to 20%.⁹⁹ To date, formal comparison of donor lymphocyte infusions versus TKIs has been undertaken. In addition, strategies need to be developed for using TKIs plus donor lymphocyte infusions for the treatment of relapse after HCT.

ADVANCED PHASE DISEASE

The transformation to advanced phase typically occurs gradually, with the disease becoming more difficult to control with medical therapy. In other patients, the disease transforms abruptly into an acute leukemia, also known as *blast crisis*. Approximately 65% of patients evolve to blast crisis with myeloid lineage blasts; 30% have blasts of pre-B-lymphoid origin; and 5% have undifferentiated or T-cell blasts. On occasion, an isolated blast phase of extramedullary origin may occur while the patient's blood and marrow still meet the criteria for chronic phase disease.

The intermediate period, during which the patient is no longer in the chronic phase but is not yet in blastic transformation, has been termed the *accelerated phase*. Currently accepted criteria for accelerated phase include: (1) progressive splenomegaly and myelofibrosis; (2) bone marrow or peripheral blood blasts $\geq 15\%$ but $< 30\%$; (3) bone marrow or peripheral blood blasts plus promyelocytes $\geq 30\%$; (4) bone marrow or peripheral blood basophils $\geq 20\%$; (5) platelet count $< 100 \times 10^9/L$ unrelated to therapy; and (6) clonal evolution in a Ph-chromosome-positive clone.¹⁰⁰ The blastic phase is defined as bone marrow or peripheral blood blast $\geq 30\%$ or the presence of extramedullary blast infiltrates.

Clonal cytogenetic abnormalities besides a single Ph chromosome may be acquired in patients with CML as their disease progresses, and up to 80% of patients with overt blastic transformation have additional cytogenetic abnormalities. The molecular basis of disease progression is poorly defined, but point mutations or deletions in the *p53* tumor suppressor gene have been observed in up to 25% of patients with myeloid blast crisis, and as many as 50% of patients with lymphoid transformation show a homozygous deletion in the *p16* tumor suppressor gene.¹⁰¹

Therapy of Advanced Phase Disease

The prognosis for patients in advanced phase remains poor. Although TKIs induce CCyR in 10% to 45% of patients treated with these drugs, remissions are typically short lasting.^{102,103} For example, dasatinib as monotherapy for patients in blast crisis induces a CCyR in 20% to 40% of the patients,^{103,104} but a majority of the patients relapse within 1 year, and the median survival is 8 months.¹⁰⁵ Conventional chemotherapy regimens such as a combination of fludarabine, cytarabine, idarubicin and filgrastim (FLAG-IDA) can induce CCyR in 30% to 40% of patients who have progressed to the blastic phase, but again, the majority of patients relapse within 6 months, and the survival is poor.¹⁰⁵ Currently, the standard therapy for patients who present with blast crisis or who have progressed to this phase on TKI

therapy consists of two or three courses of conventional acute leukemia-like chemotherapy or a TKI in monotherapy followed by stem cell transplantation in eligible patients. With this approach, only 20% of the patients are alive at 5 years⁸⁴ ($< 20\%$ at 2 years for patients who are not candidates for allogeneic HCT¹⁰⁵). Because TKIs have been used successfully in combination with conventional chemotherapy for the therapy of Ph-positive acute lymphoblastic leukemia (ALL),¹⁰⁶ clinical trials are currently exploring the combination of chemotherapy with TKIs for patients in blast crisis.

The accelerated phase is a heterogeneous entity, and there are no large studies dissecting the prognosis of patients according to the different accelerated phase criteria. Most investigators consider patients in the accelerated phase due to a high percentage of blasts to have a similar prognosis to patients in the blastic phase. One of the major limitations of TKI therapy in accelerated phase patients is that the majority of these patients have also already received a TKI. Dasatinib induces a 20% to 30% CCyR rate in patients who have progressed to the accelerated phase on imatinib.¹⁰⁷ Because relapses in these patients are common, HCT should remain a consideration for eligible patients whose disease can be returned to the chronic phase and for patients who fail to achieve an MCyR by 3 months or a CCyR by 6 months.

FUTURE DIRECTIONS

There are now numerous treatment options available for patients with CML. While long-term disease control appears possible with current therapies, disease is not eradicated. Therefore, the most critical area for future development is minimal residual disease. Although the molecular basis of disease persistence is poorly understood, studies of the mechanism are ongoing. Meanwhile, a variety of therapies based on the manipulation of the immunologic system and signal transduction pathways are being investigated for their ability to impact CML stem cells, although it is not clear that it is necessary to eradicate every CML stem cell in order to achieve a cure. Several groups have discontinued imatinib in patients with a consistently negative RQ-PCR for BCR-ABL transcripts using a sensitive assay (> 4.5 logs). In these studies, up to 40% of patients have maintained their PCR undetectable status with the majority of molecular relapses occurring within the first 6 months off of therapy.^{108,109} With newer TKIs potentially achieving deeper molecular remissions, studies have commenced on the discontinuation of these drugs to see if a larger percentage of patients can discontinue therapy. If a larger percentage of patients achieve a molecular remission and a similar or greater percentage are able to discontinue therapy, the goal of achieving molecular remission may become a goal of treatment guidelines.

110 Chronic Lymphocytic Leukemias

William G. Wierda and Susan M. O'Brien

INTRODUCTION

Chronic lymphocytic leukemia (CLL) is a monoclonal hematopoietic disorder characterized by progressive expansion of B lymphocytes. These small, mature-appearing lymphocytes accumulate in the blood, bone marrow, lymph nodes, liver, and spleen. CLL is the most common leukemia in the Western world, accounting for 25% to 30% of all adult leukemias.¹

The estimated number of new CLL cases for 2014 was 15,720, with 9,100 men and 6,620 women affected; the median age at diagnosis was 72 years, and incidence increases with increasing age. During the same year, the estimated number of deaths was 4,600, with 2,800 men and 1,800 women; the median age at death was 79.^{2,3} The majority of patients have significant comorbidities, which are associated with advanced age. As a result, they tend to have health, geographic, and access limitations. Patients with CLL seen at academic centers and enrolled in clinical trials tend to be younger, with a median age of 58 to 62 years, thereby limiting the ability to generalize results from such trials to community practice.

In Asian countries, CLL represents only 5% of leukemias, with T-cell phenotype predominating. Geographic and ethnic differences in incidence are most likely the result of genetic factors, as Japanese who settled in Hawaii do not have a higher incidence of CLL than native Japanese.⁴ Population studies did not link CLL diagnosis to known occupational or environmental risk factors.⁵ CLL has a strong familial aggregation, with a two- to seven-fold higher prevalence among family clusters than in the general population.⁶

MOLECULAR BIOLOGY

Immunophenotype

Clonality of CLL is confirmed by restricted expression of either kappa or lambda immunoglobulin light chain on the cell surface membrane.¹ Immunoglobulin gene rearrangement and usage is clonal; therefore, the CLL cells possess a unique idiotypic specificity and often have cytogenetic or molecular abnormalities.⁷ With the use of sensitive techniques, monoclonal immunoglobulin can be detected in the serum of some patients, although only 5% to 10% of patients produce large enough quantities to be detected by serum electrophoresis. CLL cells express the B-cell markers CD19, CD20, CD21, CD23, and CD24; most CLL cells are also positive for major histocompatibility complex class II (DR and DQ), Fc receptors, and have receptors for mouse erythrocytes (Table 110.1).⁸ Some surface markers that are usually found on normal B cells, including CD22, are infrequently found on CLL cells. CLL cells characteristically express CD5, an antigen normally found on T cells. Small numbers of normal polyclonal B cells can express CD5 and are predominantly in fetal circulation or in tonsils of normal adults. They usually are not detected in peripheral blood using standard immunophenotyping techniques.

Unexpectedly, as high as 3.5% of otherwise normal individuals over age 40 may harbor a population of clonal (by light chain analysis) CD5+/19+/23+ B cells.⁹ These asymptomatic individuals do not have an absolute lymphocytosis, lymphadenopathy, or other clinical evidence of CLL and are referred to as having monoclonal B lymphocytosis (MBL). Furthermore, as many as 13% of family members of patients with familial CLL harbor a population of cells with an immunophenotype consistent with CLL, but do not fulfill CLL diagnostic criteria. Therefore, the prevalence of a monoclonal lymphoproliferative process is potentially much higher than previously appreciated. It is estimated that the rate of progression from MBL to CLL is 1 to 2% per year.¹⁰ Currently, there is no indication to perform screening for MBL.

Immunoglobulin Heavy Chain Variable Gene (*IGHV*) Mutation Status

Because CD5+ B cells are found in fetal spleen and because surface immunoglobulin D is present on cells that have not encountered antigen in the germinal center, it was long thought that CLL cells were derived from naïve B cells. Normal B-cell development involves an antigen-independent phase and an antigen-dependent phase. During the antigen-independent phase, B cells undergo rearrangement of the V, D, and J genes in the bone marrow. Somatic mutation of the heavy- and light-chain variable gene occurs after encounter with antigen in the germinal center. Somatic mutation has occurred when there is <98% sequence homology with the germline gene. The figure of 98% is used because polymorphisms may account for lesser degrees of disparity.¹¹

In the 1990s, data emerged that a significant percentage of patients had mutation of the immunoglobulin heavy chain variable gene (*IGHV*) in their CLL cells. Subsequently, it was confirmed that approximately 50% of patients have a mutated *IGHV* and that this provided prognostic information; patients with an unmutated *IGHV* have significantly shorter survival.^{12,13} Characterization of the *IGHV* sequence is labor-intensive and has not been readily exportable to clinical laboratories. Thus, correlates with mutation status that may be more easily identified may be more accessible. A correlation between expression of CD38 and lack of somatic mutation was described.¹² Although the correlation is significant and the presence of CD38, irrespective of mutation status, is associated with inferior survival, a significant minority of patients have mutated *IGHV* and yet express CD38, and vice versa. These patients may have an intermediate prognosis. Also, there is variation in CD38 expression over time and by disease site (e.g., blood versus bone marrow) in some patients.

It was hypothesized that as patients with CLL can be segregated into two distinct prognostic categories based on *IGHV* mutation status, CLL may represent two separate disease entities, one derived from a naïve B cell that expressed unmutated *IGHV* and the other derived from a memory B cell that had been exposed to antigen and displayed a mutated *IGHV*. This hypothesis has been examined using gene expression profiling.¹⁴ Investigators found that

TABLE 110.1

Immunophenotyping in Chronic B-Cell Leukemias

Disease	slg	CD5	CD23	FMC7	CD22	CD79b	CD10
CLL	Weak	++	++	-/+	Weak/-	Weak/-	-
B-PLL	Strong	-/+	-/+	++	+	++	-
HCL	Strong	-	-	++	++	+	-
SLVL	Strong	-/+	-/+	++	++	++	-
FL	Strong	-	-	++	++	++	++
MCL	Strong	++	-/+	++	++	++	-/+

slg, surface immunoglobulin; CLL, chronic lymphocytic leukemia; +, present; -, not present; B-PLL, B-cell polymphocytic leukemia; HCL, hairy cell leukemia; SLVL, splenic lymphoma with villous lymphocytes; FL, follicular lymphoma; MCL, mantle cell lymphoma.

mutated and unmutated CLLs show a common gene expression pattern that is clearly distinguishable from that of other lymphomas, as well as normal B cells. Nevertheless, although the overall profile was similar, there were differentially expressed genes between the two groups. The gene that was most differentially expressed in one series was zeta-associated protein 70 (ZAP-70), with unmutated cases having significant expression of ZAP-70. Interestingly, ZAP-70 is normally found in T cells, where it functions as an intracellular signal-transduction molecule for the T-cell receptor. It was subsequently shown that ligation of the B-cell receptor (BCR) in CLL cells that expressed ZAP-70 produced greater tyrosine phosphorylation of cytosolic proteins than did stimulation of CLL cells that did not express ZAP-70; therefore, it may

function in activating CLL cells. Expression of ZAP-70 was analyzed in 56 patients with CLL and was correlated with mutational status, disease progression, and survival in retrospective analyses (Fig. 110.1).¹⁵

Molecular Abnormalities

Conventional chromosome banding identified cytogenetic abnormalities in 40% to 50% of CLL cases; trisomy 12 was most common. This technique is hampered by the low mitotic activity of CLL cells. Fluorescence in situ hybridization (FISH), using genomic DNA probes to detect aberrations in interphase

Figure 110.1 Kaplan-Meier estimates of the actuarial risk of disease progression (A) and the likelihood of survival (B) among patients with Binet stage A chronic lymphocytic leukemia, according to the level of expression of zeta-associated protein 70 (ZAP-70).

cells, enhanced the ability to detect molecular abnormalities in CLL. FISH has shown molecular abnormalities in over 80% of CLL cases.⁷

Deletion 13q [del(13q)] is the most common genetic aberration in CLL; it is found by FISH as a sole abnormality in 55% of cases, followed by 11q deletion (18%) [del(11q)], 12q trisomy (16%), and 17p deletion (7%) [del(17p)].⁷ Prognosis in CLL has been correlated with the presence of these chromosomal abnormalities. When divided into five hierarchical prognostic categories in order of highest risk—del(17p), del(11q), 12q trisomy, no abnormalities, and del(13q) (sole abnormality)—the survival times were 32 months, 79 months, 114 months, 111 months, and 133 months, respectively. Patients with del(17p) or del(11q) had more advanced disease with extensive lymphadenopathy. With hierarchical categorization, patients are assigned according to their highest-risk abnormality, including when multiple abnormalities are present. Clonal evolution can occur over time, particularly in the setting of cytotoxic treatment; therefore, repeated FISH assessment is important with changes in clinical status, such as in patients needing retreatment.

The frequency of del(13q) led to a search for a potentially new tumor suppressor gene in that location. At least eight genes were identified and screened for alterations at the DNA or RNA level, or both, but studies failed to find consistent involvement of any of those genes. However, two potentially relevant microRNA (miR) genes, miR15 and miR16, were identified in the critical minimal deleted region of del(13q) and were noted to be deleted or down-regulated in more than two-thirds of all CLL cases.¹⁶ MicroRNAs are nontranslated small RNAs that function to regulate gene expression. Both miR15 and miR16 negatively regulate *BCL-2* transcript level; the absence of miR15 and miR16 in cases with del(13q) may lead to Bcl-2 overexpression and resultant resistance to apoptosis.

Whole-exome sequencing of CLL cases identified mutated genes that may contribute to the pathogenesis and biology of the disease.^{17–19} The frequency of mutated genes appears notably lower than the occurrence of cytogenetic abnormalities noted by FISH. Mutations are mostly private, and frequencies vary significantly by the patient population being characterized (e.g., untreated versus relapsed or refractory CLL). It is therefore unlikely that there is a single driver mutation that accounts for the disease. Indeed, the limited number of cases sequenced, the diversity in prior treatments among cases, and the relatively low frequency of mutations likely relate to the diversity in reported mutations. Consistently reported genes reported as mutated, albeit at low frequency, include *NOTCH1*, *SF3B1*, *TP53*, *MYD88*, *XPO1*, and *ATM*. Some of these mutations have been associated with clinical outcome such as *TP53*, *SF3B1*, *NOTCH1*, *ATM*, and *BIRC3*.^{18–20} Some mutations may result in decreased protein level or function, others may result in activation or increased protein levels, depending on the gene and mutation. Serial sampling of individual patients for whole-exome sequencing is leading to insights into diversities in clonal evolution and an appreciation for how different treatments may impact the emergence, frequency, and type of mutations and loss of others through the course of a patient's disease.^{21–23}

IMMUNE ABNORMALITIES

CLL cells disrupt immune function in patients with CLL. The most prominent manifestation of immune dysfunction is the increased risk and frequency of infections. Many patients with CLL succumb to infection or ineffectively treated autoimmunity. The treatments used for CLL, such as purine analogues, further immunosuppress patients and put them at increased risk for opportunistic infections and may exacerbate or unmask autoimmunity.

Early in the disease, in untreated CLL, the absolute number of T cells is increased with inversion of the T helper–T suppressor cell ratio.^{24,25} The CD4 to CD8 ratio continues to drop with

disease progression or after therapy with nucleoside analogues or alemtuzumab. Qualitative functional assessment of T cells has been inconclusive. Normal and decreased CD4-cell function has been reported. Similarly, decreased, normal, or excessive CD8-cell function has been reported. Others have shown that T-cell functions may be impaired by immunosuppressive factors produced by CLL cells.²⁴ Hypogammaglobulinemia is a common and progressive immune defect in patients with CLL and is another factor that increases the risk for infection. The pathogenesis of hypogammaglobulinemia in CLL is poorly understood. Impaired B-cell function and regulatory abnormalities of T cells, including the reversal of the normal helper–suppressor cell ratio, may play roles. In addition, CLL-derived natural killer (NK) cells have been shown to suppress immunoglobulin secretion by normal B cells in vitro.

DIAGNOSIS

The International Workshop on CLL (IWCLL) in 2008²⁶ updated the National Cancer Institute Working Group 1996 guidelines²⁷ for diagnostic criteria and treatment for CLL.

International Workshop on Chronic Lymphocytic Leukemia Revised Diagnostic Criteria

1. A blood monoclonal B lymphocyte count $>5 \times 10^9/L$, with $<55\%$ of the cells being atypical (prolymphocytes).
2. B-lymphocyte monoclonality should be demonstrated with cells expressing B-cell surface antigens (CD19, CD20, CD23), low-density surface immunoglobulin (M or D), and CD5.

A monoclonal B cell count $>5 \times 10^9/L$ was specified to distinguish CLL from small lymphocytic lymphoma in patients with palpable lymph nodes or splenomegaly. However, it is arguable as to whether that distinction is clinically relevant. Bone marrow aspirate typically shows $>30\%$ lymphocytes, with flow cytometry confirming monoclonality in the CD19/CD20/CD23/CD5+ population; however, diagnosis may be made solely on blood.

Other B-cell malignancies may also present with increased circulating lymphoid cells and should be differentiated from CLL. The diseases that may be confused with CLL are prolymphocytic leukemia (PLL), the leukemic phase of non-Hodgkin's lymphoma (mantle cell lymphoma, follicular lymphoma, or splenic lymphoma with circulating villous lymphocytes), and hairy cell leukemia (HCL). Immunophenotyping is helpful in differentiating these disorders (Figs. 110.2, 110.3, and 110.4; see Table 110.1).

Figure 110.2 Chronic lymphocytic leukemia. Peripheral smear showing mature-appearing lymphocytes.

Figure 110.3 Chronic lymphocytic leukemia. Bone marrow infiltration may range from nodular/focal (A) to diffuse (B).

Clinical Manifestations

The majority of individuals diagnosed with CLL are asymptomatic and initially identified on routine blood count. Some patients remain asymptomatic for a long period of time. In patients presenting with symptoms, the most common is fatigue, which is generally mild. Sometimes, enlarged lymph nodes or the development of an infection is the initial manifestation of disease. Bacterial infections, such as pneumonia, are more common in patients who present with advanced-stage disease. Infections secondary to opportunistic organisms, particularly herpes zoster, may occur. Exaggerated skin reaction to a bee sting or an insect bite (Wells' syndrome) is frequent in CLL. In contrast to the situation in lymphoma, fever in the absence of infection is rare in CLL. Lymph nodes, when enlarged, are usually discrete, freely movable, and nontender. Splenomegaly may occur, but massive splenomegaly is usually seen in patients with advanced disease. Splenic infarction is rare. Hepatomegaly occurs less frequently than splenomegaly. Skin involvement occurs in <5% of cases. Leptomeningeal leukemia is rare and, if present, is usually seen

in patients with refractory disease. Malignant pleural effusions are also rare, and when present, are associated with aggressive disease and poor prognosis.

Laboratory Findings

Absolute lymphocyte counts range from $5 \times 10^9/L$ to over $500 \times 10^9/L$. Leukostasis is uncommon in CLL, probably because of the small size and pliability of the leukemia cells. The lymphocyte count usually increases over time, but fluctuations in the absolute lymphocyte count of untreated patients may occur, particularly in the setting of infection. The lymphocytes are typically small and mature appearing, but there may be variations in cell morphology, with some lymphocytes being larger or atypical, whereas others may be plasmacytoid or cleaved or there may be prolymphocytes. Ruptured lymphocytes or "smudge" cells are commonly seen in the peripheral smear, reflecting fragility and distortion during preparation of the peripheral smear on the glass slide. Marrow infiltration by lymphocytes is universal, affecting from 30% to 100% of the cellularity, with overall increased marrow cellularity. The patterns of lymphoid infiltration of the marrow seen in biopsy specimens include nodular, interstitial, diffuse, or a combination. Patients with diffuse infiltration typically have advanced disease and a worse prognosis. Nodular and interstitial or "nondiffuse" patterns are associated with less advanced disease and better outcome.

Anemia (hemoglobin <11 g/dl) and thrombocytopenia (platelet count $<100 \times 10^9/L$) are found in a minority of patients at diagnosis but develop with disease progression. A positive direct antiglobulin (Coombs') test is seen in approximately 25% of cases, but overt autoimmune hemolytic anemia (AIHA) occurs less frequently. The incidence of a positive Coombs' test increases significantly with clinical stage.²⁸ Immune thrombocytopenia is usually diagnosed on the basis of a low platelet count in the presence of adequate numbers of megakaryocytes in the bone marrow. Neutropenia may also be encountered. These cytopenias may be the result of bone marrow failure due to "packed" marrow by CLL or occur as a result of an immune-mediated process or hypersplenism. Hypogammaglobulinemia occurs in approximately 50% of patients with CLL. At diagnosis, it may be noted in <10% of patients, but its incidence increases significantly with disease progression. Usually, all three immunoglobulin classes (G, A, and M) are decreased, but in some patients, only one or two may be low. Significant hypogammaglobulinemia and neutropenia potentially result in increased susceptibility to bacterial infections.

Figure 110.4 Prolymphocyte juxtaposed with a mature-appearing lymphocyte. Note larger size, less-condensed chromatin, and prominent nucleolus.

Autoimmune Complications

When autoantibodies occur in CLL, they are usually targeted against hematopoietic cells, resulting in AIHA, immune thrombocytopenia, immune-mediated granulocytopenia, or pure red cell aplasia; AIHA is the most frequent.²⁹ The autoantibodies are typically polyclonal and usually immunoglobulin G, indicating that they are not produced by the leukemic clone.³⁰ The severity of the autoimmune phenomenon does not necessarily correlate with the severity of CLL, and such events may develop in patients whose disease is responding to therapy. Prednisone is the most commonly used treatment for autoimmune complications, with high initial response rates. It is usually given at a dose of 1 mg/kg orally and tapered once a response is noted. Relapses are not uncommon. Cyclosporin A is another effective therapy and can produce good results, even in steroid-refractory patients.³¹ CD20 and CD52 monoclonal antibodies (mAb) rituximab and alemtuzumab have been used alone or in combination with chemotherapy in some patients in whom standard therapy fails.^{32,33} Splenectomy is also a viable therapeutic option for refractory cases.^{28,34}

Staging

The clinical course for individuals with CLL is variable; survival times range from 2 to over 20 years from diagnosis. In 1975, Rai et al.³⁵ developed a staging system consisting of five stages (Rai 0 to IV) based on Dameshek's model of orderly disease progression in CLL (Table 110.2). The Rai staging system was later modified into a three-stage system: low-risk (Rai 0), intermediate-risk (Rai I, II), and high-risk (Rai III, IV). A similar staging system was developed in Europe by Binet et al.³⁶ Both classifications reflect bulk of disease and extent of marrow compromise (i.e., anemia, thrombocytopenia). Both staging systems have been recognized as simple and reliable predictors of survival (see Table 110.2). Although most patients in the high-risk group (Rai III, IV; Binet C) have a progressive clinical course and shortened survival, the course of the disease is not uniform. Patients in the low- and intermediate-risk groups may have an indolent disease course that spans years or even decades, or the course may be progressive and associated with a shortened survival. Thus, it is helpful to have prognostic factors associated with clinical outcomes particularly for the low-risk group. Several prognostic factors have been associated with shortened survival in CLL. These include a short lymphocyte doubling time (<6 months), a diffuse pattern of bone marrow infiltration, advanced age and male gender, abnormal karyotype, high serum levels of β_2 -microglobulin and soluble CD23, and a CLL-PLL category (11% to 54% prolymphocytes in the blood).³⁷ Newer prognostic factors in CLL include *IGHV* mutation status, expression of CD38 and ZAP-70, and gene mutations. A prognostic model integrating cytogenetic abnormalities identified by FISH with

mutated *NOTCH1*, *SF3B1*, *BIRC3*, and *TP53* was proposed as a dynamic prognostic algorithm for overall survival (OS).²⁰

TREATMENT AND RESPONSE CRITERIA

An unusual feature of CLL compared to other leukemias is that making the diagnosis is not necessarily an indication to initiate treatment. This is true for several reasons. CLL is a disease of the older population; it may be diagnosed in an asymptomatic patient and have a prolonged course; CLL is not curable with current standard treatment approaches; and a survival advantage was not demonstrated in clinical trials of early intervention. Given that the majority of patients are older than 70 years, may have serious comorbid conditions associated with aging, and may have indolent disease, a significant fraction of patients will die of other causes and may never require therapy for their CLL.

The IWCLL revised criteria for active disease, an indication to initiate treatment,²⁶ include constitutional symptoms attributable to CLL: weight loss (>10% of baseline weight within the preceding 6 months), extreme fatigue (Eastern Cooperative Oncology Group performance status 2 or higher), fever (temperature higher than 38°C or 100.5°F for at least 2 weeks) or night sweats without evidence of infection; evidence of progressive bone marrow failure characterized by the development of or worsening of anemia, thrombocytopenia, or both; AIHA or autoimmune thrombocytopenia, or both, poorly responsive to corticosteroid therapy; massive (>6 cm below the left costal margin) or progressive splenomegaly; massive (>10 cm in longest diameter) or progressive lymphadenopathy; and progressive lymphocytosis defined as an increase in the absolute lymphocyte count by >50% over a 2-month period, or a doubling time predicted to be <6 months. Hypogammaglobulinemia or monoclonal gammopathy alone are not sufficient criteria to initiate therapy.

Several European groups conducted trials in the 1980s to evaluate whether immediate treatment in patients with early stage disease could improve survival.³⁸ These large randomized trials of immediate chlorambucil (CLB) therapy versus watch-and-wait were consistent in showing no survival benefit with early treatment. However, given significantly better current therapies, this question has been raised again. A limitation of randomizing all early stage patients is that approximately one-third of them may never require therapy for their disease, thus reducing the potential benefit of early treatment. Furthermore, the discovery of prognostic factors that identify early stage patients with a high likelihood of developing progressive disease may allow for randomized trials to more directly address this question of the benefit of early treatment.

The response criteria published in 1988³⁹ by the National Cancer Institute Working Group on CLL were revised in 1996²⁷ and most recently updated by the IWCLL (Table 110.3).²⁶ Updated recommendations made were that patients treated on clinical trial have

TABLE 110.2

Staging of Chronic Lymphocytic Leukemia

Rai Stage	Modified Rai Stage	Description	Binet Stage	Description
0	Low risk	Lymphocytosis only	A	Two or fewer lymphoid-bearing areas
I	Intermediate risk	Lymphocytosis and lymphadenopathy	B	Three or more lymphoid-bearing areas
II	Intermediate risk	Lymphocytosis and splenomegaly with/without lymphadenopathy	—	—
III	High risk	Lymphocytosis and anemia (hemoglobin, <11 g/dl)	C	Anemia (hemoglobin, <10 g/dl) or thrombocytopenia (platelets, 100×10^6 /dl)
IV	High risk	Lymphocytosis and thrombocytopenia (platelets, $<100 \times 10^6$ /dl)	—	—

TABLE 110.3

2008 International Workshop on Chronic Lymphocytic Leukemia Revised National Cancer Institute–Sponsored Working Group Response Criteria for Chronic Lymphocytic Leukemia

Parameter ^a	CR (all required)	PR
Lymphocytes	≤4,000/μl ^b	≥50% ↓ ^c
LNs	No palpable disease (LN <1.5 cm) ^d	≥50% ↓ ^c
Splenomegaly	None	≥50% ↓ ^c
Hepatomegaly	None	≥50% ↓ ^c
Bone marrow	<30% lymphocytes, no nodules ^e	NA
Constitutional symptoms	None	Variable
Neutrophils	≥1,500/μl	≥1,500/μl or ≥50% improvement ^f
Platelets	>100,000/μl	>100,000/μl or ≥50% improvement ^f
Hemoglobin	>11 g/dl (untransfused)	>11 g/dl or ≥50% improvement ^f

CR, complete response; PR, partial response; ↓, decrease; LN, lymph node; NA, not applicable.

^a Assessed at least 2 months after completion of therapy.

^b Include minimal residual disease assessed for clinical trials with reported sensitivity of method.

^c Must achieve at least two parameters.

^d Computed tomography scan of chest, abdomen, and pelvis desired for patients to confirm for patients on clinical trial.

^e Less than 30% lymphocytes in marrow with residual nodules should have immunohistochemistry to characterize nodules.

^f Must achieve at least one parameter.

evaluation of the blood or bone marrow by sensitive tests for minimal residual disease (MRD) such as multicolor flow cytometry or allele-specific polymerase chain reaction (PCR) for the *IGHV* gene and have confirmation of nodal response by computed tomography scan. In some patients who achieve complete remission by IWCLL criteria, one or both of these methods can demonstrate residual disease, referred to as MRD. Patients free of MRD following treatment have a longer remission duration and longer survival.^{40,41} Therefore, in addition to improving complete remission rates, investigators are focusing on eliminating MRD to improve treatment outcomes.

A sensitive four-color flow cytometry assay was developed to differentiate CLL cells (CD5/CD19 with CD20/CD38, CD81/CD22, and CD79b/CD43) from normal B cells.⁴² The assay can detect one CLL cell in 10⁴ to 10⁵ leukocytes. PCR techniques can also be used to assess MRD. Consensus primers for *IGHV* can be used in 70% to 80% of patients and may detect 1 in 10⁴ residual cells. Allele-specific oligonucleotide primers generated for individual patients are more sensitive, detecting 1 in 10⁵ CLL cells. Development of quantitative PCR techniques may aid in following patients over time but are technically complicated and therefore not available for routine clinical use.

Alkylating Agent-Based Treatments

For decades, the mainstay of therapy for CLL was alkylating agents, CLB and cyclophosphamide (CTX). These alkylating agents were given with or without corticosteroids. Various doses and schedules of oral CLB have been used. CLB is usually administered for several months, and the dose is adjusted to avoid its primary toxicity, myelosuppression. The overall response rate with either CLB or CTX monotherapy is approximately 40% to 60%, with 3% to 5% complete remission. Alkylating agents were combined with steroids to improve response rates.⁴³ Alkylating agent–based combinations have also included an anthracycline. No superior alkylating-agent combination has been identified.

Purine Analogues

Purine analogues, including fludarabine monophosphate, 2-chlorodeoxyadenosine (2-CdA), and pentostatin (deoxycorformycin), all have activity in treating patients with CLL.⁴³

In a phase 2 trial conducted at MD Anderson Cancer Center, fludarabine was given at a dose of 30 mg/m² per day for 5 days every 4 weeks. A response rate of 59% was observed in 68 previously treated patients, with 15% achieving complete remission. A subsequent study explored the combination of fludarabine and prednisone. Response rates were identical to those seen with fludarabine monotherapy, but the addition of prednisone was associated with increased incidence of *Pneumocystis jiroveci* and *Listeria monocytogenes* infections. The major side effects associated with fludarabine were myelosuppression and immunosuppression, with low CD4 counts lasting for many months to years after completion of treatment.⁴³

Single-arm studies evaluated fludarabine in previously untreated patients. Overall response rates were higher at 70% to 80%, and complete remission was seen in 10% to 25%.⁴³ An oral formulation of fludarabine was evaluated in relapsed patients with CLL. Seventy-eight patients received oral fludarabine 40 mg/m² per day for 5 days every 4 weeks for six to eight courses. The overall response rate was 51%, which was almost identical to prior trials using the intravenous formulation as a salvage regimen. Furthermore, oral fludarabine was used in the first-line Leukemia Research Foundation CLL4 trial⁴⁴ comparing fludarabine plus CTX versus fludarabine versus CLB, demonstrating efficacy and tolerability with the oral formulation, which is now approved by the US Food and Drug Administration (FDA).

Comparative Studies

A randomized European trial compared six courses of fludarabine versus six courses of CTX, doxorubicin, and prednisone (CAP) in 196 patients with Binet stage B or C CLL (Table 110.4).⁴⁵ In previously treated patients, a significantly higher overall response rate was observed with fludarabine compared to CAP. In previously untreated patients (see Table 110.4), the response rates with fludarabine were similar to those with CAP, but the duration of response was significantly longer with fludarabine. The French Cooperative Group on CLL randomized nearly 1,000 previously untreated patients to one of three treatment regimens: fludarabine, CTX, doxorubicin, prednisone, and vincristine, or CAP.⁴⁶ Higher overall response rate and longer time to progression were seen with fludarabine. Infection rates were similar, but extramedullary toxicity was less with fludarabine.

CR, complete remission; OR, overall response; RD, remission duration; OS, overall survival; CAP, cyclophosphamide, doxorubicin, prednisone; CHOP, cyclophosphamide, doxorubicin, prednisone, vincristine; TTP, time-to-progression; NR, not reached; GCLLSG, German Chronic Lymphocytic Leukemia Study Group; PFS, progression-free survival.

^a Age 65 years and older.

Results from an Intergroup trial with 509 previously untreated patients with CLL showed significantly higher complete and overall remission rates in patients treated with fludarabine versus those given CLB (see Table 110.4).⁴⁷ A third arm, fludarabine plus CLB, was closed early because of infection-related toxicity. Cross-over was allowed for patients with no response or relapse. Half the patients who failed to respond to CLB responded to fludarabine, including a 14% complete remission rate. In contrast, only 7% of patients who failed to respond to fludarabine achieved partial response with CLB. Although longer response duration and improved progression-free survival (PFS) were noted in patients treated with fludarabine, no difference in OS was found between the two groups in the initial report. However, updated data, with significantly longer follow-up, reported improved OS for patients treated initially with fludarabine; this difference in the survival curves emerged after 6 years follow-up.⁴⁸ The German CLL Study Group (GCLLSG) CLL5 evaluated fludarabine versus CLB monotherapy as initial treatment for patients older than 65 years (see Table 110.4).⁴⁹ Surprisingly, while treatment with fludarabine was associated with superior complete (7% versus 0%) and overall (72% versus 51%) response rates, there was no associated improvement in PFS or OS for these “elderly” patients. Thus, standard first-line treatment of the elderly does not require fludarabine.

Bendamustine has a benzimidazole (purineline) ring structure with an alkylating group and has potent alkylating agent activity, inducing intra- and interstrand DNA crosslinks. Bendamustine was compared to CLB in a randomized phase 3 trial for previously untreated patients with CLL (see Table 110.4).⁵⁰ Treatment with bendamustine was associated with superior PFS (21.6 months versus 8.3 months), and complete (31% versus 2%) and overall (68% versus 31%) response rates; this was the basis for FDA approval of this agent. Myelosuppression was mild but more frequent with bendamustine; this did not result in an increased infection rate.

Fludarabine inhibits excision repair of DNA interstrand crosslinks induced by CTX, thereby potentiating activity and providing a rationale for combining these agents.⁵¹ Phase 2 trials, which

combined fludarabine and CTX (FC), suggested increased efficacy compared to that seen in historical patients treated with fludarabine monotherapy.^{52–54} Three large randomized trials evaluated the efficacy of FC versus fludarabine monotherapy in previously untreated patients (Table 110.5). In the GCLLSG CLL4 trial, previously untreated patients younger than 65 with indications for treatment were randomized to receive six courses of FC or fludarabine.⁵⁵ The U.S. Intergroup E2997 trial⁵⁶ randomized previously untreated patients to receive FC or fludarabine and the UK Leukemia Research Foundation CLL4 trial⁴⁴ randomized patients to FC, fludarabine, or CLB in a 1:1:2 randomization. All three trials demonstrated superior PFS with FC treatment over fludarabine or CLB, and this was associated with superior complete and overall response rates. There was more myelosuppression with the combination, yet there was no difference in the incidence of infections in any of the trials. None of these trials showed a difference in OS with the follow-up available. Patients with del(17p) were confirmed to be high-risk with lower response rates and shorter survival compared to patients with other chromosome abnormalities, regardless of treatment. Patients with del(11q) were high-risk, but there appeared to be a large benefit for those patients treated with an alkylating agent combined with fludarabine. Patients with an unmutated *IGHV* gene had similar response rates to those with a mutated *IGHV*; however, their PFS and OS was shorter for those with an unmutated *IGHV* gene.

Cladribine (2-CdA) and pentostatin (2-deoxycytosine) have activity in treating CLL.⁵⁷ There are no head-to-head comparisons available for purine analogue monotherapy. The large randomized Polish Adult Leukemia Group (PALG)-CLL2 trial compared cladribine monotherapy, cladribine with CTX, versus cladribine with CTX and mitoxantrone (CMC) as initial therapy and demonstrated a higher complete response rate for CMC compared to the other treatments (see Table 110.5).⁵⁸ Neutropenia was more common with CMC, as was infection. There were no significant differences in PFS or OS rates among the three arms. The PALG-CLL3 phase 3 trial demonstrated equivalent efficacy with cladribine

TABLE 110.5

with CTX and FC for previously untreated patients with CLL (see Table 110.5).⁵⁹ Patients with del(17p) had poor outcomes with either treatment.

Monoclonal Antibodies

Alemtuzumab is a humanized mAb targeting CD52, an antigen that is highly expressed on CLL cells and normal T and B lymphocytes. Alemtuzumab was originally approved by the FDA based on the pivotal trial that demonstrated monotherapy activity in fludarabine-refractory patients with CLL (Table 110.6).⁶⁰⁻⁷⁴ Complete and partial remissions were noted in 2% and 31% of 93 treated patients, respectively; 55 (59%) had stable disease. Similar results were reported in a trial with a similar patient population treated with the same dose and duration of alemtuzumab administered subcutaneously.⁷⁵ Subcutaneous administration eliminates the infusion-related side effects, although local injection site reactions occur. Alemtuzumab was very effective at eliminating disease in the peripheral blood and bone marrow; bulky lymphadenopathy was less effectively treated, a pattern observed in other studies with alemtuzumab. The T-cell suppression that occurred with this agent has been concerning. As a consequence, a significant incidence of infections (including cytomegalovirus reactivation) is associated with therapy. Antibacterial and antiviral prophylaxis should always be used with alemtuzumab. Other studies confirmed the activity of alemtuzumab in less heavily pretreated patients (see Table 110.6). A randomized first-line trial demonstrated superior PFS associated with alemtuzumab monotherapy compared to CLB, as well as higher complete and overall response rates (see Table 110.4).⁷⁶

The mechanism of action for alemtuzumab is independent of p53. TP53 is a gene deleted in patients who have loss of chromosome 17p. Loss of p53 function by deletion or mutation confers resistance to treatment with standard chemotherapy such as CLB and purine analogues. Alemtuzumab was reported to have activity in patients with leukemia cells that lack p53 function.⁷⁷ Despite treatment with alemtuzumab, patients with del(17p) have short remission duration and OS. Alemtuzumab was also combined with high-dose methylprednisolone for previously treated and treatment-naïve patients with better results, although there is concern for immunosuppression and risk for infection (see Table 110.6).

Rituximab is a chimeric immunoglobulin G1 CD20 mAb; CD20 is expressed on malignant and normal B cells.⁷⁸ Relatively low levels of CD20 are expressed on CLL cells compared to normal B or neoplastic B cells of other lymphomas. In addition, circulating CD20 was demonstrated in the plasma of patients with CLL; this may inhibit the capacity of rituximab to bind to CLL cells, resulting in rapid clearance and negatively affecting pharmacokinetics.⁷⁹ Rituximab binds to the large-loop domain of CD20 and mediates antileukemic activity predominantly through antibody-dependent cellular cytotoxicity and complement-dependent cytotoxicity (CDC) (type I CD20 mAb). Standard-dose rituximab monotherapy has limited activity in treating CLL (see Table 110.6). Dose-intense⁸⁰ and dose-dense⁸¹ rituximab monotherapy increased efficacy (see Table 110.6). In addition, greater efficacy was seen when rituximab was used as first-line therapy (see Table 110.6).⁸² Maintenance rituximab is not routine practice for patients with CLL.

The primary toxicity seen with rituximab is usually with the initial infusion and is predominantly fever and chills. These symptoms are generally mild to moderate, subside with completion or discontinuation of the infusion, and abate with subsequent infusions. Although normal B cells are also targeted by rituximab, trials to date have shown no significant decrease in immunoglobulin levels, and infection rates are low.

Rituximab was combined with alemtuzumab based on the rationale of targeting two distinct antigens expressed on CLL cells as well as the differential effectiveness by disease site; rituximab has activity in treating lymph node disease, and alemtuzumab is highly effective at clearing blood and bone marrow. Efficacy and tolerability were demonstrated in both untreated and previously treated CLL (see Table 110.6). In addition, rituximab was combined with high-dose methylprednisolone in an active regimen for untreated and previously treated patients (see Table 110.6). Immunosuppression was seen with this combination, owing to the use of high-dose steroids, and was effectively managed with prophylactic antibiotics.

Ofatumumab is a fully human immunoglobulin G1 CD20 mAb that binds to an epitope encompassing both large- and small-loop domains of CD20 and is highly effective at CDC (type I CD20 mAb). Ofatumumab monotherapy was first evaluated in phase 1 and 2 trials of escalating doses of four weekly infusions

(see Table 110.6).⁸³ The pivotal trial that led to FDA approval of ofatumumab enrolled patients who were refractory to fludarabine and alemtuzumab (FA-ref) as well as fludarabine-refractory patients with bulky (>5 cm) lymph nodes (and therefore poor candidates for treatment with alemtuzumab) (BF-ref); regulatory approval was based on outcome for the FA-ref group. Patients received ofatumumab 2,000 mg intravenously weekly for 8 weeks, then monthly for 4 months. The overall response rate was 58% and 47% for the FA-ref and BF-ref group, respectively. The median PFS and OS were 5.7 months and 13.7 months, respectively, in the FA-ref and 5.9 months and 15.4 months, respectively, in the BF-ref group, representing clinical benefit for these patients compared to historic outcomes with available treatment (see Table 110.6).⁸⁴ First infusion-associated toxicity was most common and effectively managed with premedication. Infection was seen, but expected in these highly refractory, heavily pretreated patients. Response rates,

median survival, and adverse effects were similar between rituximab-treated, rituximab-refractory, and rituximab-naïve patients.⁸⁵

Chemoimmunotherapy

In vitro data demonstrate synergy between fludarabine and rituximab. Rituximab downmodulates levels of the antiapoptotic protein bcl-2 and may sensitize leukemia cells to fludarabine-induced apoptosis. Furthermore, fludarabine downmodulates expression of complement-resistance proteins, CD46, CD55, and CD59 on malignant B cells and renders them more susceptible to rituximab-induced CDC. The randomized phase 2 multi-institutional Cancer and Leukemia Group B (CALGB) 9712 trial evaluated the activity of concurrent versus sequential fludarabine and rituximab as first-line treatment (Table 110.7).^{86–90} All patients in this study

Rx, treatment; CR, complete remission; OR, overall response; PFS, progression-free survival; F, fludarabine; IV, intravenous; c, course; A, alemtuzumab; TTF, time to progression; Chl, chlorambucil; R, rituximab; PO, by mouth; GCLLSG, German Chronic Lymphocytic Leukemia Study Group; Ob, obinutuzumab; CIRS, cumulative illness rating scale; CALGB, Cancer and Leukemia Group B; MDACC, MD Anderson Cancer Center; C, cyclophosphamide; M, mitoxantrone; NR, not reported; P, pentostatin; Of, ofatumumab; TTF, time to treatment failure; B, bendamustine; EFS, event-free survival.

received rituximab; the concurrent group received 2.5 times the cumulative dose given to the sequential group. This trial achieved the primary end point of demonstrating a significantly higher complete remission rate of 47% in the concurrent group versus 28% in the sequential group. The overall response rate and PFS were not significantly different between the two groups. Shorter PFS was noted for patients with unmutated *IGHV*; shorter PFS and OS were noted for patients with del(17p) or del(11q) by FISH. Notably, the incidence of grade 3 to 4 neutropenia was higher in patients who received concurrent fludarabine and rituximab (77%), compared to sequential (41%) treatment. No significant difference was seen in the incidence of infection between the two arms. Subsequently, an analysis comparing patients treated on the CALGB 9712 trial versus a historical group of patients treated first-line with fludarabine monotherapy in the randomized CALGB 9011 trial (no rituximab) demonstrated a statistically significantly higher complete remission rate, overall response rate, 2-year disease-free survival, and 2-year OS, favoring patients who received fludarabine and rituximab.⁹¹

The combination of fludarabine, CTX, and rituximab (FCR) was initially evaluated in phase 2 trials in previously treated and chemotherapy-naïve patients with CLL (see Table 110.7).^{92–95} In 300 previously untreated patients with CLL, the complete remission rate with FCR was 72% and the overall response rate was 95%, with most patients having no detectable disease by two-color flow cytometry evaluation of the bone marrow at the end of therapy.⁹² Over 40% of complete responders tested were free of disease in the bone marrow by PCR for *IGHV*. This was the highest response rate reported for any regimen in previously untreated patients with CLL. The estimated median PFS was 80 months.

The GCLLSG CLL8 trial was a randomized multicenter phase 3 clinical trial of FCR versus FC for previously untreated patients (see Table 110.7).⁹⁶ This trial clearly demonstrated superior median PFS

associated with FCR (52 months) versus FC (33 months) as well as superior complete and overall response rates at 44% and 95% versus 22% and 88%, respectively. FCR treatment was also associated with a higher incidence of grade 3 or 4 neutropenia (33.7% versus 21%; $p < 0.0001$); however, there was no difference in the incidence of grade 3 or 4 infection (18.8% versus 14.9%; $p = 0.14$). Most importantly, this trial demonstrated superior OS associated with first-line treatment with FCR (84% alive) versus FC (79% alive) at 38 months ($p = 0.01$). The largest benefit was seen for patients with Binet stage A and B disease and patients younger than 70.

The REACH trial was an international randomized phase 3 trial with identical treatment arms as CLL8 and enrolled previously treated patients (see Table 110.7).⁹⁷ Eligible patients could only have had one prior treatment that did not include rituximab or FC. The conclusions of this trial were consistent with those of CLL8: superior PFS associated with superior complete and overall response rate for FCR versus FC. Thus far, no difference in OS between treatment arms has been observed in the REACH trial.

Efforts to improve the efficacy of the FCR regimen have included adding mitoxantrone to the regimen in clinical trial (see Table 110.7).^{98–100} There was no evidence that this addition produced a marked improvement over FCR. In addition, in an effort to reduce the myelosuppression of FCR and make the regimen more tolerable, a phase 2 trial was conducted with reduced doses of fludarabine and CTX and with the addition of maintenance rituximab, referred to as “FCR-lite” (see Table 110.7).¹⁰¹ Impressive response rates, with a high complete response rate of 73%, and durable remissions were reported. Rituximab or ofatumumab was combined with pentostatin and CTX for previously treated and chemotherapy-naïve patients with CLL (see Table 110.7).^{102–104} Both studies demonstrated that this regimen was active and well tolerated; the most common toxicity was myelosuppression, and nausea and vomiting were the most common nonhematologic toxicities.

Results from a variety of clinical trials with chemoimmunotherapy regimens for CLL and non-Hodgkin's lymphomas generally indicate synergy between the mAbs and chemotherapy. Indeed, rituximab was also combined with bendamustine and evaluated in phase 2 trials for previously treated and chemotherapy-naïve patients with CLL (see Table 110.7).^{105,106} Efficacy and tolerability were demonstrated with this regimen. Furthermore, fludarabine was combined with alemtuzumab for untreated and previously treated patients with CLL; superior efficacy over fludarabine monotherapy and safety were also demonstrated for this combination (see Table 110.7). In a randomized phase 3 trial of previously treated patients with CLL, fludarabine plus alemtuzumab prolonged PFS and OS, albeit with an increase in serious adverse events in the combination treatment group.¹⁰⁷

Older (age ≥ 65 years) individuals and those with comorbidities have difficulty tolerating regimens that are more myelosuppressive such as FC or FCR. Furthermore, a randomized trial did not show benefit with fludarabine in first-line treatment for these individuals. Therefore, there have been several clinical trials combining CLB with a CD20 mAb aimed at developing an active and effective chemoimmunotherapy regimen that could be tolerated by this population, with less myelosuppression (see Table 110.7). CLB was combined with rituximab, giving encouraging preliminary results. Obinutuzumab is a type II CD20 mAb, resulting in potent direct induction of apoptosis, and is glycoengineered to enhance antibody-dependent cellular cytotoxicity. The GCLLSG conducted a three-arm, phase 3 trial (CLL11) of CLB monotherapy versus CLB with rituximab versus CLB with obinutuzumab (see Table 110.7).¹⁰⁸ This trial demonstrated superior PFS and OS with obinutuzumab and CLB over CLB monotherapy and demonstrated superior PFS with obinutuzumab over rituximab when combined with CLB. Treatment was well tolerated in these patients with comorbidities, and these trial results led the FDA to approve of obinutuzumab in this setting.

Eliminating Minimal Residual Disease

The clinical benefit of eliminating MRD was suggested in a report of 91 previously treated patients with CLL who received alemtuzumab; 20% had eradication of MRD in the blood and bone marrow evaluated by four-color flow cytometry.⁴⁰ MRD-free status was associated with longer PFS and OS. Clinical trials focused on prospectively evaluating the impact of eliminating MRD on PFS and OS are ongoing.

For patients with residual disease after purine analogue-based therapy, the marrow is the usual site of involvement. Because alemtuzumab has significant activity in clearing blood and bone marrow, it was evaluated in trials to eliminate MRD following chemotherapy.^{109,110} These studies demonstrated the ability to improve responses and achieve MRD-free status in a percentage of patients treated with alemtuzumab, with anticipated associated risk for infection. However, studies reported unacceptable toxicity with this strategy.¹¹¹⁻¹¹³

B-Cell Signaling Pathway Inhibitors for Treatment of Chronic Lymphocytic Leukemia

CLL cells receive stimulation, including growth and survival signals, from the microenvironment of bone marrow, lymph nodes, and spleen. The microenvironment provides signals directing CLL cell proliferation and survival through binding and ligation of surface receptors and soluble factors such as cytokines and chemokines. Bruton's tyrosine kinase (BTK) has emerged as a central intracellular signal transduction molecule in CLL cell interactions with the microenvironment and for survival.¹¹⁴ BTK is a central molecule in signal transduction for the BCR as well as CD19, CD38, CD40, CXCR4 chemokine receptor, tumor necrosis factor

receptors, and toll-like receptors. BCR signaling and interaction of CLL cells with the microenvironment involve complex biochemical cascades and protein interactions for intracellular signaling. Other key signal transduction molecules include phosphoinositide 3-kinase (PI3K) and spleen tyrosine kinase. These molecules are being targeted for inhibition with small molecules as a therapeutic strategy. The furthest along in clinical development is ibrutinib, an orally administered irreversible inhibitor of BTK recently approved by the FDA for patients with relapsed CLL. Idelalisib is an oral reversible inhibitor of PI3K, and there are spleen tyrosine kinase inhibitors in clinical development.

Bruton's Tyrosine Kinase Inhibitors

X-linked agammaglobulinemia results from mutation in BTK, leading to lack of mature B cells. BTK is essential in the Akt, extracellular signal-regulated protein kinase, and nuclear factor- κ B signaling pathways of B cells. BTK inhibition occurs following covalent binding of ibrutinib to cysteine-481. Preliminary studies with ibrutinib demonstrated inhibition of BCR-stimulated activation of nuclear factor- κ B and extracellular signal-regulated protein kinase, resulting in death of malignant B cells; antitumor activity was also seen in animal models of B-cell malignancies. A phase 1/2 clinical trial was reported with ibrutinib administered to 85 previously treated patients with CLL demonstrating durable disease control with continuous 420 mg or 840 mg daily monotherapy.¹¹⁵ There were no dose-limiting toxicities, and target inhibition was associated with clinical reductions in tumor bulk. There was not a difference in activity between the two dose levels; 420 mg once daily is the recommended dose. The overall response rate was 71% (2 complete responses; 58 partial responses) by standard response criteria. Similar responses were noted across risk categories, including for high-risk del(17p), heavily pretreated, and advanced-stage disease. Best response was typically achieved by 1 year on treatment, with lymph node responses occurring rapidly, and lymphocytosis requiring longer time to improve. Most patients had transiently increased lymphocytosis upon initiating treatment, which likely represents egress of leukemia cells from lymph nodes and other protective niches. The 2-year PFS rate was 75% and OS rate was 83%, indicating durable responses with limited follow-up. Grade 3-4 treatment-related toxicity was rare. The most common toxicity was diarrhea, occurring in 49% of patients, 95% of which were grade 1-2. Ibrutinib monotherapy was evaluated as first-line treatment in 31 patients 65 years old or older.¹¹⁶ The most common toxicities were diarrhea and nausea, occurring in 68% and 48% of patients, respectively; nearly all were grade 1-2. This was a very well-tolerated treatment, and the overall response rate was 71%, with 13% complete response and 58% partial response, with durable remissions although limited follow-up.

Ibrutinib was evaluated against ofatumumab monotherapy in 391 patients with relapsed CLL in an international randomized phase 3 clinical trial.^{117,118} Treatment consisted of either ibrutinib 420 mg orally daily until progression or ofatumumab 300 mg first dose then 2,000 mg for seven weekly followed by four monthly doses. The primary end point was reached with an impressive improvement in PFS for ibrutinib (ibrutinib hazard ratio = 0.22; $p < 0.001$), with a relatively short overall median follow-up time of 9.4 months. Remarkably, there was a significant improvement in OS for those patients treated with ibrutinib (hazard ratio for death = 0.43; $p = 0.005$). Similarly improved outcomes were seen for high-risk patients, including those with del(17p) and those with fludarabine-refractory CLL. Diarrhea, fatigue, fever, and nausea were the most commonly reported adverse effects experienced by the patients treated with ibrutinib and were mild. According to early reports, mechanisms of ibrutinib resistance appear to include mutation of BTK at cysteine-481 (C481S) and gain-of-function mutations in PLC γ 2, a signaling molecule immediately downstream of BTK.¹¹⁹

Phosphoinositide 3-Kinase Inhibitor

There are four class I PI3K isoforms; PI3K-delta is expressed by leukocytes and participates in B cell development, signaling, and survival. PI3K mediates downstream signaling for the BCR as well as CXCR4, CD40, and CD49d. Idelalisib is an orally bioavailable, reversible small molecule inhibitor of p110δ of the PI3K complex; it produces no significant inhibition of other class I isoforms and no significant off-target inhibition of PI3K class II or III isoforms, mammalian target of rapamycin, or DNA protein kinases.

A phase 1 trial of idelalisib was conducted in relapsed and refractory patients with low-grade lymphoproliferative diseases, including CLL.¹²⁰ Idelalisib was well tolerated; elevated liver enzymes was the most frequent toxicity, and treatment resulted in a 30% response rate in relapsed patients with CLL.¹²⁰ There was rapid and marked reduction in lymph node size and an initial increase followed by decrease in circulating leukemia cells, indicating an initial redistribution of cells followed by cell death. A phase 3 clinical trial evaluated the activity of idelalisib in combination with rituximab versus rituximab with placebo as treatment for patients with relapsed CLL in 220 frail individuals with comorbidities or cytopenias.¹²¹ Idelalisib 150 mg was dosed twice daily continuously in 110 patients. Rituximab was administered to all patients at 375 mg/m² first dose, 500 mg/m² every 2 weeks for four doses, then every 4 weeks for three doses (eight total doses). This trial demonstrated superior efficacy for combined idelalisib and rituximab over rituximab and placebo with a hazard ratio for PFS of 0.15 ($p < 0.001$) and hazard ratio for OS of 0.28 ($p = 0.02$); serious adverse events occurred in 40% and 35%, respectively this led to FDA approval of the combination.

NEW AND NOVEL TREATMENTS FOR CHRONIC LYMPHOCYTIC LEUKEMIA

A number of new therapeutic approaches are under development for patients with CLL. Important novel strategies or novel targets and pathways include targeting Bcl-2 family members for inhibition with BH3-mimetics, immune-modulating agents such as lenalidomide, and cellular therapy strategies.

Bcl-2 Inhibitors

CLL cells express high levels of antiapoptotic proteins of the Bcl-2 family, rendering them long-lived and resistant to senescence and death. Small molecule inhibitors of Bcl-2 family members are in therapeutic development. Navitoclax (ABT-263) is an orally administered small molecule inhibitor of Bcl-2, Bcl-w, and Bcl-xL. In vitro treatment of CLL cells with navitoclax induced cell death. A phase 1/2 trial of orally administered navitoclax was conducted and generated promising results. The majority of patients treated in the study had >50% reduction in leukemia counts, and some patients experienced reduction in lymph node size.¹²² The dose-limiting toxicity was thrombocytopenia secondary to accelerated platelet senescence from inhibition of Bcl-xL in platelets. Given this activity, ABT-199 was designed as a molecule with greater affinity for Bcl-2 and reduced affinity for Bcl-xL.¹²³ A phase 1 trial is ongoing with ABT-199 monotherapy¹²⁴ and in combination with CD20 mAb.

Immunomodulation

Lenalidomide, a thalidomide analogue, has immunomodulatory and antiangiogenic activities. The mechanisms of action and effects on the microenvironment are not well understood. Lenalidomide monotherapy was initially studied in relapsed CLL. Phase 2 clinical trials in relapsed or refractory patients with CLL evaluated continuous and interrupted (21 of 28 days) administration of up to 25 mg daily and reported overall response rates of 32% to 47%

with 7% to 9% achieving complete remission, including patients who achieved MRD-free status.^{125,126} Furthermore, responses were noted in patients with high-risk features including del(11q) and del(17p). Subsequently, trials evaluated first-line monotherapy, demonstrating tolerability, good responses, and durable disease control.^{127,128} In a study of 60 symptomatic patients with untreated CLL age 65 years or older, lenalidomide at an initial dose of 5 mg/d (and titrated up) was well tolerated and resulted in a 65% response rate.^{128,129} Improvement in hypogammaglobulinemia and T-cell counts were noted in this setting, suggesting immune restoration. Subsequently, lenalidomide was evaluated in combination with rituximab for previously treated CLL.¹³⁰ The addition of CD20 mAb appeared to improve outcomes compared to monotherapy for relapsed disease.

Lenalidomide safety and toxicity concerns have been tumor lysis syndrome and tumor flare reaction, which occur upon initiation of treatment, as well as myelosuppression, which can be dose-limiting and occurs while patients are on treatment. Tumor lysis syndrome and tumor flare reaction have been minimized by initiating lenalidomide at low dose (2.5 mg to 5 mg daily), and by initiating CD20 mAb prior to lenalidomide in patients receiving the combination. Lenalidomide remains a promising agent with unique properties and is being studied earlier in treatment, in combinations and as maintenance therapy in CLL.

Cellular Therapy for Chronic Lymphocytic Leukemia

Chimeric Antigen Receptor–Bearing T-Cell Therapy

Immune-based cellular therapy takes advantage of the ability of the immune system to seek out and eliminate malignant cells in the body. It potentially provides a mechanism of surveillance to prevent recurrence of disease. Allogeneic stem cell transplant is a form of immune cellular therapy, which is curative for some patients with CLL. Another strategy of immune cellular therapy is being developed, based on T-cell expression of chimeric antigen receptors (CARs).^{131–134} CARs are engineered immune receptors introduced ex vivo into T cells, usually autologous, that redirect these cells to react against CLL cells. Graft-versus-host reactions are avoided with autologous T cells, while inducing and enhancing a graft-versus-leukemia effect. The CAR is a recombinant protein composed of an antigen-binding domain derived from single-chain immunoglobulin variable genes, hinge-stalk-transmembrane domain, derived on CD8, constant domain of immunoglobulin or other molecule, and intracellular signaling domains derived from CD3ζ and costimulatory domains derived from CD28 and/or CD137. The engineered gene is transduced into autologous T cells and expressed on the surface where it can bind to target antigen and induce T-cell activation, cytokine production, proliferation, and killing of cells expressing the target antigen. CD19 is expressed by malignant B cells, including CLL, as well as normal B cells and has been targeted with CARs. On-target effects include a leukemia-specific reaction as well as elimination of normal B cells, resulting in hypogammaglobulinemia. While very robust treatment effects were reported, including durable complete remissions, infusion-related side effects, and more notably, cytokine-release syndrome have been challenging. Hypogammaglobulinemia has inspired a search for better and more specific leukemia-associated or leukemia-specific antigens. This strategy is in early phase trials and appears promising.

Allogeneic Stem Cell Transplantation

Myeloablative allogeneic stem cell transplantation was not a viable option in CLL in the past because of the prohibitive toxicity of this approach in older patients. Autologous bone marrow transplantation

has been evaluated for CLL,^{135,136} but does not appear to have a role. Reduced-intensity conditioning has made allogeneic stem cell transplant (allo-SCT) available for significantly more patients with CLL. While allo-SCT was associated with long-term remissions and possible cure, there is patient selection and reporting bias in these data. Early data with nonmyeloablative allogeneic transplant indicated almost universal engraftment, although the development of chimerism was slower than with myeloablative transplants. Patients with sensitive disease who were transplanted had a better outcome than those who had resistant disease.¹³⁷ Long-term follow-up data have been reported showing a 5-year OS rate of 50%.^{138,139} Notably, immune manipulation by withdrawal of immunosuppression or donor lymphocyte infusions enhanced clinical responses, indicating that CLL is a disease vulnerable to immune-mediated elimination and control. A 6-year OS rate of 58% was reported in a series of 90 previously treated patients who underwent reduced-intensity conditioning and allo-SCT, with an event-free survival of 38% for the same period.¹⁴⁰ Furthermore, no association was noted between the presence of mutations in *TP53*, *SF3B1*, or *NOTCH1* and OS or EFS, indicating efficacy for patients with high-risk features. Smaller series reported similar outcomes.¹⁴¹⁻¹⁴³ A single-center retrospective study of outcomes for individuals with relapsed CLL who had a matched allogeneic donor versus no donor showed improved survival for individuals who had a matched donor in landmark analysis starting 3 months after donor search was initiated. These data indicate that allo-SCT may improve survival for patients with relapsed high-risk CLL.¹⁴⁴

Splenectomy

Studies suggest hematologic and survival benefits from splenectomy in patients with CLL. Splenectomy may be beneficial in individuals with immune-mediated cytopenias such as AIHA and immune thrombocytopenia purpura after corticosteroid failure or in improving blood counts in patients with hypersplenism. In a study from MD Anderson Cancer Center,³⁴ perioperative mortality among 55 patients was 9%, mostly related to poor preoperative performance status. Improvements in the platelet count, neutrophil count, and hemoglobin occurred in 81%, 59%, and 33% of patients, respectively. Among patients with Rai stage IV disease, a trend for improved survival was observed using case-control analysis.

Therapeutic Considerations for Specific Problems in Patients with Chronic Lymphocytic Leukemia

The most common cause of morbidity in patients with CLL is infection. Because hypogammaglobulinemia is a contributing factor to patients' increased susceptibility to infections, a randomized double-blind study evaluated the use of intravenous immunoglobulin, 400 mg/kg, versus placebo given every 3 weeks for 1 year to 84 patients with CLL.^{145,146} A significant reduction in bacterial infections was seen in the group treated with intravenous immunoglobulin, but no statistically significant difference was observed in the number of life-threatening infections or nonbacterial infections. Because of the high cost of this therapy, monthly intravenous immunoglobulin therapy is best used in patients with hypogammaglobulinemia who experience repeated bacterial infections.^{147,148}

SECOND MALIGNANCIES AND TRANSFORMATION

Approximately 25% of patients with CLL develop second neoplasms, the most common being skin cancer. Second neoplasm is the cause of death in 7% to 10% of patients. In approximately 2% to 6% of patients, CLL may evolve into a high-grade lymphoma

of the diffuse large-cell type (Richter's transformation); less commonly Hodgkin's histology is diagnosed. Richter's transformation may arise from the original CLL clone, and its onset is heralded by fever, weight loss, a rising lactate dehydrogenase, and an asymmetric rapid lymph node enlargement.¹⁴⁹ Because the lymphoma may be patchy, a gallium or positron emission tomography scan, usually negative in CLL, may aid in identifying a "hot" lymph node that can be targeted for biopsy. Transformation must be diagnosed by histology. The prognosis of Richter's transformation is poor, with a median survival of only 6 months. Prolymphocytic transformation develops in approximately 2% to 5% of patients with CLL. This transformation is different immunophenotypically and clinically from primary or de novo PLL. Secondary PLL is marked by development of refractory anemia and thrombocytopenia, progressive splenomegaly, and an increase in the percentage of prolymphocytes to >30% of the leukemia cells. As with Richter's transformation, PLL transformation portends a poor prognosis despite aggressive therapy.

Therapy-related myeloid neoplasia (myelodysplasia or acute myeloid leukemia) is also a concern in CLL. In long-term follow-up of the US Intergroup Study E2997, 4.7% of patients developed therapy-related myeloid neoplasia at a median of 5 years from initial therapy.¹⁵⁰

PROLYMPHOCYTIC LEUKEMIA

PLL is characterized by a high number of circulating prolymphocytes, splenomegaly, minimal lymphadenopathy, and a median survival of <3 years. This leukemia can be present at diagnosis or evolve from CLL.¹⁵¹ Prolymphocytes are larger and less homogeneous than CLL cells and have abundant clear cytoplasm, clumped chromatin, and a prominent nucleolus. Prolymphocytes can be of either B- or T-cell type. B-PLL cells usually do not express CD5 but stain strongly for surface immunoglobulin and FMC7 (see Table 110.1). In 20% of cases of PLL, T-cell markers are expressed.

Splenectomy and lymphomalike regimens have been used to treat PLL without much success. Nucleoside analogue-based regimens appear to be the most effective, and alemtuzumab has shown promising activity in T-PLL.¹⁵²

LARGE GRANULAR LYMPHOCYTE LEUKEMIA

Large granular lymphocytes (LGLs) are larger than normal lymphocytes and contain azurophilic granules in their cytoplasm. LGLs comprise 10% to 15% of peripheral blood mononuclear cells and are predominantly of NK-cell phenotype, a smaller fraction being of T-cell phenotype. There are generally four lymphoproliferative disorders of LGL: reactive/transient LGL expansion, chronic LGL lymphocytosis, indolent LGL leukemia, and aggressive LGL leukemia.¹⁵³ Clonal expansion of LGL can be of NK-cell or T-cell phenotype; the T-cell phenotype comprises 80% of LGL leukemias. T-LGL cells have a CD3+/CD57+/CD56- immunophenotype, and NK-LGL express CD3-/CD56+/CD57-. Clonality in T-LGL leukemia may be established by T-cell receptor gene rearrangement studies. T-LGL leukemia is usually indolent. Patients present with cytopenias, including neutropenia with accompanying infections, pure red cell aplasia, thrombocytopenia, and anemia. Serologic abnormalities, such as the presence of rheumatoid factor or antinuclear antibody, or both, hypergammaglobulinemia, and high β_2 -microglobulin are frequent. A small percentage of LGL leukemias have a more aggressive course, and these cases tend to have an NK-cell phenotype. Because lymphocyte counts are usually not elevated, diagnosis requires a high degree of suspicion and a careful examination of the peripheral blood smear and bone marrow. Although the disease may be indolent, most patients

require treatment for cytopenias. Various therapies, including low-dose methotrexate (10 mg/m² orally once weekly), cyclosporine (2 mg/kg orally every 12 hours), or CTX (100 mg orally daily) with or without oral prednisone (1 mg/kg orally daily) have all been effective. Complete remissions may be seen in up to 50% of cases. Lymphoma-type regimens, such as CTX, doxorubicin, prednisone, and vincristine, have not been effective for aggressive disease.

HAIRY CELL LEUKEMIA

HCL is a rare B-cell lymphoproliferative disorder that affects adults and represents 2% of all leukemias. It has a marked preponderance in men. Most patients have cytopenias; splenomegaly is also frequent.¹⁵⁴ Hairy cells can be seen in the peripheral blood, but at low frequency, and therefore are easily missed. These cells are twice as large as normal lymphocytes, with the nuclei showing a loose chromatin pattern and villi-like cytoplasmic projections (best viewed under phase contrast microscopy). Hairy cells infiltrate the bone marrow in an interstitial or focal pattern, with clear zones in between cells (“fried egg appearance”). Marrow reticulin is increased, and aspirates may result in a dry tap. Immunophenotypic analysis of hairy cells shows the presence of CD19, CD20, CD22, CD25, and CD103, and, in contrast to CLL, hairy cells are negative for CD5 and CD23. Hairy cells also stain strongly for surface immunoglobulin and FMC7. Use of the CD103 antibody, which stains tartrate-resistant acid phosphatase, has obviated the need for cytochemical staining for tartrate-resistant acid phosphatase.

The BRAF V600E mutation was recently found to be present in all patients with HCL, a finding that is likely to have an impact on the diagnosis and possibly the treatment of this disease.^{155,156} Vemurafenib is a BRAF inhibitor¹⁵⁷ currently in clinical trials as therapy for relapsed or refractory HCL.

HCL has no staging system. For many years, the only effective therapy was splenectomy.

Treatments for Hairy Cell Leukemia

Nucleoside Analogues

Pentostatin (2'-deoxycoformycin) and cladribine (2-CdA) are the nucleoside analogues that are the mainstay of treatment of HCL.¹⁵⁸ Pentostatin is administered at 4 mg/m² every 2 weeks until maximum response, and cladribine is given at 0.1 mg/kg per day as a continuous intravenous infusion for 7 days; the same total dose can

be administered as a 2-hour infusion over 5 days. Because cladribine involves a single course of therapy and produces remission rates comparable to those of pentostatin, cladribine is used more frequently in the United States for the treatment of HCL. Multiple series have reported high response rates, with patients remaining in remission for many years. The majority of relapsed patients achieve second remission when retreated with pentostatin or cladribine. The choice of agent may depend on the duration of the first remission: if <3 years, an alternate agent should be used; if >5 years, the same agent may be given. The role of interferon-alpha is currently limited to patients who are unresponsive to nucleoside analogues.

Monoclonal Antibody-Drug Conjugate

A percentage of patients may relapse with cladribine-resistant disease. In addition, 10% to 20% of patients have a variant form of HCL with high numbers of circulating hairy cells and a poor response to nucleoside analogues. Classic and variant hairy cells strongly express CD22, a B-cell adhesion molecule. Data suggest marked efficacy of a recombinant immunotoxin, BL22, in the treatment of chemotherapy-resistant HCL.¹⁵⁹ This immunotoxin contains the variable domain of the anti-CD22 mAb RFB4, which is fused to a fragment of *Pseudomonas* exotoxin called PE38 that lacks the domain necessary for cell binding and contains only the domain responsible for cell death. The phase 1 trial of BL22 included 16 cladribine-resistant patients with HCL; 11 achieved complete remission and 2 partial remissions were reported. Side effects included transient hypoalbuminemia, elevated aminotransferase levels and in 2 of 16 patients, a reversible hemolytic-uremic syndrome developed. A phase 2 trial was conducted with BL22 in 36 patients with relapsed or refractory HCL.¹⁶⁰ Overall, 47% achieved complete response and 25% partial response; 2 (6%) patients experienced reversible hemolytic-uremic syndrome. Patients with smaller spleen were more likely to achieve complete response. Neutralizing antibodies were identified in four (11%) patients, which prevented retreatment. Moxetumomab pasudotox (HA22 or CAT-8015) is derived from BL22, selected for high-affinity for CD22. A phase 1 trial of moxetumomab pasudotox was performed in 28 patients with chemotherapy-resistant HCL.¹⁶¹ Doses included 5 mcg/kg to 50 mcg/kg intravenously every other day for three doses for each course, with up to 16 courses repeated every 4 weeks. The median number of courses given was four, and no dose-limiting toxicity was observed up to the highest dose tested. The overall response rate was 86% and 46% achieved CR; these responses were durable.

INTRODUCTION

The myelodysplastic syndromes (MDS) represent a spectrum of hematopoietic stem cell malignancies that share morphologic features of dysplasia, ineffective hematopoiesis, and a risk for leukemia evolution. The hallmark of early disease is accelerated apoptosis and proliferation of bone marrow precursors that drives increased marrow cellularity and peripheral cytopenias. In advanced disease, increasing maturation impairment is accompanied by the acquisition of survival signals that leads to increasing proportions of myeloblasts. MDS are clonal stem cell neoplasms that arise from interplay of genetic and epigenetics events with altered microenvironmental pressures that are senescence dependent. Although the risk of progression to acute myeloid leukemia (AML) varies, the majority of patients succumb to complications related to cytopenias.¹

HISTORICAL PERSPECTIVE

The description of MDS dates back to early 1900s when reference was first made to a group of patients with a form of anemia refractory to available treatments. The term *anemia pseudoaplastica* was one of the earliest descriptions of MDS.² In the late 1940s, it was thought that the disease progresses to leukemia and, hence, the term *preleukemia* was applied.³ The definition was expanded to include peripheral blood descriptors such as neutropenia and thrombocytopenia in the early 1950s.⁴ The French-American-British (FAB) group coined the term *myelodysplastic syndromes* in a series of proposals on acute leukemias in 1976 and later expanded the FAB classification in 1980s.^{5,6} The original FAB classification included only two categories: refractory anemia with excess blasts (RAEB) and chronic myelomonocytic leukemia (CMML), to which others were added in 1982. In 1997, the International Prognostic Scoring System (IPSS) was introduced.⁷ Under the auspices of the World Health Organization (WHO), the pathologic classification of MDS was refined and later revised in 2008.^{8,9} New prognostic models were later introduced, such as the WHO Prognostic Scoring System (WPSS), the Global M.D. Anderson Risk Model, the Lower Risk M.D. Anderson Model, and more recently, the revised-IPSS (IPSS-R).¹⁰⁻¹³

Recent years witnessed an acceleration in understanding the disease biology and associated molecular genetics events. Today, molecular abnormalities are demonstrable in more than 80% of MDS patients. Finally, in the past decade, three medications were approved specifically for the treatment of MDS: azacitidine, decitabine, and lenalidomide.

EPIDEMIOLOGY

MDS is one of the most common hematologic malignancies. According to the Surveillance, Epidemiology, and End Results (SEER): the United States cancer surveillance program 2006 to

2010 statistics, the age-adjusted incidence rate of MDS was 4.8 per 100,000 and 0.4 per 100,000 for CMML.¹⁴ MDS was more common in males (6.5 per 100,000) than in females (3.7 per 100,000). MDS is a disease of the elderly (median age at diagnosis is 72 years); the incidence rate was highest among 80 years and older (20 per 100,000).¹⁴ SEER/North American Association of Central Cancer Registries (NAACCR) reported a similar MDS annual age-adjusted incidence rate of 3.27 per 100,000.¹⁵ The incidence rate among the Medicare population (age >65 years) was 162 per 100,000, which translates to approximately 45,000 newly diagnosed cases per year.¹⁶ Recent data suggest a high rate of uncaptured MDS cases among hospital cancer registries.¹⁷ The incidence of MDS reported from Europe is similar to that observed in the United States, ranging from 3.2 to 8.1 per 100,000.¹⁸ Interestingly, a lower incidence, younger age, and different spectrum of pathologic subtypes have been reported in Asia.¹⁹

ETIOLOGY

For the vast majority of cases, senescence per se is the highest risk factor for MDS development. Familial/genetic predisposition contributes to a small proportion of MDS cases.²⁰ There is an increased risk of MDS among inherited bone marrow failure syndromes (BMFS), such as Fanconi anemia, dyskeratosis congenita, severe congenital neutropenia, and Shwachman–Diamond syndrome.²⁰ Familial cases of MDS beyond BMFS are well recognized and molecularly distinct. Two important familial syndromes are the familial platelet disorder with a propensity to myeloid malignancy, arising from an autosomal-dominant *RUNX-1* germ-line gene mutation that results in thrombocytopenia with a corresponding frequency of MDS/AML in carriers that approaches 50%²¹ and familial MDS/AML with *GATA2* mutation, which is also autosomal dominant but with variable penetrance.²²

Benzene exposure is a well-recognized environmental exposure linked to AML/MDS.²³ The risk of MDS but not AML was increased among petroleum distribution workers at relatively lower levels of exposure in a dose-dependent manner.²⁴ Cigarette smoking had also been associated with an increased risk of developing MDS. In a meta-analysis, current and former smokers had increased risks of MDS, with an odds ratio (OR) of 1.81 (95% confidence interval [CI], 1.24 to 2.66) and 1.67 (95% CI, 1.42 to 1.96), respectively.²⁵ A population-based study from Sweden suggested that a prior history of infection (OR, 1.3; 95% CI, 1.1 to 1.5) or autoimmune disease (OR 2.1-fold; 95% CI, 1.7 to 2.6) significantly increased the probability of developing MDS.²⁶

A case-control study was conducted to investigate associations between lifestyle characteristics and MDS risk.²⁷ A family history of hematopoietic cancer (OR = 1.92), smoking (OR = 1.65), and exposure to agricultural chemicals (OR = 4.55) or solvents (OR = 2.05) were associated with MDS. The highest risk was among smokers exposed to solvents/agricultural chemicals (OR = 3.22).

In the context of successful chemotherapeutic treatment of other hematologic malignancies and solid tumors, a growing

percentage of MDS cases are considered secondary or arising from prior radiation or chemotherapy. Treatment-related MDS (t-MDS) accounts for 10% to 20% of all MDS cases. It is generally characterized by a high rate of unfavorable cytogenetics and poor outcome. Chemotherapy and, to a lesser extent, radiotherapy are associated with an increased risk of developing AML/MDS.^{28,29} The risk of t-MDS varies from less than 1% (adjuvant breast cancer chemotherapy studies) to 15% (heavily treated lymphoma patients). Two types of t-MDS are recognized: Type I is related to alkylating agent exposure where MDS occurs after a latency period of 3 to 5 years in which monosomy 5 or 7 are cytogenetic characteristics of the disease; and type II t-MDS is related to treatment with topoisomerase II inhibitors, which generally arises after a short interval from chemotherapy exposure and rapidly progresses to AML. Chromosome 11q23 abnormalities that involve the *MLL* gene are characteristic of this type.³⁰ Radiation-related MDS have a prognosis similar to de novo MDS.³¹

PATHOLOGY

The diagnosis of MDS requires the presence of persistent cytopenia(s) in the absence of hematinic deficiencies such as vitamin B12 or folic acid, and one of the following: (1) demonstration of cytologic dysplasia in $\geq 10\%$ of cells in a given lineage, (2) demonstration of increased myeloblasts (5% to 19%) (Fig. 111.1),³² or (3) a specific cytogenetic abnormality detected in the setting of sustained unexplained cytopenia ("presumptive MDS" by WHO 2008 criteria). In certain cases, the diagnosis of MDS can be made without clear evidence of morphologic dysplasia, such as CMML if monocytes are persistently elevated.

A 500 cell count differential is recommended, with exclusion of lymphocytes and plasma cells. Cytologic dysplasia must exceed 10% of cells in any lineage and the percentage of myeloblasts calculated. If the absolute percentage of erythroid precursors is 50% or greater, the percentage of myeloblasts is estimated among nonerythroid precursors. Iron stains are essential to address the percentage of ring sideroblasts. The bone marrow core biopsy could complement the bone marrow aspirate in several aspects,³⁰ namely, cellularity, dysmegakaryopoiesis, and identifying clusters of abnormal localization of immature precursors (ALIP), which are immature cells/myeloblasts or promyelocytes that are displaced from the paratrabecular area to the intertrabecular areas often corresponding to the vascular niche. In addition, the reticulin stain provides information regarding medullary fibrosis, which can add prognostic information.^{33,34}

The French-British-American Classification

The original FAB classification (Table 111.1) included only two of the subtypes.⁵ In 1982, a revision to the FAB classification expanded that to five subgroups: refractory anemia (RA), refractory anemia with ring sideroblasts (RARS), RAEB, RAEB in transformation (RAEB-t), and CMML.⁶

The World Health Organization Classification

The WHO classification was proposed to address some of the FAB shortcomings.^{35,36} WHO distinguishes between single lineage and multilineage dysplasia: Categories of refractory cytopenia with multilineage dysplasia (RCMD) and RCMD with ring sideroblasts (RCMD-RS) were added, capturing those cases with dysplastic changes in either myeloid or megakaryocytic lineages in addition to erythroid dysplasia. The 5q- syndrome was recognized as a distinct subset, with an isolated cytogenetic abnormality involving del(5q) and less than 5% myeloblasts. RAEB was divided into RAEB I with 5% to 9% blasts and RAEB II with 10% to 19% blasts.^{35,37} RAEB-t was omitted and the blast threshold for AML diagnosis lowered

to 20% rather than 30%.^{35,37,38} Finally, WHO recognizes MDS/myeloproliferative neoplasms (MPN). This includes diseases such as CMML, juvenile myelomonocytic leukemia (JMML), and atypical chronic myeloid leukemia (aCML).^{35,37,38} CMML is further classified based on the percentage of bone marrow blasts, where CMML type 1 includes 0% to 4% blasts and/or promonocytes on peripheral blood or $< 10\%$ in the bone marrow, and type 2 includes 5% to 19% blasts and promonocytes in the peripheral blood or $< 20\%$ in the bone marrow.⁸

The WHO classification was revised in 2008,^{39,40} adding the category of refractory cytopenia with unilineage dysplasia (RCUD) that include RA, refractory neutropenia (RN) and refractory thrombocytopenia (RT). The patients may have a corresponding cytopenia but not pancytopenia. Patients with pancytopenia and unilineage dysplasia, patients with no overt dysplasia but cytogenetic evidence of MDS, and cases of RCUD or RCMD with peripheral blood (PB) blasts of 1% are categorized as MDS unclassified (MDS-U). RAEB-I includes 2% to 4% peripheral blood blasts and RAEB-II includes 5% to 19% peripheral blood blasts. The presence of Auer rods regardless of blast percentage qualifies as RAEB-II or CMML-2.⁴¹ A provisional entity of refractory anemia with ring sideroblasts and thrombocytosis (RARS-T) was proposed in which there is a sustained thrombocytosis of $450,000/\text{mm}^3$ or greater.⁴² Up to 50% of RARS-T patients harbor a gain-of-function mutation involving the Janus kinase 2 (*JAK2*) gene. A subset of patients with CMML and eosinophilia with accompanying genetic abnormalities involving the platelet-derived growth factor receptor alpha (*PDGFR α*) or *PDGFR β* were reclassified as myeloid neoplasms with eosinophilia.⁴³

Hypocellular MDS (or *hypoplastic MDS*) is not recognized as a distinct entity with the WHO classification. It accounts for 10% to 20% of MDS cases. The challenge on diagnosis is to distinguish those cases from aplastic anemia.⁴⁴ Although not part of the WHO classification, the term idiopathic cytopenia of unknown significance (ICUS) was proposed for those cases with persistent cytopenia(s) unrelated to nutritional deficiency that have dysplasia in less than 10% of cells in any lineage and that lack cytogenetic abnormalities. Many of those patients may develop MDS over time. Whether the latter cases can be distinguished a priori by the presence of gene mutations is under investigation. Some cases may also demonstrate dysplasia below the 10% WHO cutoff with no cytopenia, referred to as idiopathic dysplasia of unknown significance (IDUS).⁴⁵

PATHOGENESIS

MDS is a clonal disease driven by acquisition and expansion of genetic alterations (Fig. 111.2). The clonal nature of many MDS cases was first apparent by the conventional metaphase karyotype analysis. Studies leveraging restriction fragment length polymorphisms (RFLP) of X-chromosome genes in females, single nucleotide polymorphism (SNP) arrays, and glucose-6-phosphate dehydrogenase (G6PD) analyses confirmed that hematopoiesis is clonal across all subtypes of MDS.⁴⁶⁻⁴⁹ The two most comprehensive studies demonstrating the frequency and nature of chromosome abnormalities in MDS confirmed that approximately 50% of patients with MDS harbor a chromosome abnormality.^{50,51} The most common recurrent abnormalities were del(5q) (30%), -7 or 7q- (21%), and +8 (16%). Deletion of genes encoded within the commonly deleted region (CDR) of human del(5q) MDS is sufficient to induce an MDS phenotype, indicating that these recurrent genetic lesions are critical to the development of the disease.⁵²

In addition to large chromosomal deletions or duplications, DNA sequencing technology has uncovered gene mutations that aggregate within pathways previously unrecognized to be important in MDS pathogenesis. These include mutations predicted to result in deregulation of genes involved in signaling pathways and epigenetic control, RNA splicing, and transcription factors.⁵³

Figure 111.1 Morphologic findings of myelodysplasia in peripheral blood and bone marrow. **A:** Erythroid precursors displaying cytoplasmic to nuclear maturation asynchrony and multinucleation in bone marrow aspirate smear (Wright Giemsa stain). **B:** Bone marrow aspirate with erythroid hyperplasia, left shifted and megaloblastoid maturation, occasional nuclear budding and binucleation (Wright Giemsa strain). **C:** Numerous ringed sideroblasts are highlighted by Prussian-blue iron stain in bone marrow aspirate. **D:** Circulating granulocytes showing pseudo-Pelger-Huet change with hyposegmentation and hypogranulation in cytoplasm in peripheral blood smear (May-Grünwald-Giemsa stain). **E:** Abnormal distribution of cytoplasmic granules or patch loss of granules in eosinophilic precursors as well as abnormal lobation of neutrophils are present in the peripheral blood of a MDS patient (May-Grünwald-Giemsa stain). **F:** Predominant myeloid dysplasia including marked hypogranulation, cytoplasmic to nuclear maturation asynchrony with increased immature precursors/myeloblasts noted in bone marrow aspirate (Wright Giemsa stain). **G:** Circulating blasts with round to oval nucleus, lacy chromatin, one to more than one very prominent nucleoli and a small amount of cytoplasm are identified in peripheral blood smear (May-Grünwald-Giemsa stain). There is a single Auer rod noted in the cytoplasm of one blast, and a background of hypogranulated granulocytes is present (May-Grünwald-Giemsa stain). **H:** Bone marrow aspirate containing small to large blasts with fine chromatin, visible to prominent nucleoli and scant to some amount of basophilic cytoplasm admixed with dysplastic polychromatic normoblasts showing nuclear budding (Wright Giemsa stain). **I:** Bone marrow core biopsy showing non-paratrabeular-located immature myeloid precursors in cluster; abnormal localization of immature precursors (ALIPs) (hematoxylin and eosin [H&E] stain). **J:** Dysplastic platelets displaying variable in size and shape including giant hypogranulated platelets. **K:** Medium-sized megakaryocytes with single lobated nucleus characterized in 5q- syndrome, subtype of myelodysplastic syndrome. **L:** Representative bone marrow core biopsy of 5q- syndrome with moderately increased in single or hypolobated megakaryocytes (H&E stain).

^a Diagnosis and Classification of MDS.

Mutations are common in MDS, because targeted sequencing of select genes can identify at least one event (average: three events per sample) in approximately 80% of cases.⁵⁴ Although there are no MDS-defining mutations, a *genomic fingerprint*, which is characteristic of MDS is materializing as a result of several large-scale gene sequencing efforts. Among the most common gene mutations in MDS is that involving the gene, ten-eleven-translocation-2 (*TET2*).⁵⁵ Inactivating *TET2* mutations, which disrupt *TET2*

enzymatic activity, are frequently observed in MDS. *TET2* catalyzes the conversion of methyl cytosine to hydroxymethylcytosine (5-hmC), thereby inducing subsequent DNA demethylation and the release of epigenetic repression.⁵⁶ Patients with *TET2* gene mutations have lower DNA levels of 5-hmC with consequent increased genomic methylation. Other commonly mutated epigenetic modifiers include the associated sex-linked combs like 1 (*ASXL1*) gene.⁵⁷⁻⁶⁰ *ASXL1* belongs to the polycomb gene family

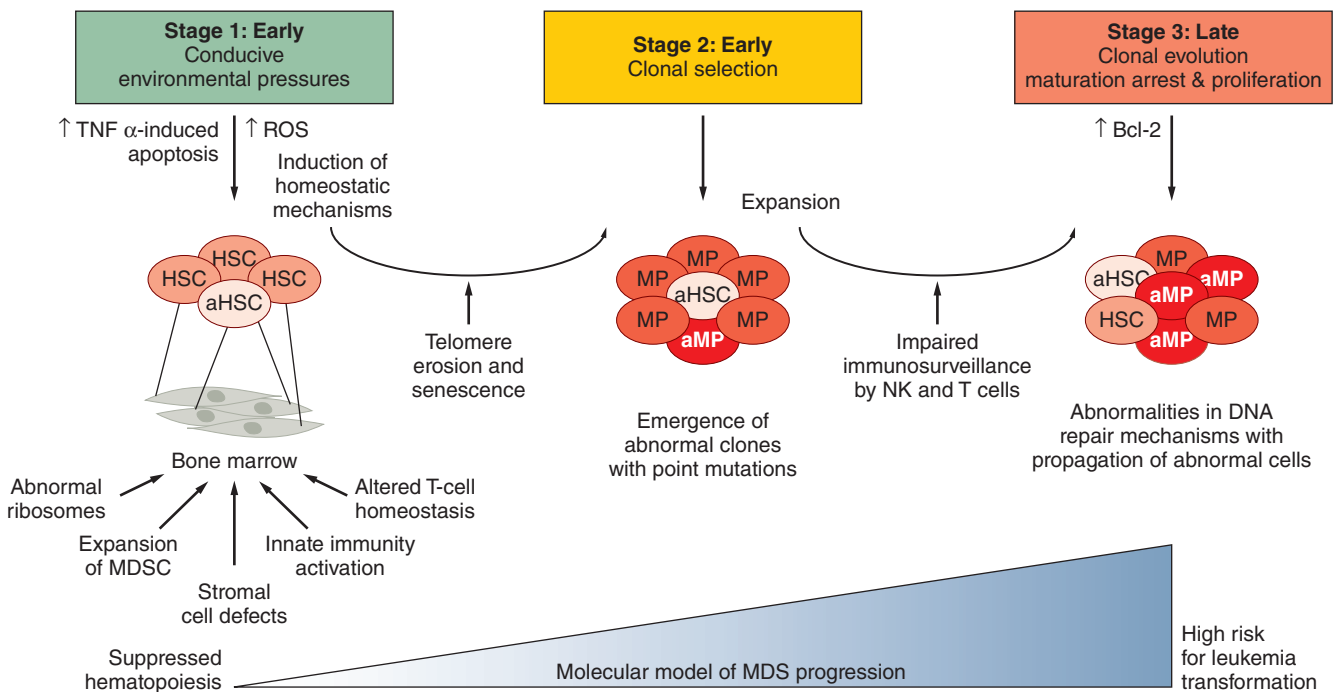

Figure 111.2 Model of MDS progression. TNF α , tumor necrosis factor alpha; ROS, reactive oxygen species; HSC, hematopoietic stem cell; aHSC, abnormal hematopoietic stem cell; MDSC, myeloid derived suppressor cells; MP, myeloid progenitors; aMP, abnormal myeloid progenitor; NK, natural killer. (Modified from Epling-Burnette PK, List AF. Advancements in the molecular pathogenesis of myelodysplastic syndrome. *Curr Opin Hematol* 2009;16:70-76.)

and is an essential component of chromatin remodeling through its interaction with the polycomb repressive complex 2 (PRC2).^{61,62} Deletion and conditional knock-in murine models for both *TET2* and *ASXL1* demonstrate that these lesions are sufficient to induce a myeloid neoplasm akin to MDS.^{61,63,64}

Next-generation sequencing of MDS genomes recently identified genes involved in the regulation of alternative gene splicing.⁶⁵ Subsequent studies have shown that they are among the most common gene mutations in MDS.^{53,54} They appear to occur early in disease pathogenesis, alter RNA splicing, and are prognostically relevant.^{66–68} Interestingly, the two most common mutations involving the splicing factor 3b subunit 1 (*SF3B1*) and serine/arginine-rich splicing factor 2 (*SRSF2*) genes have strong phenotypic linkage with ringed sideroblasts and monocytic expansion (CMML), respectively.^{67,69}

Lastly, the specific type and number of gene mutations directly impacts clinical behavior and risk of progression to AML. Elegant work using whole-genome sequencing to reconstruct the clonal architecture of MDS cases that transform to AML at sequential time points demonstrates that this transformation is associated with the acquisition and expansion of distinct genetic events.⁷⁰ Emerging data, however, suggest that these events do not display complete fidelity. That is, the same genetic events can be responsible for disease initiation, and therefore, disease founding in one case while representing a secondary event in another case with the same diagnosis. Collectively, these and other gene mutations described in Table 111.2 demonstrate that distinct genetic events can result in MDS and are likely the major drivers of the disease and its behavior.

Dysregulation of Immunity as a Driver in MDS

The environmental cues that are conducive to emergence of the genetic events that lead to MDS are unknown. Bone marrow stromal alterations have been implicated, but an intriguing emerging hypothesis that immune dysregulation and associated chronic inflammatory changes may be a critical environmental pressure in MDS pathogenesis. Clinical and laboratory evidence suggests that both adaptive and innate immunity is altered and potentially

contributory to MDS pathogenesis. It is this inflammation that could represent the nidus for mutational acquisition in some patients, or these inflammatory changes are induced by an expanded clone. A recent population-based study demonstrated a strong linkage between chronic immune stimulation and autoimmune disorders with MDS predisposition.²⁶ Several studies confirmed the higher than expected association between MDS and autoimmune disease.^{26,71–73}

Impaired T-cell homeostasis and early senescence is a feature of patients with MDS.⁷⁴ Indeed, up to 50% of T cells are clonal and even more appear to have intrinsic defects in telomerase function, perhaps accounting for their premature senescence.^{75,76} In addition to expansion and senescence, the T-cell receptor (TCR) repertoire appears to be augmented and hematopoietic inhibitory capacity appears to be increased.⁷⁷ Lastly, T-cell characteristics can mark clinical parameters in MDS. For instance, the expansion of effector memory T-regulator cells (T_{regs}) is associated anemia and increased blast percentage, and represents an unfavorable prognostic biomarker.⁷⁸

Activation of innate immunity with consequent nuclear factor kappa B (NF- κ B) induction contributes to the inflammatory microenvironment in MDS.^{79,80} Haplodeficiency of two micro-RNA genes, *miR-145* and *miR-146a*, located within the distal commonly deleted region of chromosome 5q at 5q32, results in constitutive activation of Toll-like receptor (TLR) signaling in del(5q) MDS. Toll-interleukin 1 receptor domain-containing adapter protein (*TIRAP*) and tumor necrosis factor receptor-associated factor-6 (*TRAF6*), which encode key intermediates involved in the MyD88-dependent TLR-signaling pathway, are targets of miR-145 and miR-146a, thereby upregulating their expression with allelic insufficiency. Myeloid-derived suppressor cells (MDSC), potent effectors of innate immunity, are recently recognized as critical cellular effectors involved in the pathogenesis of MDS. MDSCs are markedly expanded in the bone marrow of MDS patients and promote ineffective hematopoiesis. These MDSCs are genetically distinct from the MDS clone, overproduce hematopoietic suppressive cytokines, and also act as potent effectors of apoptosis that target autologous hematopoietic progenitors. MDSC expansion is driven by excess generation of the proinflammatory molecule S100A9, which is a ligand for TLR4. Moreover, a transgenic S100A9 mouse model phenocopies human MDS, displaying bone marrow accumulation of MDSC accompanied by progressive age-dependent multilineage cytopenias and cytologic dysplasia.⁸¹

TABLE 111.2

Spectrum of Genetic Alterations in Myelodysplastic Syndromes

Gene Symbol	Molecular Pathway Affected	Incidence in MDS (%)
<i>ASXL1</i>	Epigenetics	20–25

The 5q Minus Syndrome

The hematologic and pathologic phenotype of the 5q- syndrome is now recognized to be a product of haploinsufficiency of several genes located within the CDR at 5q32.⁸² Among 40 genes residing in the CDR, only inactivation of *RPS14* impaired erythroblast proliferation and viability, whereas corresponding overexpression of *RPS14* was sufficient to rescue erythropoiesis in primary del(5q) MDS specimens.⁸³ Haploinsufficiency for *RPS14* disrupts ribosome assembly, leading to nucleolar stress and sequestration of the human homolog of the mouse double minute 2 protein (MDM2) by free ribosomal proteins, thereby triggering its degradation and p53 stabilization.⁸⁴ A murine model of the human 5q- syndrome generated by allelic deletion of the genes in the human CDR showed that p53 inactivation rescues the hematologic features.⁵² Gene dosage of two dual specificity phosphatases encoded within or adjacent to the proximal CDR at 5q31 (i.e., cell division cycle 25C [Cdc25C] and protein phosphatases 2A catalytic domain alpha [PP2A α]), underlies the selective suppression of del(5q) clones.⁸⁵

CLINICAL PRESENTATION

The most common clinical presentation of MDS is sustained and progressive cytopenia with corresponding symptoms and complications. Macrocytic anemia is the most common hematologic

feature, mandating the exclusion of common causes of anemia and nutritional deficiencies. In one analysis, MDS was the fifth most common cause of anemia in elderly patients after iron deficiency, bleeding, renal insufficiency, and anemia of chronic disease.^{30,86} Thrombocytopenia and/or platelet dysfunction are common in MDS patients, with an overall prevalence ranging from 40% to 65%. Thrombocytopenia is more common in higher risk diseases, but occurs in lower risk patients and can be exacerbated by therapy. The frequency of hemorrhagic death ranges from 14% to 24%.⁸⁷ Bleeding can occur even in the absence of thrombocytopenia attributable to platelet dysfunction as evidenced by a prolonged bleeding time corresponding to an increase in atypical megakaryocytes.⁸⁸

Among all patients with MDS, over one-third will undergo transformation into AML. In the remaining patients, the majority will succumb to infection, in part from neutropenia, iron overload, and granulocyte dysfunction illustrated by impaired phagocytic adhesion, chemotaxis, and microbicidal killing.⁸⁹ Bacterial pneumonias and skin abscesses are most common, but unusual/opportunistic infections such as disseminated *Mycobacterium avium-intracellulare*,⁹⁰ *Aeromonas hydrophila* endocarditis,⁹¹ bacterial thyroiditis,⁹² and Epstein-Barr virus hepatitis may arise.⁹²

MDS patients can also manifest a wide range of autoimmune phenomena such as cutaneous vasculitis, polymyalgia rheumatica, necrotizing panniculitis, Coombs-positive autoimmune hemolytic anemia, sweet syndrome, and a seronegative arthritis.⁹³⁻⁹⁶

In patients with MDS/MPN such as CMML, hepatosplenomegaly, lymphadenopathy, and pleural effusion are manifestations attributed to the proliferative nature of this group.⁹⁷ In patients with RARS-T, the risk of thrombotic events is similar to essential thrombocytosis.⁹⁸

RISK ASSESSMENT AND PROGNOSIS

Risk stratification and prognostic assessment represent a critical first step in the management of MDS (Table 111.3). It provides useful information for the patients as to “the disease forecast” and, more importantly, allows physicians to tailor therapy accordingly. For patients with a higher risk, the goal of therapy is to alter the natural history of the disease and to extend survival. The goal of therapy in lower risk MDS is to alleviate symptomatic cytopenias using treatments that may restore effective hematopoiesis and lessen associated complications. The prognosis will depend on the inherent disease’s specific features and host-related features. Risk models in MDS are constructed by incorporating several validated prognostic variables in a weighted scoring system, permitting patients to be divided into defined risk groups.

The International Prognostic Scoring System

The IPSS remains the most widely used staging system in MDS.⁷ It has been embraced by community oncologists, adopted in clinical trials, and forms the basis of determining the time table for allogeneic hematopoietic cell transplantation in decision models. However, IPSS has several shortcomings. It was not developed as a dynamic system. It does not account for severity of cytopenias, and it overlooks two-thirds of the cytogenetic abnormalities encountered. Moreover, the IPSS is not applicable to patients with MDS/MPN or t-MDS.

The Revised IPSS

The IPSS-R was proposed as a refinement to adjust for those deficiencies of the original IPSS.¹³ The major changes include the incorporation of less common karyotype abnormalities, the prognostic relevance of which was discerned from the larger patient cohort, and the weighing of the severity of each lineage of cytopenia. Several groups have validated the new prognostic system.^{99,100}

The Global M.D. Anderson Scoring System

The Global M.D. Anderson Scoring System (MDAS) incorporates host factors such as age and performance status,¹¹ as well as anemia, transfusion burden, karyotype, and most importantly, the severity of thrombocytopenia. It captures the prognostic impact of leukocytosis for MDS/MPN. This model further refines IPSS. The MDAS upstaged 25% of patients to a higher risk category.¹⁰¹ It can be applied for MDS/MPN cases, as well as t-MDS.

Other risk models that had been utilized and validated include the *Lower Risk M.D. Anderson Scoring System (LR-MDAS)*,¹⁰² and the WPSS, which is more widely used in Europe.¹⁰ For MDS/MPN subtypes, only the MDAS, discussed previously, can be applied. Several other models have been developed specifically for CMML (Table 111.4).

Five gene mutations independently predicted overall survival in a large cohort of MDS patients after adjusting for age and IPSS score.¹⁰³ These five genes include mutations involving *TP53* (hazard ratio [HR], 2.48), *EZH2* (HR, 2.13), *ETV6* (HR, 2.04), *RUNX1* (HR, 1.47), and *ASXL1* (HR, 1.38). In lower risk MDS, *EZH2*, *NRAS*, and *ASXL1* gene mutations upstaged 21% of low/intermediate 1 (int-1) IPSS risk MDS patients.¹⁰⁴ Only the *EZH2* mutation provided additional risk discrimination to upstage 8% of the patients classified by LR-MDAS.¹⁰⁴

The causes of death in MDS include AML transformation in 30% to 40% of all patients (10% to 20% of lower risk MDS patients), whereas the vast majority, unfortunately, succumb due to complications secondary to the disease, namely infection and bleeding.¹⁰⁵ Other important prognostic factors in MDS include red blood cell (RBC) transfusion dependence¹⁰⁶ and elevated serum ferritin >1,000 ng/mL, which is associated with both inferior overall survival and time to AML transformation.¹⁰⁷ Bone marrow fibrosis in MDS is typically associated with a higher risk disease, increased myeloblasts, or complex cytogenetics, and worse outcome. Patients with bone marrow fibrosis are often categorized morphologically as MDS-U or MDS with fibrosis (MDS-F).³⁴

Patients with MDS often suffer from other medical comorbidities that may impact survival, affect performance status, and limit therapeutic options. Using the ACE-27 comorbidity index, the median survival was 31.8, 16.8, 15.2, and 9.7 months for those with none, mild, moderate, and severe comorbidities, respectively ($p < 0.001$). A prognostic model including age, IPSS, and comorbidity score predicted median survival.¹⁰⁸ The Italian group added further refinement by developing an MDS-specific comorbidity index (MDS-CI). Cardiac disease, moderate to severe liver disease, severe pulmonary disease, renal disease, and history of solid tumors were found to independently affect the risk of nonleukemic death, whereas diabetes and cerebrovascular disease did not.¹⁰⁹

MANAGEMENT OF MYELODYSPLASTIC SYNDROMES

Erythropoiesis-Stimulating Agents

More than 90% of MDS patients have anemia, and 30% to 50% are transfusion dependent.¹¹⁰ Erythropoiesis-stimulating agents (ESA) are the most widely used treatment for anemia in lower risk MDS; more than 50% of newly diagnosed and established patients in the United States receive ESA. Response rates range from 15% to 20% in unselected patients receiving doses equivalent to 40,000 to 60,000 U of epoetin alpha weekly.¹¹¹ Treatment lasting 8 to 12 weeks provides an adequate trial to assess ESA responsiveness, with median duration of responses ranging from 12 to 24 months.¹¹² Case-matching studies suggest a survival advantage among erythroid responders.¹¹² Darbepoetin is at least as effective as epoetin alpha.¹¹³ Patient selection improves response probability to ESAs and conserves resources. Using a simple model based on

pretreatment endogenous serum erythropoietin (EPO) concentration (<100, 100 to 500, or >500 U per liter) and RBC transfusion burden (< or ≥2 U per month one would distinguish three response categories: high probability of erythroid response (74%), intermediate (23%), and low (7%).¹¹⁴

Lenalidomide

Lenalidomide is approved by the U.S. Food and Drug Administration (FDA) for the treatment of transfusion-dependent anemia in lower risk MDS patients with a chromosome 5q deletion (del[5q]) with or without additional cytogenetic abnormalities. In the lenalidomide registration (MDS-003) phase II clinical trial, the overall transfusion response rate was 76%, with 67% achieving transfusion independence.¹¹⁵ The median time to response was 4.6 weeks, accompanied by a median rise in hemoglobin (Hgb) of 5.4 g/dL. Median duration of response exceeded 2 years and is longer in patients with isolate del(5q). Lenalidomide was administered at a dose of 10 mg daily either continuously or for 21 days every 4 weeks. Cytogenetic response and hematologic improvement were the strongest independent covariates for overall survival (OS) (HR, 5.295; $p < 0.001$).^{116,117} Recent studies indicate that TP53 gene mutations are demonstrable in approximately 20% of del(5q) MDS patients, expand over time, and are associated with a higher risk of disease progression and a lower frequency of cytogenetic response to lenalidomide.^{118–120}

The most commonly observed adverse event was early myelosuppression, generally occurring in the first 8 weeks of treatment (62%). More than half of the patients (55%) experienced neutropenia, and 44% had thrombocytopenia. Dose reduction or treatment interruption for hematologic adverse events was necessary in the majority (84%) of patients. The median time to first dose reduction was 22 days. At week 24, only 32% of patients were receiving a 10-mg dose. Early cytopenias with lenalidomide treatment correlated with the probability of achieving RBC transfusion

independence.¹²¹ Non-hematologic adverse events include dry skin, rash and pruritus, itching of the scalp, and diarrhea. Hypothyroidism has been reported in approximately 7% of patients.^{122,123} Patients with renal insufficiency were excluded. In such patients, it is prudent to adjust the dosage based on creatinine clearance given the renal excretion of lenalidomide.¹²⁴ The incidence of venous thromboembolic events (VTE) in MDS patients treated with lenalidomide monotherapy was low, with VTE reported in 3% of the del(5q) patients.

A subsequent phase III, placebo-controlled study (MDS-004) compared two different doses and schedules of lenalidomide in the same del(5q) MDS population.¹²⁵ Two hundred and five patients were randomized to receive treatment with either lenalidomide 10 mg daily for 21 days every 4 weeks, continuous treatment with lenalidomide 5 mg daily, or placebo. The rates of sustained transfusion independence (>24 weeks) were 53.6%, 33.3%, and 6%, respectively ($p < 0.001$). Cytogenetic response rates were also highest in the 10-mg arm. The median rise in hemoglobin was highest in patients treated with the 10-mg lenalidomide dose. No difference was observed in the frequency or magnitude of myelosuppression between the two lenalidomide doses, nor was there a difference in the rate of AML transformation.

The use of lenalidomide in lower risk non-del(5q) MDS was explored in a phase II study (MDS-002), which enrolled 214 non-del(5q) patients.¹²⁶ Based on the International Working Group 2000 (IWG 2000) response criteria, 26% patients achieved transfusion independence. Median rise in hemoglobin was 3.2 g/dL, and median duration of response was 41 weeks. Attempts to improve the activity of lenalidomide in non-del(5q) patients include biomarker-guided patient selection and combination strategies with an ESA.^{127,128} Preliminary results of a randomized phase II clinical trial comparing lenalidomide to a lenalidomide/ESA combination yielded higher erythroid response rates with the combination treatment: 23% versus 40%, respectively ($p = 0.043$).

Lenalidomide's mechanism of action in MDS is karyotype specific. In del(5q) MDS, lenalidomide relieves p53 arrest by

stabilizing MDM2 to permit cell cycle reentry by inhibiting the haplodeficient PP2A. The resulting hyperphosphorylation of inhibitory serine/threonine residues on MDM2 suppresses its autologous ubiquitination, thereby stabilizing the protein and, in turn, promoting the proteasomal degradation of p53.⁸⁴ In non-del(5q) MDS, lenalidomide enhances erythroid receptor signaling. The inhibition of PP2A promotes coalescence of lipid rafts with attendant incorporation of the erythropoietin receptor along with its signaling intermediates to yield a more efficient receptor signaling platform.¹²⁹

The use of lenalidomide in higher risk MDS patients remains investigational. Several studies reported modest response rates and rates of transfusion independence.¹³⁰⁻¹³² A high rate of complete response have been reported when combining azacitidine and lenalidomide in higher risk MDS in a phase I/II trial, which is the subject of an ongoing intergroup randomized phase II clinical study.¹³³ Use of lenalidomide in the treatment of MDS/MPN subtypes is often extrapolated from its use in MDS. Nonproliferative lower risk CMML patients were included in the studies summarized previously. Anecdotal case reports suggest lenalidomide activity in patient with the RARS-T subtype.¹³⁴

Azanucleosides

Azacitidine and decitabine are azanucleoside analogs with varied capacity to act as hypomethylating agents (HMA) to reverse epigenetic gene repression. Covalent bonds formed between deoxycytidine nucleotides and DNA methyltransferase deplete the enzyme and, as a consequence, promotes demethylation of silenced genes. These agents also are cytotoxic as DNA interactive nucleoside analogs and, in the case of azacitidine, which is incorporated largely into RNA, by inhibiting RNA translation and protein synthesis.

Azacitidine was the first FDA-approved drug for the treatment of all FAB MDS subtypes.¹³⁵ The overall CR+partial response (PR) rate was 23% (CR, 7%; PR, 16%), with a corresponding extension in median time to AML transformation from 12 to 21 months. The subsequent AZA-001 trial was the first study to demonstrate a survival advantage for any treatment in higher risks MDS.¹³⁶ Patients with intermediate 2 (Int-2) or high-risk MDS (n = 358) were randomized to treatment with either azacitidine or conventional care regimens (CCR) that included either best supportive care (BSC) alone, low-dose cytarabine, or intensive AML-type induction chemotherapy. The median OS was significantly extended in the azacitidine group compared to CCR: 24.5 months versus 15 months, respectively ($p = 0.0001$). AML progression was delayed by more than 14 months with the azacitidine treatment. Hematologic response rates also favored azacitidine, with 45% achieving RBC transfusion independence compared to 11% with CCR. The OS benefit with azacitidine treatment extended to those patients with AML according to the WHO classification (myeloblasts: 20% to 30%). A landmark analysis at cycle four revealed that patients who achieve hematologic improvement (HI) or better response according to IWG criteria experienced a survival advantage.¹³⁷ The probability of HI response, and therefore the potential for survival improvement, diminish with time, reaching less than 15% after 6 months of treatment.¹³⁸ Poor-risk cytogenetics, increased myeloblasts, and prior treatment with low-dose cytarabine are predictive variables for a lower response rate.¹³⁹ The loss of function mutations involving the *TET2* gene is associated with a higher rate of response to azacitidine.¹⁴⁰ In lower risk MDS, nearly 50% of patients achieve HI and/or RBC transfusion independence (TI). The HI rate with treatment with a 5-day regimen appears equivalent to 5-2-2 or 5-2-5 regimens with less toxicity; however, its impact, if any, on OS is unknown.¹⁴¹

Decitabine was FDA approved based on a phase III trial in the United States comparing 15 mg/m² intravenously (IV) administered over 3 hours every 8 hours for 3 consecutive days to BSC in patients with INT-1, -2, and HR MDS.¹⁴² The overall response

rate was 30% with decitabine (9% CR, 8% PR, and 13% HI). Kantarjian et al.¹⁴³ compared three decitabine schedules using a reduced cumulative dosing schedule in a similar population. This study identified 20 mg/m² IV daily for 5 days as the preferred schedule, where the CR rate was 39%. The ADOPT trial was a multicenter validation study involving 99 MDS patients treated with the 20 mg/m² 5-day regimen; the study reported 17% CR with a corresponding median OS of 19.4 month.¹⁴⁴ A subsequent phase III study compared the effects of the FDA-approved decitabine regimen to supportive care in Int-2 and high-risk MDS.¹⁴⁵ The OS and the median time to AML transformation or death were not significantly different from the supportive care (SC) arm.

Outcomes after azanucleoside failure is poor, with median OS ranging from 4 to 8 months, and a 12-month survival of approximately 30%.¹⁴⁶⁻¹⁴⁸ CR rates with standard intensive chemotherapy are 20% or less. Treatment of patients who fail azanucleosides represent an unmet need. Recent data suggest that outcomes are poor after azanucleoside failure in lower risk MDS as well.¹⁴⁹

Small numbers of MDS/MPN patients, namely CMML, were included in the original azanucleoside clinical trials. Large retrospective series suggest similar response rates, but probably an inferior effect on OS. Splenomegaly and leukocytosis are predictors for worse outcomes among CMML patients treated with azacitidine.¹⁵⁰

Immunosuppressive Therapy

HI is observed in approximately one-third of unselected MDS patients treated with antithymocyte globulin (ATG) with or without cyclosporine. Age is the strongest covariate for hematologic response. In a multivariate analysis age, the duration of RBC TD and the presence of a human leukocyte antigen DR15 were independent response variables.¹⁵¹ Other retrospective studies identified bone marrow hypocellularity and the presence of a paroxysmal nocturnal hemoglobinuria clone as covariates for response to immunosuppressive therapy (IST). Rabbit ATG offers comparable effectiveness in treating MDS patients.¹⁵² Alemtuzumab was reported to yield high response rates in preselected patients with the previously described features associated with the probability for response to IST.¹⁵³

Allogeneic Hematopoietic Cell Transplantation

Allogeneic hematopoietic cell transplantation (AHCT) remains the only known curative treatment for patients with MDS. Unfortunately, the majority of MDS patients are not candidates for the procedure due to advanced age or comorbidities, and the procedure itself carries significant morbidity and mortality. With the decision of Medicare to provide coverage with evidence development for the AHCT in MDS patients in 2008, the number of procedures performed in the United States for patients with MDS, particularly those older than 60 years, has significantly increased over the past decade.

Using a markovian decision analysis model, early AHCT is recommended for higher risk MDS patients to maximize survival potential, whereas for lower risk patients, delaying AHCT until disease progression is a strategy that offered best overall survival.¹⁵⁴ A subsequent decision model in the azanucleoside era utilizing data from reduced intensity AHCT and predominantly in elderly patients (60 to 70 years) confirmed the recommendation of early AHCT for higher risk MDS and delayed AHCT for those with a lower risk.¹⁵⁵ No randomized controlled trials, evaluating AHCT versus nontransplant strategies, are available.

The most important predictors of outcome after AHCT are disease status (myeloblasts >5% and poor risk cytogenetics), but not age.¹⁵⁶ A study reported experience involving 1,333 MDS patients >50 years (449 patients >60 years) who underwent HCT. Four-year OS estimates for the 50 to 60 year olds and the <60 years cohort was 34% and 27%, respectively.

The question of therapy prior to AHCT remains controversial. Earlier studies did not show a convincing advantage for induction

chemotherapy prior to AHCT; however, those studies were not randomized and were subject to selection bias by treating higher risk patients with chemotherapy. Among patients who receive intensive chemotherapy, those who achieved CR prior to AHCT had a better outcome. A phase II study evaluated 265 consecutive patients who received an AHCT. There was no difference in 3-year OS whether patients received azacitidine, intensive chemotherapy, or azacitidine preceded or followed by intensive chemotherapy (55% versus 48% versus 32%, respectively; $p = 0.07$).¹⁵⁷ Azanucleosides may also play a role as a maintenance strategy post-HCT. de Lima et al.¹⁵⁸ demonstrated that maintenance therapy with low-dose azacitidine (32 mg/m² for four cycles) is feasible in the post-AHCT setting for recurrent AML or MDS. This strategy is the subject of a prospective randomized clinical trial.¹⁵⁸ An analysis of 435 patients with higher risk MDS who had failed treatment with azanucleosides showed that patients who proceeded to AHCT or investigational agents had better survival compared to those offered supportive care or conventional chemotherapy, whether a low or an intensive dose.¹⁴⁷

Iron Chelation Therapy

Several groups reported that iron overload and elevated serum ferritin in MDS patients is associated with inferior OS and higher rate of leukemia evolution.¹⁰⁷ Nonrandomized studies suggest that iron chelation therapy (ICT) impacts outcomes in lower risk MDS.^{159,160} Two studies showed that the oral iron chelator deferasirox (Exjade) effectively lowered serum ferritin and labile plasma iron concentration in lower risk MDS.^{161,162} Adverse effects from deferasirox may include renal failure, diarrhea, hepatic failure, and gastrointestinal hemorrhage. Deferasirox is contraindicated in patients with a creatinine clearance less than 40 mL per minute, higher risk MDS patients, and in patients with platelet count less than $50 \times 10^9/L$. Deferiprone (Ferriprox) is another oral iron chelator approved in the United States. The adverse effect of greatest concern is agranulocytosis, but it has less renal toxicity.¹⁶³ The MDS foundation recommends the consideration of ICT in transfusion-dependent lower risk MDS patients with serum ferritin persistently $>1,000$ ng/mL, whereas the National Comprehensive Cancer Network (NCCN) guidelines use a $>2,500$ ng/mL threshold. An ongoing randomized phase III, placebo-controlled study (TELESTO) is intended to address the potential clinical benefit of deferasirox chelation therapy.

How Do I Treat MDS Patients?

The first step in the management of MDS requires confirming the diagnosis, which in many instances, may require a hematopathologist's experienced eyes.¹⁶⁴ After establishing a diagnosis, risk stratification is critical for management decisions. We complement the standard IPSS risk model by newer clinical risk models such as IPSS-R and MDAS (or CMML-specific models in cases of CMML), and a molecular profile to more precisely delineate the disease risk category.^{7,11,13,165}

For higher risk patients, we initiate treatment with azacitidine 75 mg/m² SC for 7 days every 28 days and assess patients for hematopoietic stem cell transplant (HCT) in the absence of major comorbidities and a good performance status.¹⁵⁵ For patients who do not proceed to AHCT, we continue treatment until disease progression or loss of response. The response to azacitidine is evaluated after 4 to 6 cycles. If the disease is stable or better, treatment is

continued. Experience from the AZA-001 trial tells us that hematologic improvement is predictive for improved overall survival.^{136,166} In patients with baseline thrombocytopenia and neutropenia, we do not delay therapy or reduce dose, but rather provide more focused supportive care with close hematologic monitoring. We avoid the use of granulocyte-colony stimulating factor (G-CSF) or GM-CSF except in the setting of febrile neutropenia. Combination strategies adding to the backbone of azacitidine are being explored in clinical trials such as the combinations with lenalidomide, vorinostat, or pracinostat.¹⁶⁷⁻¹⁶⁹ Crossing over to the alternate azanucleoside is generally minimally effective.¹⁷⁰ We consider a clinical trial or AHCT for those patients after azanucleoside failure.¹⁴⁷ Several agents are under investigation in patients after azanucleoside failure. A phase III trial with rigosertib, a multikinase inhibitor, recently completed accrual.¹⁷¹ In cases of secondary AML, response rates to standard 3 + 7 induction chemotherapy is disappointing, with short OS. In this setting, we offer patients intensive chemotherapy, preferably in the context of a clinical trial such as the phase III randomized study comparing CPX-351 (liposomal formulation of a 5:1 molar ratio of cytarabine and daunorubicin), which demonstrated promising efficacy in a phase II randomized study.¹⁷² Outside the context of a clinical trial, we favor the use of cladribine, cytarabine, G-CSF, and mitoxantrone (CLAG-M) regimen for induction in secondary AML after azacitidine failure, for which we previously reported a $>50\%$ complete response rate.¹⁷³

In lower risk MDS, anemia remains the most common indication for therapy. In patients with a low endogenous serum erythropoietin level (<500 mU/mL) and low transfusion burden, we begin treatment with an ESA. An 8- to 12-week minimum trial of epoetin alfa is started at a dose of 40,000 to 60,000 U weekly or darbepoetin alfa dose equivalence as sufficient. In the absence of response, and particularly for patients with RARS, we consider the addition of G-CSF.¹¹¹ Subsequent treatment alternatives are guided by the type and severity of additional cytopenias, and include lenalidomide or azacitidine. For non-del(5q) lower risk MDS, lenalidomide may be considered in patients with isolated anemia and adequate platelets and neutrophils.¹²⁶ Use of lenalidomide prior to azanucleosides may yield higher response rates.¹⁷⁴ Lenalidomide in combination with ESA is currently under investigation with promising higher responses than lenalidomide alone.^{127,128} Azacitidine is also used for lower risk MDS patients. We commonly use azacitidine at a dose of 75 mg/m² for 5 days in lower risk patients.¹⁴¹ For MDS patients younger than 60 years of age with a short duration of transfusion dependence, a cluster of differentiation 4 cells (CD4):CD8 ratio <2.0 or those with trisomy 8, immunosuppressive therapy is a reasonable treatment strategy. For lower risk MDS patients with thrombocytopenia or neutropenia, particularly if the goal of treatment is to improve thrombocytopenia, azanucleosides are the treatment of choice or IST if there is a high chance of response. In del(5q) lower risk MDS patients who either failed or are not a candidate for treatment with an ESA, lenalidomide is the treatment of choice in the presence of adequate neutrophil and platelet counts.¹¹⁵ Lenalidomide is administered daily at a dose of 10 mg orally. Complete blood counts are monitored weekly during the first 8 weeks. The vast majority of patients will need dose interruption after 2 to 3 weeks, with resumption of lenalidomide treatment upon hematologic recovery at the next lower dose level. In selected patients with lower risk MDS who are younger and who have no major comorbidities, AHCT may be discussed after failure of standard therapy. In our opinion, clinical trials remain the standard of care for treating MDS patients and should be considered whenever available.

112 Plasma Cell Neoplasms

Nikhil C. Munshi and Kenneth C. Anderson

INTRODUCTION

Plasma cell neoplasms represent a spectrum of diseases characterized by clonal proliferation and the accumulation of immunoglobulin-producing terminally differentiated B cells. The spectrum includes clinically benign common conditions, such as monoclonal gammopathy of unknown significance (MGUS), as well as rare disorders such as Castleman's disease and α heavy chain disease; indolent conditions such as Waldenström's macroglobulinemia; the more common malignant entity, plasma cell myeloma; and a more aggressive form, plasma cell leukemia, with circulating malignant plasma cells in the blood. All of these disorders share common features of plasma cell morphology, production of immunoglobulin molecules, and immune dysfunction. A plasma cell neoplasm is considered to originate from a single B cell, with resultant monoclonal protein secretion that characterizes its type. Occasional oligoclonal or polyclonal protein abnormalities are observed in conditions such as Castleman's disease.

There are five major classes of immunoglobulin (Ig) synthesized by normal B cells and plasma cells: IgG, IgA, IgM, IgD, and IgE. The dysfunctional plasma cells secrete one of these intact immunoglobulin molecules; however, there may be a discrepancy in the production of the heavy and light chains leading to an imbalance with an excess of κ or λ light chain that is excreted in the urine (Bence Jones proteinuria), or in some instances, a production of only excess κ or λ light chain molecules. Occasionally, plasma cells do not secrete any paraproteins (nonsecretory type myeloma); however, they usually have cytoplasmic immunoglobulin and produce low levels of immunoglobulins undetectable by current methods. Although myeloma can be associated with any of the immunoglobulin subtypes, the IgM type is predominately associated with other malignant conditions such as Waldenström's macroglobulinemia and chronic lymphocytic leukemia (CLL).

HISTORY

The earliest evidence of myeloma has been reported from Egyptian mummies; however, the first published clinical description of the disease was reported in 1850 in England. A patient, Thomas Alexander McBean, presented to Dr. William Macintyre of London in 1845 with symptoms of episodic fatigue, diffuse bone pain, and urinary frequency. The urinalysis detected a urinary protein with a peculiar heat property, and Macintyre called it *mollities and fragilitas ossium* due to the patient's bony symptoms.¹ Later that year, Dr. Henry Bence Jones also tested urine specimens provided by Macintyre and corroborated the heat properties of urinary light chains. Bence Jones thought that the protein was the *hydrated deuterioxide of albumin* (now called Bence Jones proteins) and published his findings several years before Macintyre published his case report.² After the patient died in 1846, a surgeon, Dr. John Dalrymple, examined several bones, and his gross and microscopic observations are consistent with morphology of myeloma cells.

The term *multiple myeloma* was coined by Rustizky in 1873 following his independent observation in a similar patient with multiple bone lesions. Kahler, in 1889, published a review on this condition and the disease became known, particularly in Europe, as Kahler's disease.³ Ellinger, in 1899, described the increased serum proteins and sedimentation rate in myeloma. In 1900, Wright described the involvement of plasma cells in this neoplasm and, for the first time, he described roentgenographic abnormalities in myeloma, which to date remain a hallmark of this disease.

The development of bone marrow aspiration in 1929,⁴ electrophoresis to separate serum proteins in 1937,⁵ and a later report of a specific spike in the γ globulin region, enhanced the diagnosis and understanding of myeloma. Identification of the heavy and light chains in the monoclonal protein by immunoelectrophoresis was described by Grabar in 1953, confirming the monoclonality of immunoglobulin in this disease. Other developments in recent times include understanding of the role of the bone marrow microenvironment in myeloma cell growth, survival, and development of drug resistance through cell-cell interactions and activation of cytokine networks.^{6,7} The significance of chromosomal translocations in myeloma pathobiology, and more recently, the use of gene expression profiling and whole genome sequencing, are providing insights into the molecular pathogenesis of the disease.

No effective systemic therapy existed before 1947, when urethane was reported to show an effect in a few patients. However, a subsequent randomized trial indicated that the survival of patients receiving urethane was inferior to that observed with a placebo.⁸ The first successful use of chemotherapeutic agent in myeloma was reported in 1958 by Blokhin and colleagues with the use of a racemic mixture of D- and L-phenylalanine mustards (Sarcocysine). Subsequently, the D- and L-isomers of phenylalanine mustard were tested separately, and the antimyeloma activity was found to reside in the L-isomer, melphalan. In 1962, Bergsagel and colleagues from the Southwest Oncology Group reported remissions in about one-third of myeloma patients treated with melphalan.⁹ The administration of high doses of glucocorticoid was first reported to induce remissions in relapsing or refractory myeloma in 1967.¹⁰ The use of melphalan in combination with prednisone was then studied extensively.¹¹ The role of high-dose therapy was investigated by McElwain in 1983, and the addition of bone marrow and, subsequently, stem cell transplantation improved safety and allowed for further dose escalation.¹² In the last 10 years, an elucidation of the genomic changes driving the disease process, coupled with improved understanding of the role of the bone marrow microenvironment in myeloma biology and the development of drug resistance, has led to the identification of novel targets and directed agents including immunomodulatory drugs, thalidomide, lenalidomide, and pomalidomide; proteasome inhibitors, bortezomib and carfilzomib; inhibitors directed at histone deacetylases, phosphoinositide 3-kinase (PI3K)/Akt signaling; as well as antibodies targeting CS1, CD138, and CD38.

EPIDEMIOLOGY

According to the most recent data from the Surveillance, Epidemiology, and End Results (SEER) program, multiple myeloma (MM) is a relatively uncommon malignancy in the United States, representing 1.4% of all malignancies in Caucasians and 2.0% in African Americans. Among hematologic malignancies, it constitutes 10% of the tumors and ranks as the second most frequently occurring hematologic cancer in the United States after non-Hodgkin's lymphoma. The prevalence of myeloma in the United States in 2011 was over 83,367 and estimated new cases in 2014 are approximately 24,050; 11,090 patients are expected to die from myeloma in 2014. The disease is more common in men and has an average annual age-adjusted (1970 US standard) incidence rate per 100,000 among Caucasians of 7.2 in men and 4.3 in women, whereas for African Americans, the incidence is 14.7 in men and 10.5 in women. The increased incidence in African Americans is not explained by factors such as social or economic condition, household size, or family income.¹³ A study in the African population from Ghana has demonstrated an incidence of MGUS similar to the African American population, possibly implicating genetic risk factors.¹⁴ The incidence rates for other ethnic groups including Asian/Pacific islanders, American Indians, and Alaskan natives are also lower relative to US Caucasians. The Chinese and Japanese populations similarly have a lower incidence than Caucasians. A recent survey of MGUS in 12,481 US patients showed significantly higher ($p < 0.001$) prevalence of MGUS in African Americans (3.7%) compared with Caucasians (2.3%) ($p = 0.001$) or Hispanics (1.8%).¹⁵ The incidence of multiple myeloma has slowly increased in the US Caucasian population since 1970; however, the incidence among African Americans has increased more prominently during the 1970s to 1990s. These observed differences in the prevalence have not been associated with any difference in the disease characteristics, response to therapy, and prognosis of myeloma worldwide.

The incidence of myeloma and other plasma cell disorders increases with advancing age. The median age at diagnosis is 69 years. The mortality pattern also closely follows the incidence curves for age distribution, with a median age at death of 75 years. The proportion of patients surviving at 5 years in 2010 was 45%. As seen in Figure 112.1, fewer than 2% of patients are younger than 40 years, whereas almost 50% patients are older than 70 years. A similar age distribution is also observed in other related plasma cell disorders including MGUS and Waldenström's macroglobulinemia.

ETIOLOGY

Environmental Exposure

Exposure to ionizing radiation is the strongest single factor linked to an increased risk of multiple myeloma.¹⁶ This has been documented in atomic bomb survivors who have a five times greater incidence than a control group with a latent period of approximately 20 years from exposure.¹⁷ People exposed to low levels of radiation also demonstrate an increased incidence of myeloma, including radiologists, employees in the nuclear industry, or those handling radioactive materials. An association between exposure to various chemicals and the risk of multiple myeloma remains ill defined. Exposure to metals, especially nickel; agricultural chemicals; benzene and petroleum products; other aromatic hydrocarbons; agent orange; and silicon have been considered as potential risk factors.^{16,18-20} In contrast, alcohol and tobacco consumption has not been clearly linked to myeloma. Among medications, only mineral oil used as a laxative has been reported to be associated with an increased risk of multiple myeloma in some patients.^{21,22}

Hereditary and genetic factors may predispose patients to myeloma development.^{23,24} Among 37 families with at least two family members who had myeloma, occurrence among siblings was reported in 25 of the families. However, direct genetic linkage has not been established. Myeloma risk also appears to be enhanced by the presence of HLA-Cw2 in both African American and Caucasian populations. In a study in 917 Ghanaian men, the prevalence of MGUS was twice that in Caucasian men, implicating race-related genetic susceptibility in the higher rates of MGUS in African populations.¹⁴ More recently, high throughput genomic studies have identified various novel genomic changes in myeloma with significant clinical implications. A meta-analysis of two genome-wide association studies in myeloma ($N = 1,661$) showed that the $t(11;14)(q13;q32)$ translocation, in which *CCND1* is placed under the control of the immunoglobulin heavy chain enhancer, was strongly associated with the *CCND1* c.870G>A polymorphism ($p = 7.96 \times 10^{-11}$), suggesting a model where a specific chromosomal translocation is associated with a constitutive genetic factor.²⁵ Recently, Genome Wide Association Studies (GWAS) have identified common single nucleotide polymorphisms (SNP) at 2p23.3(rs6746082), 3p22.1(rs1052501), 3q26.2(rs10936599), 6p21.33(rs2285803), 7p15.3(rs4487645), 17p11.2(rs4273077), and 22q13.1(rs877529) to influence MM risk; the same SNPs were also evaluated for MGUS risk and four of these SNPs (rs1052501,

Figure 112.1 Multiple myeloma averages for age-, sex-, and race-specific incidence per 100,000 in United States, 1996 to 2000. An increase in incidence is noted with advancing age, and a higher incidence is observed in males than females and in the African American than in the Caucasian population.

rs2285803, rs4487645, and rs4273077) independently also influenced the development of MGUS. Collectively, these data support the view that genetic variation predisposes one to MGUS, thereby influencing the risk of developing MM.²⁶

MGUS has been considered to be a premalignant condition; however, the rate of conversion to myeloma remains extremely low and is often associated with additional genetic changes.^{27,28} Repeated infections or antigenic stimulation of the plasma cell compartment has also been proposed as a possible predisposing condition for developing myeloma. In one interesting patient report in the literature, a prior therapy with horse antiserum against tetanus led to a subsequent development of MGUS that lasted for 3 decades before conversion to MM. At the time of myeloma diagnosis, the serum IgG component was found to react specifically against horse α -2 macroglobulin.²⁹ This report suggests an initial antigen-driven stimulation of monoclonal protein-producing plasma cells, which eventually became malignant after acquiring additional genetic alterations. MGUS has been observed in mice dependent on strain of mice, age, preexisting immune status, and antigenic stimulation. MGUS has been associated with immune disorders and infectious diseases. In one report of 57 patients with MGUS who had undergone an evaluation for *Helicobacter pylori* infection for various gastrointestinal (GI) symptoms, 39 (68%) had evidence of *H. pylori* infection and 11 of these 39 patients (28%) had normalization of the serum paraproteins following eradication of this infection.³⁰ Seroprevalence of *H. pylori*, however, has not been consistently correlated with MGUS.³¹ Development of MGUS has also been reported with T-cell deficiency disorders as in AIDS.³² Importantly, a recent study indicates that the diagnosis of symptomatic MM is always preceded by MGUS by 2 or more years.³³

Although epidemiologic studies have not been able to conclusively establish an association between MM and infectious or autoimmune diseases, a recent retrospective cohort study in US veterans demonstrated significantly elevated risks of MM in patients with a history of autoimmune, infectious, and inflammatory disorders. Risks for MGUS were generally of similar magnitude. These results indicate that various types of immune-mediated conditions might act as triggers for MM/MGUS development.³⁴ Although an initial report suggested the presence of the human herpes virus 8 (HHV8; Kaposi's sarcoma herpes virus) in the bone marrow dendritic cells of the majority of patients with MM,³⁵ analogous to its association with other lymphoproliferative diseases such as Castleman's disease,³⁶ body-cavity lymphoma,³⁷ and Kaposi's sarcoma,³⁸ other investigators have failed to identify HHV8 in myeloma cells or dendritic cells from various sources including mobilized peripheral blood stem cells.³⁹⁻⁴² Because HHV8 produces unique gene products, including possible growth promoting factors for myeloma such as analogs of interleukin 6 (IL-6), insulin-like growth factor 1 (IGF-1), and an IL-8, the possible linkage of HHV8 to myeloma was intriguing. However, even antibodies against HHV8 have not been observed in MM.⁴³

PATHOGENESIS

MM is a germinal center-derived tumor with a mainly postswitch B-cell phenotype characterized by extensive Ig gene hypermutation in a pattern suggesting antigen selection. This is reflected in the exceedingly rare occurrence of IgM myeloma. Somatic mutations of other loci, such as B-cell lymphoma 6 (BCL-6), have also been reported in myeloma B cells, along with characteristic immunoglobulin gene rearrangement.⁴⁴ Similar mechanisms may be affecting other cell-cycle control genes whose products regulate cell proliferation and malignant transformation.

As in most malignancies, the pathogenesis of MM appears to be associated with dysregulated expression and function of multiple key cellular genes controlling apoptosis, cell growth, and proliferation. Understanding the evolution of myeloma from MGUS

has provided a background for a multistep process involving alterations in various oncogenes and tumor suppressor genes.⁴⁵ In one study, the presence of 14q32 abnormalities were reported in patients with MGUS, and the addition of chromosome 13 change was associated with a transformation to overt MM.⁴⁶ This led to a theory that a subset of myeloma may derive from prior MGUS with a high incidence of monosomy 13, versus a second group of de novo myeloma in which other genetic abnormalities may be involved.⁴⁶ However, two recent reports suggest that all myelomas are preceded by MGUS^{33,47} and that a small subset of MGUS carry del(13) along with t(4;14), which is not associated with an increased rate of progression to myeloma.^{48,49} In one study in patients with smoldering myeloma, high-risk chromosomal aberrations (del(17p13), t(4;14), and +1q21) were observed in 35.9% of patients and predicted adverse prognostic factors for the progression to active myeloma, independent of tumor mass. Moreover, hyperdiploidy, which in myeloma is considered to be a low-risk feature, was present in 43.3% of smoldering and indolent multiple myeloma (SMM) patients and was an adverse prognostic factor.⁵⁰

Myeloma occurs not only in humans, but also in mice, canines, and hamsters. In fact, genetic susceptibility to plasma cell tumors has been demonstrated in an inbred strain of mice. A common factor in various species has been the prevalence of endogenous retroviruses.^{51,52} Animal models are now providing a basis for understanding the role of activation of oncogenes and tumor suppressor genes, cytokines, and the role of the bone marrow microenvironment in promoting and sustaining myeloma cell growth.

Cytogenetic and Molecular Genetic Alterations

Myeloma karyotypes are complex, with an average of 11 numeric and structural abnormalities per cell.⁵³ The relative incidence of gain or loss of various chromosomes with involved p and q arms are shown in Figure 112.2. The low proliferative activity of the tumor cells and possible clonal evolution have been obstacles to the identification of specific chromosomal and molecular changes in myeloma. The frequency and complexity of the chromosomal aberrations increases with advanced disease, and is uniformly abnormal in plasma cell leukemia. The detection of a complex karyotype predicts for poor prognosis. The newer techniques of multicolor fluorescent in situ hybridization (FISH) and spectral karyotyping, along with refined G-banding techniques, have identified many nonrandom changes in a large number of patients.⁵⁴⁻⁵⁶ Using these techniques, over 90% of patients have involvement of at least one chromosome. A substantial fraction of MGUS plasma cells are also reported to have aneuploidy. By FISH analysis, the incidence of trisomy for at least one chromosome was reported in over 40% of MGUS cells.⁵⁷ The characteristic numerical abnormalities are monosomy 13 and trisomies of chromosomes 3, 5, 7, 9, 11, 15, and 19.

The most frequent structural abnormality involves chromosome 1 and the immunoglobulin heavy chain gene at 14q32. By conventional cytogenetics, the 14q32 region is involved in translocation in 20% to 40% of cases, and by molecular and FISH techniques it is detectable at higher frequency, ranging from 50% in MGUS to 90% in advanced myeloma.^{53,58,59} The demonstration of this abnormality in MGUS suggests its involvement in the initial step of transformation.^{46,60,61} Light-chain translocations involving Ig λ (22q11) or Ig κ (2p12) are less commonly observed, with only 20% of cases even in advanced MM. The most common translocation involving 14q32 results in the overexpression of cyclins D1 (on 11q13) and D3 (on 6p21).^{58,62} The other biologically important partner chromosomes are 4p16 (fibroblast growth factor receptor 3 [FGFR3]) and multiple myeloma SET domain [MMSET]), 16q23 (c-MAF), and 20q11 (MAFB) (Table 112.1). Other recurrent partner loci less frequently identified include 8q24 (c-myc) in less than 5% cases, 18q21 (bcl-2), (11q23 mixed lineage leukemia 1 [MLL-1]), and 6p21.1. The 4p16 region con-

(Courtesy of J. R. Sawyer.)

tains *FGFR3* and *MMSET* genes. *FGFR3* and its activating mutations trigger mitogen-activated protein (MAP) kinase signaling and growth of myeloma cells.⁶³ Mutated *FGFR3* also confers resistance to caspase 3–related apoptosis.^{64–66} This translocation also activates the *MMSET* gene, a homolog of *MLL1*, which is also independently involved in 11q23 translocation. With the enhanced sensitivity of spectral karyotyping, a nonrandom involvement of

t(14;16) (q32;q22-23) has been described. A molecular analysis of the locus at chromosome 16q22 shows fusion of the immunoglobulin heavy chain with the sequence near the *c-MAF* oncogene, a b-ZIP transcription factor.⁶⁷ Additionally, translocation partners t(9;14) involving the paired box gene 5 (*PAX-5*) and t(6;14) involving interferon regulatory factor 4 (*IRF4*) gene have been described.^{68,69} In the majority of cases, however, the translocating

partner chromosome locus is not yet identified. Although 14q32 is one of the common translocations, its role in myeloma pathogenesis remains unclear due to the variety of partner chromosomes involved and its lack of prognostic significance.

Standard cytogenetics techniques did not identify rearrangements involving 8q24, which contains the *c-MYC* oncogene and is commonly involved in murine plasmacytoma. However, FISH analyses in one study identified karyotypic abnormalities that involve *c-MYC* in 45% cases of advanced myeloma.⁷⁰ Another study using interphase FISH confirmed *c-MYC* rearrangement in 15% of MM cases, with increasing frequency correlating with severity of disease. Interestingly, *c-myc* involvement is heterogeneous, suggesting its role in the evolution of disease.⁷¹ Changes in *c-MYC* in the form of either abnormal size transcript or high level of expression have been reported in a majority of patients in one study.^{72,73}

A deletion of chromosome 13 or 13q arm identified by conventional karyotyping confers a poor prognosis, even after high-dose therapy.⁷⁴ Using the *RB1* gene as a probe, a FISH analysis reveals *RB1* deletion in >40% of these patients.⁷⁵ In a detailed analysis of the 13q chromosome using an 11 probe FISH panel, >80% of 50 patients showed molecular deletions, with 13q14 representing a critical region most frequently involved.⁷⁶ Additionally, constitutive phosphorylation of retinoblastoma (pRB) in myeloma cells can be further enhanced by IL-6.⁷⁷ Cyclin D, cyclin-dependent kinases (CDK), and CDK inhibitors p15 and p16 (ink), p21 and p27 (cip), and p57 (kip), have also been investigated in myeloma due to their effect on pRB phosphorylation. Abnormalities in p16 and p15 have been reported in 75% and 67% of myeloma patients, respectively, suggesting an important defect in the pRB regulatory pathway.⁷⁸⁻⁸⁰

Mutations involving Ras are observed in about 39% of newly diagnosed MM patients, and are more frequently observed following progressive disease. Activating mutations of the ras oncogenes may also result in growth factor independence and the suppression of apoptosis in MM. One of the commonly altered genes in many malignancies is p53. In myeloma, abnormalities in p53 are detected in less than 10% of patients with early stage disease.^{81,82}; however, p53 abnormalities represent an important late event associated with progression to an aggressive form of the disease. A study of p53 gene mutations in 52 patients with myeloma showed 7 of 52 patients to have p53 abnormalities, all with a clinically advanced and aggressive acute/leukemic stage of MM.⁸¹ Murine double minute 2 (MDM2), an important inhibitor of p53 function, is overexpressed in the majority of myeloma cell lines; however, increased MDM2 expression is infrequently observed in primary myeloma cells.⁸³

An important antiapoptotic gene, *BCL-2*, is uniformly overexpressed in low-grade non-Hodgkin's lymphoma. In this family of genes, *BCL-2* and *BCL-XL* are antiapoptotic genes, whereas *BAX*, *BAD*, and *BCL-XS* are proapoptotic genes. A balance between these genes determines cell survival. The t(14:18) translocation involving the *BCL-2* gene is quite rare (2% to 3%) in myeloma. However, numerous myeloma cell lines as well as primary cells, express high levels of *BCL-2*.^{84,85} Its relationship to development of drug resistance, as well as radiation resistance in myeloma cells is also well described.^{86,87} One study in 63 patients showed a significant correlation between *BCL-2* expression and resistance to therapy with interferon, but not melphalan and prednisone.⁸⁸ The association of *BCL-2* expression with prognosis remains controversial, as one small study failed to show a correlation with short survival. *BCL-XL* is upregulated in myeloma cells as a consequence of IL-6-induced activation of signal transducers and activators of transcription 3 (STAT-3).⁸⁹ It confers a drug-resistant phenotype and, in conjunction with *bcl-2*, leads to increased genetic instability. *Mcl-1*, another antiapoptotic gene, is overexpressed in MM and is upregulated by IL-6. Its overexpression mediates potent resistance to apoptosis, and conversely, its downregulation by antisense oligonucleotide triggers apoptosis. Finally, *Bcl-6* expression in MM cells is induced by its interaction with BMSC and is modulated, at least in part, via Janus kinase (JAK)/STAT-3 and canonical nuclear factor kappa B (NF- κ B) pathways, and targeting *Bcl-6*, either directly or via these cascades, inhibits MM cell growth in the bone marrow (BM) milieu.⁹⁰

High telomerase activity has also been demonstrated in myeloma cells, relative to normal cells and other malignant cell lines.⁹¹ Telomerase activity confers growth and survival in MM, and is therefore an additional target for therapeutic intervention.

Transcriptional and Genomic Studies

Gene expression profiling, as well as studies focused on relative gains or loss of genomic DNA, have provided both prognostic and therapeutic information in MM. Molecular diagnostic tools and novel therapeutics now offer the potential for more accurate prognosis and personalized treatment.

The expression profiling studies in MM have provided insight into the progression of MGUS to MM, and provided the basis to predict outcome, as well as to identify potential therapeutic targets.⁴⁵ Expression studies have identified subtypes within the nonhyperdiploid group associated with specific chromosomal translocations.⁹² A comprehensive expression profiling the survey of uniformly treated MM patients has identified 70 genes predictive of early disease-related death. Interestingly, one-third of these genes are located on chromosome 1, confirming the potential significance of chromosome 1 in MM pathobiology.⁹³ Patients with a high risk score using this gene signature had significantly shorter complete response (CR) duration (20% patients at 3 years) compared to those patients without such high risk features (60% at 5 years). A multivariate discriminant analysis identified a 17-gene signature that performed as well as the 70-gene model. A second large study by the Intergroupe Francophone du Myelome (IFM) group studied gene expression profiles in 182 newly diagnosed patients and developed a 15-gene model to calculate a risk score associated with overall survival. In this study, the high-risk group had an overexpression of cell cycle progression and its surveillance-related genes, whereas a hyperdiploid signature and heterogeneous gene expression characterized low-risk patients. Overall survival at 3 years in the low-risk group was 91% versus only 47% in the high-risk group, and these results were independent of traditional prognostic factors.⁹⁴ In a recent study in 320 newly diagnosed myeloma patients from the Dutch-Belgian/German HOVON-65/GMMG-HD4 trial, gene expression profiling identified a 92-gene signature and 10 subgroups in MM, which may represent unique diagnostic entities with potential novel therapeutic targets.⁹⁵ Additional expression profile studies have begun to define subtypes of myeloma with different prognostic significance following various therapies. An apparent lack of uniformity in the genes identified by these investigations suggests that therapy-related factors may determine the influence of different classes of genes in MM. Based on cytogenetics as well as expression data, cyclin D dysregulation occurs in the early pathogenesis of MM.

A high-resolution analysis of recurrent copy number alterations, coupled with expression analyses in MM cell lines and primary MM cells using array comparative genomic hybridization (aCGH), has identified distinct genomic subtypes. Additionally, this study has defined 87 discrete minimal common regions that have identified gene candidates for targeted drug discovery, improved the understanding of MM initiation and progression, and improved the prediction of clinical outcomes (Fig. 112.3). A high-density, SNP array analysis of myeloma cells from 192 newly diagnosed patients identified genomic copy number alteration in 98% of patients.⁹⁶ Amplifications in 1q and deletions in 1p, 12p, 14q, 16q, and 22q were the most frequent lesions associated with adverse prognosis, whereas amplifications of chromosomes 5, 9, 11, 15, and 19 were linked to a favorable prognosis. Amp(1q23.3), amp(5q31.3), and del(12p13.31) have been identified in a multivariate analysis to be independent prognostic factors. This prognostic model was validated in an independent validation cohort of 273 patients with myeloma, and identified patients with amp(5q31.3) alone and low serum beta-2-M to have an excellent prognosis (5-year overall survival, 87%) versus patients with del(12p13.31)

Figure 112.3 An array-based comparative genomic hybridization analysis evaluating 55 cell lines and 73 patient samples identified recurrent areas of gains and losses in multiple myeloma (MM) with the potential for understanding biology and validating target genes, which will then be potential therapeutic targets.

alone or amp(5q31.3) and del(12p13.31) and high serum beta-2-M with a poor outcome (5-year overall survival, 20%).

Epigenetic changes modulating myeloma cell growth and survival genes are also reported. For example, methylation of *p16*, a negative cell cycle regulator, is common and reported to be an early event even in MGUS. However, p16 methylation was not predictive of overall survival in a single large cohort study. The acetyl-lysine recognition domains (bromodomains) of putative coactivator proteins have been shown to play a significant role in transcriptional initiation and elongation as well as chromatin-dependent signal transduction. The bromodomain and extraterminal (BET) bromodomain proteins have been identified as regulatory factors for c-Myc expression in myeloma, and their inhibition induces antiproliferative effects associated with cell-cycle arrest and cellular senescence in both in vitro and in vivo models.⁹⁷ A recent global methylation analysis (N = 159) of purified myeloma cells has identified prognostically important, epigenetically inactivated tumor suppressor genes. In this analysis, the combination of DNA methylation and gene expression profile identified hypermethylated *GPX3*, *RBPI*, *SPARC*, and *TGFBI* genes to be associated with significantly shorter overall survival, independent of other high-risk features such as International Staging System (ISS) stage or adverse cytogenetics.⁹⁸

A role of microRNAs (miR) and potential therapeutic targeting of multiple mRNAs has recently been described in myeloma. miRNA expression profiling of MM and MGUS cells compared to normal donor plasma cells identified the overexpression of miR-21, miR-106b, and miR-181a and b in MM and MGUS samples, as well as selective upregulation of miR-32 and miR-17-92 in MM, but not in MGUS.⁹⁹ Another study analyzed the expression level of miRs and the gene expression profile in 60 newly diagnosed myeloma patients, and identified significantly dysregulated miRs expression in cytogenetically distinct subtypes.¹⁰⁰ The putative targets and their function are now being defined (e.g., miR-192, 194, and 215), which are downregulated in a subset of newly diagnosed myeloma, are transcriptionally activated by p53 and then modulate MDM2 expression. In addition, miR-192 and 215 target the IGF pathway, prevent the enhanced migration of plasma cells into bone marrow, and are positive regulators of p53, suggesting that their downregulation plays a key role in myeloma pathogenesis.¹⁰¹ Recently, a role for miR-21,¹⁰² miR-29,¹⁰³ and miR-34a¹⁰⁴ in

supporting myeloma cell growth and survival have been defined, suggesting their potential as novel therapeutic targets.

Mutational changes in myeloma have now been evaluated using whole genome sequencing. An initial report using massively parallel sequencing of 38 tumor genomes and their comparison to matched normal DNAs identified several new oncogenic mechanisms based on the pattern of somatic mutations across the data set. These include mutations of genes involved in protein translation (seen in nearly half of the patients), histone methylation, and blood coagulation as well as NF- κ B signaling, evidenced by mutations in 11 members of the NF- κ B pathway.¹⁰⁵

Using high-resolution SNP arrays (N = 24), clonal content and evolution was evaluated in myeloma. This analysis suggested selection and growth of genetically distinct subclones, which were not initially competitive against the dominant population but survived following therapy, with new acquired anomalies and subsequent outgrowth. These data point to the need to target and eradicate even a minor clone.¹⁰⁶ Recently, whole exome sequencing, copy number profiling, and a cytogenetics analysis performed in 84 myeloma samples have identified new candidate genes, including truncations of *SP140*, *Lymphotoxin-beta (LTB)*, *roundabout*, *axon guidance receptor, homolog 1 (ROBO1)*, and clustered missense mutations in early growth response protein 1 (*EGR1*). A further analysis revealed a complex subclonal structure including subclonal driver mutations. Serial sampling was performed in 15 patients, which revealed diverse patterns of clonal evolution: linear evolution, differential clonal response, and branching evolution. Diverse processes contributing to the mutational repertoire including kataegis and somatic hypermutation have been identified, and their relative contribution changed over time. This study demonstrates that the myeloma genome is heterogeneous, with clonal diversity at diagnosis and further evolution over time.¹⁰⁷

Microenvironment and Cell Signaling

Myeloma cells express adhesion molecules that mediate interaction with the microenvironment, including both bone marrow stromal cell elements and extracellular matrix proteins (Table 112.2). These adhesion molecules mediate both homotypic and heterotypic adhesion. Adhesion not only plays a role in migration and

localization of myeloma cells in the bone marrow, but also induces tumor cell growth and survival. For example, syndecan-1, a cell surface transmembrane heparan sulfate proteoglycan present on MM cells, interacts with type I collagen, and regulates growth of MM cells; it also mediates increased osteoclast activity.^{108,109} Elevated levels of syndecan-1 shed into serum correlate with increased tumor mass, decreased matrix metalloproteinase-9 activity in the serum, and a poor prognosis.¹⁰⁸

The BM microenvironment consists of a variety of cell types including stromal cells (BMSC), endothelial cells, osteoclasts, osteoblasts, as well as immune cells. The physical interaction between myeloma cells and these cells in the BM milieu plays a crucial role in MM pathogenesis both by direct adhesion-mediated signaling, as well as by secretion of factors such as IL-6, IGF-1, vascular endothelial growth factor (VEGF), B-cell activating factor (BAFF), fibroblast growth factor (FGF), stromal cell-derived factor (SDF) 1 α , and tumor necrosis factor alpha (TNF- α), which mediate tumor cell growth, survival, drug resistance, and migration.^{110–114} These interactions lead to the activation of several proliferative/antiapoptotic signaling cascades in MM cells: PI3K/Akt, Ras/Raf/mitogen-activated protein kinase (MAPK) kinase (MEK)/extracellular signal-related kinase (ERK), JAK 2/STAT-3, and NF- κ B pathways. These pathways lead to MM cell growth, survival, antiapoptosis, migration, and development of drug resistance. Additionally, adhesion as well as cytokines secreted from MM cells and accessory cells in turn further augment cytokine secretion from these cells.

Activation of NF- κ B has been noted in myeloma cells, especially following their interaction with BMSC. A number of abnormalities contributing to the dysregulation of NF- κ B and constitutive activation of the noncanonical NF- κ B pathway have recently been described.¹¹⁵ Elevated expression of NF- κ B-inducing

kinase (NIK) due to genomic alterations or protein stabilization, and inactivating mutations of TNF receptor-associated factor 3 (TRAF3) able to trigger both classical and alternative NF- κ B pathways have been reported.¹¹⁶ These alterations activating the NF- κ B pathway may allow MM cells to achieve autonomy from the bone marrow microenvironment.¹¹⁷

Each accessory cell in the BM milieu contributes differently to the overall effect of the microenvironment. The biologic and clinical relevance of increased angiogenesis, although established in solid tumors, has only recently been appreciated in hematologic malignancies. Increased bone marrow microvessel density (MVD) has been reported in MM patients compared to individuals with MGUS.^{118–120} Moreover, the degree of MVD myeloma BM has been correlated with the prognosis.^{121,122} Immunohistochemical studies show that the angiogenic factor VEGF is expressed by MM cells.¹²³ Hepatocyte growth factor, which also promotes angiogenesis, is increased in the serum of myeloma patients and predicts for poor outcome, especially in patients with increased β 2 microglobulin levels.¹²⁴ Finally, novel agents such as thalidomide inhibit angiogenesis and can also overcome drug resistance in myeloma. Plasmacytoid dendritic cells (pDC), another component of the BM microenvironment, support MM cell growth, survival, and drug resistance, as well as mediate the immune deficiency characteristic of MM. Therefore, targeting pDC–MM interactions represent a therapeutic strategy to both overcome drug resistance and restore immune function in MM.¹²⁵

Role of Cytokines

Myeloma cells and BMSCs produce cytokines including IL-6,¹¹⁰ IGF-1,¹¹⁴ VEGF,¹¹² SDF-1,¹¹⁵ TNF- α ,¹¹¹ TGF- β ,¹²⁶ IL-21,¹²⁷ and others that mediate tumor cell growth, survival, antiapoptosis, migration, and the development of drug resistance.

Interleukin 6

IL-6 is an essential growth and survival factor for myeloma. The IL-6 receptor expressed by myeloma cells is composed of two polypeptide components: the α chain (gp80, IL-6R α) and the signal transducing β chain (gp130). The gp130 component is shared by a family of cytokines including oncostatin M and leukemia inhibitory factor. The interaction of IL-6 with its receptor activates Ras/RAF/MEK/ERK, JAK/STAT, and PI3K/Akt signaling pathways, mediating growth, survival, and drug resistance (Fig. 112.4). IL-6 is mainly produced by stromal cells following the binding of myeloma cells and is also triggered by other cytokines including TNF- α ,¹¹¹ IL-1 β VEGF, and IL-17 in the BM milieu.¹¹² IL-6 mediates both autocrine and paracrine growth of myeloma cells. It increases the proportion of cells in S phase, prevents apoptosis of malignant plasma cells, and confers resistance to antitumor agents such as dexamethasone (Dex). Soluble IL-6R α , shed by myeloma cells into the serum, can amplify the response of myeloma cells to IL-6; both high serum IL-6R α levels and high serum IL-6 levels portend a poor prognosis. IL-6 and soluble IL-6R α also mediate enhanced bone resorption by osteoclasts. To date, IL-6 has been targeted therapeutically using antibodies specific for IL-6 or its receptor. However, these treatment approaches have produced only transient responses in a small number of patients.

Insulin-like Growth Factor 1

IGF-1 is a growth and survival factor for human MM, which activates PI3K and MAPK signaling pathways mediating proliferation and antiapoptosis.^{128,129} It induces more potent protection against Dex than does IL-6. IGF-1 upregulates FLICE-like inhibitory protein (FLIP), X-linked inhibitor of apoptosis (XIAP), and Bcl-2-related protein A1 (A1/Bfl1),¹²⁸ and increases telomerase activity, thereby further enhancing tumor cell growth and survival.¹³⁰ IGF-1 also mediates the adhesion and migration of myeloma cells via β 1-integrin.¹¹⁴ These studies have identified IGF-1 as a novel therapeutic target; both antibodies and small molecule inhibitors against IGF-1 have been investigated in preclinical studies.

Growth of the MM cell in the BM microenvironment

Figure 112.4 The interaction and adhesion of multiple myeloma (MM) cells to the bone marrow (BM) stromal cells (BMSCs) leads to adhesion- and cytokine-mediated signaling. MM cell binding to BMSCs induces the activation of p42/44 mitogen-activated protein kinase (MAPK) and nuclear factor kappa B (NF- κ B) in BMSCs. The activation of NF- κ B upregulates adhesion molecules on BMSCs. Cytokines secreted through this interaction includes interleukin-6 (IL-6) secretion, tumor necrosis factor α (TNF- α), and vascular endothelial growth factor (VEGF) to activate the main signaling pathways (p42/44 MAPK, Janus kinase (JAK)/signal transducer and activator of transcription 3 (STAT3) and/or phosphatidylinositol 3-kinase (PI3K)/Akt and their downstream targets, which triggers MM cell growth, survival, and migration.

The RAS/RAF/MAPK kinase (MEK)/MAPK pathway mediates the proliferation of MM. JAK/STAT3 along with upregulation of BCL- X_L and MCL1 mediates survival. PI3K/Akt through downstream activation of BAD and NF- κ B, and/or inactivation of caspase-9 mediates antiapoptosis. NF- κ B and forkhead in rhabdomyosarcoma (FKHR) modulate cyclin D and KIP1, thereby regulating cell-cycle progression. Signaling through PI3K induces downstream protein kinase C (PKC) activity and MM cell migration. ICAM1; intercellular adhesion molecule 1; LFA1, lymphocyte function-associated antigen 1; muc1, mucin 1; VCAM1, vascular cell adhesion molecule 1; VLA4, very-late antigen 4; IGF1, insulin-like growth factor-1; IL, interleukin; SDF-1 α , stromal-cell-derived factor-1 α . (Adapted from Hideshima T, Mitsiades C, Tonon G, et al. Understanding multiple myeloma pathogenesis in the bone marrow to identify new therapeutic targets. *Nat Rev Cancer* 2007;7:585.)

Vascular Endothelial Growth Factor

VEGF has only modest proliferative effects on myeloma cells; however, it plays a more important role in triggering tumor cell migration and angiogenesis.^{131,132} Its production in the BM milieu is upregulated both by myeloma cell adhesion to BMSCs and by IL-6.¹³³ Because it is a specific endothelial cell mitogen, elevated levels in myeloma may account, at least in part, for increased angiogenesis.¹²³ Myeloma cells express fms-related tyrosine kinase 1 (FLT1), and VEGF triggers its phosphorylation and activation of downstream MEK and protein kinase C (PKC) signaling. These data have provided the preclinical rationale to evaluate VEGF as a therapeutic target. Although PTK787, a potent inhibitor of VEGF receptor, has shown antimyeloma activity in vitro,¹³⁴ it has not shown clinical activity.

Other Cytokines

TNF- α is secreted by myeloma cells and does not have any significant direct effect on myeloma cell growth and survival; however, it induces the secretion of IL-6 by BMSCs. It is also a strong inducer of NF- κ B activation, thereby upregulating adhesion molecules, with resultant binding of myeloma cells to BM and cell adhesion-mediated drug resistance (CAMDR). Although specific antibody inhibitors of TNF- α have not shown a clinical response, thalidomide and its immunomodulatory drug (IMiD) analogs have potent anti-TNF- α activity and can overcome CAMDR.

SDF-1 is expressed by BMSCs, and its receptor CXCR4 is expressed by myeloma cells. It induces only a minimal proliferative effect; however, it plays a more important role mediating migration.

TGF- β is produced by MM cells and induces the secretion of IL-6 by BMSCs; it also contributes to immunosuppression, which is characteristic of myeloma.

Increased serum levels of IL-17, IL-21, IL-22, and IL-23, the proinflammatory cytokines associated with Th17 cells, are also observed in myeloma. IL-17 promotes myeloma cell growth and adhesion to bone marrow stromal cells, as well as contributes to bone disease in myeloma. In combination with IL-22, it also inhibits the production of Th1-mediated cytokines including interferon gamma (IFN- γ).¹³⁵ IL-21 induces proliferation and inhibits apoptosis independent of IL-6 signaling. It triggers phosphorylation of Jak1, Stat3, and Erk1/2 (p44/42 MAPK). TNF- α upregulates expression of both IL-21 and IL-21 receptor (IL-21R).

DRUG RESISTANCE

Intrinsic and acquired resistance of plasma cells to conventional chemotherapy is common, and as a result, only 50% of patients achieve a partial response, with few complete responses to melphalan. Drug resistance is mediated by several mechanisms.¹³⁶ An altered intracellular drug concentration may be due to overexpression of the MDR1 gene, encoding for P-glycoprotein, an integral membrane protein that functions as an ATP-dependent drug efflux pump, a multidrug resistance-associated protein (MRP), and a lung resistance-related protein (LRP), a member of the class of major vault proteins.¹³⁷ To date, however, strategies targeting these mechanisms have not been successful in overcoming drug resistance. Recently, mechanisms operative in inducing resistance to proteasome inhibition have been identified that have included upregulation or activation of Hsp90, Akt, and aggresomal protein degradation. Downregulation of Cereblon or lack of degradation of IKZF1 or 3 has been shown to mediate resistance to immunomodulatory agents.

Phenotype

Myeloma cells display heterogeneous cell surface phenotypes, with differences both between different patients and within the same patient at different disease stages. In general, all myeloma cells express high levels of CD38, with immature plasma cells additionally expressing CD45 and the IL-6 receptor.¹³⁸⁻¹⁴⁰ More mature myeloma cells do not express CD45 and lack IL-6 receptor expression.¹⁴¹ A subpopulation of myeloma cells may also express CD10, CD56, or CD49e (very late activation antigen 5 [VLA5]).¹⁴¹⁻¹⁴³ CD28 expression is associated with more aggressive disease¹⁴⁴; CD20 expression is present on 20% to 30% of myeloma patients, and can be further upregulated with IFN- α .¹⁴⁵ The identity of the myeloma stem cell still remains an enigma. B cells expressing CD19 and CD11b can be induced to mature on stromal cells into monotypic plasma cells, suggesting that this cellular compartment may contain myeloma cell progenitors.^{146, 147} Using allele-specific oligonucleotide polymerase chain reaction (PCR) and the severe combined immunodeficiency (SCID)-hu model, the myeloma stem cell will be better defined in the future. These cell surface characteristics have also allowed for the development of eight color flow cytometries to measure minimal residual disease.

Immune Status

Myeloma patients present with suppressed immune function due to a variety of factors. Most significant is the suppression of uninvolved immunoglobulins (e.g., in patients with IgG myeloma, there is suppression of serum IgA and IgM levels).¹⁴⁸ The factors causing this suppression include a direct effect of monoclonal immunoglobulin, increased soluble Fc receptor or Fc expressing cells, suppression of helper cell functions, monoclonal Ig, and macrophage-related factors that affect B-cell maturation to plasma cells.¹⁴⁹ The recovery of uninvolved immunoglobulins to normal

levels following effective therapy has been associated with both improved survival and protection from infectious complications.

The total T-cell count may be decreased; however, in a substantial number of patients, it may be normal, with no significant changes in CD8 cells.¹⁵⁰⁻¹⁵² A stage-dependent suppression of natural killer (NK) cells has been observed.¹⁵³ Deficiency of CD4 helper cells is also pronounced.¹⁵⁴ In one study, the proliferation and frequency of Epstein Barr virus (EBV)- and influenza A (inf A)- specific T cells was significantly reduced in a cohort of 24 newly diagnosed or conventionally treated MM patients when compared with 19 healthy individuals, suggesting an impaired response of CD8+ T cells in MM patients.¹⁵⁵ Although a defect in NK T-cell function has also been detected in patients with progressive myeloma compared to patients with MGUS or nonprogressive disease,¹⁵⁶ invariant NK T cells from myeloma patients can be activated and expanded in vitro.¹⁵⁷ Dysfunctional T regulatory cells have been associated with disturbed immune homeostasis in both MGUS and MM.¹⁵⁸ Elevated levels of IL-17 producing Th17 cells, possibly related to high IL-6 and transforming growth factor beta (TGF- β) expression, have also been described in myeloma, and promote myeloma cell growth, immune suppression, and osteoclast function.¹⁵⁹ CD11b(+)/CD14(-)/HLA-DR(-/low) CD33(+)/CD15(+) myeloid-derived suppressor cells (MDSC) are a heterogeneous, immature myeloid cell population that is also significantly increased in both the peripheral blood and the bone marrow of patients with active MM; these cells both induce MM growth and suppress T-cell-mediated immune responses.¹⁵⁹

Anti-idiotypic T-cell response has been demonstrated in the majority of patients, with higher Id-specific T-cell frequency in MGUS and early stages of myeloma compared to advanced disease.¹⁶⁰ This observation has led to a provocative hypothesis that immunologic response plays an important role in controlling the proliferation of the malignant clone in early stages of the disease, whereas loss of immune regulation is associated with evolution to an overt or more aggressive form of the disease. These data also provide the scientific basis to induce idiotype-specific T-cell responses for therapeutic application through either vaccination in vivo or the production of idiotype- or myeloma-specific cytotoxic T lymphocytes (CTL) in vitro.¹⁶¹

Murine Models

Three different models of murine myeloma have been described to study myeloma pathogenesis. In an inbred C57BL/Ka strain of mice, 16% spontaneously developed monoclonal gammopathies without tumor formation by 2 years.^{51,52,162} In another model, BALB/c mice with a low spontaneous incidence of monoclonal gammopathies, the induction of plasmacytoma or myeloma is observed after the intraperitoneal injection of mineral oil or pristane.⁵¹ Plasmacytomas, which develop within the oil, or other foreign body-mediated granulomas and lymphoplasmacytic infiltration can be blocked by the administration of indomethacin and accelerated by subsequent infection of the mice with Abelson's virus. Interestingly, however, the C57BL/Ka strain, with a high incidence of spontaneous monoclonal gammopathies, is relatively resistant to the induction of plasmacytoma by mineral oil. Plasmacytoma progression is associated with the dysregulated expression of *c-myc* as a result of translocation analogous to t(8;14) in humans. These plasmacytomas produce IgA immunoglobulins, and a growth factor present in the peritoneal fluid has been confirmed to be IL-6. Additionally, when animals are raised in a germ-free environment, the incidence of myeloma after mineral oil stimulation is markedly reduced, whereas that of other lymphoid neoplasms increases.⁵¹ These studies suggest an important role of immune stimulation in myeloma development. A third model uses subcutaneous growth of murine plasmacytoma cell lines such as MOPC11 in immunocompetent mice, which allows for the study of immune modulation.

Human myeloma cell lines can grow and disseminate in a SCID mouse model, providing a unique opportunity to study this disease in an *in vivo* setting.¹⁶³ The introduction of fetal human bone into SCID mice (SCID-hu) has allowed for the engraftment and proliferation of the stromal cell–dependent human myeloma cell line,¹⁶⁴ as well as primary human myeloma cells^{165,166} in >80% mice and the monitoring of tumor burden by the detection of human myeloma–specific protein (soluble IL-6 receptor) or human Ig and light chains in murine blood samples, respectively. In this murine model of primary human disease, the fetal bone undergoes osteoporotic and osteolytic change as a consequence of clonotypic plasma cell proliferation and production of human cytokines. This model provides a unique opportunity to study the importance of stromal cell–myeloma cell interactions, as well as genetic and molecular mechanisms critical for myeloma growth and dissemination *in vivo*, and may provide clues to the origin of myeloma stem cells, thereby providing the opportunity to evaluate new treatment approaches targeting the myeloma cell and its microenvironment and bone disease in myeloma. A transgenic Eu-directed X-box Binding Protein-1 (XBP-1) spliced isoform mouse model has been generated in which mice develop features of MGUS and progress to MM.¹⁶⁷ XBP-1 is a transcription factor that is required for plasma cell differentiation, which is expressed at high levels in MM cells versus normal plasma cells.¹⁶⁸ This model provides a unique opportunity to study the biology of human myeloma and assess novel therapies *in vivo*. Recently, conditional MYC transgene expression has been demonstrated in Vk*MYC mice, which eventually develop an indolent multiple myeloma with features characteristic of human disease. This model serves to highlight the role of *myc* in myeloma and provides a unique animal model to test therapeutic or preventative strategies in myeloma.¹⁶⁹

CLINICAL MANIFESTATIONS

Patients with MM may be entirely asymptomatic and diagnosed on routine blood work or may present with a myriad of symptoms such as hematologic manifestations, bone-related problems, infections, various organ dysfunctions, neurologic complaints, or bleeding tendencies (Table 112.3). These signs and symptoms result from direct tumor involvement in BM or extramedullary plasmacytomas, the effect of the protein produced by the tumor cells deposited in various organs, the production of cytokines by the tumor cells or by the BM microenvironment, and effects on the immune system.

TABLE 112.3

Clinical Features of Multiple Myeloma

Symptoms	Common Cause
Bone pain	Pathologic fracture
Easy fatigue	Anemia, high serum IL-6, therapy
Nausea and vomiting	Renal failure, hypercalcemia
Recurrent infections	Low uninvolved Ig, T cell dysfunction, therapy
Paraplegia	Cord compression
Confusion and CNS symptoms	Hyperviscosity or hypercalcemia
Peripheral neuropathy	Nerve compression, amyloidosis, POEMS, immune-mediated effects, therapy induced

CNS, central nervous system; Ig, immunoglobulin; POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes.

Anemia

A normochromic normocytic anemia is usually observed in myeloma patients due to tumor cell involvement of the marrow as well as inadequate erythropoietin responsiveness. The suppressive effects of various cytokines on erythropoiesis and the effect of renal dysfunction on erythropoietin production are also contributing factors. High immunoglobulin levels exacerbate the anemia due to dilutional effects. Anemia gives rise to fatigue, weakness, and occasionally, shortness of breath. Erythropoietin (Epo) administration is, therefore, an important supportive care therapy for patients with symptomatic anemia. In one study, improvement in hemoglobin by more than 2 g per deciliter was observed in 60% of treated patients, and responses were more frequent in patients with low Epo levels than in patients with normal or high levels (72% versus 20%).

Renal Failure

Nephropathy is one of the serious adverse complications that can be observed at the time of clinical presentation. The etiology of renal failure can be multifactorial. The most common cause is the development of light chain tubular casts leading to interstitial nephritis (myeloma kidney).¹⁷⁰ Another common cause of renal dysfunction is hypercalcemia leading to osmotic diuresis, volume depletion, and prerenal azotemia. Other modes of kidney involvement in myeloma include light chain deposition disease, which is more commonly associated with kappa light chain proteins and impaired glomerular filtration; AL amyloidosis, which is more frequently associated with lambda light chain (especially lambda light chain subtype VI) and may have an initial presentation as nephrotic range proteinuria; and renal calcium deposition, leading to interstitial nephritis.^{171–173} The presence of lambda light chains in the urine is also more commonly associated with myeloma kidney. Bence Jones proteins bind to a common peptide segment of Tom-Horsfall glycoprotein to promote heterotypic aggregation and deposition in the kidney.¹⁷⁴ Additional factors exacerbating renal failure in myeloma patients include the use of nonsteroidal anti-inflammatory drugs for pain control, hyperuricemia, nephrotoxic chemotherapeutic agents, intravenous contrast for radiographic studies, bisphosphonate therapy, as well as calcium deposition and stones in the kidney. The proteinuria observed in patients with amyloidosis is more often nonspecific, which can help to differentiate it from typical myeloma-related kidney disease characterized by excessive light chain excretion.¹⁷⁵ Pathologic renal changes similar to human myeloma–related nephropathy develop in IL-6 transgenic mice expressing IL-6 under metallothionein-1 promoter, indicating a relationship between constitutive high IL-6 expression in the liver, dysproteinemia and long acute-phase response, and renal changes.¹⁷⁶

Hypercalcemia and Bone Disease

The mechanism of bone abnormalities in myeloma, especially destruction, is an unbalanced process of increased osteoclast activity and suppressed osteoblast activity. These changes are due to an increase in osteoclast-activating factors produced predominantly by the BM microenvironment and also by myeloma cells.^{177,178} These factors include IL-1 β , TNF- β (lymphotoxin), IL-6, and macrophage inflammatory proteins-1 (MIP-1) alpha.^{179–182} The receptor activator of nuclear factor kappa B ligand (RANKL) plays an important role in osteoclast differentiation via its receptor located on the osteoclast membrane. A member of the TNF family, it was originally described as a factor secreted by T cells, which induces maturation of dendritic cells. RANKL is also secreted by stromal cells and osteoblasts and induces differentiation and maturation of osteoclast progenitors. Moreover, its production is elicited by factors such as parathyroid hormone (PTH), PTH-related peptide (PTHrP), and OAFs.^{178,183} Osteoprotegerin (OPG) acts as a decoy receptor for RANKL,^{184,185} and has been implicated in the

development of bone changes in myeloma. Additionally, a recently identified soluble factor produced by myeloma cells, DKK-1, inhibits osteoblast activity and is being therapeutically targeted.^{186,187} Similarly, activin A, a TGF- β family member that induces osteolysis by inhibiting osteoblast differentiation via SMAD2-dependent distal-less homeobox-5 downregulation, is now being targeted therapeutically.¹⁸⁸

All of these factors contribute to the development of osteoporosis and lytic bone lesions. Radiographic findings of such destruction are shown in Figure 112.5. These bone changes frequently involve the vertebral column and result in compression fractures, lytic bone lesions, and related pain.

A new onset of back pain or other bone pain is a frequent presenting symptom in myeloma patients. Changes in the cytokine milieu and bone destruction may also lead to the development of hypercalcemia, which is observed in approximately 25% of patients at some stage of the disease. Symptoms of high calcium include mental status changes, lethargy, constipation, and vomiting. High paraprotein levels, low albumin levels, or both are commonly observed in patients with myeloma, and require measurement of ionized calcium. Hypercalcemia may also contribute to renal failure and should, therefore, be considered an oncologic emergency requiring prompt intervention.

Infections

Myeloma patients are at risk for developing recurrent bacterial infections due to deficiencies in both humoral and cellular immunity.^{149,189,190} Various factors including high monoclonal immunoglobulin levels, soluble Fc receptor in serum, and TGF- β lead to the suppression of B-cell function, which in turn leads to

depressed uninvolved immunoglobulins.^{126,191} This impairment in the patients' ability to mount humoral responses predisposes patients to infections with bacteria that are ordinarily opsonized by antibodies against bacterial antigens. Patients also have profound T-cell dysfunction due to various immunosuppressive cytokines such as TGF- β and IL-6 secreted by the microenvironment and fas ligand, which is present on the membrane of myeloma cells. Additional causes of immune suppression include programmed death-ligand 1 (PD-L1) and programmed cell death protein 1 (PD-1) expression on MM cells and MM T cells, respectively, as well as increased T-regulatory cells in MM. The therapy for myeloma, especially high-dose corticosteroids, increases infection-related risks in these patients. Therapy with bortezomib is also associated with a higher frequency of herpes zoster.¹⁹² The highest risk of infection is within the first 2 months of initiation of therapy, as well as in patients with renal failure and in those with relapsed and refractory disease. Recurrent bacterial, fungal, and viral infections in myeloma require prompt diagnosis and treatment with additional prophylactic measures while receiving immunosuppressive therapy. Infections are an important cause of morbidity and the most common cause of death in patients with myeloma.¹⁹³

Neurologic Symptoms

The most common cause of neurologic abnormalities is related to a tumor mass effect, especially compression of the spinal cord or cranial or spinal nerves. This may present as motor or, less frequently, sensory neuropathy. An interesting constellation of symptoms described as POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) is observed in osteosclerotic myeloma with prominent

Figure 112.5 The biology of bone destruction in multiple myeloma (MM): **1.** MM cells adhere to stroma. **2.** Stromal cells secrete osteoclast activating factors (OAFs). **3.** OAFs elicit stroma and osteoblasts to secrete receptor activator of NF- κ B ligand (RANKL). **4a.** DKK-1 produced by myeloma cells blocks osteoblast activity. **4b.** RANKL is blocked by osteoprotegerin (OPG); OPG levels are reduced in MM due to syndecan trapping OPG. **4c.** Excess RANKL is available to stimulate osteoclast differentiation and maturation. **5.** Increased osteoclastic activity leads to increased cytokine release from the bone matrix. **6.** These cytokines stimulate MM cell growth, which increases process number 1. **7.** These cytokines also cause a release of parathyroid hormone-related protein (PTHrP) from MM cells, which activate stromal cells to secrete additional RANKL. TGF, tumor growth factor; FGF, fibroblast growth factor; IGF, insulin-like growth factor; PDGF, platelet-derived growth factor; IL, interleukin; TNF, tumor necrosis factor.

sensory neuropathy.^{194–197} The biologic and cellular basis of these manifestations is not yet well understood. Additionally, neurologic symptoms may occur as a consequence of hypercalcemia or hyperviscosity. Leptomeningeal involvement in myeloma with manifestations involving the central nervous system (CNS) has been described, usually in the late phase of the disease and associated with high-risk chromosomal abnormalities, plasmablastic morphology, and extramedullary manifestations.^{198,199} Paraneoplastic CNS syndromes have also been described, possibly related to an immune mechanism directed at proteins present in the CNS, including the cerebellum. Peripheral neuropathy in myeloma may be due to an infiltrative process associated with the deposition of amyloid protein in the paraneural or *vasa nervorum*; due to a metabolic abnormality such as hypercalcemia, uremia, or hyperviscosity; or mediated by an autoimmune process or cytokines.²⁰⁰ Peripheral neuropathy is also observed in patients with MGUS and more frequently associated with IgM paraprotein. More recently, peripheral neuropathy has been observed frequently with therapeutics, including thalidomide and bortezomib, especially with their prolonged use.

Hyperviscosity

The M components in myeloma can cause hyperviscosity and compromise circulation when the serum immunoglobulin levels exceed certain levels. The incidence is highest in Waldenström's macroglobulinemia with IgM, followed by IgA myeloma (25% patients), and is least common in IgG myeloma (<10% patients).^{201–205} It can also be observed when immunoglobulins have a self-aggregating property leading to increased viscosity—for example, the IgG3 subclass is more commonly associated with hyperviscosity.²⁰⁴ The syndrome is usually observed when serum viscosity exceeds 4.0 centipoise (cP) units relative to normal serum and manifests with circulatory compromise involving the CNS, the kidneys, and the lungs; it may also be associated with bleeding complications. Due to varying characteristics of idiotypes, the same level of increased viscosity may produce different severities of symptoms in individual patients. A high level of suspicion for this syndrome is important in any patient with paraproteinemia and either mental status changes or pulmonary distress, because prompt plasmapheresis can alleviate symptoms and avoid irreversible organ damage.

Coagulopathy

Myeloma patients may acquire coagulation abnormalities related to a high level of paraprotein interfering with the normal coagulation cascade or exhibit specific antibody activity leading to a clinical syndrome similar to acquired deficiency of factor VIII.^{205,206} Additional factors, such as thrombosis in capillary circulation associated with hyperviscosity and anoxia, may lead to coagulation-related complications in 15% of patients with IgG myeloma and in more than 33% of patients with IgA myeloma. Although platelet counts are not suppressed in the early stages of myeloma, functional abnormalities of platelets have been described and may also contribute to bleeding.

Acquired activated protein C resistance is reported as a common single transitory baseline coagulation abnormality associated with venous thromboembolism (VTE) in myeloma patients.²⁰⁷ Additionally, patients may also present in a hypercoagulable state related to acquired deficiencies in protein S, or lupus anticoagulants leading to thromboembolic complications.²⁰⁸ The Fab fragment of the myeloma protein binds to fibrin and may prevent its aggregation.²⁰⁹ Factor X deficiency is reported in patients with systemic AL amyloidosis²¹⁰; however, an inhibitor has not been demonstrated in vitro to account for this manifestation.

Therapy may also increase the hypercoagulable state in myeloma. An increased incidence of deep venous thrombosis (12% to 24%) is observed in patients taking thalidomide and lenalidomide,

especially along with dexamethasone or other combination chemotherapies. In one study, 12 out of 50 patients (24%) receiving thalidomide developed deep vein thrombosis (DVT), compared to 2 out of 50 (4%) patients receiving identical therapy without thalidomide.²¹¹ Activated protein C resistance in the absence of factor V Leiden mutation and high serum homocysteine levels are associated with an increased risk of thrombotic complications with thalidomide.²¹²

Extramedullary Disease

Extramedullary disease manifestations are uncommon in patients with myeloma at presentation. However, such manifestations have been observed more frequently in the setting of advanced stage disease or relapse following allogeneic transplantation. In a large study of 1,965 patients, primary extramedullary plasmacytoma was detected in 66 patients and secondary plasmacytoma was detected in 35 patients. The most common sites for extramedullary disease at diagnosis were the skin and soft tissues, whereas liver involvement was most prominent at relapse or progression. Extramedullary involvement may be suspected in patients who have more aggressive features of myeloma, including high lactate dehydrogenase levels, immunoblastic morphology, high tumor cell labeling index, and complex karyotypic features.²¹³ In the 70- and 80-gene risk models, it is associated with high-risk features and shorter survival.²¹⁴

Diagnosis

As myeloma patients present with a variety of symptoms not specific to the disease, the diagnosis of myeloma is quite often delayed. An older patient with a new onset of unexplained back pain or bone pain, recurrent infection, anemia, or renal insufficiency should be screened for myeloma. Additional findings, including hyperproteinemia or proteinuria, anemia, hypoalbuminemia, low immunoglobulin levels, or marked elevation of erythrocyte sedimentation rate, should prompt for a further complete evaluation for a diagnosis of plasma cell myeloma.

The first step in the evaluation includes tests to confirm the presence, type, and quantity of monoclonal protein, as well as the detection and quantification of clonal plasma cells (Table 112.4). The second component to differentiate MGUS, SMM versus symptomatic myeloma is to identify end organ damage by performing a hemogram to detect anemia, a complete skeletal radiographic survey to detect bone lesions, and a chemistry profile to detect renal dysfunction and hypercalcemia. The diagnostic criteria for MGUS, SMM, and active MM are shown in Table 112.5.²¹⁵ A third component in the investigative workup involves an evaluation of prognostic variables including markers of tumor burden, genomic profiles, and therapy-related changes. Guidelines by the International Myeloma Workshop and National Comprehensive Cancer Center Network summarizes the standard investigative workup in myeloma.^{216,217}

Protein Electrophoresis

Among patients with myeloma, 70% have IgG, 20% have IgA, and 5% to 10% have production of monoclonal light chains only. A small proportion (less than 1%) of patients produce monoclonal IgD, IgE, IgM, or have nonsecretory myeloma. The suppression of uninvolved immunoglobulins (e.g., IgM and IgA in IgG myeloma) is present in a majority of the patients at diagnosis. Suppression of all three major classes of immunoglobulins should raise the possibility that the patient may have light chain–only disease, IgD or IgE myeloma, or nonsecretory disease. Patients producing intact immunoglobulin can also have excess light chain production and excretion in the urine (Fig. 112.6). The distribution of κ and λ light chains in the majority of myeloma cases is similar, except in

IgD myeloma in which the λ light chain is more common. Currently, there is no difference in therapeutic approach between the different types of myeloma; however, patients with IgA myeloma, despite a higher initial response rate, have inferior survival.

Myeloma plasma cells usually produce a single, abnormal, and unique monoclonal antibody with a constant isotype and light-chain restriction. Rare occurrences of biclonal and triclinal cases have been reported at the time of diagnosis.²¹⁸ Occurrence of isotype switch and the appearance of abnormal protein bands have been reported in myeloma patients after treatment, especially high-dose therapy,²¹⁹ which appears to be related to the recovery of normal immunoglobulin production rather than alteration in disease biology. This change is also associated with improved survival. Occasionally, patients with initial intact Ig production relapse with only Bence Jones proteinuria (light chain escape) or nonsecretory disease, and this change has been correlated with more aggressive disease.²²⁰

A further analysis of a unique variable region in the myeloma-related idiotype (e.g., CDRIII) provides information on the monoclonal nature of the protein and also provides a tool to investigate minimal residual disease.²²¹

Serum Free Light and Heavy/Light Chain

The measurement of serum free light chain (FLC) concentration has become an important tool to diagnose and follow the disease process, including response to therapy. It is especially useful in patients with light chain–only disease, oligo or nonsecretory myeloma, renal disease, amyloidosis, and as a prognostic marker, in MGUS and SMM, where an abnormal kappa/lambda free light chain ratio predicts a higher likelihood of progression to active myeloma.^{222–226} Recently, a novel heavy/light chain (HLC) assay has been developed to quantitate the different light chain types of each immunoglobulin class (e.g., IgG κ , IgG λ , IgA κ , and IgA λ), which has been applied for both response assessments²²⁷ and for prognostication.²²⁸ For example, in a study where both HLC and FLC testing was utilized in 156 patients with IgG or IgA myeloma, the HLC ratio identified the presence of disease in 8 out of 31 patients with CR by conventional criteria.

Bone Marrow Examination

Various degrees of BM infiltration are observed in myeloma, with the majority of patients having an excess number of plasma cells. The pattern of BM involvement (diffuse versus nodular) is important, because patients with nodular disease seem to have poorer outcomes (in contrast to CLL).²²⁹ The morphology of the plasma cell seems to be an important factor determining the severity of the disease. This is based on a histologic examination (Bartl grade) in which grade I suggests a slow growing disease, whereas grade III represents plasmablastic disease with an aggressive course.²³⁰ There is also an increased incidence of cytogenetic abnormalities in patients with higher grade disease. Plasma cells contain cytoplasmic immunoglobulins with a constant heavy and light chain, which can be evaluated by a flow cytometric analysis or immunohistochemical staining of plasma cells.²³¹ When coupled with DNA staining using propidium iodide, a two-parameter analysis can detect changes in DNA content in myeloma cells (Fig. 112.7). DNA aneuploidy is observed in the BM of more than 80% patients, suggesting the existence of chromosomal abnormalities in the majority of patients.²³¹ This analysis also provides an objective marker to evaluate the response to therapy and to distinguish reactive from clonal plasmacytosis, especially in nonsecretory disease. A hypodiploid tumor cell has also been associated with refractoriness to standard-dose therapy.

Radiographic Evaluation

The radiographic survey of bone still remains a standard diagnostic evaluation, which shows osteopenia in an early phase of the disease and lytic punched out lesions associated with increasing tumor burden (Fig. 112.8). Osteosclerotic lesions are observed in POEMS syndrome.^{194,196} Due to the predominant osteoclastic activity with osteoblastic inactivity, bone scans are seldom positive and are therefore not useful in the diagnosis of MM.

As demineralization of bone (osteoporosis) is one of the common manifestations of myeloma, measurement of bone mineral density (BMD) by dual-energy X-ray absorptiometry (DEXA) is an important evaluation at diagnosis.²³² In a study of 66 patients at diagnosis, the majority of the patients had decreased BMD with lumbar mean BMD value (Z score) -1.24 ± 1.45 . Following standard-dose therapy, lumbar BMD increased by 0.7%, whereas, in a group treated with high-dose therapy, the improvement was by 4.6% ($p = 0.02$).²³³ Similar improvements in BMD have also been noted in patients undergoing high-dose therapy with the addition of bisphosphonates.²³⁴ Differential effects of pamidronate on cortical and cancellous bone have been described in patients with myeloma undergoing autotransplants.^{233,234}

TABLE 112.5**Diagnostic Criteria for Multiple Myeloma, Myeloma Variants, and Monoclonal Gammopathy of Unknown Significance²¹⁵****Monoclonal Gammopathy of Undetermined Significance (MGUS) or Monoclonal Gammopathy, Unattributed/Unassociated (MG[u])**

M protein in serum <30 g/L

Bone marrow clonal plasma cells <10%

No evidence of other B-cell proliferative disorders

No myeloma related organ or tissue impairment (no end organ damage, including bone lesions)

Asymptomatic Myeloma (Smoldering Myeloma)

M protein in serum >30 g/L and/or

Bone marrow clonal plasma cell ≥10%

No related organ or tissue impairment (no end organ damage, including bone lesions) or symptoms

Symptomatic Multiple Myeloma

M protein in serum and/or urine*

Bone marrow (clonal) plasma cells* or plasmacytoma

Related organ or tissue impairment (end organ damage, including bone lesions)

*If flow cytometry is performed, most plasma cells (>90%) will show a neoplastic phenotype.

Solitary Plasmacytoma of Bone

No M protein in serum and/or urine*

Single area of bone destruction due to clonal plasma cells

Bone marrow not consistent with multiple myeloma

Normal skeletal survey (and MRI of spine and pelvis if done)

No related organ or tissue impairment (no end organ damage other than solitary bone lesion)*

*A small M component may sometimes be present

Nonsecretory Myeloma

No M protein in serum and/or urine with immunofixation

Bone marrow clonal plasmacytosis ≥10% or plasmacytoma

Related organ or tissue impairment (end organ damage, including bone lesions)

Extramedullary Plasmacytoma

No M protein in serum and/or urine*

Extramedullary tumor of clonal plasma cells

Normal bone marrow

Normal skeletal survey

No related organ or tissue impairment (end organ damage including bone lesions)

*A small M component may sometimes be present.

Multiple Solitary Plasmacytomas (± Recurrent)

No M protein in serum and/or urine*

More than one localized area of bone destruction or extramedullary tumor of clonal plasma cells, which may be recurrent

Normal bone marrow

Normal skeletal survey and MRI of spine and pelvis if done

No related organ or tissue impairment (no end organ damage other than the localized bone lesions)

*A small M component may sometimes be present.

Myeloma-Related Organ or Tissue Impairment (End Organ Damage) (ROTI)

Calcium levels increased: serum calcium >0–25 mmol/L above the upper limit of normal or >2–75 mmol/L

Renal insufficiency: creatinine >173 mmol/L

Anemia: hemoglobin 2 g/dL below the lower limit of normal or hemoglobin <10 g/dL

Bone lesions: lytic lesions or osteoporosis with compression fractures (MRI or CT may clarify)

Other: symptomatic hyperviscosity, amyloidosis, recurrent bacterial infections (more than two episodes in 12 months)

MRI, magnetic resonance imaging; CT, computed tomography.

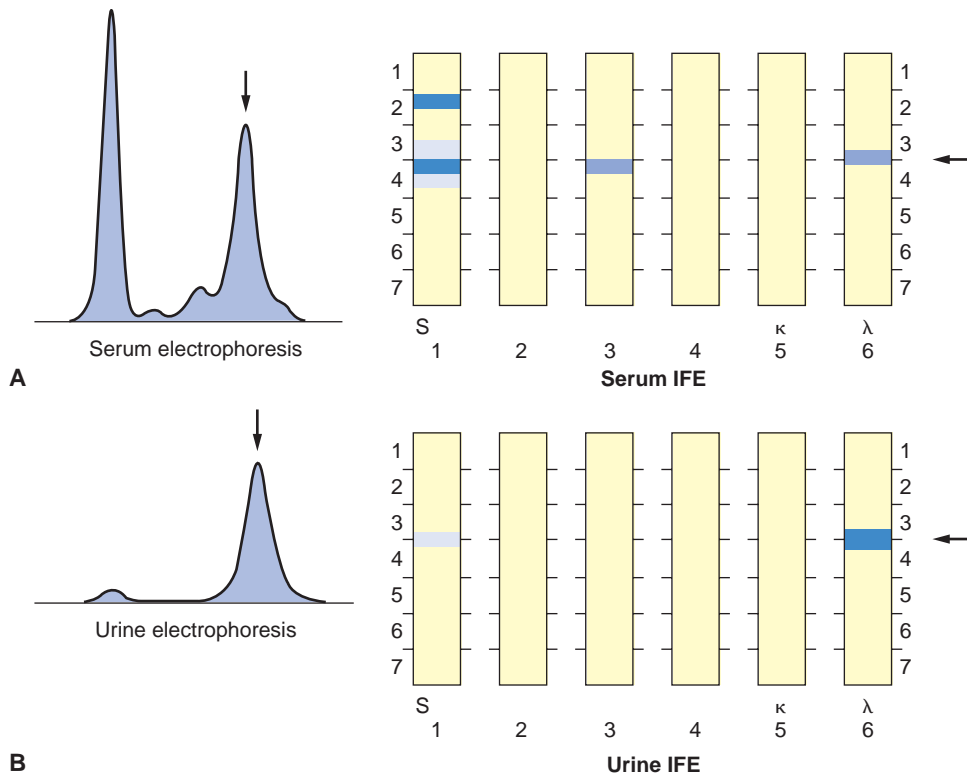

Figure 112.6 A: Serum (top) and urine (bottom) protein electrophoresis showing abnormal monoclonal protein bands (arrow). Quantitation of the M protein is performed by nephelometric measurement of the band. **B:** Identification of serum (top) and urine (bottom) M component by immunofixation technique. The labels indicate the specificity of the antiserum used in developing the immunofixation pattern. The top is IgA- γ in serum and the bottom is free γ light chain in urine

Magnetic resonance imaging (MRI) of bone marrow provides a better assessment of tumor burden. More than 95% of myeloma patients have MRI abnormalities: one-third each have diffuse involvement of the bone marrow, focal lesions, or heterogeneous focal and diffused marrow involvement (Fig. 112.9A). Because myeloma is a macrofocal disease, random BM sampling may not

be diagnostic or predictive of disease status, and MRI short tau inversion recovery images (STIR) may provide a better assessment of bone marrow involvement in myeloma.²³⁵⁻²³⁷ An MRI of the spine and pelvis is required in all patients with a solitary plasmacytoma and SMM, both to detect occult lesions and to predict progression. In symptomatic myeloma, an MRI can be considered as a

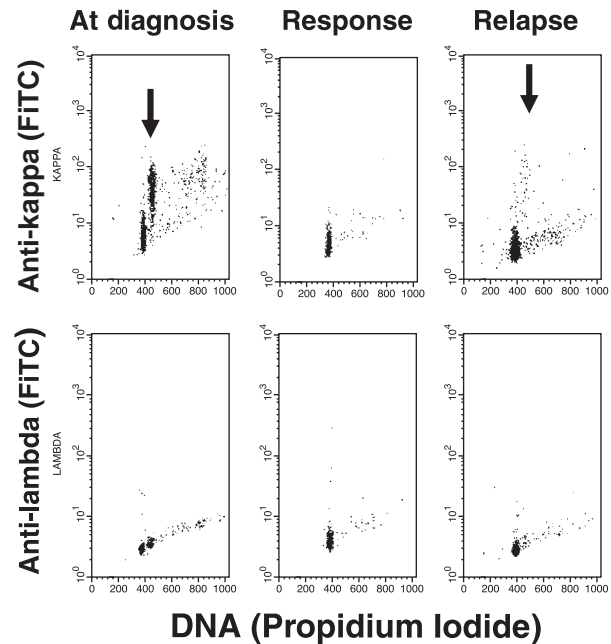

Figure 112.7 A: Bone marrow plasma cells in a patient with IgG myeloma showing neoplastic plasma cells at various stages of differentiation. **B:** Two parameter flow cytometry of DNA content of bone marrow cells; abscissa (propidium iodide) and cytoplasmic immunoglobulin (ordinate, anti- κ or anti- λ fluorescein isothiocyanate [FITC]). At diagnosis, approximately 45% hyperdiploid tumor cells show κ light chain restriction (left panel); at the time of maximal response, no hyperdiploid light chain restricted cells are seen (middle panel); at the time of early relapse, the reappearance of small hyperdiploid and κ light chain restricted population (<1%) is indicative of reemergence of small number of clonal cells, which may not yet be apparent on cytological examination of the bone marrow (right panel). A population of κ restricted but diploid cell population (small arrow) may represent a second clone.

routine evaluation to detect unsuspected focal lesions and plasmacytomas involving the spine and pelvis, to define patterns of bone marrow involvement (i.e., diffuse pattern or a high number of focal lesions), to obtain a detailed evaluation of a painful area of the skeleton, and to investigate suspicion of cord compression.^{238,239} A focal marrow plasmacytoma can be further analyzed through computerized tomography (CT)-guided fine needle aspiration (see Fig. 112.8), allowing for cytologic diagnosis. With effective therapy, the MRI pattern may change (Fig. 112.9B): Diffuse involvement of the marrow may evolve into focal disease, and normalization of MRI abnormalities may provide a better definition of complete responses.²³⁷ Positron-emission tomography (PET) scanning has also been evaluated in a small number of studies and may provide a better functional definition of lesions observed on MRI or CT scans, as well as allowing for the selection of lesions for biopsy.^{237,240} The PET-CT scan is utilized for the detection of extraosseous soft tissue masses, as well as for the evaluation of rib and appendicular bone lesions. A combination of PET-CT and MRI scans may improve the diagnostic accuracy for solitary plasmacytoma.²³⁸ A recent study has identified the independent predictive value of baseline fludeoxyglucose (FDG)-PET/CT and of FDG suppression before high-dose therapy.²⁴¹

Differential Diagnosis

In the presence of end organ damage associated with monoclonal protein and clonal plasma cells in bone marrow, the distinction of

active myeloma from SMM and MGUS can be readily established (see Table 112.5). Patients with nonsecretory myeloma are diagnosed based on marrow plasmacytosis and the presence of bone lesions. MRI abnormalities and CT- or MRI-guided fine-needle aspiration biopsy of involved anatomic sites are important for the follow-up of the disease.

The diagnosis of solitary plasmacytoma of bone or soft tissue requires intense investigation to rule out systemic disease. Bone marrow examination in a true solitary lesion is normal, with no evidence of a clonal cell population. An MRI evaluation for myelomatous involvement of the BM helps detect early lesions before their detection by standard roentgenographic examination. The detection of such lesions and cytologic confirmation through CT- or MRI-guided fine-needle aspiration biopsy may help confirm a solitary plasmacytoma and its genetic makeup. In an individual with MGUS, such detection may change the diagnosis to solitary plasmacytoma or MM. It is important to note that patients with MGUS or solitary plasmacytoma seldom have suppression of uninvolved immunoglobulins. Conventional cytogenetic results are usually normal in MGUS; however, monoclonal plasma cells in some individuals with MGUS may be aneuploidy, and chromosomal abnormalities including IgH translocations and chromosome 13 deletions of unclear prognostic significance have been reported in MGUS.

Besides plasma cell neoplasms, various other conditions can present with monoclonal immunoglobulin secretion. These conditions include other B-cell neoplasms including CLL and B-cell non-Hodgkin's lymphoma; autoimmune conditions such as cold

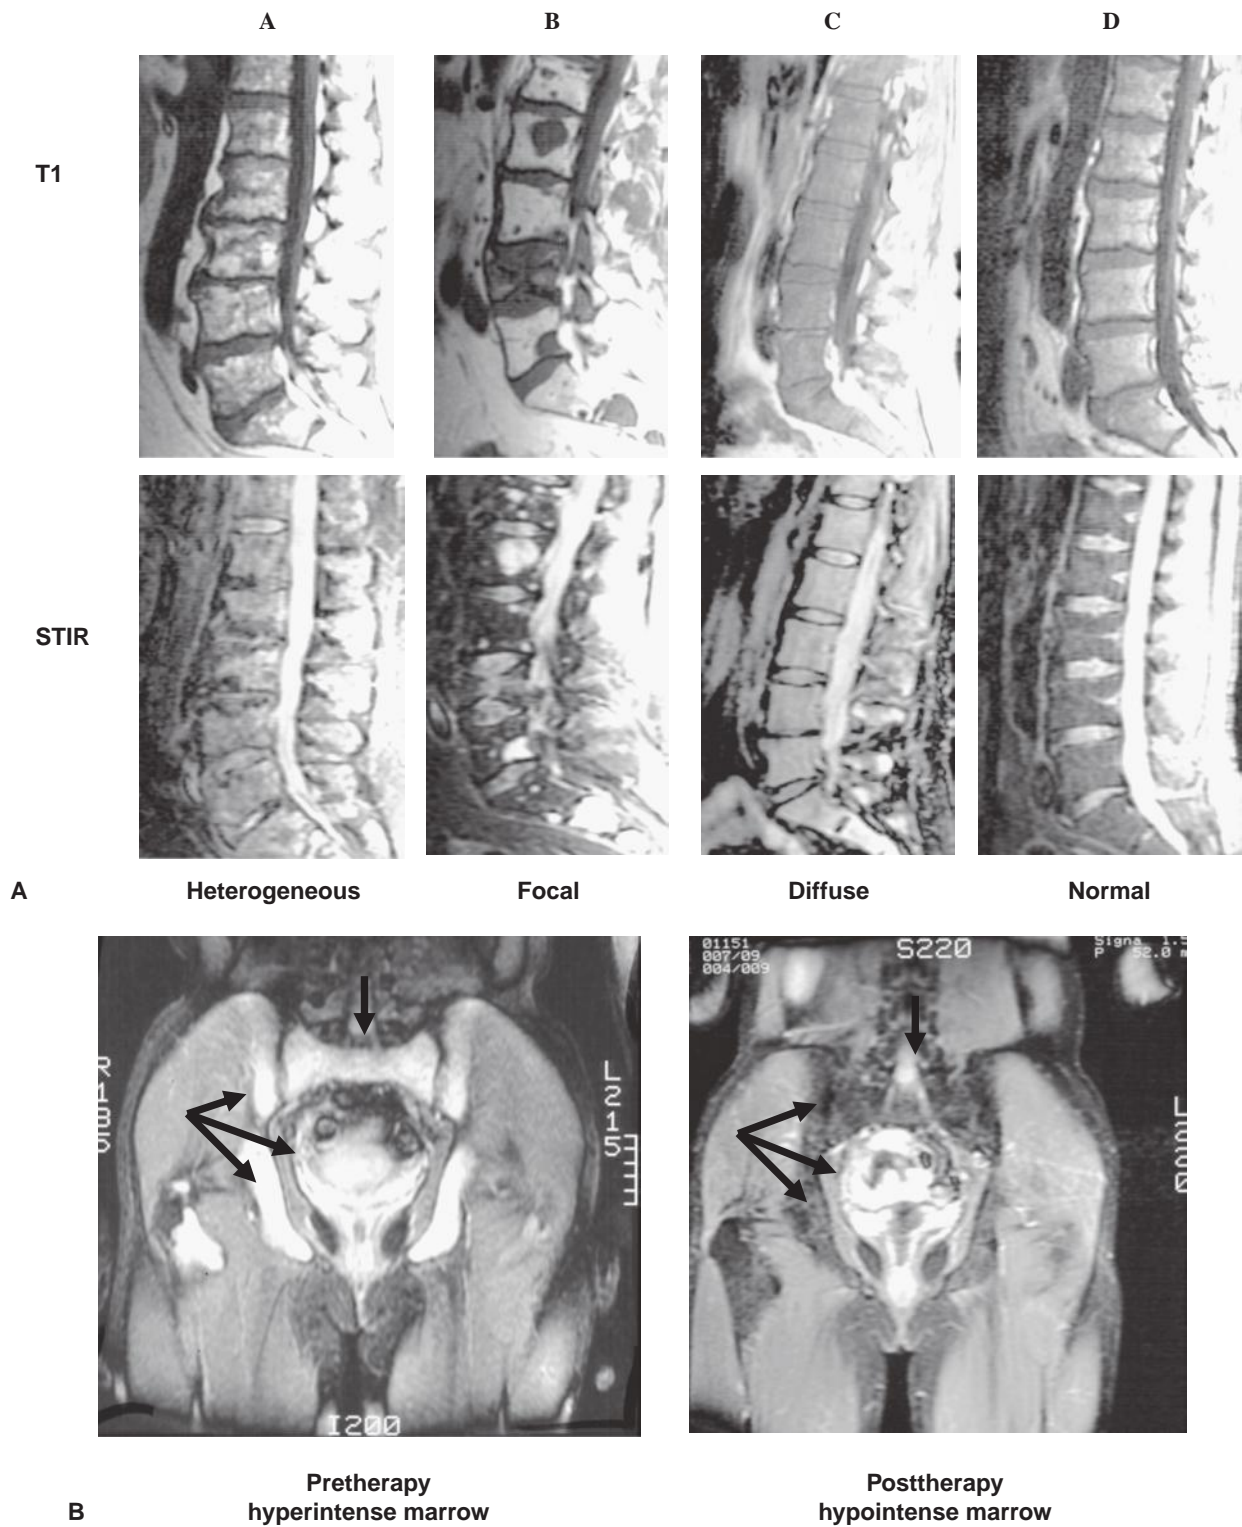

Figure 112.9 A: Magnetic resonance imaging (MRI) pattern in multiple myeloma at diagnosis: T1-weighted and STIR (short inversion-time inversion recovery) imaging shows approximately one-third of patients each presenting with heterogeneous pattern (*panel 1*), focal plasmacytoma lesions (*panel 2*), or diffuse homogeneous hyperintense marrow pattern (*panel 3*). Hyperintensity of marrow on STIR image is suggestive of uniform marrow involvement by myeloma. Few patients have a hypointense and homogenous pattern also seen in normal individuals (*panel 4*). **B:** The hyperintense marrow pattern suggestive of extensive marrow involvement pretherapy (*left; arrows*) changes to hypointense pattern following complete response and normalization of marrow (*right, arrows*); fine-needle aspiration examination in 72 patients with MRI-focal disease showed a tumor in 92%, indicating that minimal response focal lesions in myeloma represent a tumor.

agglutinin diseases, mixed cryoglobulinemia, hypergammaglobulinemia, and Sjögren's syndrome; inflammatory or storage diseases such as lichen myxedema, Gaucher's disease, sarcoidosis, and cirrhosis; and rarely, other malignancies such as chronic myeloid leukemia as well as colon, breast, or prostate cancer.

Protein deposition disease involving various organs requires additional special diagnostic procedures. Deposition of amyloid protein (amyloidosis) can be clinically suspected based on macroglossia, vascular fragility (raccoon's eyes, periorbital subcutaneous hemorrhages), carpal tunnel syndrome, organomegaly, nephropathy, and cardiomegaly with arrhythmia. The detection of Congo red-positive amyloid with classic apple-green birefringence when visualized under polarized light in perivascular areas and subcutaneous fat, as well as bone marrow or rectal biopsy specimens, are diagnostic of AL amyloid. Electrocardiography may reveal low voltage, and an echocardiographic evaluation shows thickening of the interventricular septum or classic speckled pattern in the myocardium. Endomyocardial biopsy may establish the diagnosis of cardiac amyloid, which is usually associated with elevated serum brain natriuretic peptide (BNP) levels. Another manifestation of amyloid deposition includes autonomic dysfunction due to amyloid deposition in the vasa nervorum of the autonomic nerves, leading to orthostatic hypotension. Amyloid deposition in adrenal glands leads to hypoadrenalism; in the spleen, it may lead to hyposplenism with thrombocytosis; in the liver, it may be suspected based on elevated alkaline phosphatase and γ -glutamyl transpeptidase; and in the gastrointestinal tract, it may lead to malabsorption syndrome. Renal dysfunction must be further investigated with a renal biopsy, because light chain cast nephropathy or light chain deposition disease may be reversible following aggressive therapy, whereas deposition of amyloid requires a different therapeutic approach. As the deposition of immunoglobulin and light chain can mimic many manifestations of AL amyloid, an immunofluorescence analysis of unfixed tissue is important for a diagnosis.

Staging and Risk Assessment

Following the diagnostic investigation, more detailed cellular and molecular studies are required to stage myeloma and evaluate prognostic variables that determine the patient's probable outcome.

Patients with MM have variable disease courses, with survival ranging from less than 1 year with high-risk aggressive disease to more than 10 years with indolent presentation or sensitive disease. Various characteristics have been identified to predict the possible course of the disease. An evaluation of prognostic factors is important to define therapeutic strategies, permit comparison of clinical trial results, and predict life expectancy after diagnosis. The current risk stratification is applicable to newly diagnosed patients using parameters obtained at the diagnosis. On relapse, there is often an acquisition of additional or new risk features in which case patients should be reclassified as having high-risk disease. As shown in Table 112.6, prognostic factors are related to the tumor burden, the intrinsic property of the tumor, host and microenvironmental influences, and treatment/intervention-related factors.

A clinical staging system for MM using a standard laboratory measurement was developed by Durie and Salmon, which was predictive of clinical outcomes after standard-dose chemotherapy.²⁴² However, this staging system is not predictive of outcomes in patients undergoing high-dose chemotherapy as well as novel agents-based therapy and is no longer used clinically.

β 2-microglobulin (β 2M) has been identified as one of the most consistent predictors of survival in plasma cell myeloma. β 2M, the light chain gene of the class I histocompatibility antigens expressed on the surface of all nucleated cells, is shed into the blood. Its renal excretion explains its elevation in renal failure. In MM, β 2M, therefore, reflects both tumor burden and renal function.^{243,244} High β 2M (>2.5 mg per liter) levels carry a poor

prognosis for treatment with both standard-dose and high-dose therapy.²⁴⁵ The combination of serum β 2M along with serum albumin has been proposed as a three-stage ISS (Table 112.7). Although this system predicts for outcome following both high-dose therapy as well as novel agents-based treatment, it lacks consideration of tumor biology-related factors, such as cytogenetics or molecular markers.

Cytogenetics

Because the myeloma cell represents a mature differentiated cell with low proliferative activity, cytogenetic abnormalities are not frequently detected. Abnormalities are observed in only one-third of the patients at the time of diagnosis; however, a repeated analysis increases the yield to almost one-half of patients. The normal karyotypic pattern observed in the remaining half most likely originates from dividing normal hematopoietic cells.⁵³

Cytogenetic abnormalities have been identified as a major prognostic factor in plasma cell myeloma. Although the detection

TABLE 112.7

International Staging System		
Stage	Criteria	Median Survival (mo)
I	Serum β_2 microglobulin <3.5 mg/L Serum albumin \geq 3.5 g/dL	62
II	Not stage I or III	44
III	Serum β_2 microglobulin \geq 5.5 mg/L	29

There are two categories for stage II: serum β_2 microglobulin <3.5 mg/L but serum albumin <3.5 g/dL; or serum β_2 microglobulin 3.5 to <5.5 mg/L irrespective of the serum albumin level.

of any cytogenetic abnormality is considered to suggest a higher risk disease, the specific abnormalities considered as poor risk are cytogenetically detected chromosomal 13 or 13q deletion and detection by FISH of t(4;14); t(14;16) and del17p. Del13 or 13q-detected only by FISH and in the absence of other abnormality does not carry significantly higher risk, whereas t(11;14) does not predict superior outcome. The cytogenetic and interphase FISH analysis has identified numeric aberrations involving trisomies of chromosomes 3, 5, 7, 9, 11, 15, 19, and 21, which predict for favorable outcomes.⁵⁵ Limited studies have shown that 1q34+, and del1p may have clinical significance as a poor risk feature. Importantly, both bortezomib and lenalidomide are able to overcome adverse outcomes associated with chromosome 13 deletion and, to a lesser extent, t(4;14).²⁴⁶

Other independent factors associated with poor prognosis include elevated C-reactive protein (CRP), elevated serum lactate dehydrogenase (LDH) with extramedullary disease, serum IL-6, serum soluble IL-6 receptor, and IgA isotype.²⁴⁷ Because CRP levels reflect IL-6 activity and elevated CRP levels can be associated with acute-phase reactions including inflammation and infections, the predictive value of elevated CRP in myeloma is important only when other possible causes for its elevation are ruled out. BM plasmacytosis reflects tumor burden, but does not predict survival. Peripheral blood monoclonal plasma cells predict for survival in myeloma: In a study of 254 patients, blood monoclonal plasma cell counts \geq 4% in 57% patients were associated with a median survival of 2.4 years compared with 4.4 years in patients with less than 4% circulating plasma cells.²⁴⁸

Among the various other disease biology-related variables, plasma cell proliferation rate, as measured by the labeling index (LI), is a valuable prognostic factor: Early in the disease, the proportion of myeloma cells in the cell cycle is small; bromodeoxyuridine or tritiated thymidine methods show a median of 1% cycling cells at the diagnosis. With progressive disease, the LI increases, suggesting a more proliferative phenotype. The LI has important prognostic significance, because patients with more than 1% cells in the S-phase in BM have worse outcomes^{231,249,250}; however, the lack of standardized reproducible methods to measure the LI has limited its use as a prognostic marker. One study combining β_2 M and LI identified a low-risk group with both parameters low, an intermediate-risk group with one parameter high, and a high-risk group with both parameters high to have median survivals of 71 months, 40 months, and 15 months, respectively.²⁵⁰ Additional tumor-related factors predictive of inferior survival include an increased soluble IL-6 receptor level, elevated serum LDH with extramedullary disease, and increased tumor cell mitotic activity (greater than 1 per high power field).

Among the microenvironment-related factors, BM MVD has been identified as an important prognosticator. High MVD in BM (\geq 4 per high power field) at the diagnosis confers shorter event-free survival (EFS; 2.7 versus 4.3 years; $p = 0.03$) and overall survival (OS; 7.9+ versus 4.3 years; $p = 0.006$) after high-dose

chemotherapy.²⁵¹ An increased level of serum syndecan-1, as well as reduced levels of soluble CD16, have been described to portend a poor prognosis.²⁵²

Among therapy- and intervention-related prognostic factors, the type of response and length of response to prior therapy are additional risk stratification criteria; progression while on therapy and a short duration of response to prior therapy are poor risk features. The speed of response does not suggest poor overall outcomes with newer agents.

The risk stratification is applicable to newly diagnosed patients. However, the myeloma cell can acquire new changes over time, acquiring the same genomic abnormalities at relapse that are predictive of poor outcomes at diagnosis. Thus, in good-risk patients, it is necessary to evaluate for high-risk features at relapse. There is also a consensus that the high-risk features will change in the future, with the introduction of other new agents or possibly new combinations.²⁵³

An analysis of genome-wide copy number alterations (CNA) in 192 newly diagnosed, uniformly treated patients with MM using high-density SNP array suggested global genomic instability in MM.⁹⁶ One of three distinct patterns of CNAs are present in 98% of cases. A multivariate analysis identified a prognostic model that includes amp(1q23.3), amp(5q31.3), and del(12p13.31) as the most powerful independent adverse markers ($p < 0.0001$). The availability of larger scale expression profiling data in uniformly treated patient populations has provided the basis for RNA-based prognostic classification systems.⁹² Three large studies have evaluated the prognostic significance of gene expression profiling to identify poor-risk patient populations; the UAMS 70-gene model,⁹³ the 15-gene IFM model,⁹⁴ and the 92-gene HOVON model.⁹⁵ Interestingly, these studies identified patients with a short survival, but were not designed to select patients with very good risk. It is intriguing that none of these models share common genes, highlighting the redundancy in the genes and pathways that control growth, proliferation, and survival; differences in the treatment used to define the patient population; and the complexity of tumor cell biology. These initial attempts at molecular classification and prognostication will need further validation and incorporation into more commonly available methods for larger application. Moreover, the high-risk features identified previously are highly dependent on the therapeutic intervention used. For example, the newer biologically based therapies such as lenalidomide and bortezomib are able to overcome drug resistance, and some traditional adverse prognostic factors are no longer predictive of survival. Additional molecular studies with FISH analysis, as well as proteomic and genomic analyses, including SNP, may identify future uniformly applicable prognostic systems.

TREATMENT

The therapeutic intervention in plasma cell disorders is dependent on the presenting condition. For example, individuals with the diagnosis of MGUS do not require immediate treatment. Patients with solitary plasmacytomas can be treated with local therapy only, whereas those with indolent asymptomatic myeloma can smolder for a long period of time prior to becoming symptomatic and requiring treatment.

Solitary Plasmacytoma

Solitary plasmacytoma requires specialized techniques for accurate staging, including a CT scan and MRI to exclude more disseminated disease. Solitary plasmacytomas of the bone involve vertebral bodies in one-third of patients and frequently affect men (70%) at a younger age (median 56 years).²⁵⁴ A monoclonal protein in the serum is observed in 24% to 54% of patients, but no detectable monoclonal protein is observed, even on immunofixation, in the

remaining cases. Extramedullary plasmacytomas are diagnosed less frequently and require a workup including MRI and PET scanning to rule out additional sites or disseminated disease. The optimal therapy for true solitary plasmacytoma is curative-dose (4,000 to 5,000 cGy) radiotherapy.^{255,256} With this dose, local tumor recurrence rates have been less than 10%; 30% of patients with solitary osseous plasmacytomas versus more than 70% of patients with solitary extramedullary plasmacytomas achieve long disease-free survival.^{257,258} Monoclonal protein disappears after radiotherapy in 25% to 50% of patients, suggesting a possible eradication of the disease; conversely, the reappearance of monoclonal protein predicts for recurrence of the disease. With better staging using MRI, true solitary plasmacytoma of bone can be cured in a high proportion of patients.

Monoclonal Gammopathy of Unknown Significance and Smoldering Myeloma

Patients with MGUS or smoldering myeloma have a low tumor mass and indolent disease course presenting without specific symptoms. Such patients do not have end organ damage. In patients with indolent light chain disease, Bence Jones proteinuria does not exceed >10 g per day. About 1% patients with MGUS per year progress to symptomatic myeloma. Non-IgG subtype, abnormal kappa/lambda free light chain ratio, and serum M protein more than 1.5 g per deciliter are associated with higher incidences of progression from MGUS to myeloma. Patients with none of these risk features have a 5% chance of progression, whereas those with all three features have a 60% chance of progression to myeloma in 20 years. The features responsible for the higher risk of progression from smoldering myeloma to active MM are bone marrow plasmacytosis >30%, abnormal kappa/lambda free light chain ratio, and serum M protein >30 g per liter (3.0 g per deciliter). Patients with all three adverse features have a nearly 50% chance of progression in 2 years.^{259,260} Typically, patients with MGUS require no therapy. Similarly, patients with smoldering myeloma are also not treated routinely until disease progression or the appearance of end organ damage, such as the development of bone lesions or anemia. However, ongoing clinical trials have focused on evaluating the role of early intervention to prevent the progression of smoldering to symptomatic myeloma. For example, an evaluation of thalidomide in 31 patients with indolent myeloma showed responses in 66% of patients, with the potential to delay the progression to symptomatic disease.²⁶¹ In a recent phase 3 randomized, open-label, trial, 119 high-risk smoldering myeloma patients were assigned to treatment (lenalidomide at a dose of 25 mg per day on days 1 to 21, plus dexamethasone at a dose of 20 mg per day on days 1 to 4 and days 12 to 15, at 4-week intervals for nine cycles) or observation.²⁶² Patients in the treatment group received a maintenance regimen (lenalidomide at a dose of 10 mg per day on days 1 to 21 of each 28-day cycle for 2 years) after completing induction treatment. After the induction phase, a partial response or better was achieved in 79% of patients in the treatment group, which increased to 90% during the maintenance phase. With a median follow-up of 40 months, the median time to progression was significantly longer in the treatment group compared to the observation group (median not reached versus 21 months, respectively; $p < 0.001$). Importantly, the 3-year overall survival rate was also significantly higher in the treatment compared to the control group (94% versus 80%; $p = 0.03$). The treatment was well tolerated. This study for the first time suggests that an early intervention in patients with high-risk smoldering myeloma may provide survival benefit. However, further investigations are necessary to establish an optimal patient population and directed intervention that may help with the prevention of progression of SMM to active MM and may prolong overall survival.

Symptomatic Multiple Myeloma

Standard-Dose Conventional Therapy

Oral melphalan and prednisone was the first successful combination chemotherapy for myeloma; subsequently, various other single agents and combinations, as well as high-dose chemotherapy regimens, have been investigated and reported to have significant antimyeloma activity.

Melphalan and Prednisone. Treatment with oral melphalan and prednisone (MP) achieves a partial response (PR) in 50% to 60% of patients, with 3% to 5% of patients achieving a CR, and provides symptomatic relief as well as tumor mass reduction.²⁶³ The median response duration is 18 months, and OS is 24 to 36 months. The absorption of oral melphalan is unpredictable, requiring its ingestion on an empty stomach and an increase in dose if the patient does not develop cytopenia.²⁶⁴ With the availability of an intravenous formulation, dose and pharmacokinetics are now predictable. Frequent complications after MP therapy include the development of cytopenia and, with chronic administration, myelodysplastic changes in the marrow. MP in any combination should not be used as induction therapy in patients eligible for high-dose therapy and stem cell transplant because melphalan damages stem cells and compromises the ability to mobilize adequate numbers of stem cells. As described as follows, MP is now combined with one of the novel agents.

VAD and Alkylating Agent-Based Combinations. Various chemotherapeutic combinations have been investigated in myeloma, including vincristine (V), cyclophosphamide (C), BCNU (B), melphalan (M), adriamycin (A), and prednisone (P). Commonly used combinations in the past include VBMCP or VMCP/VBAP.^{265,266} These combinations are no longer utilized. Similarly, high-dose dexamethasone (40 mg orally on days 1 through 4, 9 through 12, and 17 through 20) in combination with 24-hour continuous infusion of vincristine (0.25 mg/m^2) and adriamycin (9 mg/m^2) (VAD) for 4 days²⁶⁷ was once a preferred induction regimen achieving a nearly 50% response rate; however, with the availability of novel agent-based combinations, VAD is no longer used as an induction regimen.²⁶⁸ Although effective, high-dose dexamethasone used in various dosages (20 to 40 mg) and schedules (once a week, 4 days every 2 weeks to a 4 days on and 4 days off regimen) have been associated with predisposition to systemic infections, as well as insomnia, hyperactivity, hyperglycemia, and psychiatric problems. An Eastern Co-operative Oncology Group study suggests that dexamethasone once a week in combination with lenalidomide may be less toxic and more effective than a high-dose dexamethasone regimen.²⁶⁹ Glucocorticoids downregulate IL-6 production and induce apoptosis in vitro; conversely, myeloma cells can be rescued from glucocorticoid-mediated killing by the addition of IL-6 to in vitro cultures or by coculturing them with bone marrow stromal cells, which are a source of IL-6 in vivo.

Interferon. Interferon causes direct growth inhibition, as well as antiangiogenic and immunomodulatory activity. Although it has been one of the most investigated agents in myeloma especially in maintenance settings, it has not demonstrated significant beneficial effects.^{270,271} A meta-analysis of eight trials involving 929 patients showed prolongation of relapse-free survival by 7 months and OS by 5 months in patients receiving IFN. However, a large US intergroup study failed to show a benefit of IFN maintenance after high-dose therapy.²⁷² IFN is associated with flulike symptoms, weight loss, impotence, depression, mental status changes, and cytopenias; in addition, its prolonged use has been associated with inability to mobilize stem cells, therefore, it is no longer utilized.

Radiation Therapy

Radiation therapy was considered the mainstay of treatment for myeloma prior to the availability of chemotherapeutic options. However, with more effective therapy, the role of radiation has now been limited.²⁷³ A definitive role remains in patients with solitary bone and extramedullary plasmacytoma. Importantly, patients with solitary bone plasmacytoma treated with definitive radiation therapy (4,000 to 5,000 cGy) have progression-free survival of 30%, compared to 70% in those with extramedullary plasmacytomas.^{255–258,274} The indication for radiation therapy in MM remains palliation in cases of impending pathologic fracture and to treat spinal cord compression. In patients with bone pain or symptomatic soft tissue masses, radiation is only considered when patients have failed chemotherapeutic options.^{275,276} Radiation to BM-containing areas, such as the pelvic bone, should be used judiciously if there is a need for the collection of stem cells. The dose of palliative radiation therapy ranges from 1,500 to 2,500 cGy. Studies to date have failed to show any benefit of hemibody radiation in MM. However, total body radiation has been used prior to allogeneic and autologous transplantation. More recent studies have demonstrated that total body radiation does not provide additional cytoreductive potential; moreover, when combined with high-dose melphalan conditioning, it increases treatment-related morbidity and mortality, as well as delays immune recovery compared to high dose melphalan alone. Recent studies with nonmyeloablative regimens followed by allogeneic stem cell transplantation use low-dose radiation and achieve adequate engraftment, avoiding myeloablation and attendant toxicity of total body irradiation.

Novel Biologically Based Agents

Novel therapeutic agents specifically targeting the mechanisms whereby myeloma cells grow and survive in the BM milieu can overcome resistance to standard-dose and high-dose therapies. The immunomodulatory agents thalidomide and its analog lenalidomide, as well as the proteasome inhibitor bortezomib, are agents that have demonstrated efficacy in both relapsed and newly diagnosed myeloma and have now been integrated into standard algorithms for myeloma management.

Thalidomide. The initial rationale for use of thalidomide in myeloma was its known antiangiogenic activity, coupled with reports of increased angiogenesis in MM BM. Further investigations have shown that besides their direct effect on MM cells, thalidomide and other immunomodulatory agents (lenalidomide and pomalidomide) abrogate the adhesion of MM cells to BMSCs and block the secretion of MM growth and survival factors such as IL-6, TNF- α , VEGF, and FGF triggered by the binding of

MM cells to BMSCs.²⁷⁷ Additionally, these agents significantly modulate immune responses by expanding the number and function of NK cells, improving DC function, and enhancing T-cell function by providing T-cell costimulatory signals through the B7-CD28 pathway.²⁷⁷ Importantly, two recent studies have shown that lenalidomide binds to cereblon (CRBN), the substrate-recognition subunit of a ubiquitin ligase complex. This in turn leads to specific ubiquitination and, subsequently, degradation of two related transcription factors, Ikaros family zinc finger 1 (IKZF1) and Aiolos IKZF3, with essential roles in B- and T-cell differentiation, as well as myeloma cell survival (Fig. 112.10).^{278,279} A glutamine residue within the second zinc finger of IKZF1 and IKZF3 seems to provide the specificity of this interaction, because its absence in the highly homologous Ikaros family members IKZF2 and IKZF4 makes them resistant to lenalidomide. Importantly, the expression of IKZF1 or IKZF3 mutants lacking the key glutamine residue in the CRBN degron sequence or knockdown of CRBN conferred lenalidomide resistance. These results now provide a unique molecular understanding of lenalidomide activity, as a single agent or in combination.

Thalidomide was initially evaluated in a phase 2 study in 169 posttransplant-relapsed MM patients in incremental doses of 200 mg to 800 mg. A partial response was observed in 26% patients, with an overall response rate of 34%.^{280,281} Subsequently, the efficacy of thalidomide alone and in combination has been confirmed in several phase 2 and 3 studies in MM (Table 112.8A). In combination with dexamethasone, it achieved >50% responses in relapsed MM patients and 70% responses in newly diagnosed patients. Additional combinations of thalidomide with MP have improved overall response, as well as both EFS and OS, in newly diagnosed patients over the age of 65 years (Table 112.8B). The major toxicities of thalidomide are somnolence, constipation, and neurologic symptoms, including neuropathy, fatigue, and DVT.²¹¹ Due to the significant risk of DVT and pulmonary embolism when thalidomide is used in combination with dexamethasone, a prophylaxis against clotting is warranted in all patients. Although aspirin has been used as prophylaxis in patients at a low risk of DVT, either standard-dose Coumadin or low-molecular-weight heparin is indicated in patients at a higher risk of DVT.²⁸²

Lenalidomide. Lenalidomide, a more potent analog of thalidomide, in a phase 1 clinical trial, achieved at least a minimal response (at least a 25% reduction in paraproteins) in 15 of 24 (63%) patients, including in 11 patients who had received prior thalidomide.²⁸³ A subsequent randomized study in patients with at least one prior therapy of lenalidomide and dexamethasone versus dexamethasone alone achieved PR or better rate (61% versus 20%; $p < 0.001$); CR rate (14% versus 0.6%; $p < 0.001$); a median time to progression (11.1 months versus 4.7 months;

$p < 0.001$); and median overall survival (29.6 versus 20.2 months; $p < 0.001$). In newly diagnosed patients, lenalidomide combined with dexamethasone achieves PR or better in over 90% of patients.²⁸⁴ A similar study in Europe had almost identical results. Recently, lenalidomide and low-dose dexamethasone (Rd) versus melphalan, prednisone, and thalidomide (MPT) have been compared in a multicenter, open-label, phase 3 trial in newly diagnosed transplant-ineligible MM patients ≥ 65 years of age. A total of 1,623 patients (median age, 73 years) were randomized to one of three arms: Rd in 28-day cycles until disease progression (Arm A); Rd in 28-day cycles for 72 weeks (18 cycles, Arm B); or MPT in 42-day cycles for 72 weeks (12 cycles, Arm C). Overall response was 75%, 72%, and 62%, for Arms A, B, and C, respectively ($p < 0.00001$). Continuous treatment with Rd (Arm A) had a 28% reduction in the risk of progression or death (hazard ratio [HR] = 0.72; $p = 0.00006$), with a 22% reduction in risk of death in favor of Arm A versus Arm C (HR = 0.78; $p = 0.01685$). All other secondary end points also showed an improvement in favor of Arm A versus Arm C; DOR (HR = 0.63; $p < 0.00001$), and PFS2 (HR = 0.78; $p = 0.0051$). In Arm A versus Arm C

grade 3/4 neutropenia was 28% versus 45% and neuropathy 5% versus 15%. This study establishes Rd with continuous treatment until progression as a standard of care in newly diagnosed MM in older individuals.²⁸⁵ Tables 112.9A and B list selected major studies demonstrating the activity of lenalidomide in both relapsed and newly diagnosed myeloma. Importantly, no significant somnolence, constipation, or neuropathy is observed with lenalidomide. However, myelosuppression was the dose-limiting toxicity and requires monitoring during therapy. Similar to thalidomide, it is associated with an increased incidence of DVT and requires concurrent prophylactic measures for its prevention.²⁸² Due to its renal excretion, a dose modification is necessary when used in patients with renal dysfunction.

Bortezomib. Bortezomib is the first-in-class proteasome inhibitor originally used in MM due to its blockade of NF- κ B activation and related paracrine IL-6 production by BMSCs. Bortezomib has been subsequently demonstrated to act directly on MM cells to induce apoptosis through both caspase 8 and 9 activation, to overcome the protective effects of IL-6, and to add to the anti-MM

effects of Dex. Importantly, it acts in the microenvironment to inhibit the binding of MM cells to BMSCs, the secretion of MM growth promoting cytokines, and BM angiogenesis.²⁸⁶⁻²⁸⁹ Based on its efficacy and safety profile in a phase I study, a multicenter phase 2 trial in 193 evaluable patients showed a 35% PR or greater response.²⁹⁰ The median duration of response was 12 months, and the median OS was 16 months. Grade 3 adverse events included thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), and neutropenia (11%). The addition of Dex in this study improved responses in 19% patients, confirming synergism between these two agents. A subsequent randomized study in 669 patients with relapsed myeloma comparing bortezomib versus Dex reported a higher response rate (38% versus 18% respectively; $p < 0.001$), a longer time to progression (6.22 months versus 3.49 months, respectively; $p < 0.001$), and a longer survival (1-year survival rate 80% versus 66%, respectively; $p = 0.003$).²⁹¹ Tables 112.10A and B list selected major studies demonstrating its activity in both relapsed and newly diagnosed myeloma. In a randomized multicenter international study, the combination of bortezomib and pegylated liposomal doxorubicin was shown to be superior to bortezomib alone for both overall response (50% versus 42% respectively; $p = 0.05$) and time to progression (9.3 months versus 6.5 months respectively; $p < 0.0001$), leading to U.S. Food and Drug Administration (FDA) approval of this combination in relapsed MM.²⁹² Bortezomib has been shown to overcome the adverse outcome associated with t(4;14),²⁹³ can be given safely in patients with renal failure,²⁹⁴ and improves osteoblastic activity.²⁹⁵ The major toxicities include fatigue, diarrhea, reversible thrombocytopenia, and peripheral neuropathy. In a randomized phase 3

study of 222 relapsed MM patients, the subcutaneous administration of bortezomib was compared with traditional intravenous administration. overall response rates (ORR) after four cycles was 42% in both groups, and no significant differences in time to progression (median 10.4 months versus 9.4 months; $p = 0.387$) and 1-year OS (72.6% versus 76.7%; $p = 0.504$) were observed. Importantly, toxicity profiles were improved with the subcutaneous versus intravenous administration, including peripheral neuropathy of any grade (38% versus 53%; $p = 0.044$) and grade 2 or worse (24% versus 41%; $p = 0.012$), making subcutaneous administration a preferred route of administration.²⁹⁶

Induction Therapy in the Newly Diagnosed Patient

Decision about the induction regimen and its dose and schedule in newly diagnosed MM is partly influenced by the patient's age and comorbidities. Importantly, in a transplant-eligible patient, alkylating agents should be avoided because these agents may compromise stem cell collection. In newly diagnosed patients, thalidomide and dexamethasone have been demonstrated to be superior to dexamethasone alone (ORR 63% versus 41%, respectively; $p = 0.0017$).²⁹⁷ Based on this data, thalidomide and dexamethasone is approved by the FDA as an induction regimen. With the availability of lenalidomide and bortezomib, alternative combinations have been investigated and are now preferred. The Southwest Oncology Group (SWOG) compared lenalidomide plus dexamethasone (LD) ($n = 97$) to placebo plus high-dose

dexamethasone (D) (n = 95) in newly diagnosed myeloma in a randomized study.²⁹⁸ Overall response rate and 1-year progression-free survival were superior with LD (78% versus 48%; p < 0.001 and 78% versus 52%; p = 0.002, respectively), whereas 1-year OS was similar (94% versus 88%; p = 0.25). Toxicities were more pronounced with LD (neutropenia grade 3 to 4: 21% versus 5%; p ≤ 0.001 and DVT despite aspirin prophylaxis: 23.5% versus 5%; p ≤ 0.001). A randomized study performed by ECOG compared lenalidomide at 25 mg daily for 3 weeks out of 4 along with high-dose Dex (40 mg days 1 through 4, 9 through 12, and 17 through 20) versus lenalidomide with low-dose Dex (40 mg once a week).²⁶⁹ With 445 patients randomized, 79% patients receiving high-dose and 68% patients on low-dose dexamethasone had CR or PR within four cycles (p = 0.008). However, OS at 1 year was 96% versus 87% in favor of the low-dose dexamethasone group (p = 0.0002); and toxicity was also higher in the high-dose versus low-dose dexamethasone group (any grade 3 or 4 toxicity 52% versus 35%, respectively, p = 0.0001; early mortality 5.4% versus 0.5% respectively, p = 0.003 and DVT 26% versus 12% respectively, p = 0.0003). Bortezomib-containing regimens have also been evaluated in newly diagnosed patients. Jagannath et al.²⁹⁹ have reported 18% CR and 88% overall response rates in a phase 2 study using a combination of bortezomib and Dex in newly diagnosed patients.

The IFM group has randomized 242 newly diagnosed patients to VAD or bortezomib plus dexamethasone (VD) followed by dexamethasone, cyclophosphamide, etoposide, cis-platinum (DCEP) consolidation and autologous stem-cell transplantation.³⁰⁰ CR/nCR (15% versus 6%), at least VGPR (38% versus 15%), and overall response (79% versus 63%) rates after four cycles of induction therapy were significantly higher with VD compared to VAD. Interestingly, the superior response after induction also translated into significantly improved response after transplant with CR/nCR (35% versus 18%) and at least VGPR (54% versus 37%) rates in favor of VD compared to the VAD group. Median progression-free survival (PFS) was 36.0 months versus 29.7 months (p = 0.064) with VD versus VAD. The incidence of severe adverse events appeared similar between the groups. A short-term bortezomib induction has been reported to improve outcomes of patients with t(4;14) but not del(17p).³⁰¹ The recently approved proteasome inhibitor carfilzomib has also been evaluated in newly diagnosed patients. In combination with lenalidomide and dexamethasone, it achieves 94% overall response and 80% CR/nCR after 12 cycles. In a phase 1/2 study in patients with newly diagnosed MM (n = 53) after a median of 12 cycles of carfilzomib, lenalidomide, dexamethasone (CRd) (range, 1 to 25), 62% patients achieved at least a near CR and 42% stringent CR. In 36 patients completing eight

CR, complete response; VGPR, very good PR; PR, partial response; Bort (V), bortezomib; Dex (D), dexamethasone; N/R, not reported; Thal (T), thalidomide; MP, melphalan, prednisone; PAD, bortezomib, adriamycin, dex; PLD, liposomal doxorubicin; TT3, total therapy 3.

or more cycles, 78% patients reached at least a near CR and 61% achieved a stringent CR. With a median follow-up of 13 months (range, 4 to 25 months), the 24-month PFS estimate was 92%. Thus, CRd is well tolerated with exceptional response rates.³⁰²

With the success of two-drug combinations, three-drug combinations have been investigated with demonstrated high response rates. Bortezomib and dexamethasone have been combined with thalidomide (VTD: CR 32%, VGPR: 62%, and ORR: 94%), doxorubicin (VDD CR/nCR: 31%, VGPR: 42%, and ORR: 83%), cyclophosphamide³⁰³ (VCD CR/nCR: 39%, VGPR: 61%, and ORR: 88%), and lenalidomide³⁰⁴ (VRD CR/nCR: 52%, VGPR: 74%, and PR: 100%). A four-drug combination combining VRD with cyclophosphamide has not shown a clear benefit. These novel agent combinations have progressively improved both frequency and depth of responses in newly diagnosed patients with myeloma (Fig. 112.11).

For patients who are not transplant candidates, the same regimen described previously can be utilized. In addition, MP in combination with novel agents has significantly improved outcomes. Five randomized studies have compared MP with thalidomide (MPT) versus MP (Table 112.11) and demonstrated both superior overall response and complete response rate, as well as event-free survival (four out of five studies) and OS (two out of five studies), suggesting MPT as an active regimen in this patient population. The combination of bortezomib with MP (VMP) has been compared with MP in a randomized study,³⁰⁵ which demonstrated superior CR and PR rates for the VMP regimen (71% versus 35% and 30% versus 4% respectively; $p < 0.001$). The time to progression for the VMP group was 24.0 months, as compared with 16.6 months for the MP cohort ($p < 0.001$). The combination of lenalidomide with MP followed by lenalidomide maintenance (MPRR) has been compared with

MP and demonstrated higher response rates (CR 18% versus 5% and ORR 76% versus 49%; $p < 0.001$) and PFS (not reached versus 13.2 months; $p = 0.002$). A four-drug combination combining MPT with bortezomib has not shown significant further improvements.

High-Dose Therapy with Peripheral Blood Stem Cell Support

To overcome resistance to standard-dose therapy, a pilot study by the late Tim McElwain and his colleagues at the Royal Marsden Hospital evaluated the role of melphalan dose escalation (140 mg/m²). They reported complete remissions in refractory patients¹²; however, treatment-related mortality was high due to BM toxicity. Bone marrow support in subsequent studies improved the treatment-related mortality, and dose escalation of melphalan to 200 mg/m² further improved response.

Transplant in Newly Diagnosed Patients

The initial demonstration of activity of high-dose melphalan therapy led to series of evaluations of the role of high-dose therapy with stem cell support in myeloma. These studies reported complete remissions in up to 50% of patients, with prolongation of EFS and OS to more than 3 years and more than 5 to 6 years, respectively.³⁰⁶⁻³¹⁰

The superiority of high-dose chemotherapy with autologous BM support was confirmed in a randomized trial conducted by IFM. The response rate ($\geq 50\%$ reduction in myeloma protein) in 100 patients receiving high-dose therapy (Mel-140 + TBI) was 81% (22% complete remission) compared with 57% (5% complete

Figure 112.11 Progressive improvement in response to combination therapies incorporating newer agents. The nCR/CR, VGPR, and ORR rates following induction therapy of newly diagnosed multiple myeloma patients is plotted for common novel agent combinations selected from larger phase III and II studies and compared with VAD regimen. VAD, vincristine, adriamycin, and dexamethasone; T, thalidomide; D, dexamethasone; R, Lenalidomide; P, bortezomib; V, bortezomib (except in VAD); A, adriamycin; C, cyclophosphamide. CR/nCR, complete response/near CR; VGPR, very good partial response; ORR, overall response rate.

remission) in a similar number of patients receiving standard-dose chemotherapy consisting of VMCP (vincristine, melphalan, cyclophosphamide, and prednisone) alternating with a BVAP (carmustine, vincristine, doxorubicin, and prednisone) regimen ($p < 0.001$). Significantly longer event-free (median, 28 versus 18 months) and overall (median, 57 versus 42 months) survivals were reported after high-dose therapy (Fig. 112.12). The projected 5-year EFS and OS were 28% and 52% after high-dose therapy compared to 10% and 12% following standard-dose therapy, respectively.³¹¹

A similar response and survival benefit has been reported from the Medical Research Council (MRC)-VII trial, which randomized 407 patients to either standard-dose chemotherapy or HDT with transplantation.³¹² A Spanish trial of 164 patients treated with HDT versus conventional therapy also showed a superior CR rate in the HDT arm, with a trend for prolonged EFS and OS in the HDT arm (Table 112.12).³¹³ In contrast, the Myelome Autogreffe Group (MAG) trial by Fermand et al.³¹⁴ in 190 newly diagnosed MM pa-

tients failed to show superiority of HDT. The US intergroup study, which randomized patients between HDT versus conventional therapy followed by delayed HDT at relapse, failed to show superiority of HDT for either achievement of CR or OS; EFS benefit was modest (4 months) in the high-dose therapy cohort.²⁷² A meta-analysis combining nine studies comprising 2,411 patients reported a combined hazard of death with HDT of 0.92 (95% confidence interval [CI], 0.74 to 1.13) and a combined hazard of progression with HDT of 0.75 (95% CI, 0.59 to 0.96). The analysis of the randomized data indicated PFS benefit, but not OS benefit, for HDT with single autologous transplantation in multiple myeloma.³¹⁵

Although the responses to induction therapy have now significantly improved with the use of novel agent combination therapies (see Fig. 112.11), some recent studies have indicated that HDT is able to further improve the depth of response (Fig. 112.13). These observations have raised questions about the role of HDT in newly diagnosed patients with myeloma receiving novel agent

Figure 112.12 Comparative trials of high-dose therapy (HDT) versus standard-dose chemotherapy (SDT). IFM-90 (Intergroupe Francais de Myelome) randomized trial with 100 patients accrued to each arm comparing SDT with VMCP-VBAP and HDT with melphalan 140 mg/m² plus total body irradiation (800 cGy). Higher complete remission rates and significantly longer event-free and overall survival were noted with HDT. (From Harousseau JL, Attal M, Divine M, et al. Autologous stem cell transplantation after first remission induction treatment in multiple myeloma. A report of the French Registry on Autologous Transplantation in Multiple Myeloma. *Stem Cells* 1995;13:132–139, with permission.)

combination therapy. Two recent studies have reconfirmed the role of high-dose therapy in myeloma. In one study, patients received four cycles of lenalidomide and dexamethasone and were then randomized to either Cytosan, lenalidomide, and dexamethasone (CRD) for six cycles or HDT with melphalan 200 mg/m² (Mel200) with transplant. PFS with Mel200 was significantly longer than after CRD: 27 months versus not reached ($p = 0.012$). A second study compared MPR versus Mel200 after Rd induction therapy and reported superior PFS (24 versus 36 months respectively ($p < 0.0001$)) with a trend in improved 5-year OS, 62 versus

71% ($p = 0.27$) in favor of Mel200. An ongoing study is evaluating the role of transplant in patients receiving RVD combination.

Tandem Transplants

Attempts to further improve the results of autotransplantation have included intensification with tandem transplants. Harousseau et al.³¹⁶ were the first to report feasibility of tandem autologous BM transplantation, with a 69% CR rate in a small select group of patients. Barlogie et al.³¹⁷ investigated a sequential non-cross-resistant

Figure 112.13 Despite improvements in response with novel agents, high-dose therapy further improves the depth of response. * Posttransplant intention-to-treat data not available. Figure 112.14 Comparative trial of single versus double high-dose therapy (HDT). IFM 94 trial with 399 patients randomized to a single HDT with melphalan 140 mg/m² plus total body irradiation (800 cGy) versus first HDT with melphalan 140 mg/m² and subsequent second HDT with melphalan 140 mg/m² plus total body irradiation (800 cGy). Superior event-free and overall survival was noted with double HDT. (From Attal M, Harousseau JL, Facon T, et al. Single versus double autologous stem-cell transplantation for multiple myeloma. *N Engl J Med* 2003;349:2495–2502, with permission.)

remission induction regimen followed by tandem autologous transplantations (*total therapy*) in 231 newly diagnosed patients: 41% of patients achieved CR after two transplants, and the median EFS and OS times were 43 months and 68 months, respectively.

Attal et al.²⁴⁵ (IFM-94) reported a randomized comparison of single HDT (melphalan [140 mg/m²] and TBI [8 Gy]) versus double HDT (melphalan [200 mg/m²], followed by melphalan [140 mg/m²] and TBI [8 Gy]) in 399 newly diagnosed patients. This study reported no significant improvement in CR or very good PR rate between the two arms (42% versus 50% respectively; $p = 0.10$); however, there was a significant improvement in the double HDT arm in probability of EFS at 7 years (10% versus 20%; $p = 0.03$) and estimated OS at 7 years (21% versus 42%; $p = 0.01$) (Fig. 112.14). A similar study by the Dutch-Belgian Hematology-Oncology Cooperative Group (HOVON) ($n = 255$) showed a su-

perior CR rate (13 versus 28%) and EFS (20 versus 22 months) in favor of tandem transplants; however, it failed to show OS benefit. The MAG ($n = 193$) and Bologna ($n = 178$) trials, with a median follow-up of 27 to 30 months, have not yet shown a significant benefit for tandem transplantation (Table 112.13).

Various factors need special consideration in the management of myeloma with high-dose chemotherapy. These factors include a source of stem cells, the conditioning regimen, the timing of transplant, and tumor-cell purging.

Timing of High-Dose Therapy. To obtain high-quality hematopoietic stem cells, the ideal timing for stem cell collection is early in the course of the induction treatment. The ability to collect adequate stem cells ($\geq 2 \times 10^6$ CD34+ cells per kilogram) in patients with less than 12 months of prior therapy is 86% compared

to 48% in patients with >24 months of prior therapy.³¹⁸ Prolonged lenalidomide induction therapy has been reported to affect stem cell mobilization. Patients undergoing PBSC mobilization with granulocyte-colony stimulating factor (G-CSF) following lenalidomide induction had a significant decrease in total CD34 (+) cells collected, the average daily collection, and the increased number of aphereses.³¹⁹ However, there is no effect on quality of PBSC collected based on similar engraftment times across all groups. Based on these studies, PBSC collection within 6 months of lenalidomide therapy and with cyclophosphamide-based mobilization is recommended.^{320,321}

Multi-institutional trials demonstrating that initial HDT prolongs remission duration and survival but is not curative has led to the exploration of whether HDT should be used early after diagnosis versus delayed as a treatment for relapsed myeloma. To evaluate this important question, Fermand et al.³¹⁴ randomized 185 newly diagnosed patients to undergo three to four cycles of VAMP (vinblastine, doxorubicin, methotrexate, and prednisone) followed by early HDT and autotransplantation (n = 91) versus conventional chemotherapy with VMCP for 1 year and HDT at relapse (n = 94). Although patients who underwent early transplantation had significantly longer EFS times (39 months versus 13 months), OS was identical in both arms (median, 64.6 and 64 months). Importantly, the time without symptoms and toxicity analysis reflecting quality of life (mean, 27.8 versus 22.3 months) showed superior results for the early HDT arm (Table 112.14). Vesole et al.³²² have confirmed effectiveness of high-dose chemotherapy as a salvage therapy achieving EFS and OS times of 21 and >43 months, respectively, in 135 patients with advanced refractory MM. In this study, patients with primary unresponsive disease had superior outcomes to patients with resistant relapse (progression on last-salvage chemotherapy), with EFS of 37 months versus 17 months, respectively (p = 0.0004), and OS of 43 months versus 21 months, respectively (p = 0.0003). Gertz et al.,³²³ from the Mayo clinic, have also reported a similar experience in 64 patients undergoing elective delayed transplant at the time of progression following standard therapy. Finally, the Intergroup trial in the United States randomizing patients to up-front high-dose therapy or standard therapy with high-dose therapy as a salvage treatment also confirms a similar modest EFS benefit for early versus late transplants.²⁷²

High-Dose Regimen. High-dose melphalan (140 to 200 mg/m²), with or without total body irradiation, is the most common conditioning regimen used in myeloma.^{324–326} Melphalan's predominant myelotoxicity and metabolism independent of renal function is ideal for MM patients who commonly have renal function abnormalities. Melphalan seems to be superior to thioTEPA when given with total body irradiation, with patients achieving longer relapse-free and overall survival duration.³²⁶ A combination regimen containing high-dose carboplatin with etoposide and

Cytosan, or a combination with CBV, has achieved only occasional responses in resistant patients.^{327,328} No regimen has shown marked superiority over others. The addition of TBI has not been shown to improve cytoreduction and, in fact, increases morbidity and treatment-related mortality. A poor outcome in one study utilizing total body irradiation was attributed to delayed immune recovery.

Stem Cell Purging. Myeloma cell contamination, as evaluated by PCR or sensitive immunofluorescence, is universally observed in stem cell products. The purging of tumor cells by the positive selection of CD34+ cells leads to a 3 to 5 log reduction in contamination.^{329,330} Negative selection using the monoclonal antibody cocktail containing CD10 (common acute lymphoblastic leukemia antigen); CD20 (a pan B-cell antigen); and PCA-1 (plasma cell-associated antigen) or peanut agglutinin (PNA) and anti-CD19 antibodies results in undetectable myeloma cells by conventional flow cytometry.³⁰⁹ The early follow-up results from these studies have not revealed any significant advantage in responses or survival, but they consistently show a delay in engraftment posttransplantation. A multicenter, randomized study comparing CD34-selected PBSCs versus unselected PBSCs in 131 patients failed to show any significant difference in EFS or OS time.³³¹ Even when cells were purged using FACS sorting of very early hematopoietic stem cells (CD34+, Thy1+, and Lin), relapses were frequent and patients had delayed hematopoietic engraftment and suppressed immune status for prolonged periods of time.^{332,333} Due to these data, emphasis is now on strategies to improve responses to HDT, rather than on purging autografts.

Hematopoietic Stem Cell Source. Mobilized PBSCs provide for more rapid engraftment compared to BM. Myeloma patients with less than 1 year of prior therapy had faster granulocyte and platelet recovery after peripheral blood stem cell transplants compared with BM autografts.³³⁴ The duration of prior chemotherapy, especially with stem-cell-damaging agents (melphalan, BCNU, and high-doses of cyclophosphamide) along with radiation to BM-containing areas, significantly affects the ability to procure adequate quantities of PBSCs and engraftment kinetics posttransplant.³³⁵ After mobilization with cyclophosphamide and GM-CSF, normal PBSCs are mobilized during the first 3 days of leukapheresis, whereas peak levels of contaminating myeloma cells are present on subsequent days. These myeloma cells show a higher LI and a more immature phenotype (CD19+).³³⁶

Management of Older Patients

Unlike in the past, melphalan and prednisone is no longer a standard of care for older adults with myeloma. The two- and three-drug combinations of novel agents described previously for newly diagnosed patients remains an important option. In this age group, which most of the time is not considered eligible for transplant, the combination of bortezomib, or lenalidomide, or both with dexamethasone is considered the preferred option. However, MP in combination with these novel agents also achieves high levels of response and can be considered an alternative (see Fig. 112.11). A recent study showing superiority and decreased secondary malignancy risk of continuous Rd combination over MPT suggests that future utilization of MP based therapy will decrease in newly diagnosed older individuals with myeloma. To manage toxicity, the dose of therapeutic agents, including dexamethasone, needs to be reduced in patients >75 years of age.³³⁷ The presence of comorbidities, frailty, and disabilities needs to be assessed and considered in the selection of agents and dose modifications.³³⁸ As the incidence of myeloma increases with age, the role of HDT has also been evaluated in patients >65 years old. Older age does not impact stem cell mobilization or engraftment.³³⁹ The feasibility and efficacy of HDT with PBSC transplant has been evaluated

TABLE 112.14

Stem Cell Transplantation as Upfront Versus Rescue Treatment: Results of a Randomized Study

^a Significant difference.

in patients 70 years old (median age, 72 years of age; range, 70 to 83 years of age) treated with melphalan (200 mg/m² or 140 mg/m²).³⁴⁰ Of note, treatment-related mortality was higher (16%) in the initial 25 patients receiving melphalan at 200 mg/m². CR was achieved in 27% patients, but median CR duration was only 1.5 years, with 3-year EFS and OS rates projected at 20% and 31%, respectively. Although this study confirms the feasibility of HDT in older patients with MM, it also indicates a higher risk in this patient population. High response rates using the novel agent combinations are decreasing the consideration of HDT in this elderly population.

Management of Patients with Renal Dysfunction

One-third of patients with overt MM present with renal insufficiency. With hydration, control of hypercalcemia, and effective therapy, it is reversible in 50% cases. Renal dysfunction of <6 months duration and the rapid initiation of therapy with a reduction in monoclonal protein are associated with a higher likelihood of improvement in renal function. Improved renal function is observed mainly in patients with light chain cast nephropathy and light chain deposition disease; therefore, renal biopsy is used to identify these reversible conditions and the need for aggressive treatment. A number of agents can be safely used in patients with renal dysfunction. This includes steroids, melphalan,³⁴¹ cyclophosphamide, bortezomib,^{294,342} and thalidomide. Ease of administration, limited toxicity, and effectiveness make these novel agents the primary modes of therapy for myeloma patients with renal failure. In one retrospective analysis, 24 patients on dialysis were treated with bortezomib or bortezomib-based combinations. Of 20 patients with available response data, 75% patients achieved at least PRs, with 30% patients achieving CRs + near CRs. One patient was spared dialysis, and three other patients became independent of dialysis following bortezomib-based treatment.^{294,342} Lenalidomide has predominant renal excretion and requires dose modification if used in patients with renal failure based on creatinine clearance.³⁴² However, pomalidomide can be safely administered in these patients. Because the pharmacokinetics of melphalan are unaltered by renal failure, such patients have been previously considered as potential candidates for high-dose therapy.³⁴¹ In one study, high-dose melphalan and PBSC transplantation was used to treat 81 patients with MM and renal dysfunction (creatinine >2 mg per deciliter).³⁴³ Although renal failure had no impact on the quality of stem cell collection and/or engraftment, treatment-related mortality rates were 6% and 13% after the first and second autologous SCTs, respectively, and melphalan at 200 mg/m² caused excessive toxicity. Complete remission was achieved in 31 patients (38%) after tandem SCT, and the probabilities of EFS and OS at 3 years were 48% and 55%, respectively. Dose reduction and close monitoring are therefore needed to ensure the safety of the procedure, and the role of transplantation in the setting of renal failure remains investigational.

Maintenance Therapy

Despite improvements in remission rates, there is no clear plateau in the survival curves following conventional or HDT. Although the proportion of patients achieving complete responses has increased, all patients eventually relapse. Various maintenance therapies have been evaluated in MM in an effort to sustain remission. IFN- α is the most widely evaluated agent as maintenance therapy; however, randomized studies have only demonstrated modest improvements in EFS and OS times (5 to 12 months) in patients achieving remission with standard-dose therapy, and its role following HDT has not been confirmed.³⁴⁴ Low-dose prednisone administered on alternate days has prolonged remission duration following standard-dose therapy in a single randomized study.³⁴⁵ In the last few years, many studies have evaluated novel agent-based maintenance regimens (Table 112.15). Attal and his

colleagues from the IFM group reported improved probability of EFS and OS at 3 years in patients receiving thalidomide and pamidronate compared to the patient cohorts receiving either pamidronate alone or no maintenance therapy following high-dose therapy (PFS 52%, 37%, and 36%, respectively; p < 0.009; OS 87%, 74%, and 77%, respectively; p < 0.04).³⁴⁶ In this study, patients had not received thalidomide prior to its evaluation as maintenance therapy, and the benefit was observed in those patients who had further evidence of response to thalidomide. The prolonged use of thalidomide leads to the development of neuropathy, and more recently, lenalidomide, which has a more favorable toxicity profile, has been evaluated as maintenance therapy in the dose of 10 to 15 mg daily for 21 out of a 28-day cycle in three different studies: two posttransplantations and one following standard-dose MPR therapy.³⁴⁷⁻³⁴⁹ All three studies show clear evidence of benefit, evidenced by the prolongation of PFS. One of the studies (CALGB 100104) has now shown OS benefit with lenalidomide maintenance, whereas two other studies with limited follow-ups are yet to observe an OS improvement. Importantly, all three studies show a small increased incidence of second primary malignancy in the arms receiving lenalidomide compared to placebo. This has prompted a careful evaluation and discussion with the patient of the benefit of lenalidomide maintenance. Because of its significant benefit, lenalidomide is considered the standard of care for maintenance therapy in myeloma. The HOVON trial has compared vincristine, adriamycin, and dexamethasone induction followed by high-dose melphalan and transplantation with Velcade maintenance versus Velcade, adriamycin, and dexamethasone induction high-dose melphalan and transplantation followed by thalidomide maintenance. With a 5-year follow-up, there is a PFS and OS benefit in the Velcade arm, including patients with high-risk (p17 deleted) MM.³⁵⁰ In the nontransplant population, a recent study has also highlighted the use of a Velcade-based maintenance regimen especially in combination with low-dose

thalidomide.³⁵¹ Additional immune manipulations, such as idiotype vaccinations, protein-pulsed dendritic cell-based vaccinations, dendritic cell-MM cell fusion vaccinations, and/or PD-1 checkpoint blockades are all strategies under evaluation as maintenance treatments to prolong EFS and OS in patients with myeloma.^{352,353}

Minimal Residual Disease

Due to improvements in therapies, higher frequencies and depth of responses are being observed. There is emerging data that patients achieving CRs have superior survival outcomes compared to those achieving partial responses or no responses. This has now led to the investigation of methods to refine CR definition. The current definition includes the absence of paraprotein in the urine and serum by immunofixation and the disappearance of clonal plasma cells in the bone marrow using cytologic examination; stringent CR in addition requires normalization of the kappa/lambda free light chain ratio. The newer sensitive seven-color flow cytometric immunophenotypic assays can detect 1 clonal cell in 10^4 normal cells, and a molecular method that incorporates allele-specific oligonucleotide PCR (ASO-PCR) can detect up to 1 clonal cell in 10^{5-6} normal cells, each enhancing the ability to detect greater depth of response. To obviate the need for patient-specific customization, a sequencing-based molecular method is now being developed that identifies clonal gene rearrangements using consensus primers to universally amplify rearranged IgH and k gene segments, followed by high-throughput sequencing to quantify these rearrangements in follow-up minimal residual disease (MRD) samples.³⁵⁴ In early studies using multiparameter flow cytometry, the prognostic value of MRD was assessed: in 378 patients after induction therapy and at day 100 after autologous stem cell transplantation (ASCT) and in 245 patients at the end of induction therapy in nontransplant patients. In patients undergoing ASCT, the absence of MRD at day 100 after ASCT was highly predictive of a favorable outcome (PFS, $p < 0.001$; OS, $p = 0.0183$), including in patients achieving immunofixation-negative CR ($p = 0.0068$). An MRD assessment after induction therapy in the non-intensive-pathway patients was not predictive of outcome (PFS, $p = 0.1$). This and other emerging data highlight the need to measure and achieve molecular CR in myeloma.³⁵⁵ Similarly, in a study using a multiparameter flow cytometry method to detect MRD in 241 patients in CR at day +100 after ASCT, the detection of persistent MRD after ASCT was the only independent factor (HR, 8.0; $p = 0.005$), besides high-risk cytogenetics, that predicted for unsustained CR and a poor outcome.³⁵⁶

Allogeneic Transplantation

Syngeneic Transplantation

Bensinger et al.³⁵⁷ have reported their experience with 11 patients receiving syngeneic transplants: Five patients achieved CR and three achieved PR, with one patient from both groups alive at 9 and 15 years after transplantation, respectively. A larger experience from the European bone marrow transplant (EBMT) Registry compared 25 patients undergoing syngeneic transplants with 125 case-matched patients undergoing autotransplantation or allogeneic transplantation.³⁵⁸ The complete remission rate was not significantly different between the three grafts (twin: 68%, autologous: 48%, and allogeneic: 58%). However, patients undergoing syngeneic transplantation had significantly superior median survival time compared with autologous (72 months versus 25 months; $p = 0.009$) or allogeneic (72 months versus 16 months; $p = 0.008$) transplant recipients.

Allogeneic Transplantation

Allogeneic transplantation has remained a difficult procedure in myeloma. An elder age population with limited donor availability coupled with frequent renal impairment has restricted the use of

TABLE 112.16

^aT-cell depleted.

matched sibling transplantation in MM. Additionally, almost 50% 1-year mortality has limited use of this procedure to only a high-risk patient population. Importantly, the allogeneic graft versus myeloma (GVM) effect may result in a favorable long-term outcome after allogeneic transplantation. Results of three large studies are listed in Table 112.16. A retrospective analysis of a case-matched analysis of EBMT registry data compared 189 patients receiving allografts with an equal number of patients from the same time period receiving autotransplants. This study showed a superior median survival outcome for patients undergoing autotransplants compared to allogeneic transplants (34 versus 18 months, respectively).³⁵⁹ The 1-year treatment-related mortality was significantly higher following allogeneic transplantation (41% with allotransplants and 13% with autotransplants). However, patients undergoing allogeneic transplantation and surviving the 1st year had a tendency for better PFS and OS.

A very low transplant-related mortality of 10% has been reported from a single-center experience from the Dana-Farber Cancer Institute due to the selective depletion of CD6⁺ T cells as the sole form of a graft versus host disease (GvHD) prophylaxis.³⁶⁰ However, the median PFS time was 12 months, and the median OS time was 22 months, a result inferior to their previous experience of autologous transplantation. Case-matched comparative studies from other single institutions have also failed to show a survival advantage for allotransplants.³⁶¹

Donor Lymphocyte Infusions

A GVM effect has been demonstrated by the induction of CR with donor lymphocyte infusion (DLI) following relapse after allogeneic transplantation.³⁶² In a large study, Lokhorst et al.³⁶³ have reported 6 CR and 8 PR following DLI in 27 patients after allotransplant. Five of these patients remained disease free >30 months after DLI. However, DLI was associated with acute GvHD in 55% and chronic GvHD in 26% of patients. Five patients experienced BM aplasia, which was fatal in two cases. A similar DLI experience has been reported by Salama et al.³⁶⁴ Several strategies have been explored to reduce GvHD after DLI,^{365,366} including lowering the number of T cells infused, the selective depletion of CD8⁺ T cells, and the use of herpes simplex virus (HSV) thymidine kinase gene transduction of DLI to allow for use of ganciclovir to deplete T cells if significant GvHD develops. Immunizing donors with an idiotype vaccine may allow for the selective transfer of T cells specific for GVM without increasing the incidence of GvHD.

Nonmyeloablative Transplants

Studies in a canine model showed that a nonmyeloablative dose of TBI could lead to successful engraftment when used in conjunction with a combination of cyclosporine and

TABLE 112.17

mycophenolate mofetil.³⁶⁷ This animal experience, coupled with reduced day 100 transplant-related mortality in pilot studies in patients, has allowed for allogeneic-matched sibling transplantation in patients who were otherwise considered poor risk for the standard allogeneic preparative regimen. Results from larger published studies evaluating nonmyeloablative regimens with allogeneic transplantation are listed in Table 112.17. Badros et al.³⁶⁸ first reported on 31 patients undergoing allogeneic transplants following nonmyeloablative conditioning with melphalan (100 mg/m²). Transplant-related mortality in the first 120 days was low (10%). Nineteen (61%) patients achieved CR or near CR; however, acute GvHD developed in 18 patients (58%), and chronic GvHD was seen in 10 patients (35%).³⁶⁸ Giralt et al.³⁶⁹ have used reduced intensity conditioning with fludarabine and melphalan in 16 patients; successful engraftment was observed in all patients; however, the 100-day mortality rate was 20% and the 1-year mortality rate was 40%, with only six patients alive after a median follow-up period of 15 months. Maloney et al.³⁷⁰ have evaluated the combination of initial autotransplantation for tumor cytoreduction followed by nonmyeloablative matched-sibling transplantation in 54 patients. The treatment was performed in an outpatient setting with a low 100-day mortality (2%). The overall response rate was 83%, with 53% achieving CRs. With a median follow-up of 552 days after allografting, OS is 78%. However, GvHD continues to be a problem; 38% of patients developed acute GvHD and 46% developing chronic GvHD requiring therapy.

In a more recent clinical study, 162 consecutive patients with newly diagnosed myeloma who were less than 65 years of age received induction therapy with VAD, followed by either nonmyeloablative total-body irradiation and stem cells from the HLA-identical sibling after an initial autograft (n = 80) or two consecutive myeloablative doses of melphalan, each of which was followed by autologous stem-cell rescue if an HLA-identical donor was not available (n = 82). After a median follow-up of 45 months (range, 21 to 90), the median OS (80 months versus 54 months; p = 0.01) and event-free survival (35 months versus 29 months; p = 0.02) were longer in the patients with HLA-identical siblings than in the patients without HLA-identical siblings. Treatment-related mortality did not differ significantly between the two groups, (p = 0.09) but disease-related mortality was significantly higher in the double-autologous transplant group (43% versus 7%; p < 0.001). The cumulative incidence rates of > grades I and grade IV GvHD were 43% and 4%, respectively. These results suggest a role for allografting, especially in patients with high-risk disease where improvement in long-term outcome has been limited.³⁷¹ Although the early clinical results with nonmyeloablative transplants are encouraging, this

strategy is associated with significant morbidity due to acute and chronic GvHD and a mortality rate of 10% to 20% at 1 year. Another study by Risonol et al.³⁷² reported on 110 patients with MM undergoing ASCT, who either received a second ASCT (85 patients) or a reduced-intensity conditioning allograft (allo-RIC; 25 patients), depending on the HLA-matched sibling donor availability. Although there was a trend toward a longer PFS (median, 31 months versus not reached; p = 0.08) in favor of allo-RIC, it was associated with a trend toward a higher transplantation-related mortality (16% versus 5%; p = 0.07), and there was no statistical difference in event-free survival and overall survivals.³⁷² It should, therefore, only be utilized in the context of clinical trials attempting to improve patient outcome by both enhancing efficacy and reducing toxicity.³⁷³ The CTN most recently compared single autografts followed by nonmyeloablative allografts if a matched donor was available versus a second autograft in the absence of an appropriate donor and found that the outcome was similar in both arms.³⁷⁴ Due to attendant toxicity in all allografting studies, including nonmyeloablative regimens, allotransplant is recommended primarily in the context of a clinical trial to exploit the graft versus MM immune effect while avoiding attendant toxicity.

Bisphosphonates

The second- and third-generation bisphosphonates, pamidronate and zoledronate, reduce skeletal complications and bone pain in myeloma (Table 112.18).^{375,376} Their mechanism of action includes the downregulation of osteoclast activity, decreased IL-6 production, the activation of gamma/delta T cells with antimyeloma activity, and the induction of apoptosis of osteoclasts through the inhibition of farnesyl and geranylgeranyl transferase activity.^{377,378} Besides reducing bone-related problems, the continued administration of pamidronate over 21 months showed some survival advantage (21 versus 14 months; p = 0.041) in patients receiving salvage chemotherapy and pamidronate versus chemotherapy alone.^{375,379} In vitro cytotoxic effects of bisphosphonates have been observed in myeloma cell lines^{380,381} and patient cells in vitro, as well as in patient tumor specimens in the SCID-hu in vivo model. Preliminary reports of pamidronate administered alone frequently (every 2 weeks) have shown a response or delay in disease progression in occasional patients.³⁸² Pamidronate 90 mg and zoledronic acid 4 mg are equipotent in reducing bone-related problems in myeloma; the infusion time for zoledronic acid is 15 minutes compared to 1 to 2 hours for pamidronate.

The role of zoledronic acid was confirmed by the MRC Myeloma IX study, in which 1960 patients were randomized to

intravenous zoledronic acid or oral clodronic acid (1,600 mg per day): There was a significantly lower incidence of skeletal-related events with zoledronic acid (27% versus 35%, respectively; $p = 0.0004$) both in patients with and without bone lesions at baseline.³⁵³ The results of this study support the early use of zoledronic acid in newly diagnosed MM, irrespective of bone disease status. A further analysis of this data suggested that its continued use beyond 2 years was beneficial. Interestingly, the study also showed that zoledronic acid reduced mortality by 16% versus clodronic acid ($p = 0.0118$), and extended median OS by 5.5 months (50.0 months versus 44.5 months; $p = 0.04$). Zoledronic acid also significantly improved PFS by 12% (95% CI, 2 to 20) versus clodronic acid ($p = 0.0179$), for the first time confirming antimyeloma activity of bisphosphonates. Rates of complete, very good partial, or partial response did not differ significantly between the zoledronic acid and clodronic acid groups.³⁵⁴ Patients on long-term bisphosphonates should be monitored for development of renal toxicity. Renal dysfunction induced by pamidronate affects mainly tubules and manifests first as proteinuria followed by a rise in creatinine, whereas zoledronic acid affects glomeruli and manifests as a rise in creatinine without proteinuria. Even mild renal dysfunction requires bisphosphonate dose adjustment, and renal effects of bisphosphonates can be partly prevented by extending the duration of infusion. Osteonecrosis of the jaw (ONJ) is another complication of prolonged bisphosphonate therapy, which is observed in patients with dental procedures and in relationship to dental infection. In one study, 11 of 292 patients with MM (3.8%) had ONJ.³⁵⁵ There is also some association between prolonged use and development of ONJ. Due to the increased detection of this complication, a prophylactic dental checkup and follow-up is recommended. After 2 years of administration, the frequency of administration of bisphosphonate may be modified in patients achieving VGPR or CR.³⁵⁶ In a large phase 3 study, the antimyeloma activity of zoledronic acid has been described. Multiple agents directed at novel bone-directed targets are under investigation. The efficacy of denosumab, a RANKL-targeting antibody, has been confirmed in a phase 3 study in myeloma and breast cancer. An antibody targeting DKK-1 (BHQ-880), which improves osteoblastic activity, and a chimeric protein targeting

activin A (ACE-011), are currently under evaluation in phase 1/2 clinical studies.

Therapy in Relapsed Patients

The options and therapeutic strategies for relapsed MM patients depend on the induction regimen used and whether the patients have undergone high-dose therapy and stem cell transplant. With the availability of multiple novel agents that have been approved for clinical use in MM—bortezomib, lenalidomide/dexamethasone, bortezomib and liposomal doxorubicin, pomalidomide, and carfilzomib—the choice will partly depend on the agent or combination not used as an induction and on the presence of existing toxicity such as neuropathy, cytopenias, or DVT.

The results of the international randomized phase III trial of bortezomib (1.3 mg/m² intravenously [IV] on days 1, 4, 8, and 11 every 3 weeks for eight cycles) have demonstrated its superiority over dexamethasone alone (40 mg by mouth [PO] on days 1 through 4, 9 through 12, and 17 through 20 every 5 weeks for four cycles) in terms of response rates (38% versus 18%, respectively; $p < 0.001$), median time to progression (6.22 months versus 3.49 months respectively; $p < 0.001$) and survival (1-year survival 80% versus 66%, respectively; $p = 0.003$) in 669 relapsed patients with MM who had received one to three prior therapies.²⁹¹ Another open label study has further confirmed the ability of added dexamethasone to improve response in relapsed patients. Various combinations of bortezomib with other agents such as doxorubicin, cyclophosphamide, and melphalan have been used to treat patients with MM, and results of larger representative studies are shown in Table 112.10B. For example, a randomized phase 3 multicenter international study has confirmed that the combination of bortezomib and pegylated liposomal doxorubicin is superior to bortezomib alone for both overall response (50% versus 42% respectively; $p = 0.05$), and time to progression (9.3 months versus 6.5 months, respectively; $p < 0.0001$) in relapsed MM patients. Additionally, a combination of oral cyclophosphamide, dexamethasone, and bortezomib in 50 patients with relapsed/refractory MM has been reported to achieve ORR in 88% of patients, with a median event-free survival of 10 months and median overall survival not yet reached. The broader clinical benefit of other regimens remains to be determined.

Lenalidomide has been evaluated in two large phase 3 studies comparing it in combination with dexamethasone to high-dose dexamethasone and placebo. The combination of lenalidomide and dexamethasone showed significant advantages in the response rate (CR + PR: 56% versus 24%, respectively; $p < 0.001$) and in time to progression (14 versus 5 months, respectively; $p < 0.01$), as well as OS (30 versus 20 months, respectively; $p < 0.01$). Lenalidomide was equally active in patients with or without previous exposure to bortezomib or thalidomide. However, lenalidomide in combination with high-dose dexamethasone had significantly higher rates of DVT (14% versus 5%, respectively; $p < 0.01$). Lenalidomide has also been assessed in combination with bortezomib and dexamethasone in a phase 1/2 trial in patients with relapsed or refractory MM.

A pilot phase 1/2 study in relapsed refractory myeloma has evaluated the combination of lenalidomide and bortezomib in 38 patients. A 61% minimal response or better was observed, and 83% patients achieved stable disease or better when dexamethasone was added, including patients whose MM was resistant to either agent alone. Thalidomide has also been an active agent, both alone and in combination with dexamethasone in relapsed patients (see Table 112.8B). Although lenalidomide activity has been demonstrated in patients relapsing after thalidomide, it is unclear whether patients relapsing after lenalidomide will respond to thalidomide. A combination of bortezomib (1.0 to

1.3 mg/m²), thalidomide (50 to 200 mg per day) and dexamethasone (40 mg for 4 days) has been evaluated by Zangari et al.: In 83 patients with relapsed/refractory disease (over 70% patients having previously received thalidomide), 80% overall response with 16% CRs was reported. In relapsed MM, the combination of conventional chemotherapy not previously used with or without novel agents can be effective. Four-drug combinations, such as DCEP (dexamethasone, cyclophosphamide, etoposide, and cis-platinum), have been reported to achieve high response rates in relapsed patients, especially with aggressive disease. A regimen incorporating thalidomide + adriamycin with DCEP (DTPACE) for relapsed/refractory MM (n = 236) prior to HDT/SCT achieved 32% PR after two cycles of DTPACE, with 16% attaining a CR or nCR.³⁸⁷

A number of newer agents have been investigated in relapsed and/or refractory myeloma. In 2013, two novel agents, carfilzomib and pomalidomide, have been approved by the FDA for use in relapsed/refractory patients with myeloma. Carfilzomib, a second-generation proteasome inhibitor that selectively and irreversibly binds its target, has demonstrated single-agent and combination activity in relapsed and refractory patients with MM. In patients with relapsed MM after ≥ two previous therapies including bortezomib and an immunomodulatory agent and refractory to the last treatment (n = 42), the best ORR was 16.7%, and the median duration of response was 7.2 months.³⁸⁸ In another phase 2, open-label, multicenter clinical trial (n = 35), patients with relapsed and/or refractory MM following one to three prior therapies including at least one bortezomib-based regimen, the best ORR was 17.1%, the median duration of response was >10.6 months, and the median time to progression was 4.6 months.³⁸⁹ In an expanded single-arm phase 2 study, patients received single-agent carfilzomib 20 mg/m² intravenously twice weekly for 3 of 4 weeks in cycle 1, then 27 mg/m² for ≤12 cycles. In this study, 95% of 266 patients were refractory to their last therapy and 80% refractory or intolerant to both bortezomib and lenalidomide. In this study, ORR was 23.7%, with a median duration of response of 7.8 months, and median OS was 15.6 months.³⁹⁰ Based on results of these studies, carfilzomib is now FDA approved for the treatment of relapsed myeloma. In another study in 129 bortezomib-naïve patients with relapsed MM, ORR was 42.4% in Cohort 1 and 52.2% in Cohort 2, in which patients received an increased dose of 27 mg/m² after the first cycle.³⁹¹ A low incidence of peripheral neuropathy (17.1% overall; one grade 3; no grade 4) was observed in these bortezomib-naïve patients. Notably, in all studies, peripheral neuropathy and neuropathy-related AEs were generally mild and infrequent. An analysis of response and survival data from the PX-171-03 study (n = 229) identified 62 patients (27.1%) with high-risk cytogenetics profiles (del 17p13, t[4;14] or t[14;16] by FISH or deletion 13 or hypodiploidy by metaphase cytogenetics) versus 167 patients (72.9%) with standard risk. Overall response was comparable between these two groups (25.8% versus 24.6%, respectively), but there was a trend in high-risk patients for a shorter median duration of response (5.6 months versus 8.3 months, respectively) and OS (9.3 months versus 19.0 months, respectively; p = 0.0003). This study suggests that single-agent carfilzomib is efficacious and has the potential to at least partially overcome the impact of high-risk cytogenetics in heavily pre-treated MM.³⁹²

Pomalidomide, a more potent immunomodulatory drug, has demonstrated activity even in patients with MM resistant to lenalidomide. Pomalidomide at doses of 2 or 4 mg per day with weekly dexamethasone at 40 mg has demonstrated excellent activity in patients with MM. A phase 2 study (n = 35) confirmed responses in the 2-mg cohort (14% VGPR, 11% PR, and 23% MR), with an overall response rate (ORR) of 49%; and in the 4-mg cohort (3% CR, 9% VGPR, 17% PR and 14% MR), with an ORR of 43%. Overall survival at 6 months was 78% and 67% in the 2- and 4-mg cohort, respectively. Myelosuppression was the most common toxicity.³⁹³ In another study (n = 60), pomalidomide

2 mg daily with Dex 40 mg orally on days 1, 8, 15, and 22 of each cycle in relapsed or refractory MM achieved a 63% response, including 5% CR and 28% VGPR. Responses were observed in 40% patients with lenalidomide-refractory MM. The median PFS was 11.6 months.³⁹⁴ A phase 1 dose-escalation study determined the maximum tolerated dose (MTD) of oral pomalidomide 4 mg to be administered on days 1 to 21 of each 28-day cycle in patients with relapsed and refractory MM, with Dex added if no response occurred after four cycles. Among the 38 patients enrolled (including 22 with added dexamethasone), 42% achieved a minimal response or better, 21% achieved a partial response or better, and 3% achieved a complete response. The median duration of response, PFS, and OS were 4.6, 4.6, and 18.3 months, respectively.³⁹⁵ IFM conducted a phase 2 randomized study comparing pomalidomide (4 mg) on days 1 to 21 (n = 43) or continuously (n = 41) over a 28-day cycle, plus dexamethasone given weekly, and reported similar response rates (35% versus 34%); time to progression (5.8 versus 4.8 months) and OS (14.9 versus 14.8 months); along with a similar toxicity profile, primarily myelosuppression, in both groups.³⁹⁶ These studies have established pomalidomide 4 mg per day on days 1 to 21 of a 28-day cycle with 40-mg weekly dexamethasone as a standard for future studies. A phase 3, multicenter, randomized, open-label study of pomalidomide in combination with low-dose demonstrated a significant PFS and OS advantage over dexamethasone alone in patients with relapsed/refractory MM.³⁹⁷ In a recent phase 1 study combining pomalidomide with bortezomib and dexamethasone in patients with relapsed/refractory MM showed 73% ORR and 27% VGPR, in patients who had previously received both bortezomib and lenalidomide, including 73% patients whose disease progressed on lenalidomide.³⁹⁸

Based on preclinical synergistic activity and phase 2 studies showing the ability of HDAC inhibitors (vorinostat and panobinostat) to overcome bortezomib resistance, ongoing phase 3 studies comparing bortezomib with combination of bortezomib with vorinostat and with panobinostat have been completed. Although increased responses were noted in relapsed MM treated with bortezomib and vorinostat versus vorinostat, alone, the PFS advantage was only one month, with treatment limited by diarrhea, thrombocytopenia, and fatigue.³⁹⁹ The more selective HDAC inhibitor rocinostat has been combined with bortezomib, as well as with lenalidomide/dexamethasone⁴⁰⁰ and has achieved responses with a more favorable side effect profile. The combination of bortezomib and Akt inhibitor perifosine is able to overcome bortezomib resistance.⁴⁰¹ Finally, an antibody targeting CS-1 cell surface molecule (elotuzumab) has been shown to achieve over 80% response when combined with lenalidomide/dexamethasone in relapsed MM, and anti-CD38 monoclonal antibodies (daratumumab) are similarly achieving responses, even in high-risk relapsed MM.

Other Potential Agents and Future Direction

Both in vitro systems and in vivo animal models have been developed to characterize mechanisms of MM cell homing to BM, as well as factors (MM cell–BM stromal cell interactions, cytokines, angiogenesis) promoting MM cell growth, survival, drug resistance, and migration in the BM milieu. These model systems have allowed for the development of several promising biologically based therapies including the previously mentioned anti-CS1 antibody elotuzumab, the anti-CD38 antibody daratumumab, the HDAC6 inhibitor ricolinostat, as well as heat shock protein 90 inhibitor (AUY 922) and telomerase inhibitor GRN 163L, among many others (Fig. 112.15). Detailed oncogenomic studies are identifying novel targets and pathways operative in myeloma, and ongoing studies are determining mechanisms of action of novel agents at a gene and protein level in order to provide the framework for rational combination clinical trials that will overcome drug resistance and improve patient outcomes.

Targeting MM cell

Telomerase inhibitor GRN 163L, IGF1R inhibitor, AKT inhibitor perifosine liposomal doxorubicin, epothilone B, farnesyltransferase inhibitor, trial genasense, monoclonal antibodies targeting CD40, CD56, CS1, vaccination

113 Cancer of Unknown Primary Site

F. Anthony Greco and John D. Hainsworth

INTRODUCTION

Cancer of unknown primary (CUP) site is a clinical syndrome that includes many types of advanced cancers. Patients are considered to have CUP if no anatomical primary site is identified after clinical evaluation. As diagnostic techniques improve, the spectrum of patients with CUP continues to evolve.

Patients with CUP are common. The exact incidence is unknown because many of these patients are assigned other diagnoses and therefore are not accurately represented in tumor registries. Nonetheless, in the United States, CUP accounted for approximately 2% of all cancer diagnoses reported by Surveillance, Epidemiology, and End Results (SEER) registries.¹ International registries from seven other countries have reported incidences ranging from 2.3% to 7.8%.² The authors believe a more realistic estimate of the incidence of these patients is 5% of all invasive cancers, or approximately 80,000 to 90,000 patients per year in the United States.

Patients in this heterogeneous group have a wide variety of clinical presentations and histologic tumor types. Most patients have metastatic carcinoma; however, many neoplasms are difficult to categorize using histologic features alone. At autopsy, primary sites (usually <2 cm in size) can be located in the majority of patients; the molecular basis of this unusual biologic behavior is undefined. The preponderance of poorly treated tumor types in autopsy series (lung, pancreas, stomach, colon, liver) has led to negativity surrounding the diagnosis of CUP.³

Until recently, the major advance in the management of CUP was the recognition of several important patient subsets, identified by clinical and/or pathologic features and shown to benefit from specific first-line therapy. For the remainder of CUP patients (about 80%), empiric chemotherapy regimens were developed and resulted in modest benefit. At the time these regimens were developed, most types of solid tumors were poorly treated, and considerable overlap existed in the chemotherapy regimens used to treat sensitive tumor types. In this context, the possibility of developing a broad-spectrum chemotherapy regimen to adequately treat most of the treatable tumor types within the CUP population seemed feasible. However, during the last 20 years, treatments have not only improved for many tumor types, but have also become more site specific. Therefore, the idea of providing optimal treatment to patients with a diverse group of solid tumors using a single chemotherapy regimen is no longer feasible.

An accurate prediction of the tissue of origin is now possible for the majority of patients with CUP, using either improved panels of immunohistochemical (IHC) stains or molecular gene expression tumor profiling (MTP). Although the anatomical primary sites cannot be found in most patients even after the tissue of origin is predicted, increasing clinical experience confirms that these predictions can effectively guide site-specific therapy for patients with CUP.

This chapter is divided into three major sections. The first section reviews the pathologic evaluation of patients with CUP. New information regarding the emerging and important role of MTP assays is included. In the second section, the clinical evaluation of CUP patients is summarized. Situations in which results from the pathologic evaluation direct the clinical evaluation are addressed. Finally, the treatment of patients with CUP is discussed, with an emphasis on the favorable prognostic subsets and the new paradigm of site-specific therapy directed at the tissue of origin.

PATHOLOGIC EVALUATION

Histologic examination by hematoxylin and eosin (H&E) staining of a biopsy tumor specimen remains the gold standard for the initial evaluation and provides a practical classification system on which to base a subsequent evaluation. In the broad category of CUP, there are five major light microscopic histologic diagnoses: (1) poorly differentiated neoplasm, (2) poorly differentiated carcinoma (with or without features of adenocarcinoma), (3) well-differentiated and moderately well-differentiated adenocarcinoma, (4) squamous cell carcinoma, and (5) neuroendocrine carcinoma. Sarcoma and melanoma are also occasionally diagnosed without an obvious primary tumor site, and management of these patients follows established guidelines. These histologic diagnoses define patient groups that vary to some extent with respect to clinical characteristics, a recommended diagnostic evaluation, treatment, and prognosis (Fig. 113.1). Because a histologic examination rarely allows for the identification of the site of tumor origin, an additional pathologic evaluation is important in almost every patient with CUP. A fine-needle aspiration biopsy usually does not contain enough of a biopsy specimen for the necessary pathologic evaluation, and should not be performed as the initial diagnostic procedure. Close communication between the oncologist and pathologist is critical to ensure that the most important diagnostic studies are obtained with the available biopsy material.

Poorly Differentiated Neoplasms of Unknown Primary Site

If the pathologist cannot differentiate a general category of neoplasm (e.g., carcinoma, lymphoma, melanoma, sarcoma), the tumor is designated a poorly differentiated neoplasm. A more precise diagnosis is essential because many patients in this category have responsive tumors. Approximately 5% of all patients with CUP (4,000 patients annually) present with this diagnosis after a standard histologic evaluation. However, only a few remain without a defined lineage after specialized pathologic studies including IHC staining, electron microscopy, and, recently, MTP.⁴⁻⁷ (These techniques are discussed separately.) In reported series, 35% to 65%

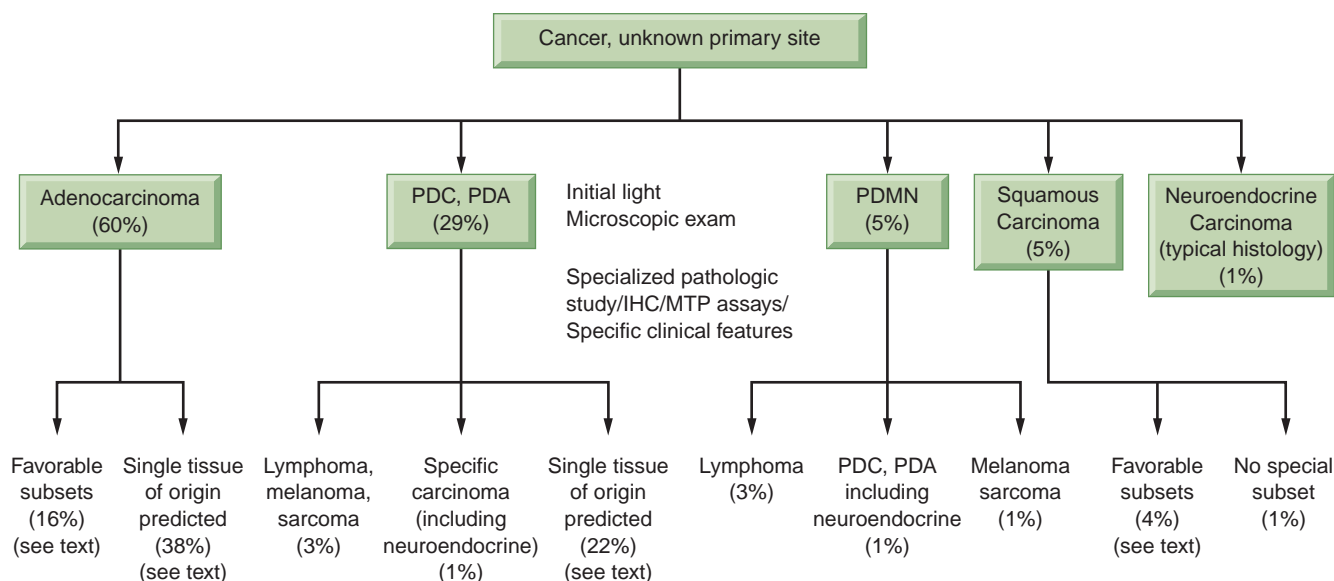

Figure 113.1 Relative size of various subgroups of patients as determined by clinical, specialized pathologic, and molecular evaluations. PDC, poorly differentiated carcinoma; PDA, poorly differentiated adenocarcinoma; IHC, immunohistochemistry; MTP, molecular tumor profiling; PDMN, poorly differentiated malignant neoplasm.

of poorly differentiated neoplasms were found to be lymphomas, which were highly responsive to specific therapy.^{4,5} Most of the remaining tumors were carcinomas, including poorly differentiated neuroendocrine tumors. Melanoma and sarcoma together account for less than 15% of all patients.

Poorly Differentiated Carcinoma

Poorly differentiated carcinomas (PDC) account for approximately 30% of CUP (about 25,000 patients annually). In approximately one-third of these patients, some features of adenocarcinomatous differentiation can be identified (poorly differentiated adenocarcinoma). Some patients have extremely responsive neoplasms, and therefore, a careful pathologic evaluation is crucial.

Histopathologic features that can differentiate chemotherapy-responsive tumors from nonresponsive tumors have not been identified.⁸ Even with a careful retrospective review of these tumors, responsive tumors of well-defined types (e.g., germ cell tumor, lymphoma) are only rarely identified.

All PDCs should undergo additional pathologic study for the purposes of (1) identifying other tumor types (e.g., lymphoma, sarcoma, melanoma) occasionally mistaken for carcinoma, (2) identifying neuroendocrine tumors, and (3) to determine the tissue of origin. Additional pathologic studies should include IHC stains, an MTP assay, and occasionally, electron microscopy and a karyotypic/cytogenetic analysis.

Adenocarcinoma

Well-differentiated and moderately differentiated adenocarcinomas are the most common tumors identified by light microscopy and account for 60% of CUP diagnoses (about 50,000 patients annually). These are the patients that many physicians associate with the entity of CUP. Typically, patients are elderly and have metastatic tumors at multiple sites. The sites of metastasis frequently determine the clinical presentation; common metastatic sites include the lymph nodes, the liver, the lung, and the bone.

The diagnosis of adenocarcinoma is based on light microscopic features, particularly the formation of glandular structures by neoplastic cells. All adenocarcinomas share histologic features, and the primary tumor site usually cannot be determined by a

histologic examination. Certain histologic features are typically associated with a particular tumor type (e.g., papillary serous features with ovarian cancer and signet ring cells with gastric cancer). However, these features are not specific enough to be used as definitive evidence of their origin.

The identification of relatively cell-specific proteins by IHC staining has improved the ability to predict the tissue of origin in CUP patients.^{7,9,10} Panels of IHC stains are most useful and are often directed by clinical features (e.g., sites of metastases, gender). Molecular tumor profiling assays are relatively accurate and often provide additional diagnostic information. Both of these diagnostic modalities should be utilized in the pathologic evaluation of adenocarcinoma of unknown primary site.

Squamous Carcinoma

Squamous carcinoma represents approximately 5% of patients with CUP (about 4,000 patients annually). Approximately 90% of these patients have specific clinical syndromes for which effective treatment is available; therefore, an appropriate clinical evaluation is important.

A definitive diagnosis of squamous carcinoma is usually made by a histologic examination. On occasion, an MTP assay may diagnose the tissue of origin. An additional pathologic study with IHC and MTP should be considered in patients with poorly differentiated squamous carcinoma, particularly if the clinical presentation is atypical.

Neuroendocrine Carcinoma

Neuroendocrine carcinoma with widely varying clinical and histologic features account for approximately 3% of all CUP (about 3,500 patients annually). Improved pathologic methods for diagnosing neuroendocrine tumors have resulted in the recognition of an increased incidence and wider spectrum of these neoplasms.¹¹

Two general subgroups can be routinely recognized by histologic features. Low-grade tumors share the same histologic features as carcinoids and islet cell tumors and may secrete bioactive substances. An MTP assay may point to the tissue of origin^{12,13}; in some instances (e.g., pancreatic origin), defining the site of origin carries treatment implications. A second histologic group

(variously described as small-cell carcinoma, atypical carcinoid, or poorly differentiated neuroendocrine carcinoma) has typical neuroendocrine features and a high-grade histology.

A third group cannot be recognized on a histologic examination, because neuroendocrine features are absent. These tumors appear histologically as poorly differentiated neoplasms or PDCs; an accurate identification requires IHC staining, an MTP assay, or occasionally, electron microscopy.

Immunohistochemical Tumor Staining

Immunohistochemical staining is the most widely available specialized technique for the classification of neoplasms.^{7,9-22} Staining usually can be done on formalin-fixed, paraffin-embedded tissue, which broadens its applicability. Most IHC antibodies are directed at normal cellular proteins that are retained during neoplastic transformation. The ongoing development of antibodies to increasingly tissue-specific proteins makes this area of diagnostic pathology a dynamic and evolving field.

Several important questions can usually be answered by IHC staining. The correct lineage of poorly differentiated neoplasms can usually be identified (Table 113.1).^{7,9,10,14-16} In particular, lymphomas (common leukocyte antigen staining) and poorly differentiated neuroendocrine carcinomas (chromogranin, synaptophysin, and CD56 staining) can be recognized,^{10,15} and staining for germ cell tumors (octamer-binding transcription factor 4 [OCT4], placental alkaline phosphatase [PLAP]) may be diagnostic in an appropriate clinical situation.

The ability of IHC staining to identify the origin of various neoplasms has improved, but in most cases, the staining results must be interpreted in the context of clinical and histologic features. An exception is the prostate-specific antigen (PSA) stain, which is very specific for prostate carcinoma.⁷ Stains suggestive of other primary sites are summarized in Table 113.1. The use of panels improves specificity^{7,9,10,19-22}; several classic staining patterns have been described that are usually diagnostic of the tissue of origin (e.g., CK7+/CK20-/TTF-1+ in lung adenocarcinoma or CK7-/CK20+/CDX2+ in colorectal carcinoma). Four stains (CK7, CK20, thyroid transcription factor-1 [TTF1], CDX2) form the

TABLE 113.1

Immunohistochemical Tumor Staining Patterns in the Differential Diagnosis of Cancer of Unknown Primary^a

Tumor Type	Immunohistochemical Staining
Carcinomas	Pan-cytokeratin AE1/3 (+), EMA (+), S100 (-), CLA (-), vimentin (-), CK7, 20 (variable)
Lymphomas	CLA (+), pan-cytokeratin AE1/3 (-), EMA (-), S100 (-)
Melanoma	S100 (+), HMB45 (+), melan-A (+) (all variable), pan-cytokeratin (-), CLA (-)
Sarcoma	Vimentin (+), desmin (+), CD117 (+), myogen (+), factor VIII antigen (+) (all variable), pan-cytokeratin AE1/3 (usually -), S100 (usually -), CLA (-), HMB45 (-), melan-A (-)
Neuroendocrine	Epithelial stains (+), chromogranin (+), synaptophysin (+), CD56 (+) (all variable)
<i>Specific Sarcomas</i>	
Gastrointestinal stromal tumor	CD117 (+), CD34 (+), DOG1 (+)
Mesothelioma	Calretinin (+), CD5/6 (+), WT1 (+), mesothelin (+)
<i>Specific Carcinomas</i>	
Colorectal	CK20 (+), CK7 (-), CDX2 (+)
Lung: adenocarcinoma	CK7(+), CK20 (-), TTF1 (+), napsin A (+)
Lung: squamous	CK7 (+), CK20 (-), P63 (+), CK5/6 (+)
Lung: neuroendocrine (small cell/large cell)	TTF1 (+), chromogranin (+), synaptophysin (+), CD56 (+)
Breast	CK7 (+), ER (+), PR (+), GCDFFP-15 (+), Her2/neu (+), mammaglobin (+), GATA3 (+) (all variable)
Ovary	CK7 (+), ER(+), WT1 (+), PAX8 (+), mesothelin (+) (all variable)
Bladder (transitional cell)	CK20 (+), CK5/6 (+), p63(+), GATA3 (+), urothelin (+) (all variable)
Prostate	PSA (+), CK7 (-), CK20 (-)
Pancreas	CK7 (+), Ca19-9 (+), mesothelin (+)
Renal	RCC (+), PAX8 (+), CD10 (+), pan-cytokeratin AE 1/3 (+) (all variable)
Liver	Hepar1 (+), CD10 (+)
Adrenocortical	Alpha-inhibin (+), melan-A (+), CK7(-), CK20(-)
Germ cell	PLAP (+), OCT4 (+)
Thyroid/follicular/papillary	Thyroglobulin (+), TTF1 (+), PAX8 (+)

EMA, epithelial membrane antigen; S100, calcium-binding protein expressed in melanocytes; CD56, neural cell adhesion molecule; CLA, common leukocyte antigen; CK, cytokeratin; HMB-45, anti-human melanosome antibody; melan-A, melanoma antigen; CD34, cluster of differentiation molecule; CD117, tyrosine kinase receptor (c-kit); CDX2, intestinal specific transcription factor; DOG1, calcium dependent chloride channel; Napsin A, novel aspartic proteinase of the pepsin family; TTF1, thyroid transcription factor 1; ER, estrogen receptor; PR, progesterone receptor; GCDFFP-15, gross cystic fluid protein 15; GATA3, zinc finger transcription factor family; WT1, Wilms' tumor transcription factor; PAX8, paired box gene 8; p63, tumor suppression gene protein; PSA, prostate specific antigen; RCC, brush border of proximal kidney tubule antibody; CD10, common acute lymphocytic leukemia antigen; hepar1, hepatocyte paraffin 1 marker; PLAP, placental alkaline phosphatase; OCT4, octamer-binding transcription factor 4.

basis of several diagnostic patterns or suggest other possibilities and are appropriate initial stains on most CUP biopsies.

Several problems are associated with the IHC stains. Technical expertise is required to perform these tests accurately; interpretation is subjective and requires an experienced pathologist. False-positive and false-negative results can occur with any of these stains. For example, some carcinomas stain with vimentin, some sarcomas stain with cytokeratins, and a wide variety of carcinomas do not always stain in the expected patterns.^{7,22} Some classic staining patterns (see Table 113.1) can overlap with staining patterns of other carcinomas, forcing the pathologist to consider two or three possible primary sites. It is not feasible to routinely perform multiple unselected stains on biopsy specimens, and management of the tissue is becoming extremely important. Consideration of the clinical setting helps to direct the selection of stains and may narrow the spectrum of possibilities if patterns are not completely specific. For example, in a patient with mucin-positive adenocarcinoma and metastases to the liver, a CK20+/CK7-/CDX-2+ staining pattern provides strong evidence for colorectal carcinoma. The IHC findings may lead to additional diagnostic procedures; in the previous example, a colonoscopy should be performed and may identify the anatomical primary site.

In many cases, a single tissue of origin site cannot be identified with certainty even after an histologic examination, IHC staining, and correlation with clinical features. An electron microscopy or karyotypic analysis is occasionally helpful in this setting. However, the use of MTP assays allows for the identification of the tissue of origin in many cases where IHC is nondiagnostic.

Electron Microscopy

A diagnosis can be made by electron microscopy in some poorly differentiated neoplasms, but should be reserved for the study of neoplasms whose lineage is unclear after a routine light microscopy, IHC staining, and an MTP assay. Electron microscopy may be useful in undifferentiated sarcoma. Ultrastructural features such as neurosecretory granules (neuroendocrine tumors) or premelanosomes (melanoma) can suggest a particular tumor. Undifferentiated tumors can lose these specific ultrastructural features; therefore, the absence of a particular ultrastructural finding cannot be used to rule out a specific diagnosis. Electron microscopy is not able to distinguish among various adenocarcinomas and cannot usually identify a tissue of origin.

Karyotypic or Cytogenetic Analysis

The existence of specific chromosomal abnormalities is well characterized in several neoplasms. Most B-cell non-Hodgkin's lymphomas are associated with tumor-specific immunoglobulin gene rearrangements, and typical chromosomal changes have been identified in some B-cell and T-cell lymphomas and in Hodgkin's lymphoma.^{23,24} In rare instances, these studies or an MTP assay is necessary when a diagnosis of lymphoma cannot otherwise be established.

The recognition of specific chromosome 12 abnormalities in germ cell tumors (e.g., i[12p], del[12p], multiple copies of 12p) occasionally allowed for the identification of extragonadal germ cell tumors in young men with poorly differentiated carcinoma of unknown origin. Motzer et al.²⁵ performed a karyotypic analysis on tumors in 40 young men with the extragonadal germ cell syndrome or midline carcinomas of uncertain histogenesis. In 12 of the 40 patients, abnormalities of chromosome 12 (e.g., i[12p]; del [12p]; multiple copies of 12 p) were diagnostic of a germ cell tumor. Other specific abnormalities were diagnostic of melanoma (two patients) and one patient each with lymphoma, peripheral neuroepithelioma, and desmoplastic small cell tumor. Of the germ cell tumors diagnosed on the basis of genetic analysis, five patients achieved a complete response to cisplatin-based chemotherapy.

These data confirm the authors' previously formulated hypothesis that some of these patients have histologically atypical germ cell tumors.

A few other nonrandom chromosomal rearrangements have been identified and occasionally can be useful in the diagnosis of CUP. Some examples include: t(11:22) in peripheral neuroepitheliomas, desmoplastic small round cell tumors, and Ewing's tumor;²⁶⁻²⁸ t(15:19) in children and young adults with carcinoma of midline structures of uncertain histogenesis;²⁹ chromosome 12 abnormalities in germ cell tumors³⁰⁻³²; t(2:13) in alveolar rhabdomyosarcoma; 3p deletion in small-cell lung cancer; 1p deletion in neuroblastoma; t(X:18) in synovial sarcoma; and 11p deletion in Wilms' tumor. Epstein-Barr viral genomes in the tumor cells of CUP patients with cervical node metastases highly suggest nasopharyngeal primaries.^{33,34}

However, most of these neoplasms can now be identified using methods that are more widely available (IHC, MTP assays), and karyotypic analyses should be reserved for patients with the histologic diagnoses of poorly differentiated neoplasm or PDC, in whom other studies fail to narrow the diagnostic spectrum.

Molecular Tumor Profiling Assays and Cancer Classification

Gene expression or molecular profiling of human neoplasms arose from a DNA microarray analysis described about 20 years ago,^{35,36} and subsequent studies have expanded genomic understanding of neoplasms.³⁷⁻⁴⁵ A pivotal study in cancer classification was reported by Golub et al.,³⁷ and demonstrated for the first time that patterns of gene expression alone could discriminate acute myeloid leukemia from acute lymphoblastic leukemia. Other investigators demonstrated that numerous cancer types could be classified accurately by measuring the differential expression of specific gene sets.⁴¹⁻⁶¹ The basis of molecular profiling in recognizing specific cancer types is the identification of the genes responsible for the synthesis of proteins required for specific normal cellular functions or relatively specific cytoplasmic microRNAs in the many different normal cell types in humans. Cancer cells often retain some of the functional characteristics specific to their tissues of origin, and can be recognized by their gene expression profiles.⁵⁹ Therefore, molecular profiling assays designed to determine the type of cancer measure gene expression dynamics in relation to cell lineage, rather than cancer-specific molecular abnormalities.

Patients with CUP represent a large heterogeneous group with clinically undefined anatomical primary tumor site and are ideal candidates for classification by molecular profiling.³⁸ Several MTP assays (molecular cancer classifiers) have been validated in the identification of known cancers and studied in CUP.

Two such assays are commercially available.^{59,61} One of these is a 92-gene reverse transcription polymerase chain reaction (RT-PCR) mRNA assay⁵⁹ (Cancer TYPE ID; bioTheranostics, Inc.), whereas the other uses microarray methodology⁶¹ to measure tissue-specific microRNAs (Cancer of Origin Test, Rosetta Genomics). A third microarray mRNA assay was previously also offered (Tissue of Origin Test), but is no longer available.⁴⁹

Two studies of more than 100 tumors each have compared the accuracy of IHC and MTP assays in determining the tissue of origin of known primary cancers.^{62,63} These blinded studies usually had generous amounts of tissue to test and allowed the participating pathologists to do numerous IHC stains. The MTP assay diagnostic accuracy was superior to IHC, particularly when tumors were poorly differentiated, or when the IHC diagnosis was unclear following the first round of IHC stains. In addition, the molecular diagnosis required much less tumor tissue (two to three unstained slides). These data support a further evaluation of MTP assays in CUP, particularly when IHC staining is inconclusive or when limited biopsy tissue is available.

STUDIES OF MOLECULAR GENE EXPRESSION TUMOR PROFILING ASSAYS IN CANCER OF UNKNOWN PRIMARY DIAGNOSIS

Accuracy in Tissue of Origin Diagnosis

The determination of the tissue of origin in CUP patients has fundamental importance and has always been the goal of their evaluation. Improved IHC and MTP assays have the potential, when used in conjunction with other clinicopathologic data, to determine the tissue of origin in most CUP patients. However, in order to feel confident in the use of an MTP assay, three questions needed to be addressed: (1) Are they accurate in diagnosing known primary cancers? (2) Are they accurate in diagnosing the tissue of origin in CUP? (3) Are the outcomes of CUP patients improved by site-specific therapies directed by MTP diagnoses? Substantial evidence supports the accuracy of MTP in diagnosing known cancers and CUP, and some of these data are reviewed here. The third question has also been addressed and is discussed in a later section (see Site-Specific Treatment Directed by Results of Molecular Gene Expression Tumor Profiling Assays).

When applied to biopsy specimens from metastatic sites or primary tumors of known cancers, various MTP assays have correctly predicted the tissues of origins and/or primary sites in about 85% of patients.^{46-51,59-61} All these studies were blinded and used the known cancer type as the reference. The accuracy of the various MTP assays has not been directly compared.

Accurate identification of the tissue of origin in CUP by MTP is difficult to validate, because the anatomical primary tumor site is unknown and only rarely becomes apparent during the subsequent clinical course of these patients. It would seem reasonable to assume that these assays have a similar accuracy rate in CUP because they have previously demonstrated in metastatic cancers of known types. This assumption is supported by the results of several studies in CUP patients (Table 113.2).^{46,47,53-58,64-68} Most studies of the accuracy of MTP assay diagnoses have been indirect, based on the correlation of the assay diagnosis with clinical features and other pathology studies (particularly IHC). In these studies, the MTP predictions correlated closely with the diagnoses suspected on the basis of standard clinical/pathologic findings. In a total of 698 CUP patients from a dozen studies using various MTP assays/platforms, an average of 80% of the molecular diagnoses were consistent with one of the suspected tissues of origin.^{46,47,53-58,64-68}

The authors and associates have studied the initial version of the 92-gene RT-PCR MTP assay in CUP patients to determine the accuracy and ability to complement standard pathology.⁶⁹ Three methods were used to assess the accuracy of the MTP assay, including a direct validation (gold standard reference) in patients who had their anatomical primary sites (latent primaries) found months to years after their initial CUP diagnoses. Two other indirect methods were used: (1) a comparison of the MTP and IHC diagnoses when IHC was able to predict a single tissue of origin, and (2) additional supportive directed IHC and clinical/histologic findings obtained after the MTP assay diagnoses.

A total of 171 CUP patients were evaluated: 151 prospectively seen from 2008 through 2010, and 20 others with latent primaries identified retrospectively from 501 patients seen from 2001 through 2008. The molecular diagnoses of these patients are listed in Table 113.2. Although the assay requires only 300 to 500 tumor cells, there was insufficient biopsy remaining (RNA) to perform the assay in 22 patients (12.9%). In 5 others (3%), the assay results were unclassifiable or not diagnostic of a single site. Of the 149 patients with sufficient tumor specimens, 144 (96%) were diagnosed with a single tissue of origin (23 tumor types).

Twenty-four patients (20 from retrospective group,⁵⁸ and 4 from prospective group) had their latent primary sites detected at a median time of 12 months (range: 2.2 to 78.5 months) after their

initial diagnosis/evaluation of CUP. In 75% (18 of 24 patients), the MTP assay diagnosis of their initial biopsies matched the latent primary tumor sites. In contrast, the IHC evaluation was successful in identifying the site of tumor origin in only 6 of 24 patients (25%).

The second method to assess the accuracy of MTP involved a comparison with IHC predictions in the 52 cases (30%) in which IHC suggested a single tissue of origin (Table 113.3). In 40 of these 52 patients (77%), the MTP and IHC diagnoses were identical. Others have reported similar results from five studies in a total of 65 patients (78% with identical IHC and MTP assay diagnoses) using various assays.^{54,55,57,67,70}

The third method to assess MTP assay accuracy involved performing additional directed diagnostic studies not included in the initial evaluation (IHC studies, clinical testing, histology review) to support the MTP assay diagnoses. Fifty-four patients (32%) had MTP assay diagnoses that did not match any of the suggested IHC diagnoses; 35 of these patients had remaining biopsy specimens available for additional studies. In 74% of these patients (26 of 35), additional findings supported the accuracy of the MTP assay diagnoses (Table 113.4).

All three methods used in this study support the accuracy (75% to 80%) of the 92-gene RT-PCR assay in determining the tissue of origin in CUP. The accuracy is similar to that seen with MTP assays when tested in known cancer types. The aggregate data from many other studies in patients with CUP^{46,47,53-58,64-68} provide additional support of the value of molecular diagnoses. Molecular tumor profiling complements IHC, and usually provides a single

diagnosis when IHC is inconclusive. When IHC predicted a single tissue of origin (as in 33% of patients in our series) the MTP assay prediction has high concordance and is probably not necessary.

As MTP is incorporated into the diagnostic evaluation of CUP patients, several potential pitfalls should be considered.⁶⁹ First, tumor biopsy specimens are often small, and the medical oncologist and pathologist should use available tissue judiciously. Performing multiple IHC stains in a tumor that is difficult to classify can deplete the biopsy and preclude MTP. In some cases, a repeat biopsy should be considered. Second, MTP assay diagnoses are not 100% accurate, even in the identification of known cancer types. MTP predictions should always be considered in context with clinical features and results of other pathologic studies. If the MTP diagnosis is inconsistent with other findings, additional directed IHC stains or a clinical evaluation may help to support the diagnosis. Third, several neoplasms have overlapping gene expressions, and a misdiagnosis may occur in these circumstances (e.g., breast, salivary gland, and skin adnexal tumors have similar gene expression profiles). Fourth, any tumor types that are not included in the MTP assay panel cannot be diagnosed, and may be considered unclassifiable or misdiagnosed as a cancer with an overlapping gene expression profile.

Diagnosis in Poorly Differentiated Neoplasms

The use of modern IHC staining is usually effective at defining the tumor lineage in CUP patients with poorly differentiated neoplasms. In the uncommon tumor that defies classification, MTP usually clarifies the lineage and, in some cases, can identify the tissue of origin.⁷¹

From 2000 through 2012, 751 CUP patients were seen at the authors' referral center,⁷¹ and 30 (4%) had no definitive lineage determined after extensive IHC (median of 18 stains; range: 9 to 51). The archival biopsies were tested with the 92-gene RT-PCR assay and when feasible, the additional evaluation was performed to support the molecular diagnoses (e.g., directed IHC not previously done, fluorescence in situ hybridization (FISH) for specific molecular abnormalities, gene sequencing, repeat biopsies, and correlation with clinical features). Four tumors were unclassifiable by

MTP, and one additional tumor had insufficient biopsy material available (17%). A lineage diagnosis was made in 25 of 30 patients (83%), including carcinoma in 10 (germ cell: 3, neuroendocrine: 2, others: 5), sarcoma in 8 (mesothelioma: 3, primitive neuroectodermal tumor [PNET]: 1, others: 5), melanoma in 5, and hematopoietic neoplasm in 2 (lymphoma: 2). Additional directed IHC, genetic testing (BRAF, i12p), or repeat biopsies done after MTP confirmed the MTP diagnoses in 11 of 15 patients (73%). Earlier use of MTP in the diagnosis of these difficult cases would have resulted in the expedited identification of tumor lineage in almost all patients, and often in a prediction of the specific tissue of origin. Because this group of tumors contains germ cell tumors, lymphoma, neuroendocrine tumors, and melanomas, an accurate diagnosis is critical. Molecular tumor profiling appears superior to IHC in the diagnosis of these undifferentiated cancers.

Diagnosis of the Cancer of Unknown Primary Renal Cell Carcinoma Subset

The renal carcinoma subset of CUP has not been previously systematically addressed. A few CUP cases have been reported^{72,73} after recognition by pathologic features or MTP. The diagnosis of renal carcinoma is of practical importance, because these tumors are usually insensitive to cytotoxic chemotherapy, yet may often be treated with good control by a number of approved targeted/biologic drugs. When clear cell histology is seen in a CUP biopsy, the possibility of renal carcinoma is considered, and IHC may be diagnostic. However, histologies of adenocarcinoma or poorly differentiated carcinoma may not suggest renal carcinoma, and IHC stains to support the diagnosis of renal carcinoma may not be done.

In order to further characterize the renal cancer subset, 488 CUP patients seen from 2008 to 2012 had MTP of their biopsies using the 92-gene RT-PCR assay.⁷⁴ In many of these patients, MTP results were available for patient management. A renal carcinoma diagnosis was made in 22 patients (4.5%), including the subtypes papillary in 8, clear cell in 7 and unknown in 7. None of these patients had a primary site detected by abdominal computed tomography, and the metastatic sites most often included retroperitoneal nodes (63%), mediastinal nodes (31%), lung (22%), and bone

(18%). Only 1 biopsy had clear cell histology; 15 were PDC and 6 were adenocarcinomas (4 with papillary features). Because the histology did not suggest renal carcinoma in most patients, only three tumors (14%) had renal directed IHC (RCC, PAX8 stains) performed. However, additional IHCs performed to support the MTP assay diagnoses were typical of a renal origin in seven of nine tumors where a remaining biopsy was available. Sixteen patients received first-line treatment for advanced renal carcinoma; the objective response was 18% and the median survival was 13.4 months.

Renal cell carcinoma is a subset of CUP, which can be diagnosed by MTP assay and/or IHC. When the histologic examination does not identify clear cell features, the diagnosis of renal carcinoma may not be considered, and IHC staining for renal cancer may not be done. Papillary renal carcinoma was a relatively common subtype in the group studied. These patients are important to identify because they may benefit from renal cell-directed targeted drugs but not from empiric chemotherapy.

Diagnosis of the Cancer of Unknown Primary Colorectal Subset

These patients have been characterized recently and are a favorable subset. These data are discussed later (see section Treatment: Favorable Subsets: Colorectal Profile).

Summary

Molecular tumor profiling can predict the tissue of origin in a majority (about 95%) of patients with CUP when there is sufficient biopsy material available. These predictions are accurate in 75% to 80% of patients, as determined by several methods, including an evaluation of CUP patients who developed latent primaries. The correlation between IHC and MTP diagnoses is good (about 80%) when IHC predicts a specific tissue of origin; in patients with

diagnostic IHC, MTP is not necessary. However, in the majority of patients, IHC is inconclusive and MTP provides valuable additional diagnostic information. The optimal identification and evaluation of several subgroups of potential therapeutic importance, including colorectal, renal cell, and poorly differentiated neoplasms now requires the use of MTP in conjunction with a standard pathologic evaluation. A specific diagnosis of some tissues of origin by MTP should trigger additional molecular analysis, because effective targeted therapy for patient subsets is becoming common. For example, a prediction of non-small-cell lung cancer, should prompt an analysis for treatable molecular alterations, including epidermal growth factor receptor (EGFR)-activating mutations and anaplastic lymphoma kinase (ALK) or ROS1 rearrangements.

CLINICAL FEATURES AND EVALUATION

Most patients with CUP develop signs or symptoms at the site of a metastatic lesion and are diagnosed with advanced cancer. The subsequent clinical course is usually dominated by symptoms related to metastases; a latent primary site becomes obvious in about 5% of patients during their lifetime. At autopsy, a primary site is identified in about 75% of patients.^{3,6} Primary sites in the pancreas, lung, colon/rectum, and liver account for approximately 60% of those identified. Primary sites in the breast, ovary, and prostate are uncommon in autopsy series, but data from MTP assay series suggest that the biliary tract, the urothelial tract, the breast, and the ovarian tissues of origin are more common than previously recognized.^{6,52}

Although some clinical differences exist, there is substantial overlap between the clinical features of patients with adenocarcinoma and PDC. Patients with PDC have a somewhat younger median age and usually exhibit rapid tumor growth. These patients may also have a more frequent location of dominant metastatic sites in the mediastinum, retroperitoneum, and peripheral lymph nodes. The clinical evaluation of patients with these histologies should follow the same guidelines. Patients with neuroendocrine carcinoma and squamous carcinoma are discussed separately.

TABLE 113.5

Initial Diagnostic Evaluation

- Complete history: including detailed review of systems
- Complete physical examination: including pelvic examination, stool for occult blood
- Complete blood cell count, comprehensive metabolic panel, lactate dehydrogenase, urinalysis
- Computed tomography scans of chest, abdomen, and pelvis
- Mammography in women
- Serum prostate-specific antigen in men
- Positron emission tomography scan in selected patients
- Pathology: including screening immunohistochemistry marker stains (CK7, CK20, TTF-1, CDX2)
- MTP assay if small biopsy specimen

Clinical Evaluation

The recommended clinical evaluation for all patients is summarized in Table 113.5. In actuality, many of these procedures are usually done in the process of diagnosing CUP. The goal is to find the anatomical primary site or, if not possible, the tissue of origin. Although positron-emission tomography (PET) scanning may be useful in some patients,⁵⁷ it should not be considered routine in the initial CUP evaluation; definitive data in large numbers of patients have not been published⁷⁵ and PET was not superior to computed tomography (CT) in finding a primary site in one comparative study.⁷⁶

A further evaluation of patients should be directed by results of the initial clinical and pathologic evaluations. A focused evaluation may: (1) identify an anatomical primary site, (2) narrow the spectrum of possible tissues of origin, (3) identify specific favorable subsets of patients, or (4) identify the tissue of origin even if the anatomical primary site is undetectable.

Table 113.6 summarizes the additional evaluation indicated for several common clinical presentations. An additional focused

TABLE 113.6

Focused Diagnostic Evaluation of Patient Subsets Defined by Initial Clinicopathologic Evaluation

Initial Evaluation	Additional Evaluation
Women with features of possible breast cancer (bone, lung, liver metastases, CK7+)	Breast magnetic resonance imaging ER, GCDFF-15, GATA3 stains, FISH for HER2 (MTP assay if necessary)
Women with features of possible ovarian cancer (pelvic/peritoneal metastases; CK7+)	Pelvic/intravaginal ultrasound WT1, PAX8 stains (MTP assay if necessary)
Mediastinal/retroperitoneal mass	Testicular ultrasound Serum HCG, AFP PLAP, OCT4 stains; FISH for i(12p) (MTP assay if necessary)
Features of lung cancer (hilar/mediastinal adenopathy; CK7+, TTF1+, Napsin A+)	Bronchoscopy (MTP assay if necessary), Genetic studies for EGFR mutations, ALK/ROS1 rearrangements
Features of colon cancer (liver/peritoneal metastases; CK20+/CK7-, CDX2+)	Colonoscopy (MTP assay if necessary), Genetic study for KRAS mutation
Poorly differentiated carcinoma, with or without clear cell features	Stains for chromogranin, synaptophysin, RCC, hepar-1, HMB-45, Melan-A (If melanoma stains +, genetic study for BRAF mutation; if hepar-1+, obtain serum AFP; if neuroendocrine stains +, obtain octreotide scan (MTP assay if necessary))

CK, cytokeratin; ER, estrogen receptor; GCDFF-15, gross cystic fluid protein 15; GATA3, zinc finger transcription factor family; WT1, Wilms' tumor transcription factor; PAX8, paired box gene 8; HCG, human chorionic gonadotropin; AFP, α -fetoprotein; OCT4, octamen-binding transcription factor 4; HMB-45, anti-human melanoma antibody 45.

evaluation should be triggered by either clinical findings or IHC results during the initial evaluation. An MTP assay is indicated when IHC or other testing is not conclusive. Panels of IHC stains and an MTP assay are complementary and when considered in conjunction with all other data provide a tissue of origin diagnosis in the majority of CUP patients.

Neuroendocrine Carcinoma

Although the initial clinical evaluation is the same (see Table 113.5), patients with neuroendocrine carcinoma require special consideration in determining appropriate treatment. Of major importance is the separation of this group into tumors with low-grade histology (classic carcinoid) and indolent clinical course versus those with high-grade histology (small or large cell with neuroendocrine features) and an aggressive clinical course. Some of the high-grade carcinomas may not be recognized as neuroendocrine by H&E staining, but are usually diagnosed by IHC or MTP assay.

Low-grade neuroendocrine carcinomas, when presenting with an unknown primary site, most frequently involve the liver. Other metastatic sites include the lymph nodes (usually abdominal or mediastinal) and bone. Some are associated with various syndromes caused by the secretion of bioactive peptides (carcinoid syndrome, glucagonoma syndrome, VIPomas, Zollinger-Ellison syndrome). An additional clinical evaluation in these patients should include serum or urine screening for these substances. In addition to the evaluation listed in Table 113.5, an octreotide scan as well as an upper and lower gastrointestinal endoscopy should be performed, because some of these patients have detectable primary sites in the gastrointestinal tract. An MTP assay may diagnose the tissue of origin in some patients^{12,13}; the identification of a pancreatic site of origin is potentially important because targeted drugs (sunitinib, everolimus) are useful in this setting.

High-grade neuroendocrine carcinomas of unknown primary site are usually found in multiple metastatic sites and rarely secrete bioactive peptides. Patients with small- or large-cell histology and a history of cigarette smoking should be suspected of having an occult lung primary and a fiber optic bronchoscopy should be considered. Patients with a positive tumor cell IHC stain for TTF1 should also be considered for a bronchoscopy. Extrapulmonary small-cell carcinomas arising from a variety of other primary sites (salivary glands, paranasal sinuses, esophagus, pancreas, colon/rectum, bladder, prostate, uterus, cervix) have been described and are occasionally identified during a clinical evaluation. A colonoscopy should be considered in patients with tumor IHC staining positive for CDX2.

The origin of these high-grade neuroendocrine carcinomas remains unclear. The tissue of origin may be determined in some patients by an MTP assay, but this knowledge now usually does not change therapy for most patients. Some patients with small-cell histology may have occult small-cell lung cancer. However, more than half of these patients have no smoking history, which makes this diagnosis unlikely. It has been speculated that these undifferentiated tumors share the same origin as the low-grade neuroendocrine tumors, and are at opposite ends of a *spectrum* of tumor biology. However, it now seems more likely that these high-grade neuroendocrine tumors have a different oncogenesis; many share the chromosomal abnormalities commonly seen in small-cell lung cancer (deletions of chromosomes 3p, 5q, 10q, and 17p), whereas no shared molecular abnormalities have been found with indolent carcinoid-type tumors.^{77,78}

Anaplastic or atypical carcinoid tumors arising in the gastrointestinal tract are responsive to platinum-based chemotherapy, whereas carcinoid tumors with typical histology are usually resistant.⁷⁹ A few reports of patients with extrapulmonary small-cell carcinomas of unknown primary site have also documented chemotherapy responsiveness and occasional long-term survival after systemic therapy.^{80,81} However, the term *extrapulmonary small-cell carcinoma* implies the existence of a known primary site; some

CUP neuroendocrine tumors may have arisen from an occult extrapulmonary site, but are aptly described as neuroendocrine carcinoma of unknown primary site.

Squamous Carcinoma

Squamous carcinoma, as opposed to other histologies, often presents with isolated metastases in the cervical or inguinal lymph nodes. The cervical nodes are the most common metastatic site. Patients are usually middle aged or elderly, and frequently, they have abused tobacco or alcohol, although recently it has also been associated with human papilloma virus infection. When the upper or middle cervical nodes are involved, a primary tumor in the head and neck region should be suspected. The clinical evaluation should include an examination of the oropharynx, hypopharynx, nasopharynx, larynx, and upper esophagus by direct endoscopy, with a biopsy of any suspicious areas. CT of the neck better defines the disease in the neck and occasionally identifies a primary site. PET scanning in this subset is indicated, because it can frequently identify primary tumor sites.⁸² Detection of Epstein-Barr virus genome in the tumor tissue is highly suggestive of a nasopharyngeal primary site,^{33,34,83} particularly in poorly differentiated carcinomas. When the lower cervical or supraclavicular nodes are involved, a primary lung cancer should be suspected. A fiber optic bronchoscopy may identify a lung primary if other evaluations are unrevealing.⁸⁴

An ipsilateral or bilateral tonsillectomy has been advocated as a diagnostic modality in patients with single nodal or bilateral nodal involvement, respectively.⁸⁵ In one series of 87 patients who had tonsillectomy as part of their workup for cervical node presentations, 26% had a tonsillar primary identified.⁸⁶ The identification of the primary site has several advantages in this group of patients, including the ability to develop a specific treatment plan, a reduction of the radiation therapy fields, more accurate assessment of prognosis, and easier follow-up.

Most patients with involvement of inguinal nodes have a detectable primary site in the anogenital area. Careful examination of the anal canal, vulva, vagina, uterine cervix, penis, and scrotum is important, with biopsy of any suspicious areas. The identification of a primary site in these patients is consequential because curative therapy is available for carcinomas of the vulva, vagina, cervix, and anus, even after it has spread to regional nodes.

Metastatic squamous carcinoma in areas other than the cervical or inguinal nodes usually represents metastasis from an occult lung cancer, but metastases from several other sites (the esophagus, skin, uterine cervix, and anal canal) are also possible. An MTP assay may be useful in the diagnosis of the tissue of origin and provides the basis of site-specific therapy.

TREATMENT

The heterogeneous group of patients with CUP contains some patients who experience long-term survival after appropriate treatment and others for whom treatment makes little or no impact. Patients who have an anatomical primary site defined during their clinical evaluation do not have CUP and should be treated appropriately for their defined tumor type. A second group of patients can be identified as having favorable subsets and, in most, their tissues of origin may be presumed, even when the anatomical primary site is not identified (Table 113.7). The management of these subsets is detailed in this section. Most CUP patients (approximately 80%) do not fit into a favorable subset, even after an appropriate clinical and pathologic evaluation. Empiric chemotherapy has been the treatment standard for many years, and will be briefly reviewed. However, there is now ample evidence to support the use of site-specific therapy for most patients, guided by IHC and MTP predictions of the tissue of origin. These new data will also be reviewed.

TABLE 113.7

Carcinoma of Unknown Primary Site: Summary of Evaluation and Therapy of Favorable Subsets

Carcinoma	Clinical Evaluation ^a	Special Studies	Subsets	Therapy	Prognosis
Adenocarcinoma (well-differentiated or moderately differentiated) ^b	Chest, abdominal CT scan; PET scan Men: Serum PSA Women: Mammogram Additional studies to evaluate symptoms, signs	Men: PSA stain Women: ER, PR, Other IHC (see text) MTP assay (see text)	1. Women, axillary node involvement ^b 2. Women, peritoneal carcinomatosis ^b 3. Men, blastic bone metastases, high serum PSA, or PSA tumor staining 4. Single metastatic site ^b 5. Colon cancer profile	1. Treat as primary breast cancer 2. Surgical cytoreduction plus chemotherapy 3. Hormonal therapy for prostate cancer 4. Resection and/or radiotherapy 5. Treat as metastatic colon cancer	Survival improved with specific therapy
Squamous carcinoma	Cervical node presentation ^b Panendoscopy PET scan Supraclavicular presentation ^b Bronchoscopy PET scan Inguinal presentation ^b Pelvic, rectal examinations, anoscopy, PET scan	Genetic analysis including MTP assay (see text)	1. Cervical adenopathy; nasopharyngeal cancer identified by PCR for Epstein-Barr viral genes 2. Supraclavicular 3. Inguinal adenopathy	1. Radiation therapy, neck dissection, chemotherapy 2. Radiation therapy, chemotherapy 3. Inguinal node dissection, radiation therapy, chemotherapy	Survival improved 1. 25%–50% 5-y survival 2. 5%–15% 5-y survival 3. 15%–20% 5-y survival
Poorly differentiated carcinoma, poorly differentiated adenocarcinoma	Chest, abdominal CT scans, serum HCG, AFP; PET scan; additional studies to evaluate symptoms, signs	IHC; electron microscopy; genetic analysis; MTP assay (see text)	1. Atypical germ cell tumors (identified by chromosome 12 abnormalities) 2. Extragonadal germ cell syndrome (two features) 3. Lymph node–predominant tumors (mediastinum, retroperitoneum, peripheral nodes) 4. Gastrointestinal stromal tumors (identified by CD117 stain) 5. Other groups (see text)	1. Treatment for germ cell tumor 2. Cisplatin/etoposide 3. Treat with site-specific therapy (see text) 4. Imatinib 5. Treat with site-specific therapy (see text)	1. 40%–50% cure rate 2. Survival improved (10%–20% cured) 3. Survival improved 4. Survival improved 5. Survival improved
Neuroendocrine carcinoma	Chest, abdominal CT	IHC, Electron microscopy Genetic analysis including MTP assay (see text)	1. Low-grade 2. Small-cell carcinoma (or Ewing's family of tumors) 3. Poorly differentiated	1. Treat as advanced carcinoid 2, 3. Carboplatin/etoposide or platinum/etoposide (or other)	1. Indolent biology/long survival 2, 3. High response rate, survival improved; rarely cured

PSA, prostate-specific antigen; ER, estrogen receptor; PR, progesterone receptor; HCG, human chorionic gonadotropin; AFP, α -fetoprotein.

^a In addition to history, physical examination, routine laboratory tests, and chest x-ray films.

^b May also present with poorly differentiated carcinoma, and management and outcome are similar.

Favorable Subsets

Women with Peritoneal Carcinomatosis

Adenocarcinoma, particularly serous adenocarcinoma, causing diffuse peritoneal involvement, is typical of ovarian carcinoma, although carcinomas from the gastrointestinal tract, lung, or breast can occasionally produce this clinical syndrome. On occasion, women with diffuse peritoneal carcinomatosis have no primary site

found in the ovaries or elsewhere in the abdomen at the time of laparotomy. These patients frequently have histologic features typical of ovarian carcinoma, such as papillary serous configuration or psammoma bodies, and also share clinical features, such as elevated serum cancer antigen 125 (CA-125) levels. These tumors are more common in women with a family history of ovarian cancer, and prophylactic oophorectomy does not always protect them from this tumor.⁸⁷ Like ovarian carcinoma, the incidence of primary peritoneal carcinoma is increased in women with *BRCA1/2* mutations.⁸⁸

It is now clear that many of these carcinomas arise from the peritoneal surface (primary peritoneal carcinoma) or from the fimbriated end of the fallopian tubes.^{89,90} Many of these tumors have characteristic IHC findings (ovary pattern) or diagnostic MTP assays. Carcinomas arising from the peritoneal (mesothelial) surface or the uterine tubes share a common lineage (müllerian derivation) and biology with ovarian carcinoma. Support for this hypothesis has been strengthened by the demonstration of gene expression profiles nearly identical to ovarian carcinoma.⁵⁸ Treatment of these women with standard ovarian carcinoma regimens (surgical cytoreduction followed by taxane/platinum chemotherapy) produces results similar to those seen in ovarian cancer.⁹¹⁻⁹³ This entity has very rarely been seen in men.⁹⁴

Women with Axillary Lymph Node Metastases

Breast cancer should be suspected in women who have metastatic carcinoma in an axillary lymph node.⁹⁵ Men with occult breast cancer can present in this fashion, but these are very rare. The initial lymph node biopsy should be stained for IHC breast markers. When positive, these findings provide strong support of the diagnosis.⁹⁶ An MTP assay may also be diagnostic in this setting.

If no other metastases are identified, these patients may have stage II breast cancer with an occult primary, which is potentially curable with appropriate therapy. Magnetic resonance imaging and PET have occasionally identified primary breast cancer even with normal mammography.⁹⁷⁻⁹⁹ A modified radical mastectomy has been recommended, even when physical examination and mammography are normal. An invasive breast primary has been identified after mastectomy in 44% to 80% of patients. Primary tumors are usually less than 2 cm in diameter and may measure only a few millimeters; occasionally in patients, only a noninvasive tumor is identified in the breast. Prognosis after primary therapy is similar to that of other patients with stage II breast cancer.⁹⁵ Radiation therapy to the breast after axillary lymph node sampling and chemotherapy represents a reasonable alternative primary therapy.¹⁰⁰ Either neoadjuvant or adjuvant systemic therapy is indicated in this setting, following guidelines established for the treatment of stage II breast cancer.

Women with metastatic sites in addition to the axillary lymph nodes, particularly when supported by IHC and/or a MTP assay diagnosis, should be managed as metastatic breast cancer. Hormone receptor and *HER2* status are of particular importance in these patients because they may derive major benefit from hormonal therapy, chemotherapy, or *HER2*-targeted agents.

Men with Elevated Serum Prostate-Specific Antigen or Prostate-Specific Antigen Tumor Staining

Serum prostate-specific antigen (PSA) concentrations should be measured in men with adenocarcinoma of unknown primary site. These tumors can also be stained for PSA. Even when clinical features (i.e., metastatic pattern) do not suggest prostate cancer, a positive PSA (serum or tumor stain) is reason for a trial of androgen deprivation.^{101,102} In some of these patients, a needle biopsy of the prostate might confirm the primary site but may not be necessary for optimal clinical management. Osteoblastic bone metastases in the absence of a defined origin and other metastatic sites are also an indication for an empiric hormone trial, regardless of the PSA findings. Although IHC is usually diagnostic, an MTP assay may also provide a definitive diagnosis.

Extragenital Germ Cell Cancer Syndrome

The extragenital germ cell cancer syndrome was first described in 1979.¹⁰³⁻¹⁰⁵ The full syndrome, which is seen in only a minority of patients, has the following features: (1) occurrence in men less than 50 years of age; (2) predominant tumor location in the midline (mediastinum, retroperitoneum) or multiple pulmonary

nodules; (3) short duration of symptoms (less than 3 months) and a history of rapid tumor growth; (4) elevated serum levels of human chorionic gonadotropin (HCG), α -fetoprotein (AFP), or both; and (5) good response to previously administered radiation therapy or chemotherapy. These tumors may be definitively diagnosed by IHC and/or an MTP assay or by testing for specific chromosome 12 abnormalities. If the diagnosis remains uncertain, patients with this syndrome may still have atypical germ cell tumors, and treatment with cisplatin-based chemotherapy is recommended.

Single Site of Neoplasm

When only one site of neoplasm is identified (e.g., one node group, one mass), the possibility of an unusual primary tumor mimicking metastatic disease should be considered. Several unusual tumors could present in this fashion, including Merkel-cell neuroendocrine tumors, skin adnexal tumors (e.g., apocrine, eccrine, and sebaceous carcinomas), sarcomas, melanomas, or lymphomas that are mistakenly interpreted as metastatic carcinoma. Patients with a clinically detectable single metastasis (brain, liver, adrenal, subcutaneous tissue, bone, intestine, lymph node, skin, or other sites) usually have other undetectable sites. Some of these patients may have a primary tumor at the single site that developed from embryonic rest cells or adult stem cells. A PET scan may be helpful to exclude other unsuspected metastatic sites.¹⁰⁶

These patients without other documented metastasis should be treated with aggressive local therapy because a minority enjoy long-term, disease-free survival. If their tissue of origin is determined by IHC or MTP, site-specific systemic chemotherapy should be considered in either the neoadjuvant or adjuvant setting.

Patients with a single small site of metastasis frequently survive 1 year or longer, regardless of their tissue of origin, and thus represent a favorable prognostic subset. In a reported group of patients presenting with single brain metastasis of unknown primary site, 15% remained progression free 5 years after definitive therapy.¹⁰⁷ The authors have treated and followed 36 patients with single site metastases (unpublished observations). All patients had local therapy (resection with or without radiotherapy) and most also received empiric chemotherapy regimens. The median survival in this group is 17 months; 1-, 2-, and 3-year survivals are 65%, 40%, and 28%, respectively. These overall results may be improved with site-specific systemic therapy.

Squamous Carcinoma Involving Cervical or Supraclavicular Lymph Nodes

Squamous carcinoma most frequently presents with unilateral involvement of the cervical lymph nodes. The recommended clinical evaluation (previously described) results in the identification of a head and neck primary site in almost 85% of patients. In those without a defined anatomical primary site, an occult primary site in the head and neck may be presumed.

When no primary site is identified, local treatment should be given to the involved neck. Results have been reviewed in more than 1,400 patients, derived primarily from retrospective single-institution experiences and treated with a variety of local treatment modalities.¹⁰⁸ In many of these series, a large minority of patients had PDC or adenocarcinoma. Long-term, disease-free survival was achieved in 30% to 40% of patients following treatment with local modalities. The results obtained using radical neck dissection, high-dose radiation therapy, or a combination of these modalities have been similar. The volume of tumor in the involved neck influences outcome, with N1 or N2 disease having a significantly higher cure rate than N3 or massive neck involvement.¹⁰⁹ Poorly differentiated carcinoma also represents a poor prognostic factor in these patients. When resection is used alone, a primary tumor in the head and neck subsequently becomes apparent in 20% to 40% of patients. Primary tumors surface less commonly when radiation therapy is used, presumably because of the eradication of occult head and neck primary sites within the radiation field. Radiation therapy

dosages and techniques should be similar to those used in patients with primary head and neck cancer, and the nasopharynx, oropharynx, and hypopharynx may be included in the irradiated field.

The role of chemotherapy for carcinoma in cervical lymph nodes is now generally accepted. No randomized studies have been performed, but a nonrandomized comparison favored chemotherapy plus radiotherapy versus local therapy¹¹⁰ (median survival: 37 months versus 24 months). Concurrent treatment with chemotherapy and radiotherapy is now standard in locally advanced head and neck carcinoma, and should be the treatment of choice for squamous cell carcinoma in cervical lymph nodes.

Patients with low cervical and supraclavicular nodes do not do as well because lung cancer is a frequent site of occult primary tumors, although the skin, uterine cervix, esophagus, and anus are also possible primary sites. Molecular assays may be helpful in predicting the primary site. Patients with no detectable disease below the clavicle should be treated with aggressive local therapy, and 10% to 15% have long-term, disease-free survival. Concurrent chemotherapy should also be considered for these patients.

Squamous Carcinoma Involving Inguinal Lymph Nodes

Most patients with squamous carcinoma involving inguinal lymph nodes have a detectable primary site in the anogenital areas. For the unusual patient in whom no primary site is identified, inguinal lymph node dissection with or without radiation therapy to the inguinal area sometimes results in long-term survival.¹¹¹ An MTP assay may diagnose the tissue of origin and suggests appropriate therapy. These patients should also be considered for neoadjuvant or adjuvant chemotherapy, because occult primaries from the uterine cervix and anal canal are likely to be responsive to chemotherapy.

Low-Grade Neuroendocrine Carcinoma

These tumors usually exhibit an indolent biology, and slow progression over the years is likely. Management should follow guidelines established for metastatic carcinoid or islet cell tumors from known primary sites. Treatment with octreotide long-acting release (LAR) results in an increase in time to tumor progression with low toxicity.¹¹² Depending on the clinical situation, appropriate management may also include local therapy (resection of isolated metastasis, hepatic artery ligation or embolization, cryotherapy, radiofrequency ablation). Several cytotoxic agents have some activity (streptozotocin, doxorubicin, 5-fluorouracil, capecitabine, temozolomide), and results with targeted agents (sunitinib, everolimus) from pancreatic primaries are promising. These neoplasms are usually refractory to intensive systemic chemotherapy, and cisplatin-based chemotherapy produces low response rates.¹⁰⁴

High-Grade Neuroendocrine Carcinomas

Patients with aggressive neuroendocrine carcinomas are those with either small-cell carcinoma or PDC (often large cell) with neuroendocrine staining by IHC or a diagnosis by MTP assay. Tumors with these histologies are initially responsive to combination chemotherapy, and patients should be considered for a trial of treatment.

The initial report of 29 patients with poorly differentiated neuroendocrine tumors¹¹³ was updated to include 99 patients, with 94 treated with combination chemotherapy.¹⁰⁸ These patients had clinical evidence of rapid tumor growth and multiple metastases. Of 87 assessable patients, 59 (68%) responded to a platinum-based combination regimen. Nineteen patients (22%) had complete responses, and 13 remained continuously disease free more than 2 years after the completion of therapy.

The results of a prospective trial using the combination of paclitaxel, carboplatin, and oral etoposide in 48 patients (of the 99 previously listed) have been reported.¹¹⁴ The majority of these

cancers were initially called PDC (about 20% were small-cell carcinoma) and were later defined as neuroendocrine by IHC staining or electron microscopy. These patients usually had several sites of metastasis, often with a predominant tumor in the bones, liver, and nodes (particularly retroperitoneum and mediastinum). The overall response rate was 55%, with six complete responses (13%). The median survival was 14 months and 10 patients survived beyond 2 years (range: 2 to 6 years).

Data remain limited in this uncommon group of patients; however, current first-line chemotherapy should include the platinum-based regimens used for small-cell lung cancer. In the uncommon patient with a single site of involvement, radiation therapy with or without resection should be added to combination chemotherapy.

In some of these patients, MTP assays may diagnose the tissue of origin,^{12,13} but it remains uncertain if this knowledge can be applied to improve therapies in the high-grade tumors, although the gastrointestinal primaries may respond to site-specific regimens such as folinic acid, fluorouracil, and oxaliplatin (FOLFOX).

Poorly Differentiated Carcinoma

Although patients with PDC form a large and heterogeneous group, the inclusion of patients with highly treatable neoplasms within this group has been recognized since the late 1970s.¹⁰³⁻¹⁰⁵ At that time, several young men with mediastinal tumors were reported who had complete responses to combination chemotherapy. Elevated serum levels of HCG or AFP were common in these young men. Although the histology was not diagnostic, these patients were thought to have histologically atypical extragonadal germ cell tumors. Several other specific cancers have also subsequently been identified in some of these patients (i.e., thymic neoplasms, neuroendocrine tumors, midline carcinoma with t[15;19], sarcomas, melanomas, lymphomas), but others defy precise classification.

Further evidence for the responsiveness of tumors in many other patients has accumulated over the years. Based on the encouraging results in a few patients treated from 1976 to 1978, the authors prospectively studied the role of cisplatin-based therapy. In a series of reports, the authors documented a high overall response rate and long-term disease-free survival in a minority of these patients¹¹⁵⁻¹¹⁸; a small cohort (5% to 10%) were long-term disease-free survivors. Other investigators also demonstrated the responsiveness of selected patients with PDCs.¹¹⁹⁻¹²⁴

Several years ago, many PDC patients included in these reports had neoplasms that are now identifiable and included either in the favorable subsets already discussed or other recognized responsive neoplasms. These patient subsets included (1) the extragonadal germ cell syndrome, (2) poorly differentiated neoplasms otherwise not specified, (3) anaplastic lymphomas misdiagnosed as carcinoma, (4) thymic carcinomas, (5) primary peritoneal carcinomas, (6) poorly differentiated neuroendocrine carcinomas, and (7) carcinomas with metastases predominantly involving the retroperitoneum, mediastinum, and peripheral lymph nodes. If a patient has PDC, the diagnostic evaluation should target these possibilities. After these subgroups are excluded, the remaining patients have a similar prognosis to the large majority of the adenocarcinoma group. These patients should be evaluated in the same fashion as those with adenocarcinomas, with particular attention given to determining the site of origin using IHC and/or MTP.

Colorectal Cancer Profile

With the introduction of more effective cytotoxic agents and targeted therapies, the median survival of patients with metastatic colorectal carcinoma has increased from 8 to about 24 months.^{125,126} It is therefore important to identify the subset of CUP patients with colorectal cancer in order to administer appropriate therapies. The improved specificity of IHC staining for colorectal cancer, coupled with the recent availability of MTP assays, facilitates the identification of this patient subset. The

outcome data in these patients treated with colorectal chemotherapy are similar to known advanced colorectal cancer; therefore, this subset merits inclusion as a CUP favorable subset.

Patients with typical clinical features (liver, peritoneal metastases), histology compatible with a lower gastrointestinal primary, and typical IHC staining (CDX2+ and/or CK20+/CK7-) have been defined as having the *colon cancer profile*. Several such patients described by Varadhachary et al.^{127,128} had excellent responses and survival when treated with colorectal cancer regimens.

Substantial data now indicate that CUP patients with a colorectal tissue of origin can be accurately identified using IHC stains and/or MTP.^{53,127-131} A total of 172 CUP patients with colorectal profiles have been treated with site-specific colorectal regimens. The objective response rates were usually above 50%, and the combined median survival of all these patients was 26 months.

Although these data are largely retrospective, the outcome results are far superior than expected from empiric chemotherapy in CUP (ineffective in colorectal carcinoma) and similar to those achieved in patients with known metastatic colorectal cancer. Further prospective studies may confirm these results. In the meantime, these data are sufficient to recommend treatment with colorectal cancer regimens for CUP patients with either an IHC or MTP colorectal profile.

Empiric Therapy for CUP

Chemotherapy

Approximately 80% of CUP patients are not represented in any of the favorable prognostic clinical subsets (see Table 113.7). In the past, empiric chemotherapy was used for most of these patients because their tissue of origin could not be determined. The history and more recent results of empiric chemotherapy have been reviewed previously.¹³²⁻¹³⁴ and will be briefly discussed here.

Several reports of survival in large groups of patients with CUP¹³⁵⁻¹⁴² help to establish a historical control and define the natural history of this syndrome. These historical series included a total of 31,419 patients. Because these reports were retrospective, treatments were not uniform, and some patients received no systemic therapy. The median survival was 5 months, with a 1-year survival of 22% and 5-year survival of 5%. Most patients who survived for 1 year or longer had clinical features now known to be associated with a favorable prognosis. Squamous cell carcinoma (usually in neck nodes) and well-differentiated neuroendocrine carcinoma (carcinoid, islet cell-type histology) reported from some of these series (N = 2,971) had median, 1-year, and 5-year survivals of 20 months, 66%, and 30%, respectively.

Between 1990 and 2000, the introduction of several new drugs with rather broad-spectrum antineoplastic activity improved treatments and prognoses for patients with several common epithelial cancers, and also resulted in a modest improvement in the empiric treatment of CUP.¹⁴³ A number of combinations containing these new drugs (taxanes, gemcitabine, vinorelbine, irinotecan, topotecan, oxaliplatin), often combined with a platinum agent, had modest activity in CUP patients and became standard regimens.

The Minnie Pearl Cancer Research Network/Sarah Cannon Oncology Research Consortium (MPCRN/SCORC) completed 10 sequential prospective trials¹⁴⁴⁻¹⁵³ (nine phase 2 with 692 patients and one phase 3 with 198 patients), often incorporating platinum with paclitaxel,^{144,145} docetaxel,^{145,146} gemcitabine,^{147,148} gemcitabine/irinotecan,^{149,150} bevacizumab/erlotinib,¹⁵¹ and oxaliplatin¹⁵² into the first-line or second-line therapy for 890 patients with unfavorable prognostic features. The median survival of the 692 first-line patients was 9.2 months and the 1-, 2-, 3-, 4-, 5-, 8-, and 10-year survivals were 39%, 20%, 12%, 11%, 9%, 8%, and 8%, respectively.

Several trials of empiric chemotherapy reported by others over the past 15 years^{119-124,132-134,154-164} revealed similar results. The primary end points of 12 of these trials were response rate or

median survival.¹³³ The median survival of all these patients was 9.1 months. The 1-year survival (reported in 12 trials) ranged from 25% to 52% (mean: 34.4%), and at 2 years, survival (reported in 8 trials) ranged from 5% to 18% (mean: 12.3%). Only one study reported a 3-year survival rate (11%). These survival results are very similar to the 692 patients reported by the MPCRN/SCORC studies,¹⁴⁴⁻¹⁵³ and superior to historical survival data and to the combined data from multiple prospective clinical trials reported from 1964 to 2002.^{2,108} It is of note that in all studies of 100 or more patients, the median survival following empiric regimens is about 9 months.^{134,147,150,153,157} The survival curve has been shifted to the right, and the survival at 2 years is comparable to the 1-year survival of historical control patients. Comparison of the existing trials does not allow for the definition of an optimum regimen; several two-drug combinations appear similar.

The era of empiric chemotherapy for most patients with CUP is nearing its end. Improved IHC stains and MTP assays accurately identify the tissue of origin in most patients and provide a more rational framework for decisions regarding therapy. The advantages of site-specific therapy are supported by an increasing amount of clinical data. In the small minority of CUP patients that remain without a defined tissue of origin, empiric chemotherapy remains the standard approach.

Targeted Therapy

A number of agents broadly targeting pathways critical to some cancers (i.e., vascular endothelial growth factor [VEGF] and EGFR inhibitors) have been incorporated into the standard therapy of various solid tumors. It is likely that some patients in the heterogeneous CUP group would also benefit from these targeted agents. Although there has been limited clinical experience with targeted agents, definite activity has been documented.

The combination of bevacizumab and erlotinib was evaluated in a group of 51 patients¹⁵¹ with very poor prognostic features and the majority in the second-line setting. The median survival was 7.4 months with 33% of patients alive at 1 year and 18% at 2 years. Survival seemed superior to second-line chemotherapy previously reported and was similar to results of many first-line chemotherapy trials.

This trial was followed by a first-line phase 2 study evaluating standard empiric chemotherapy (paclitaxel and carboplatin) plus bevacizumab and erlotinib.¹⁶⁵ Sixty patients with good performance status were treated. The median survival was 12.6 months, and the 2-year survival was 27%. In neither trial were patients selected on the basis of molecular tumor abnormalities predictive of response to the study targeted therapy.

Future development of targeted therapy in CUP will depend on the documentation of molecular targets for which drugs are available. The genomic analysis of biopsy samples, particularly with next-generation sequencing technologies, has opened the door to this potential in many cancers. Because CUP represents many types of metastatic cancer, there is an opportunity to find a variety of actionable genetic alterations. A few CUP patients with EGFR-activating mutations or ALK rearrangements have responded to treatment with inhibitors of these targets.^{166,167} Recently, a preliminary report¹⁶⁸ reviewed 1,350 biopsies of CUP patients who had molecular profiling by a number of techniques and several *actionable* biomarkers were identified, including targeted protein overexpression (steroid receptors, MET), activating mutations (BRAF, EGFR, PIK3CA), protein loss (PTEN), and gene copy number variations (HER2, TOP2A, MET amplification) in a large number of these specimens.

Although the therapeutic implications of these findings are largely unexplored, the identification of the tissue of origin should lead to a focused search for tumor-specific molecular abnormalities. Examples include BRAF in melanoma, EGFR and ALK/ROS1 in lung adenocarcinoma, HER2 in breast/gastric/gastroesophageal cancers, and KRAS in colorectal cancer. The identification of these abnormalities should guide patient management

and provide additional effective treatment options. The role of genomic testing in advanced cancer is rapidly evolving and is likely to play a larger role in the near future.

Prognostic Factors

The identification of prognostic factors in patients with CUP continues to evolve as the group is divided into an increasing number of subsets. By definition, patients who fit into the favorable subsets have better prognoses compared to the remaining patients. As new treatable subsets are identified, the clinicopathologic features of the remaining patients can be expected to change. The ability to determine the tissue of origin in most patients will make the specific type of cancer in each patient one of the most important prognostic factors. Therefore, results of previous analyses of prognostic factors, conducted primarily in CUP patients receiving empiric chemotherapy, may no longer be relevant to the current population.

Several investigators have analyzed prognostic factors and proposed models.^{118,152,169-173} These patients had unfavorable prognostic features and most received empiric chemotherapy regimens. Liver metastasis, poor performance status, elevated serum lactate dehydrogenase and/or alkaline phosphatase levels, hypoalbuminemia, multiple visceral metastasis, lymphopenia, and male gender were negative factors.

Prognostic factors that have been repeatedly identified are related to tumor location, extent of tumor, performance status, and measures of general health status. None of these features is surprising, because most have been repeatedly identified as prognostic factors in patients with various known solid tumors. The tissues of origin in CUP can now usually be determined, and further study is necessary to see if prognoses are similar to their counterparts with known cancers after appropriate site-directed therapies.

Site-Specific Treatment Directed by Results of Molecular Gene Expression Tumor Profiling Assays

Because the tissue of origin can now be accurately predicted in most patients with CUP, the assumption that this information should result in better treatment seems reasonable. However, clinical data confirming this assumption have developed only recently, and some skepticism still remains. One cause for concern is the unique biology of CUP (evidenced by the fact that the primary site does not become apparent); it has been speculated that these

cancers, regardless of their origins, will respond differently to treatment. If so, the ability to identify the tissue of origin may not lead to improved therapy.

At present, clinical data suggest that CUP represents a collection of cancer types, which, if identified, will respond to site-specific therapy in a predictable way. The largest experience comes from the treatment of patients in several of the favorable CUP subsets, where treatment follows guidelines for a specific cancer type based on a presumed (but unidentified) site of origin. Examples include women with serous adenocarcinoma involving the peritoneum who are treated for ovarian cancer, women with isolated axillary adenocarcinoma who are treated for breast cancer, and patients with squamous carcinoma involving cervical lymph nodes who are treated for head and neck cancer. In all of these subsets, treatment results are similar to results for the corresponding cancer types. Recently, CUP patients identified by IHC or MTP as having a colorectal site of origin (but with no identifiable colon anatomical primary site) have been demonstrated to respond well to treatment for advanced colorectal cancer.

A prospective evaluation of site-specific therapy selected on the basis of an MTP assay diagnoses has recently been published.¹³¹ In this large prospective phase 2 multicenter study, CUP patients had their biopsies tested with the 92-gene RT-PCR assay and were treated with standard site-specific therapies based on the assay diagnoses of the tissues of origin. Of the 253 patients with successful assays performed, 242 (98%) had a single tissue of origin predicted. Twenty-six different tissues of origin were diagnosed. Assay-directed standard therapies were administered to these patients, and the median survival was 12.5 months, comparing favorably to the median 9-month survival expected with empiric chemotherapy.

Various patient subsets also had outcomes that supported the accuracy of the MTP predictions and the efficacy of assay-directed therapy. In 115 patients, the assay predicted tumor types relatively responsive to standard therapies (colorectal, breast, ovary, kidney, prostate, bladder, lung, germ cell, high-grade neuroendocrine, and lymphoma); this group of patients had a median survival of 13.4 months. When the assay predicted less responsive tumor types in 79 patients (biliary tract, pancreas, gastroesophageal, liver, sarcoma, uterine cervix, endometrium, mesothelioma, melanoma, skin, thyroid, head/neck, and adrenal) the median survival was only 7.6 months ($p = 0.04$) (Fig. 113.2). In addition, groups of

Figure 113.2 Survival of CUP patients after site-specific treatment directed by MTP assay: responsive tumor types versus less responsive tumor types. Median survival 13.4 versus 7.6 months ($p = 0.04$). NSCLC, non-small-cell lung cancer; SCLC, small-cell lung cancer. (Adapted from Hainsworth JD, Rubin MS, Spigel DR, et al. Molecular gene expression profiling to predict the tissue of origin and direct site-specific therapy in patients with carcinoma of unknown primary site: a prospective trial of the Sarah Cannon Research Institute. *J Clin Oncol* 2012;31:217-223.)

patients with individual cancer types were assessed. Although the groups were small, the median survivals were generally within the range expected for these cancer types (median survival months: breast, 28; ovary, 30; non-small-cell lung, 15.9; colorectal, 12.5; pancreas, 8.2; biliary tract, 6.8).

These results are consistent with those from retrospective studies and provide evidence that site-specific therapy improves the efficacy of treatment for patients with CUP. As expected, patients with more responsive tumor types have greater benefit. Given the heterogeneity of CUP (at least 26 cancer types in the previous study and many more subtypes), it would be extremely challenging to perform a phase 3 randomized study comparing empiric chemotherapy to assay-directed site-specific therapy and difficult to interpret the results if it were accomplished. The varieties of cancers within CUP are diverging along different treatment pathways on the basis of their origin and knowledge of specific treatable molecular alterations, and there is no longer any reason to consider these diverse cancers for treatment with the same empiric chemotherapy regimen.

A sizable minority of patients with CUP will not currently benefit much, if at all, from site-specific therapies because therapy for their tumor types is relatively ineffective. Confidence in the tissue of origin diagnoses by IHC and/or MTP will allow these patients to receive more effective therapy once therapy for their tumor types improves.

SPECIAL ISSUES IN CARCINOMA OF UNKNOWN PRIMARY SITE

Biology of the Primary Tumor

The biology of the primary tumor in CUP remains an enigma. Most patients harbor a clinically undetectable anatomical primary tumor site, as demonstrated by autopsy series.^{3,6} It is remarkable that many of these invasive primary tumors measure less than 1 cm. The mechanism explaining clinically occult invasive primary tumor sites remains unknown, but almost certainly will be clarified by a better understanding of the molecular mechanisms controlling primary tumor growth and metastasis. These mechanisms may be different than those found in their easily detected cognate primary cancers.

There are several other potential explanations for the apparent absence of a primary cancer in some of these patients. First, the primary cancers may inexplicably regress or involute entirely, despite the fact that metastasis already occurred. This theory is supported by the scarring seen occasionally in the testicle with metastatic germ cell neoplasms (i.e., *burned-out primary*). Second, the primary may have arisen from embryonic epithelial *rest cells* that are fully differentiated but did not complete their appropriate migration in utero to their designated tissue or organ. Extragonadal germ cell tumors with primaries in the mediastinum, retroperitoneum, or undescended testicle are known examples of this phenomenon. Third, some of these patients have unrecognized primary neoplasms, such as extragonadal germ cell tumors, thymic neoplasms, lymphomas, melanomas, or sarcomas, which arise from these cellular lineages virtually anywhere in the body. Fourth, the pathogenesis of some of these carcinomas may result from a specific germ line genetic lesion present in all cells, as is suggested by the unusual occurrence of CUP in monozygotic twin brothers with primary immunodeficiency disorder (X-linked hyperimmunoglobulin M syndrome).¹⁷⁴

Finally, some of these neoplasms may arise from adult stem cells with an ability to differentiate to multiple lineages.¹⁷⁵⁻¹⁷⁹ Hematopoietic stem cells appear to be able to give rise to or transform into liver cells as well as muscle, gastrointestinal, skin, and brain cells.¹⁷⁵ Reserve precursor stem cells exist within the connective tissue compartments throughout postnatal life¹⁷⁸ and can form any

lineage in any tissue if they undergo neoplastic transformation. Therefore, some tumors might continue to reflect the differentiation or transformation of adult stem cells and may be *tumors of adult stem cells*. For example, seemingly metastatic adenocarcinoma in bone, liver, lymph node, or elsewhere may, in fact, arise in these sites from an adult stem cell with the capacity to become any type of cell and to develop as a *primary* neoplasm in any of these tissues.¹⁷⁶

Although CUPs share a metastatic phenotype, it is currently unknown whether these tumors share specific unique molecular abnormalities. A genomic analysis of CUP demonstrates multiple abnormalities, but these are not unique and are shared with many advanced known solid tumors (e.g., various chromosomal 1p abnormalities).¹⁸⁰ Similarly, the expression of p53, bcl-2, cMYC, RAS, NOTCH1-3, JAGGED1, phosphoMAPK, PTEN, pAKT, cMET, HER2, hypoxia-related protein, and MET mutations have been observed in some CUP tumors, but are not specific.^{168,181-188} Although the search for a CUP-specific gene signature continues, none has yet been identified. At present, most evidence suggests that CUP retains typical site-specific markers and can often be identified by IHC and/or MTP assays; however, this does not preclude the coexistence of CUP group-specific molecular abnormalities. Techniques are now available to study the CUP genome (next-generation sequencing technologies, proteomics, and metabolomics), and the pathogenesis of this syndrome may be eventually explained by specific genetic/epigenetic alterations.

Carcinoma of Unknown Primary Site as a Distinct Clinical Syndrome

The authors have found it amazing over the past 3 decades how often patients and their referring physicians are frustrated by CUP. Physicians are often somewhat obsessed with finding the anatomical primary site or at least with giving the patient a site diagnosis. There are many reasons underlying these feelings. Some patients think their oncologist may not be a very good diagnostician and seek the advice of others. Some oncologists feel relatively inadequate and wonder what other test(s) they might order; some have been relatively tentative, not feeling confident in recommending therapy. With improved ability to accurately predict the tissue of origin, most of these issues should be alleviated. Patients are better served, and physicians eventually feel more comfortable, and therefore manage these patients more effectively once their patients accept and understand their diagnosis. Nonetheless, these patients will still lack anatomically defined primary sites and will therefore remain a distinct population.

A second practical issue in the United States is the reimbursement for chemotherapy by Medicare for cancer diagnoses. Other than U.S. Food and Drug Administration approval for a specific tumor type, reimbursement for chemotherapy is usually determined by Medicare (and some other third-party insurers) by consulting compendia—Medicare Drug Policies or the National Comprehensive Cancer Network Compendium. The list of *approved* drugs is based on published literature showing *effectiveness* or clinical benefit in a specific tumor type. For many years, CUP was not included in any of the listings. Four drugs are currently listed as indicated for these patients (paclitaxel, carboplatin, cisplatin, and etoposide). The magnitude of this problem should be substantially diminished because the tissue of origin can now usually be diagnosed and, with these data, specific coded cancer diagnoses can be recorded.

Isolated Pleural and/or Pericardial Effusion

An isolated malignant pleural and/or pericardial effusion is most frequently a manifestation of a peripheral lung adenocarcinoma.

The diagnosis of mesothelioma or a metastatic tumor from other sites (breast, ovary, primary peritoneal, others) should also be considered. In a series of 42 patients, a primary lung cancer was eventually found in 15 patients (36%).¹⁸⁹ The primary may not be apparent even after chest tube drainage. Cytology usually shows adenocarcinoma; positive TTF1 and CK7 stains support a diagnosis of lung carcinoma. Other IHC stains (i.e., calretinin in mesothelioma) or an MTP assay may also assist in defining a primary site. An MTP assay may be successfully performed on small numbers of cancer cells, and in these circumstances should be a preferred test.

In one small series of patients,¹⁸⁹ empiric chemotherapy produced symptomatic improvement in 29 of 37 patients, and 30 of 37 patients had their pleural effusion reduced by chemotherapy; median survival was 12 months (range: 3 to 60 months).

Germ Cell Tumors with Metastases of Other Histologies

On occasion, patients with germ cell tumors, particularly extragonadal primaries, may have a metastatic lesion that consists of only somatic tumor cells. This is particularly true for neuroendocrine or sarcomatous differentiation, but can include any histology. Therefore, patients may be diagnosed as having a neuroendocrine tumor or sarcoma. In these rare instances, a primary germ cell tumor (usually extragonadal) is present elsewhere and subsequently becomes clinically apparent. It is difficult to make the diagnosis initially. An elevated plasma alpha-fetoprotein (AFP) or human chorionic gonadotropin (HCG) level and/or the presence of a mediastinal and/or retroperitoneal lesions supports this possibility. Chromosomal analysis, IHC staining, or an MTP assay may confirm the diagnosis of germ cell tumor. The treatment of choice is cisplatin-based chemotherapy. Surgical resection should be pursued later if feasible. These patients have a worse prognosis than those with typical germ cell tumors, probably because the somatic cell tumors are less sensitive to chemotherapy.

Melanoma and Amelanotic Melanoma

Approximately 10% to 15% of all melanomas that present with an unknown primary site are believed to be amelanotic. This diagnosis should be viewed with skepticism. At times, the only reason for the pathologic diagnosis is the similarity of the histologic pattern to melanoma, even though no pigment is demonstrated. Detailed pathologic and molecular study has occasionally revealed a group of other specific diagnoses, including lymphomas, neuroendocrine tumors, germ cell tumors, sarcomas, and PDC (not otherwise specified).

Melanosomes or premelanosomes seen on electron micrographs have been considered diagnostic of melanoma, but on rare occasions, these structures are seen in other tumors. Some believe amelanotic melanomas do not always form premelanosomes, raising the question as to whether they are really melanomas. Immunohistochemical panels and an MTP assay are also useful in supporting the diagnosis.

The history of a resected, abraded, or frozen pigmented skin lesion would favor melanoma. In addition, the rare primary visceral melanoma should be considered (e.g., eye, adrenal, bowel, anus, others) as the source of the disease in questionable cases. For patients with the diagnosis of amelanotic melanoma, particularly without diagnostic IHC stains, an MTP assay, or a BRAF mutation, an alternative diagnosis should be considered. Mutations of BRAF have been found in approximately 50% of melanomas, and if present, would also support a presumptive diagnosis of melanoma and consideration of therapy with a BRAF inhibitor.

UNKNOWN PRIMARY CANCER IN CHILDREN

There are limited data in children, and as expected, many of these neoplasms represent embryonal malignancies.¹⁹⁰ They are exceedingly rare. In patients with carcinoma, not otherwise specified, the authors favor following the same management plan as for adults.

Midline Carcinoma in Young Adults and Children with t(15;19) and BRD4-NUT Oncogene

A few young patients have been described with carcinomas arising from midline locations and an associated chromosomal translocation t(15;19) (q13,p13.1).^{29,191} Patients with this syndrome are usually children or young adults; most have poorly differentiated carcinoma and widespread metastasis. The primary tumor site is difficult to identify in many patients. The NUT (nuclear protein in testes) oncogene is common to all these tumors and supports their possible origin from a specific cell type, perhaps an early epithelial progenitor cell that is more common in the first 2 or 3 decades of life. Perhaps these tumors are an example of *stem cell tumors* (see section Biology of the Primary Tumor in Special Issues in Carcinoma of Unknown Primary Site).

A recent review of 54 patients¹⁹¹ revealed poor median survival (6.7 months) and 2-year survival of 19% despite surgery and radiation therapy when feasible and intensive chemotherapies. These patients are clinically similar to the extragonadal germ cell cancer syndrome and, without a positive t(15;19), some of these patients could be included in that clinical syndrome and vice versa. Further knowledge of these NUT-rearranged carcinomas and improved targeted therapies for these patients are likely to follow with their more broad recognition.

NEW TREATMENT PARADIGM

As described in this chapter, improved diagnostic methods have changed the clinical evaluation and therapy for most CUP patients. A change from empiric chemotherapy to site-specific therapy based on tissue of origin diagnosis is now indicated for the majority of patients, as we recently reviewed.¹⁹²

In Figure 113.3, we summarize the management approach. After standard initial clinical and pathologic evaluations, selected patients should have an additional directed clinical evaluation, IHC staining, and/or an MTP assay of the tumor specimen. Patients with an identified anatomical primary site should be treated accordingly, and patients who fit into an identified favorable subset should receive appropriate subset-specific therapy (see section Favorable Subsets). Patients who have their tissue of origin diagnosed by IHC should receive site-specific therapy. Patients in neither of these categories should have MTP; site-specific therapy should then be based on the tissue of origin diagnosis. Diagnoses made by IHC and/or MTP should be interpreted in conjunction with clinical features and pathologic results. Empiric chemotherapy is indicated for the small minority without a defined tissue of origin, and clinical trials should always be considered.

Some may now think that CUP will be a rare entity once most patients are assigned a tissue of origin and become a subset or member of a recognized cancer type, albeit without a defined anatomical primary site. This may be a clinical reality once it is agreed upon that the survival of CUP patients with defined origins are similar to the patients with anatomically defined primary sites. However, the syndrome persists and the biologic phenomenon explaining CUP for now remains a mystery. Further knowledge of the genetic/epigenetic mechanisms may eventually explain CUP

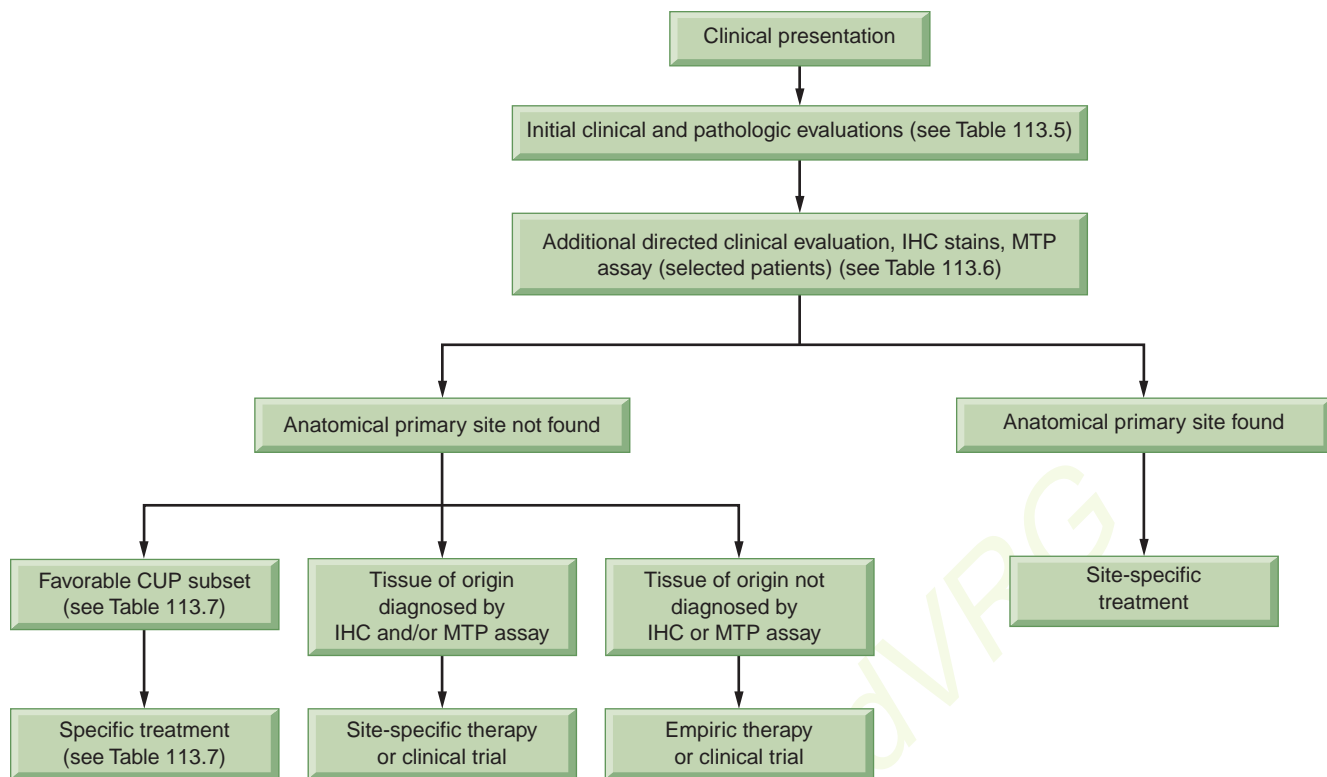

Figure 113.3 New management paradigm for the CUP patient.

and lead to new targeted therapies for patients with this enigmatic syndrome and perhaps for other patients with metastatic cancers.

The evolution of improved, more personalized therapies for CUP patients is linked to the wave of precision therapies for many types of known cancer types based on genomic understanding; in addition, the dawn of clinically impressive and beneficial immunotherapy (such as CTLA-4, PD-1, PDL-1 inhibitors, and genetically engineered T cells) for many common solid tumor patients is here. There is no other reasonable option now but to further define in

each patient the type and subtype of neoplasm he or she harbors within the CUP syndrome before planning definitive therapy.

The integration of molecular diagnostics into CUP patient management is already supported by clinical data, but continued investigation is necessary to further refine management recommendations. Even with the ability to identify the tissue of origin, further improvements in the treatment of many of these patients are dependent on the development of improved treatments for advanced solid tumors.

114 Benign and Malignant Mesothelioma

Harvey I. Pass, Michele Carbone, Lee M. Krug, and Kenneth E. Rosenzweig

INTRODUCTION

Malignant mesotheliomas (MM) are highly aggressive neoplasms that arise primarily from the surface serosal cells of the pleural, peritoneal, and pericardial cavities. The disease is characterized by a long latency from the time of exposure to asbestos to the onset of disease, suggesting that multiple somatic genetic events are required for tumorigenic conversion of a normal mesothelial cell.

MECHANISM OF ASBESTOS CARCINOGENESIS

There are six types of asbestos: amosite, crocidolite, anthophyllite, actinolite, tremolite, and chrysotile.¹ The five types other than chrysotile are termed *amphibole asbestos*. Several nonasbestos minerals (e.g., erionite, winchellite) are very similar to asbestos structurally and chemically and are also capable of causing mesothelioma in humans. The mechanisms responsible for asbestos carcinogenicity are linked to the secretion of tumor necrosis factor (TNF)-alpha by mesothelial cells and macrophages exposed to asbestos that in turn leads to NFκB activation.² The activation of the NFκB pathway in mesothelial cells allows them to survive the toxic insult and the genetic damage caused by asbestos, and these damaged but viable cells may proliferate into a mesothelioma.²

Animal Models of Asbestos Carcinogenicity

Mesotheliomas and sarcomas are induced in a dose-dependent fashion after intrapleural and intraperitoneal injection of asbestos into animals.³⁻⁵ Chronic inhalational studies are thought to be the best representation of asbestos carcinogenicity. Because of the cost of these experiments, however, very few have been performed.

Asbestos Carcinogenicity in Humans

Although injection and inhalation studies in animals suggest that all forms of asbestos are equally carcinogenic and that there is a clear dose-response relationship between asbestos exposure and mesothelioma risk, epidemiologic studies in humans do not support these observations. The proportion of mesotheliomas that are thought to be associated with asbestos varies in the literature from 16% to 90%.¹ Although this wide range may reflect the distinct populations studied, it is more likely a result of the different methodologies used to determine exposure rates.¹ Most human studies have indicated that amosite and crocidolite exposure carry a much greater risk than exposure to chrysotile.^{6,7} Chrysotile, however, is frequently combined with tremolite, an amphibole, that may instead be responsible for mesothelioma development.⁸

In humans, there is no clear dose-response curve to asbestos, and a threshold level below which mesotheliomas do not develop

has not been determined, although it is generally accepted in the scientific community that background levels of exposure, such as those found in the lungs of almost all individuals, do not increase the risk of mesothelioma. It is estimated that <5% of asbestos miners exposed to high levels of asbestos develop mesotheliomas¹; however, wives of some of these workers have developed mesotheliomas after they were presumably exposed to lower levels of asbestos compared to their husbands while washing their clothes.^{9,10} Similarly, mesothelioma development commonly occurs in workers in occupations in which asbestos exposure is higher than in the general population, but much lower than in asbestos miners. The carpenters, electricians, and construction workers who have developed mesotheliomas are a reflection of this.¹¹ These data suggest that high levels of exposure are not necessarily correlated with increased risk of malignancy compared to moderate asbestos exposure, arguing against a classic dose-response relationship.¹

Mechanism of Asbestos Pathogenicity

It is thought that when fibers reach the alveoli after inhalation, smaller fibers are phagocytized and efficiently removed from the lung. Larger fibers are not easily engulfed and can usually only be removed if solubilized. However, amphiboles are not soluble and thus remain in the lung. These fibers may eventually reach the pleura via the lymphatics or direct extension, where they may lead to pleural plaques, fibrosis, and mesothelioma. In the pleura, asbestos fibers may cause mutagenic changes through hydroxy radical and superoxide anion production during phagocytosis, leading to DNA strand breaks and deletions. Most recently, data implicating necrosis in the genesis of mesothelioma have been reported in which the release of HMGB1 is necessary as a critical initial step in the pathogenesis of asbestos-related disease and provides a mechanistic link between asbestos-induced cell death, chronic inflammation, and mesothelial carcinogenesis.¹² Inflammation due to asbestos deposition contributes to asbestos carcinogenesis.^{2,13,14} Phagocytic macrophages at these sites of inflammation internalize asbestos and release mutagenic reactive oxygen species and numerous cytokines including TNF-α and interleukin (IL)-1, which have been linked to asbestos-related carcinogenesis.^{2,15} By inducing cell necrosis, asbestos causes the release of HMGB1,¹² a typical damage-associated molecular pattern^{16,17} and a key mediator of inflammation.¹⁸ Activation of Nalp3 inflammasome ensues with subsequent IL-1β secretion, a process that is enhanced by asbestos-induced production of reactive oxygen species.^{19,20} Additionally, HMGB1 is released by reactive macrophages, other inflammatory cells, and human mesothelial cells (HMC¹²) upon exposure to asbestos. HMGB1 is a critical regulator in the initiation of asbestos-mediated inflammation leading to the release of TNF-α and subsequent NF-κB signaling¹² (Fig. 114.1). During programmed necrosis, HMGB1 translocates from the nucleus to the cytosol and the extracellular space, where it binds several pro-inflammatory molecules and triggers the inflammatory responses that distinguish this type of cell death from apoptosis. Secreted

Figure 114.1 Working hypothesis for mesothelioma carcinogenesis. Asbestos causes necrotic human mesothelial cell (HMC) death, leading to the release of HMGB1 into the extracellular space. As a typical damage-associated molecular pattern and a key mediator of inflammation, HMGB1 can induce activation of Nalp3 inflammasome and subsequent interleukin (IL)-1 β secretion, as well as eliciting macrophage accumulation and triggering the inflammatory response and tumor necrosis factor- α secretion, which increases the survival of asbestos-damaged HMCs. This allows key genetic alterations to accumulate within HMCs that sustain asbestos-induced DNA damage, leading to the initiation of mesothelioma.

HMGB1 stimulates RAGE, TLR2, and TLR4 (the three main HMGB1 receptors) expressed on neighboring inflammatory cells such as macrophages and induces the release of several inflammatory cytokines, including TNF- α and IL-1 β . TNF- α -induced NF- κ B signaling has been shown to be a critical link between inflammation and carcinogenesis in multiple cancer models, including mesothelioma.² Specifically, asbestos-mediated TNF- α signaling induces the activation of NF- κ B-dependent mechanisms, promoting the survival of HMCs after asbestos exposure,² and thus allowing HMCs with accumulated asbestos-induced genetic damage to survive, divide, and propagate genetic aberrations in premalignant cells that can give rise to a malignant clone. In addition, HMGB1 enhances the activity of NF- κ B, which promotes tumor formation, progression, and metastasis.²¹ An investigation into the targeting of extracellular HMGB1 as a novel strategy for mesothelioma prevention and/or therapy is currently under way.²²

It is difficult to reconcile what is known about the carcinogenic actions of asbestos and the long latency period between asbestos exposure and mesothelioma development. Lanphear and Buncher²³ reviewed 21 studies of 1,690 mesotheliomas and found that 96% occurred at least 20 years after exposure; the mean latency was 32 years. Several theories have been postulated to describe what happens during this latency period.²⁴ It is widely believed that asbestos induces genetic alterations in mesothelial cells over a long period that eventually lead to malignant cells. This may occur if a key regulatory gene, such as the *INK4a/ARF* locus, is deleted or silenced. With loss of key regulatory genes, additional mutations could accumulate rapidly. *INK4a/ARF* codes for p16 (a cyclin-dependent kinase inhibitor) and for p14ARF, which promotes murine double minute-2 degradation, preventing murine double minute-2 from neutralizing p53. Both p16 and p14ARF are often deleted in MM (see “Alterations of Specific Tumor Suppressor Genes in Mesothelioma”). This process may allow enough mutations to accumulate to lead to malignancy. Cell growth from this point would be rapid, leading to a clinically detectable tumor.¹

OVERVIEW OF MOLECULAR MECHANISMS IN MESOTHELIOMA

Cytogenetic Assessment of Malignant Mesotheliomas

Deletions of specific chromosomal sites in the short (p) arms of chromosomes 1, 3, and 9, and long (q) arm of 6 are repeatedly observed in these tumors. Using newer molecular platforms including array comparative genomic hybridization and representational oligonucleotide microarray analysis, deletions in chromosomes 22q12.2, 19q13.32, and 17p13.1 appear to be the most frequent events (55% to 74%), followed by deletions in 1p, 9p, 9q, 4p, and 3p, and gains in 5p, 18q, 8q, and 17q (23% to 55%). Increasing numbers of copy number abnormalities in mesothelioma are associated with poor prognosis, especially when associated with deletions in 9p21.3 encompassing *CDKN2A/ARF* and *CDKN2B*, as detailed later.²⁴ Analysis of the minimal common areas of frequent gains and losses has pointed to novel potential tumor suppressor genes (TSG) including *OSM* (22q12.2), *FUS1*, *PL6* (3p21.3), *DNAJ1* (9p21.1), and *CDH2* (18q11.2–q12.3).²⁵

Alterations of Specific Tumor Suppressor Genes in Mesothelioma

p16

Cheng et al.²⁶ reported homozygous deletions of one or more of the three *p16* exons in 34 of 40 (85%) malignant mesothelioma cell lines and a point mutation in one cell line. Downregulation of *p16* was observed in four of the remaining cell lines. Homozygous deletions of *p16* were identified in 5 of 23 (22%) malignant

mesothelioma tumor samples. Downregulation of *p16* in malignant mesothelioma cells may result from 5' CpG island hypermethylation, as has been demonstrated in other types of cancer. *P16* inactivation by homozygous deletions or methylation is a frequent event in Japanese patients with malignant pleural mesotheliomas (MPM).²⁷ Homozygous deletion is the major cause of the *P16* inactivation,²⁸ but methylation also leads to the inactivation of *P16* when the *P16* alleles are retained.²⁷ Homozygous deletions at this locus can lead to the inactivation of another putative TSG, *p14ARF*, because *p16* and *p14ARF* share exons 2 and 3 although their reading frames differ.^{29,30} The prognostic significance of *p16/CDKN2A* loss in MM has been defined both by immunohistochemistry and fluorescence in situ hybridization (FISH). With the FISH analysis of primary MM tissue samples or MM cells from the pleural effusion, over 70% of cases showed homozygous deletions of the *CDKN2A/ARF* locus. Both loss of *p16* protein expression by immunohistochemistry and homozygous deletion of *p16* by FISH are associated with an adverse prognosis.³¹ Loss of *p15* is also associated with codeletion of microRNA (miR)-31.³² Protein phosphatase (PPP6C), upregulated in MPM, is a target of miR-31, and reintroduction of miR-31 in mesothelioma cells has a suppressive effect on MM cells.³²

p53

Cell lines derived from murine models of asbestos-induced mesothelioma have reduced or absent expression of *p53* messenger RNA (mRNA) compared to the RNA from nontumorigenic cell lines or reactive mesothelial cells.³³ In human cell lines derived from patients with malignant mesothelioma, attention has turned to specific mutations or genetic abnormalities in *p53*. In general, mutational analyses of *p53* in mesothelioma have not revealed reasons for its inactivation.

Wilms Tumor Gene

The detection of Wilms tumor gene (*WT1*) mRNA or protein provides a specific molecular or immunohistochemical marker for differentiation of mesothelioma from other pleural tumors, in particular adenocarcinoma.³⁴ Vaccination protocols that exploit the selective presence of *WT1* in mesothelioma are under way at selected institutions.³⁵

Neurofibromatosis Gene

The tumor suppressor merlin is encoded by the neurofibromatosis type 2 gene (*NF2*), which is located on chromosome 22q12, and mutations in this gene have been found in 40% of mesothelioma and 50% of malignant mesothelioma cell lines.^{36,37} Mutations including deletions and insertions lead to truncated and inactivated merlin. Experimental animal models indicate that disruption of the *NF2* signaling pathway, together with a deficiency in *ink4a*, is essential for mesothelioma development.³⁸

ALTERATIONS OF ONCOGENES IN MESOTHELIOMA

C-sis (Platelet-Derived Growth Factor)

Malignant mesothelioma cell lines produce numerous growth factors and cytokines, possibly as a consequence of altered oncogene status. One of the more intriguing oncogenes in malignant mesothelioma is C-sis, which codes for one of the two chains (alpha and beta) of platelet-derived growth factor (PDGF). Gerwin et al.³⁹ were the first to describe elevation of RNA levels for both chains of PDGF in mesothelioma cell lines and correlated the increase with PDGF-like activity secreted by the cells. It is of interest that overexpression of A chain transforms human mesothelial cells to the tumorigenic phenotype in vitro and that the use of antisense

ODN to the A chain inhibits growth of mesothelioma cell lines. PDGF-D promotes mesothelioma cell proliferation by targeting ROCK or MAP kinase through autocrine activation of PDGF-beta receptor⁴⁰; however, in general, therapies targeting PDGF in mesothelioma have been unsuccessful.⁴¹

Transforming Growth Factor

Transforming growth factor-B (TGF-B) is another growth-regulatory and immunomodulatory cytokine, and high levels of TGF-B have been described in several human and mouse malignant mesothelioma cell lines.^{42,43} TGF-B may have a potential role in regulation of the differential PDGF receptor expression in malignant mesothelioma and thus have an effect on proliferation as well as other events. TGF-B production by tumors plays a significant role in blocking immune response by preventing T-cell infiltration into tumors, inhibition of T-cell activation/function, and mediation of T regulatory cell-induced immunosuppression. TGF-blockers (soluble receptors/antibodies) and receptor inhibitors have antitumor effects that, in several models, are due primarily to immunologic mechanisms. TGF blockade had antitumor effects that were CD8+ T-cell dependent in a murine malignant mesothelioma model.⁴⁴ Recently, it was reported that a combined triple treatment of anti-CD25 monoclonal antibody, anti-cytotoxic T-lymphocyte antigen-4 monoclonal antibody and TGF-beta soluble receptor resulted in long-term clearance of MPM tumors and memory against tumor rechallenge.⁴⁵

Insulin Growth Factor

Insulin growth factor (IGF) is another of the important autocrine loops in mesothelioma.⁴⁶ The IGF receptor-1 pathway is a significant regulator of mesothelioma growth acting through downstream kinases such as Akt. In humans, both normal mesothelium and mesothelioma cell lines express IGF-1 and IGF-1R RNAs (by Northern blot or reverse transcriptase polymerase chain reaction), and IGF-1 protein is detected in their conditioned media. These studies suggest that mesothelioma growth, both in human and animal models for the disease, may involve the IGFs, and trials using anti-IGF-1R antibodies or small-molecule IGF blockade are being formulated for mesothelioma.⁴⁷ Cixutumumab, a humanized monoclonal antibody to IGF-1R, has been investigated using early passage tumor cells and an in vivo human mesothelioma tumor xenograft model. Cixutumumab induced antibody-dependent cell-mediated toxicity and in vivo, cixutumumab treatment delayed growth of H226 mesothelioma tumor xenografts in mice and improved the overall survival of these mice compared to controls.⁴⁸ A phase 2 clinical trial of cixutumumab is currently ongoing for the treatment of patients with mesothelioma.

Angiogenic Mechanisms in Mesothelioma

The most relevant cytokines and growth factors in angiogenic pathways involve the ILs (specifically IL-6 and IL-8), fibroblast growth factors (FGF), vascular endothelial growth factors (VEGF), platelet-derived endothelial growth factors, and IGFs. Moreover, mutational or posttranslational silencing of TSGs or their products, particularly *p53* and *p16*, has also been associated with increased angiogenic mechanisms.

IL-6 levels are elevated in the serum and pleural effusions of patients with mesothelioma, and there have been correlations seen between the IL-6 level and the degree of thrombocytosis in these patients.⁴⁹ IL-6 expression is elevated in tissues undergoing angiogenesis, but by itself it has a limited role in proliferation of endothelial cells. IL-6, however, induces angiogenesis by elevating the expression of VEGF, a specific mitogen for vascular endothelial cells. Serum VEGF and IL-6 levels are elevated in

patients with mesothelioma, and their levels each correlate with platelet count.⁵⁰ IL-8 is also an important angiogenic factor for the development of new capillaries in vivo and has direct growth-potentiating activity in mesothelioma. Pleural fluid from patients with mesothelioma has significantly higher IL-8 levels by enzyme-linked assay compared to patients with other malignant effusions.⁵¹ Mesotheliomas present with a high intratumoral vessel density that also have prognostic relevance,^{42,52,53} and immunohistochemically, VEGF, FGF-1 and -2, and TGF- β immunoreactivity are present in 81%, 67%, 92%, and 96%, respectively, of mesotheliomas, and in 20%, 50%, 40%, and 10%, respectively, of samples of the nonneoplastic mesothelium. Depending on the study, high immunohistochemical FGF-2 expression⁵³ or VEGF expression by reverse transcriptase polymerase chain reaction correlate with more tumor aggressiveness and worse prognosis for mesothelioma.^{52,54}

Simian Virus 40

SV40 is a DNA tumor virus that has been associated with the development of malignant mesothelioma.⁵⁵ Although this virus is endogenous in rhesus monkeys, epidemiologic studies have shown that it is also widespread among the human population. The mode by which the virus was transferred from monkey to human is uncertain, but the bulk of this transfer may have occurred from 1954 to 1963 through SV40-contaminated polio vaccines administered worldwide. Moreover, polio vaccines produced in the former Union of Soviet Socialist Republics remained contaminated with infectious SV40 at least until 1978.⁵⁶

The association of SV40 with mesothelioma started with the observation that when hamsters were injected with SV40 into the pleural space, all of the animals developed mesotheliomas within 6 months. This finding prompted investigations into the possibility that some mesotheliomas in humans could be attributed to SV40 infection directly or with SV40 acting as a cocarcinogen with asbestos. Mesothelioma samples studied in 1994 showed that 60% of the samples contained SV40 DNA and expressed the SV40 large T antigen. The results were confirmed by numerous laboratories using a variety of techniques such as PCR, FISH, Western blot, immunohistochemistry, and laser dissection/PCR, but the percentage of positive samples varied from 6% to 83%, and a few studies were completely negative. Technical and geographical differences may account for these variances.

Although the epidemiologic data are not available, mechanistic experiments in human mesothelial cells^{57,58} and animal experiments⁵⁹ strongly support a pathogenic role of SV40 in mesothelioma. It is unlikely, however, that SV40 acts alone in mesothelioma development, as most cancers are multifactorial, and most mesotheliomas occur in asbestos-exposed individuals. SV40 has been shown to be a cocarcinogen in causing mesothelioma in animals and malignant transformation of mesothelial cells in tissue culture.^{60,61} It is safe to say that a definitive role for the virus in human mesothelioma has not been unequivocally demonstrated but ongoing debate regarding its role will continue.

Radiation and Mesothelioma

In the literature, there are a few studies reporting mesothelioma development in patients exposed to thorotrast (intravenously) or who had received radiation to the chest and abdomen.¹ In some of these cases, asbestos exposure could not be ruled out, and SV40 status was not investigated. However, in a few cases in which mesotheliomas developed in young adults who received radiotherapy (RT) because of Wilms tumor, radiation was the only likely causative factor. Studies in rats support a role for radiation as a causative factor. Although it appears that radiation may cause mesotheliomas, the number of mesotheliomas for which it is responsible is probably small.

Carbon Nanoparticles

Engineered single-wall carbon nanotubes (SWCNT) are a class of nanoparticles being actively evaluated for myriad industrial and biomedical applications.⁶² Preliminary cellular and animal exposure investigations on the toxicity and pathogenicity of SWCNTs have demonstrated biologic interactions, including toxicity, inflammatory reactions, oxidative stress, and fibroproliferative response.^{63–65} SWCNTs are biopersistent and have the ability to distribute to subpleural areas after pharyngeal aspiration. Reports have described the induction of mesothelioma in p53+/- mice by multiwall carbon nanotubes.^{66,67} These investigations compelled the present studies of potential interactions of SWCNTs with mesothelial cells. Exposure to SWCNTs induced reactive oxygen species generation, increased cell death, enhanced DNA damage and H2AX phosphorylation, and activated poly(adenosine diphosphate-ribose) polymerase, AP-1, NF κ B, p38, and Akt in a dose-dependent manner. These events recapitulate some of the key molecular events involved in mesothelioma development associated with asbestos exposure.^{68,69} In addition, nickel nanoparticles enhance the in vitro activity of PDGF in regulating chemokine production in rat mesothelial cells through a mechanism involving reactive oxygen species generation and prolonged activation of ERK-1.⁷⁰

Genetic Predisposition to Mesothelioma: Erionite and BAP1

Recent evidence indicates that genetic predisposition plays an important role in determining individual susceptibility to mineral fiber carcinogenesis and to the development of mesothelioma. In the villages of Karain (population ~600), Tuzkoy (population ~1,400), and Sarihidir (this village was abandoned) in Cappadocia, a region in Central Anatolia, Turkey, $\geq 50\%$ of deaths are caused by malignant mesothelioma.⁷¹ This epidemic has been linked to exposure to a mineral fiber called *erionite*, one of the most potent mineral fibers in causing mesothelioma. However, mesothelioma was more frequent in certain families than others, leading to observations that some families in Turkey were unusually susceptible to erionite carcinogenesis.⁷¹ Erionite is present in many parts of the world, including western American states such as North Dakota,^{72,73} but so far the contribution of erionite to the increased incidence of mesothelioma has not been studied except in Turkey.

Similar families have also been identified in other parts of the world⁷⁴ and in the United States, where they appear to be unusually susceptible to asbestos carcinogenesis. Recently, BRCA-associated protein 1 (BAP1) has been identified as a novel MPM TSG. BAP1 is located at the 3p21, a region frequently deleted in MM, and encodes for a deubiquitinase enzyme known to target histones and other proteins. BAP1 appears to exert its antitumor activities mainly in a BRCA-independent manner,⁷⁵ with regulation of the cell epigenome, via modulation of histone H2A ubiquitination and chromatin accessibility.⁷⁶ However, the relevance of BAP1 to the biology of normal and cancer cells remains largely unexplained; in fact, manipulation of BAP1 in cancer cells has often yielded unexpected or even contradictory results. For example, silencing of BAP1 in MM and uveal melanoma cell lines resulted in reduced cell growth.^{77,78}

Bott et al.⁷⁷ originally described the association of somatic mutations of BAP1 in 23% of mesothelioma samples. In a larger series of patients, the same group confirmed that somatic BAP1 mutations occur in about 20% of pleural MM and reported that the only clinical variable significantly different among those with and without BAP1 mutations was smoking (former or current), with BAP1 mutations more prevalent among smokers (75% versus 42%).⁷⁹ A Japanese study reported BAP1 gene alterations (either deletions or sequence-level mutations) in 61% of their 23 MM samples.⁸⁰ Whether this discrepancy results from the different methodologies

Figure 114.2 Histology of mesothelioma. **(A)** Epithelioid mesothelioma. Note tubular structures and malignant mesothelioma cells showing a hobnail morphology with bland nuclei and abundant cytoplasm. **(B)** Biphasic malignant mesothelioma, showing a nest of mesothelioma cells with epithelial differentiation within the sarcomatoid component. **(C)** Sarcomatoid mesothelioma, positivity for pankeratin, and rare foci of cells suggestive of epithelioid differentiation indicated the diagnosis. **(D)** High-grade sarcoma, a highly aggressive tumor that is vimentin-positive but vimentin-negative over 15 different immunostains for other markers and without distinctive electron microscopic features. In this case, the diagnosis of mesothelioma could not be confirmed. Original magnification: **A, C, and D**, $\times 400$; **B**, $\times 200$.

in sample preparation and detection of BAP1 mutations or it is an intrinsic difference between the two populations (e.g., due to ethnicity) has still to be determined. A third recent study from Arzt et al.,⁸¹ with a separate cohort of 52 pleural MM, reported absence of BAP1 IHC staining in 60% of pleural MM, confirming previous results. Moreover, there was no correlation between BAP1 expression and asbestos exposure, and it was suggested that expression of BAP1 in tumor samples is inversely correlated to survival.

Germline BAP1 mutations were reported by Testa and Carbone⁸² in two US families having a high frequency of MPMs. In the same study, 22% sporadic MM tumors harbored somatic BAP1 mutations. These findings have promoted speculation that BAP1 germline mutations can cause a novel cancer syndrome characterized by a significant excess of both pleural and peritoneal MM, uveal and cutaneous melanoma, and possibly other tumors.

PATHOLOGY OF MESOTHELIOMA

Benign Mesotheliomas

There are a number of benign mesothelial proliferations that must be distinguished from malignant mesothelioma including multicystic mesothelioma (*multilocular peritoneal inclusion cyst*), adenomatoid mesotheliomas, and well-differentiated papillary mesothelioma. Localized mesothelioma, better referred to as *localized fibrous tumor of the pleura* (FTP), is similar to other fibrous tumors found elsewhere in the body. The tumor

cells have a benign appearance and are usually immersed in a fibrous and characteristically vascular stroma. FTPs are characteristically negative for cytokeratin (a marker of mesothelial cells) and positive for CD34, which suggests that these cells are not of mesothelial origin. The most important predictive factor in the prognosis of FTP is whether the tumor can be completely resected. Pedunculated tumors have a much better prognosis than tumors that grow over a broad pleural area.^{83–85} Surgical resection (Fig. 114.2) is the treatment of choice, with complete resection of the tumor and its pedunculated portion along with the site of origin. Five-year survival rates as high as 97% have been reported. En bloc resection of the lung, chest wall, or diaphragm may be necessary. For recurrences, re-excision is the treatment of choice. Long-term survival with re-excision is possible, but with incomplete resection or malignant transformation the median survival is 24 to 36 months.

Malignant Mesothelioma

Histologically, malignant mesothelioma can show an epithelial morphology (malignant mesothelioma epithelial type), a fibrous morphology (malignant mesothelioma fibrous type, also called sarcomatoid type), or a combination of both (mixed type or biphasic malignant mesothelioma) (Fig. 114.3). Most MM (50% to 60%) are of the epithelial type, approximately 10% are sarcomatoid, and the remainder are biphasic MM.

The diagnosis of malignant mesothelioma is usually straightforward, in contrast to common belief, provided that the pathologist

Figure 114.3 Fibrous tumor of pleura. **(A)** Computed tomography reveals a large mass compressing the lower lobe of the lung. **(B)** Intraoperative photograph. Tumor arose from a wide stalk on the diaphragm. **(C)** Intraoperative photograph after resection of the mass revealing expansion of the lung and no other disease. **(D)** Resected specimen.

has extensive experience with this malignancy. Some epithelial mesotheliomas grow forming sheets of epithelioid cells. To rule out mimics of mesothelioma, the diagnosis should be confirmed by immunohistochemistry, which shows that the tumor cells are diffusely positive for pankeratin, keratin 5/6, calretinin, and WT-1, and negative for the epithelial markers such as CEA, CD15, Ber-EP4, Moc-31, TTF-1, and B72.3. For epithelial mesotheliomas, positive stainings for pankeratin and calretinin and negative stainings for three epithelial markers are considered sufficient for diagnosis.

Biphasic mesotheliomas can be distinguished from carcinosarcomas metastasizing from various organs and from biphasic synovial sarcomas by using either electron microscopy or molecular testing for the X;18 translocation that is diagnostic of synovial sarcoma.⁸⁶

Newer methods are under development for distinguishing mesothelioma from adenocarcinoma and include microRNA profiling of the tumors. Gee et al.⁸⁷ have described the use of seven miRNAs (miR-200c, miR-141, miR-200b, miR-200a, miR-429, miR-203, and miR-205) to distinguish lung adenocarcinoma from mesothelioma with a 10% misclassification error. Others have described a three microRNA profile (mir-205, mir-193a-3p, and mir-192) for the differential diagnosis of mesothelioma from colon, renal, lung, and breast cancer with a 95% specificity and 96% sensitivity.⁸⁸

EPIDEMIOLOGY AND CLINICAL PRESENTATION

The death rates for mesothelioma parallel the consumption of asbestos by individual countries. When one considers mesothelioma death rates from 2000 to 2004 as a function of asbestos usage in the 1960s, Australia has the highest death rate for the disease in the world.⁸⁹ It is predicted that between 2000 and 2049, over 400,000 lives will be lost in those countries from the disease.⁹⁰ In the United States, there have been 2,500 deaths per year from the disease since 1999, with workers with industrial exposures in construction and shipbuilding being at highest risk, followed by plumbers, pipe fitters, and steamers. Mesothelioma affects men in their 50s, 60s, and 70s due to the aforementioned 25- to 40-year latency period between occupational asbestos exposure and the development of the tumor.⁹¹ Women and children can have the disease, but the male-to-female ratio is approximately 4.5:1.⁹²

Symptoms

As many as 25% of patients with the disease have symptoms for ≥ 6 months before seeking medical attention. The right side is affected more than the left side (60% versus 40%), most likely because of the right side's greater volume.

Approximately 60% of the patients present with nonpleuritic chest pain that classically is located posterolaterally and low in the thorax. Dyspnea is present in 50% to 70% of the cases, and, indeed, 80% of the patients present with dyspnea and effusion. The presence of a pleural effusion is documented at some time in the course of the disease in 95% of patients with MPM. With the increasing use of positron emission tomography for pretreatment planning, between 5% and 25% of patients are found to have metastatic disease at presentation.⁹³

Physical Examination

Physical examination reveals decreased breath sounds, dullness to percussion, or decreased motion of the involved chest wall. Failure to significantly relieve the dyspnea after thoracentesis may indicate that the lung is “trapped.” In the late stages of the disease, there is often dramatic cachexia, marked contraction of the involved chest with narrowed interspaces, and hypertrophy of the contralateral hemithorax. A chest wall mass occurs in up to 25% of patients, often at the site(s) of prior thoracentesis, thoracotomy, or thoracoscopy wounds.

Laboratory Examination and Blood Biomarkers

Mesothelioma patients have nonspecific laboratory findings, including hypergammaglobulinemia, eosinophilia, and/or anemia of chronic disease. It has been recently noted that 14% to 15% of patients have elevated homocysteine levels, reflecting folic acid deficiency; 17% have biochemical evidence of vitamin B₁₂ deficiency; and 32% have biochemical signs of vitamin B₆ deficiency.⁹⁴ The most striking laboratory abnormality is thrombocytosis (>400,000), which is seen in 60% to 90% of patients,⁹⁵ and approximately 15% of patients have platelet counts >1,000,000.

Soluble mesothelin-related peptide (SMRP), osteopontin (OPN), and megakaryocyte potentiating factor are presently under investigation as early detection or therapy monitoring markers. Robinson et al.⁹⁶ reported that determination of SMRP in serum is a marker of mesothelioma with a sensitivity of 83% and specificity of 95% in the first 48 patients with MPM tested. These data have been validated by other laboratories in the United States^{97,98} and internationally.⁹⁹ Changes in serum SMRP levels parallel clinical course/tumor size, and SMRP was elevated in 75% of patients at diagnosis.¹⁰⁰ Studies using SMRP in an attempt to diagnose early mesothelioma in high-risk cohorts have so far been disappointing, but follow-up is still short.^{101,102}

OPN is a glycoprotein that mediates cell-matrix interactions and is regulated by proteins in cell-signaling pathways that have been associated with asbestos-induced carcinogenesis.¹⁰³ In a study that compared serum OPN levels of patients with MPM to those of asbestos-exposed individuals without cancer, serum OPN levels rose with duration of asbestos exposure and degree of radiographic abnormality (plaques and fibrosis versus other lesser findings¹⁰⁴), and using a cutpoint of 48.3 ng of OPN per milliliter resulted in 77.6% sensitivity and 85.5% specificity when comparing the group exposed to asbestos with the group with mesothelioma. Follow-up studies have demonstrated that serum OPN is not reliable because of the presence of a thrombin cleavage site, which causes degradation of the marker.¹⁰⁵ Plasma OPN,¹⁰⁶ although not specific to mesothelioma, is being evaluated in the disease for both prognosis and early detection utility. A blinded validation of plasma fibulin 3 confirmed excellent discrimination between MPM plasma and all non-MPM cohorts including those with benign or malignant effusions. Pleural effusion fibulin 3 was also discriminatory between MPM effusions and non-MPM effusions.¹⁰⁷

Radiologic Examination

Malignant mesothelioma can have a diverse radiographic appearance. Many of the early changes are associated with a previous exposure to asbestos, consisting both of pleural and parenchymal changes, including pleural plaques or parenchymal pulmonary fibrosis.

Chest Radiography

The most common chest radiography features associated with mesothelioma progression and symptoms include the presence of a pleural effusion, diffuse pleural thickening, and nodularity. The involved hemithorax can eventually have smooth, lobular pleural masses that infiltrate the pleural space and fissures¹⁰⁸⁻¹¹⁰ in 45% to 60% of patients with contraction and fixation of the chest (Fig. 114.4). The lung becomes encased, and the mediastinum shifts because of volume loss.

Chest Tomography

Pleural changes on chest tomography (CT) include pleural plaques, diffuse pleural thickening, and pleural effusion. Additional CT features of mesothelioma are localized nodular or plaque-like pleural thickening, possibly associated with pleural effusion. The lobulated pleural encasement frequently causes lower lobe collapse (Fig. 114.5). Intrapulmonary nodules can occur in 60% of patients, and infiltration into fissures along with enlarged hilar and mediastinal lymph nodes may be seen. The CT allows a better view of the involved pericardium, which is irregularly thickened and associated with infiltration to the pericardial fat pad. A clear fat plane between the inferior diaphragmatic surface and the adjacent abdominal organs as well as a smooth inferior diaphragmatic contour may imply resectability.¹¹¹ CT may reveal a hemidiaphragm encased by a mass or poor definition between the liver, stomach, and inferior diaphragmatic surface.

Volumetric measurements using CT have recently been studied with regard to their prognostic capability (see “Prognostic Indicators”).

Magnetic Resonance Imaging

Studies have suggested that gadolinium contrast enhancement magnetic resonance imaging can improve mesothelioma staging (Fig. 114.6). Detection of diaphragm invasion and invasion of endothoracic fascia or a single chest wall focus may be better with magnetic resonance imaging compared with CT.¹¹¹

Positron Emission Tomography Imaging

There are a number of studies of positron emission tomography (PET) and the radionuclide imaging agent [¹⁸F]fluorodeoxyglucose (FDG) in mesothelioma (Fig. 114.7). Early studies reported that FDG-PET was accurate in the diagnosis of pleural malignancies, specifically mesothelioma.¹¹²⁻¹¹⁶ Recent studies have concentrated on the accuracy of PET in defining nodal and extrathoracic metastases prior to surgical therapy.^{93,112} Because of false-positive results in patients with FDG-avid pleural inflammatory/infectious etiologies, all FDG-avid extrathoracic sites should be histologically confirmed in patients with MPM being considered for extrapleural pneumonectomy (EPP).

DIAGNOSTIC APPROACH FOR PRESUMED MESOTHELIOMA

Thoracentesis and Closed Pleural Biopsy

Patients who present with a large, unexplained pleural effusion and minimal or moderate evidence of pleural thickening should have initial thoracentesis and pleural biopsy, especially if a history of asbestos exposure or mesothelioma in a family member is elicited. By preserving a cell block from the pleural fluid and using both histochemical

Figure 114.4 Chest radiography of malignant pleural mesothelioma. **(A)** Anteroposterior view reveals a contracted right hemithorax with nodular scalloping of the pleura at the right base. There is fluid or tumor in the fissure, and the diaphragm and right heart border are obscured. **(B)** Lateral view demonstrates fluid or tumor at the right base with thickened pleura and disease in the fissure.

Figure 114.5 Computed tomography of a patient with a right-sided pleural mesothelioma. As one progresses from the apex **(A)** to the diaphragm **(D)**, loculated fluid (**bold black arrow**), thickened pleura (**thin black arrows**) **(B)**, and thickened pericardium (**white arrows**) can be appreciated in panel **C**.

and immunohistochemical staining techniques along with electron microscopic analysis, the diagnosis of mesothelioma can be obtained from the pleural effusion in as high as 84% of suspected cases.

Thoracoscopy

A video-assisted thoracoscopy is indicated for patients at risk for mesothelioma who (1) develop a large effusion and who have negative studies on thoracentesis and pleural biopsy, or (2) recur with

effusion after initial thoracentesis. Thoracoscopy can be invaluable for estimating extent of disease with regard to the lung, diaphragm, pericardium, chest wall, and nodes.^{117,118} Development of chest wall masses from seeding of the biopsy site or surgical scar is an uncommon complication (approximately 10%) of any diagnostic procedure, and the efficacy of radiotherapy to the scar to prevent recurrence is controversial.¹¹⁹⁻¹²¹

If there is no free pleural space because of previous treatment of pleural effusion and the bulk of the disease in the hemithorax is

Figure 114.7 Positron emission tomography with [¹⁸F] fluorodeoxyglucose in a patient with an unresectable stage IV mesothelioma. **(A)** *White arrows* outline the involved pleura, with an area of bulky disease superiorly. *Black arrow* points out an occult metastasis in the abdomen. **(B)** *Black arrow* depicts posterior infracural mediastinal lymph node disease. **(C)** *Bold black arrow* points out diaphragmatic involvement. *Thin black arrows* depict mesothelioma medially.

solid, open biopsy should be performed such that the scar can be incorporated into the incision at the time of cytoreduction surgery.

NATURAL HISTORY

The majority of patients with treated or untreated pleural mesothelioma die of complications of local disease because of (1) increasing tumor bulk that eventually replaces the pleural effusion and causes progressive respiratory compromise, pneumonia, or myocardial dysfunction with arrhythmias; (2) unrelenting chest wall pain requiring narcotics, which leads to cachexia; and/or (3) dysphagia from tumor compression of the esophagus. Patients generally die of respiratory failure or pneumonia. Small bowel obstruction from direct extension through the diaphragm develops in approximately one-third of patients, and 10% die of pericardial or myocardial involvement.¹²² One of the most important clinical predictor of survival in noncytoreduced patients is performance status.⁹⁵

Extrathoracic metastases occur late in the course of disease and are not usually the direct cause of the patient's death. In the largest series of patients with MPM who had autopsy, 54% to 82% had distant metastases, with the most frequently involved organs being the liver, adrenal gland, kidney, and contralateral lung.^{123,124} Intracranial metastases are seen in approximately 3% of patients and are predominantly of the sarcomatous type.^{124,125}

Prognostic Indicators

The best-known clinical prognostic scoring systems for MPM have originated from European Organisation for Research and Treatment of Cancer (EORTC) and Cancer and Leukemia Group B (CALGB), and use a combination of biologic and clinical factors. Poor performance status, nonepithelioid histology, male gender, low hemoglobin, high platelet count, high white blood cell count, and high lactate dehydrogenase were found to be poor prognostic indicators in mesothelioma.^{95,126} The EORTC model was validated at St. Bartholomew's Hospital in sequential chemotherapy trials,¹²⁷ and both models were validated by Edwards.¹²⁸ Many other studies have explored clinical and pathologic features of MPM as seen in Table 114.1. Most recently, the ratio of absolute neutrophil to lymphocyte ratio was promising in segregation of risk for death¹²⁹⁻¹³¹; however, a recent study found that the aforementioned EORTC and CALGB indices were superior.¹³²

The molecular prognostication of mesothelioma has also been explored using gene expression array technology.^{133,134} There has, however, been variability in the gene sets and results of these prognostic tests when used in other MPM cohorts.¹³⁵

The presence of a single microRNA, mir-29c*, has been associated with improved time to progression and overall survival but needs further validation.¹³⁶ A variety of other tissue-based prognostic markers, including thymidylate synthase,¹³⁷ OPN,^{138,139} and HAPLN1,¹⁴⁰ have been reported but require validation.

^aTable modified from Pass.²⁷⁵

Quantification of the standardized uptake value (SUV) for PET scanning has also been investigated in mesothelioma as a prognostic marker (Table 114.2). Low SUV and epithelial histology predict the best survival, whereas high SUV and nonepithelial histology indicate the worst survival.^{112,141-144}

Staging

The original MPM staging system proposed by Butchart et al.¹⁴⁵ relied on pathologic generalizations instead of specific quantitative aspects of the disease and was designed at a time that was well before recognition of different prognostic implications of N1 and N2 nodes. The American Joint Committee on Cancer staging system for mesothelioma (Table 114.3) was adopted from that proposed by the International Mesothelioma Interest Group (IMIG) in 1995¹⁴⁶ and has been validated in a number of surgically based trials. In collaboration with IMIG, the International Staging and Prognostic Factors Committee of the International Association for the Study of Lung Cancer recently formed a Mesothelioma Domain in order to improve the current staging system resulting in the first large, international MPM database, which included over 2,000 staged patients with MPM diagnosed from 1995 to 2008 who had a surgical procedure. As described by Rusch et al.,¹⁴⁷ a set of covariates were identified as predictive of survival in a “core” model for this analysis which included best staging information, age, sex, histology (epithelioid or not), and type of surgical procedure (palliative versus extrapleural pneumonectomy or pleurectomy decortication).¹⁴⁷

Regrouping of the T and N combinations based on relative hazard and Kaplan-Meier survival analysis of 368 patients having EPP resulted in improved stage distribution (stage I-IV: 8%, 43%, 33%, 16%, respectively) and survival stratification (51 months, 26 months, 15 months, 8 months, respectively).^{148,149} A stage-independent model of risk for death in patients having surgical cytoreduction has expanded on the data from Pass et al.,¹⁵⁰ which described the influence of tumor volume and survival in MPM. Gill et al.,¹⁵¹ in a study of 88 epithelial MPMs having EPP, reported that tumor volume, hemoglobin concentration, platelet count, pathologic TNM (tumor, node, metastasis) category, and administration of adjuvant chemotherapy or RT were associated with survival. In the final multivariate model, tumor volume, hemoglobin concentration, and administration of adjuvant chemotherapy or RT were identified as independently associated with overall survival.¹⁵¹ Richards et al.¹⁵² recently described a validated model for survival

and time to recurrence in cytoreduced MPM using hemoglobin, CT volume, thickness of the fissures, and histologic subtype.

TREATMENT

Overview

For unresectable patients who are candidates for chemotherapy, the well-powered phase 3 trial that showed a 3- to 4-month survival advantage for the two-drug regimen of pemetrexed and cisplatin compared with the one-drug regimen of cisplatin has defined the standard of care⁹⁴ (Fig. 114.8). Recommendations for the management of pleural mesothelioma have been made by the European Society for Medical Oncology¹⁵³ and the National Comprehensive Cancer Center Network.

Supportive Care

The median survival of patients with MPM who select supportive care ranges only from 4 months¹²⁸ to 13 months.¹²² This variation is likely due to variations in tumor biology, host response to tumor, detection bias, lead-time bias, and the use of ad hoc or unreported treatments by some patients and physicians.

There are a number of options for the control of pleural effusion, including repeated thoracenteses, talc pleurodesis, or placement of a PleurX (Denver Biomedical, Denver, CO) catheter.¹⁵⁴ Talc pleurodesis is performed by instilling 2 to 5 g of asbestos-free, sterile talc over the lung and the parietal surfaces. Success rates in effusion control with talc, used either via thoracoscopy or via slurry, approach 90%.

The MesoVats trial was a randomization between 2003 and 2012 of 87 video-assisted thoracoscopic pleurectomy or 88 talc pleurodesis. A total of 84% had epithelioid disease, 78% were IMIG stage 3/4, and 49% were high risk as per EORTC criteria. Although there was no difference in survival between the two groups, pleural effusion was better controlled with patients who underwent pleurectomy at 1 month and 6 months. Moreover, there was a significant benefit in quality of life at 6 months and 12 months in favor of the pleurectomy group.¹⁵⁵ Failure of these techniques is usually associated with lung trapped by the tumor, a large solid tumor mass, a long history of effusion with multiple thoracenteses leading to loculations, age older than 70 years, or

TABLE 114.3

International Staging System for Diffuse Malignant Pleural Mesothelioma

T: Tumor

T1a

Tumor limited to the ipsilateral parietal ± mediastinal ± diaphragmatic pleura
No involvement of the visceral pleura

T1b

Tumor involving the ipsilateral parietal ± mediastinal ± diaphragmatic pleura
Tumor also involving the visceral pleura

T2

Tumor involving each of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features:
Involvement of diaphragmatic muscle
Extension of tumor from visceral pleura into the underlying pulmonary parenchyma

T3

Describes locally advanced but potentially resectable tumor
Tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features:
Involvement of the endothoracic fascia
Extension into the mediastinal fat
Solitary, completely resectable focus of tumor extending into the soft tissues of the chest wall
Nontransmural involvement of the pericardium

T4

Describes locally advanced technically unresectable tumor
Tumor involving all the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features:
Diffuse extension or multifocal masses of tumor in the chest wall, with or without associated rib destruction
Direct transdiaphragmatic extension of tumor to the peritoneum
Direct extension of tumor to the contralateral pleura
Direct extension of tumor to mediastinal organs
Direct extension of tumor into the spine
Tumor extending through to the internal surface of the pericardium with or without a pericardial effusion; or tumor involving the myocardium

N: Lymph Nodes

NX: Regional lymph nodes cannot be assessed
N0: No regional lymph node metastases
N1: Metastases in the ipsilateral bronchopulmonary or hilar lymph nodes
N2: Metastases in the subcarinal or the ipsilateral mediastinal lymph nodes, including the ipsilateral internal mammary nodes
N3: Metastases in the contralateral mediastinal, contralateral internal mammary, ipsilateral, or contralateral supraclavicular lymph nodes

M: Metastases

MX: Presence of distant metastases cannot be assessed
M0: No distant metastasis
M1: Distant metastasis present

Based on Edge SB, Byrd DR, Compton CC, et al. *AJCC Cancer Staging Manual*. 7th ed. New York: Springer, 2010; and Rusch VW. A proposed new international TNM staging system for malignant pleural mesothelioma: from the International Mesothelioma Interest Group. *Chest* 1995;108:1122.

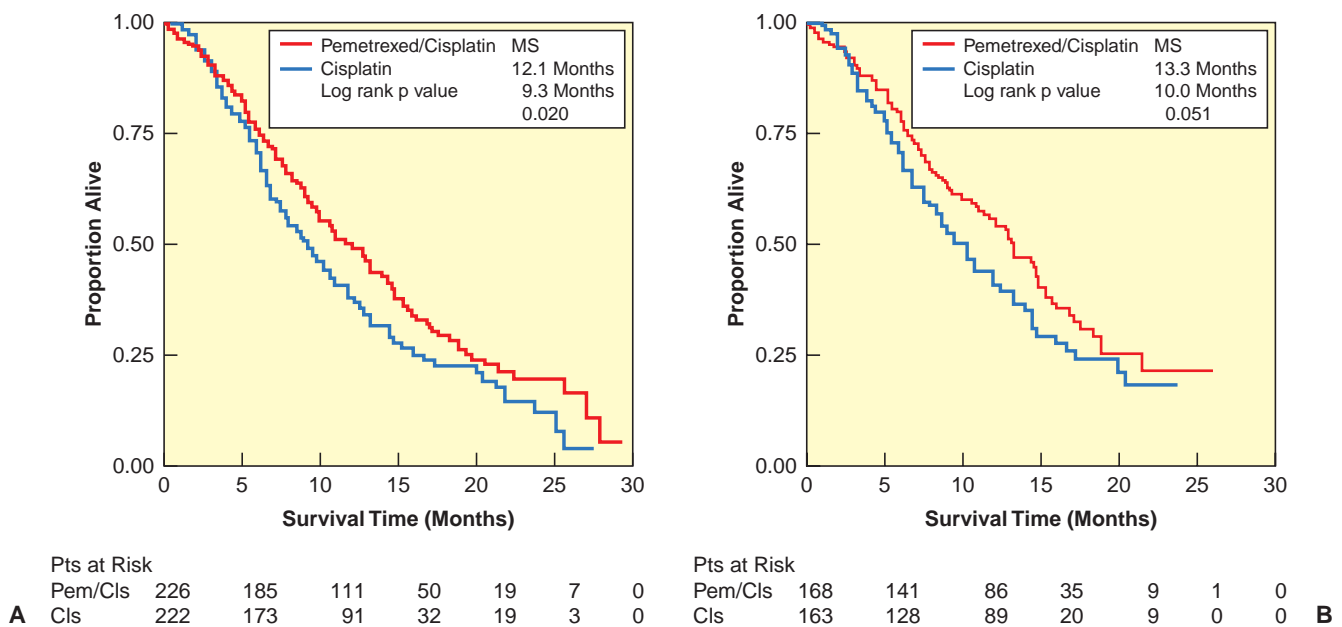

Figure 114.8 Results of the phase 3 trial of pemetrexed (Pem) and cisplatin (Cis) versus cisplatin alone. See text for details. MS, median survival; Pts, patients.

poor performance status. In such cases, the PleurX catheter with its one-way valve can be implanted under local anesthesia into pleural effusion, and patients can drain themselves at home using the available disposable drainage kits.¹⁵⁶

The chest pain of malignant mesothelioma requires narcotics, and these patients should be seen in consultation by a dedicated pain management team to assist in the optimization of the patient's quality of life. Subcutaneous tunneling of epidural catheters for long-term out-of-hospital use has also been used in selective cases. When only local RT has been delivered solely for chest wall pain or chest wall nodules, the median survival has been reported to be 4 to 5 months.^{157,158}

SURGERY FOR PLEURAL MESOTHELIOMA

The Controversy

Surgery for pleural mesothelioma remains a controversial subject not only among medical oncologists, but with thoracic surgeons. Much of the controversy remains as the result of the early trials of EPP with reported mortality rates of 31%,¹⁵⁹ as well as the lack of systemic therapies besides pemetrexed and cisplatin with response rates >30%, which can complement present surgical therapy with mortality rates of 4%. Despite strict functional criteria for the selection of patients to undergo mesothelioma surgery, there are no reliable prognostic predictors to stratify patients by the biology of the disease in order to determine which patients will recur rapidly after cytoreductive surgery. As discussed in the following, the type of operation to be performed (EPP or some sort of lung sparing pleurectomy with decortication (P/D) is one of the more debatable subjects for the management of the disease, and at present, suffers from the lack of randomized data that defines the present cadre of surgical interventions in a uniform manner. These issues, as well as the interpretation of high profile recently completed trials, have led to geographical variation in physicians' use of surgery as part of the management plan.¹⁶⁰ In a questionnaire answered by 802 thoracic surgeons belonging to The European Association for Cardio-Thoracic Surgery, The European Society of Thoracic Surgeons, or the Society of Thoracic Surgeons, EPP was believed to be more effective than P/D and the addition of

adjuvant chemotherapy and multimodality therapy were believed to increase the chance of cure (see the following). American surgeons, however, were twice as likely to believe that EPP alone can cure mesothelioma as those in Europe (45% versus 23%).

The Purpose of Surgery

Operation for malignant pleural mesothelioma can be done simply for *diagnostic* or *palliative purposes*, but in selected patients, it is performed as a maximal cytoreductive procedure in which the persistent disease at the end of the operation is microscopic.

Diagnostic Procedures

In patients with localized or free flowing pleural effusion suspected of having mesothelioma, video thoracoscopy allows for definitive diagnosis. For subtype classification of mesothelioma histology, biopsy by open pleural biopsy or thoracotomy was found to be the most accurate in subtype classification (83%) compared with thoracoscopy (74%) and imaging-guided core or needle biopsy (44%) in a study comparing histologic subtype recorded by pre-EPP diagnostic method to the EPP surgical specimen.^{161,162}

Maximal Cytoreductive Procedures

The goal of cytoreductive surgery in MPM should be the removal of all visible or palpable tumor (R0 or R1) or a "macroscopic complete resection" (MCR). MCR should be the goal of cytoreductive surgery, regardless of whether that involves EPP or a lung-preserving operation. The Mesothelioma Domain of the International Association for the Study of Lung Cancer has recommended the following as uniform nomenclature for pleural mesothelioma resections.¹⁶³

EPP: en bloc resection of the parietal and visceral pleura with the ipsilateral lung, pericardium, and diaphragm. In cases where the pericardium and/or diaphragm are not involved by tumor, these structures may be left intact (Fig. 114.9).

Extended P/D: parietal and visceral pleurectomy to remove all gross tumor with resection of the diaphragm and/or pericardium.

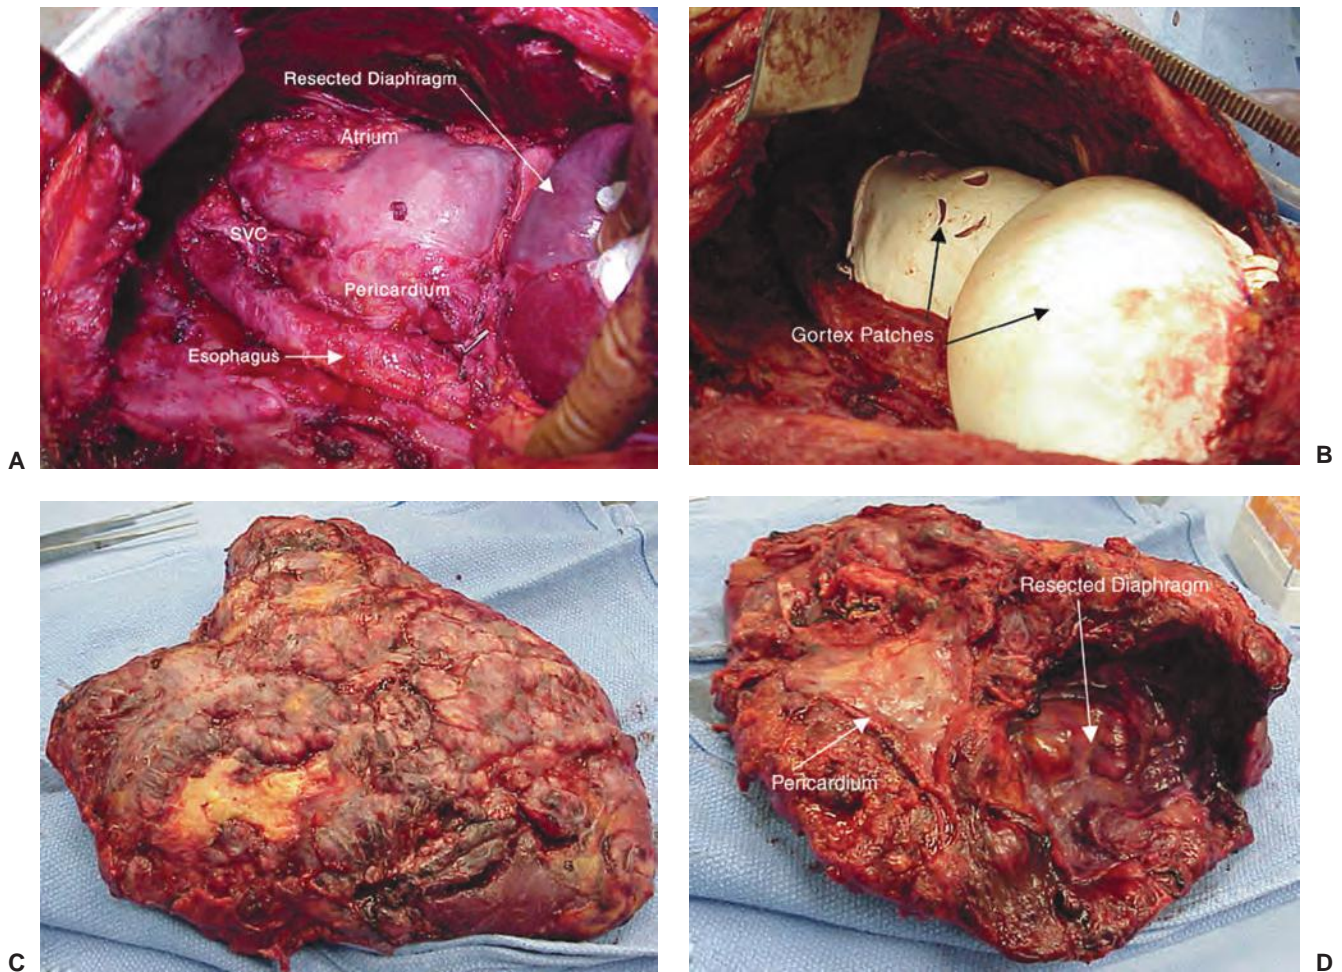

Figure 114.9 Intraoperative and specimen photography. **(A)** Right hemithorax after resection of lung, pleura, diaphragm, pericardium, and lymph nodes. **(B)** Replacement of the diaphragm and pericardium with Gore-Tex material (W.L. Gore & Associates, Inc., Reisterstown, MD). **(C)** View of lateral aspect of specimen, which reveals the entire lung coated with thickened, mesothelioma-involved pleura. **(D)** Medial view of specimen revealing the resected pericardium and diaphragm, hilar structures, and lung. SVC, superior vena cava.

P/D: parietal and visceral pleurectomy to remove all gross tumor without diaphragm or pericardial resection.

Partial pleurectomy: partial removal of parietal and/or visceral pleura for diagnostic or palliative purposes but leaving gross tumor behind.

Palliation or MCR?: Only approximately 20% of patients presenting with pleural MPM will be candidates for an MCR. The decision to actually palliate a patient with mesothelioma begins with palliation of fluid in order to improve dyspnea or cough, as described previously. Patients who have an excellent result from drainage, with partial or full lung expansion, may then be considered candidates for MCR depending on other factors including (1) the experience of the thoracic surgeon, (2) the cardiopulmonary/functional status of the patient, and (3) patient/tumor demographics at presentation. Any preoperative staging radiologic examination that points to disease outside the involved hemithorax eliminates the use of an MCR. Thoracic surgeons at major centers with mesothelioma programs decide not only whether the patient is a candidate for cytoreduction or palliation but also the appropriate cytoreductive procedure. Patients who present with Eastern Cooperative Oncology Group performance status ≥ 2 , or who have limiting cardiac reserve either with nonreversible myocardial ischemia or compromised ventricular function (ejection fraction $< 50\%$) are usually not candidates for cytoreductive procedures. Moreover, patients with compromised pulmonary function testing

who are not felt to be candidates for pneumonectomy must be carefully evaluated for either extended P/D in that the cytoreduction should not compromise existing lung function but may recruit trapped lung and possibly improve dyspnea.

CONTROVERSY REGARDING PERFORMANCE OF EXTRAPLEURAL PNEUMONECTOMY

Extrapleural Pneumonectomy Results

The use of EPP for MCR has evolved since the first description alluded to previously. As detailed in a systematic review of the use of EPP for MPM,¹⁶⁴ which included survival and perioperative outcomes, the median overall survival varied from 9.4 to 27.5 months, and 1-, 2-, and 5-year survival rates ranged from 36% to 83%, 5% to 59%, and 0% to 24%, respectively. Overall perioperative mortality rates ranged from 0% to 11.8%, and the perioperative morbidity rates ranged from 22% to 82%. In Sugarbaker and Wolf's¹⁶⁵ series, the mortality of EPP is reported at 3.4%, which has been achieved by improving preoperative staging, anesthesia, resection, reconstruction, and perioperative management of procedure-related complications. The chief complication is reversible atrial fibrillation, which occurs

in 44.2% of patients and other major causes of morbidity are myocardial infarction (1.5%), epicarditis (2.7%), pulmonary complications (7.9%), thrombosis (6.4%), empyema (2.4%), technical complications (6.1%), and gastrointestinal complications (0.9%).¹⁶⁶ Some of the technical issues include herniation of the heart due to failure of the pericardial patch or herniation of abdominal contents into the pleural space secondary to dehiscence of the diaphragmatic repair, vocal cord dysfunction secondary to recurrent laryngeal nerve injury, bronchopleural fistula, empyema, and prolonged respiratory failure. EPP alone does not appear to prolong survival. In most EPP series, median survival is <2 years, but 10% to 20% of patients are 5-year survivors. Patients with sarcomatoid histology and/or lymph node involvement have an even poorer prognosis and should not be considered as candidates for EPP.¹⁶⁷

Trimodality Therapy in the Context of an Extrapleural Pneumonectomy

Trimodality therapy (TMT) for MPM began with evidence of a decreasing mortality and standardization of techniques for EPP, as well as the demonstration of increased tumor responses and survival with cisplatin doublets using either gemcitabine¹⁶⁸ or pemetrexed.¹⁶⁹ TMT consists of induction chemotherapy, followed by EPP, and RT either as hemithorax radiation to the pneumonectomy cavity or as intensity modulated RT.¹⁷⁰ Because of the morbidity and mortality with EPP, patient selection is a critical factor. The ideal patient is younger than 65 years old, has pure epithelial histology, an absence of lymph node involvement, and is physiologically able to tolerate pneumonectomy. Although EPP has been reported thus far as the primary surgical MCR technique in this selected group of patients, it should not be considered the only option, as detailed later. Table 114.4 describes the major TMT trials to date using EPP for MCR, and overall demonstrates a 3.1% mortality for EPP, along with a 27.7-month median survival in the 60% of presenting patients who completed the full package.

Randomized Trials of Surgery for Malignant Pleural Mesothelioma Involving Extrapleural Pneumonectomy

As of 2002, only one randomized trial involving surgery for MPM had been performed,¹⁷¹ and that trial did not address the issue of the utility of surgery, specifically EPP in MPM. In an attempt to define the efficacy of EPP, Mesothelioma and Radical Surgery (MARS) was originally designed as a randomized trial with 670 patients needed comparing induction chemotherapy, EPP, and postoperative RT to induction therapy but no EPP.¹⁷² When difficulty arose in recruiting patients, an initial feasibility study was performed randomizing 50 patients to EPP or no EPP. The final results of the trial demonstrated that it may be feasible to randomize MPM patients to a surgical or nonsurgical arm; however, the conclusions of the study's authors have caused considerable controversy among surgeons and medical oncologists dealing with MPM. The study as published revealed nonsignificant differences in the 6, 12, 18 months and median survivals comparing the surgery arm to the nonsurgical arm, with a median survival of 14.4 months versus 19.5 months, respectively. Amongst many practitioners, the study has been interpreted not only as a condemnation of EPP in the management of MPM but also as an indictment of surgery as nonefficacious in the disease. One of the main criticisms of the study includes an 18% operative mortality from EPP, which is to be contrasted to the data noted previously for other phase 2 TMT trials (3.1%). Moreover, other flaws included (1) the lack of power of the study, which demanded a sample size of 670 randomized individuals; (2) the fact that the preoperative chemotherapy was not standardized; (3) the crossover of individuals from one arm to the other in six instances; (4) the lack of data on the interval from the end of chemotherapy to surgery; and (5) only one-third of the individuals received the full TMT while, as demonstrated previously, 60% of the individuals in the phase 2 setting completed the TMT and recorded a median overall survival of 27.7 months.¹⁷³

EVOLUTION OF LUNG SPARING APPROACHES FOR MACROSCOPIC COMPLETE RESECTION

Questions regarding the ability to perform the same degree of MCR and also spare lung parenchyma arose while studies investigating TMT with EPP as well the MARS trial were accruing patients. A retrospective review of 663 consecutive patients (538 men and 125 women with MPM who underwent EPP or P/D at three US mesothelioma centers) reported an operative mortality of 7% for EPP ($n = 27/385$) and 4% for P/D ($n = 13/278$).¹⁷⁴ The cytoreduction for these patients was described as a macroscopic tumor clearance, both pleurae, and as needed resection of the diaphragm and/or pericardium. Besides significant survival advantages seen for earlier stage ($p < 0.001$), epithelioid versus nonepithelioid histology ($p < 0.001$), multimodality therapy versus surgery alone ($p < 0.001$), and female versus male gender ($p < 0.001$), the type of operation, EPP versus P/D ($p < 0.001$), also influenced survival. Multivariate

analysis demonstrated a 1.4-fold greater chance for death with EPP ($p < 0.001$) controlling for stage, histology, gender, and multimodality therapy. This study was the first to postulate that patients who underwent P/D could have comparable survival to those who underwent EPP; however, the reasons for such a conclusion were multifactorial and subject to selection bias. Other studies followed as seen in Table 114.5. The studies by Nakas et al.¹⁷⁵ and Shahin et al.¹⁷⁶ highlight the difference in results for P/D performed either for palliation or for MCR, and both revealed a doubling of overall survival if the P/D is performed to remove all macroscopic disease in a compulsive fashion. All of the subsequent studies, most of which involved a postoperative multimodality adjuvant approach with or without intraoperative therapies, demonstrate superior overall survival of P/D to historical studies of palliative P/D, and exceptional survivals especially in pure epithelial MPM.

Nevertheless, short of a randomized trial, the direct comparison of EPP and P/D performed by the same surgeon. The data for four such centers is seen in Table 114.6. Essentially in all studies,

OS, overall survival; P/D, pleurectomy decortication; V/P, visceral/parietal; dgm, diaphragm; peri, pericardium; EPP, extrapleural pneumonectomy; NR, not reported.

P/D seems to have less mortality, less morbidity, and a comparable overall survival to EPP. The similarity of the data is quite striking and attests to experienced mesothelioma programs with surgical techniques that are comparable. For early stage mesothelioma, the results also seem to be similar if one compares P/D to EPP.

As extended P/D is a less extensive operation with lower morbidity and mortality than EPP, a newly designed MARS-2 trial will attempt to demonstrate whether this type of operation can offer survival and/or quality-of-life benefits to patients with MPM.¹⁷⁷ Recruitment will most likely be improved compared to MARS-1. Patients with MPM registered on MARS-2 will receive two cycles of pemetrexed-platinum chemotherapy. Patients who do not progress on CT scan will then be randomized to up to four further cycles of pemetrexed-platinum chemotherapy or extended P/D followed by up to four further cycles of postoperative pemetrexed-platinum chemotherapy. An EORTC trial will investigate the timing of the chemotherapy in combination with extended P/D.¹⁷⁸ Patients with MPM will be randomly allocated to extended P/D preceded or followed by four cycles of cisplatin/pemetrexed at standard doses. It is hoped that this randomized trial will address the feasibility of the operation in combination with standard (neo) adjuvant chemotherapy and set the experimental arm of an ensuing phase 3 trial exploring the role of surgery in MPM or could be a standard arm for future trials of surgery in MPM.

CHEMOTHERAPY

First-Line Therapy

Over the past three decades, nearly all chemotherapeutic agents have been tested for malignant mesothelioma as single agents or in combination regimens primarily in single-arm uncontrolled trials.¹⁷⁹ Most single-agent studies exhibited poor response rates and short median survival times (with the exception of cisplatin and the antifolates), while combination therapy generally demonstrated greater efficacy. A meta-analysis of 59 trials confirmed greater response rates for platinum-containing versus non-platinum-containing regimens (23.2% versus 11.6%, respectively; $p < 0.001$).¹⁸⁰

The report that first garnered enthusiasm regarding the possible chemosensitivity of MPM was the phase 2 trial of gemcitabine plus cisplatin from Byrne et al.¹⁸¹ Forty-seven percent of treated patients (10 of 21) had a $\geq 30\%$ reduction in the thickness of the pleural rind and improvement in symptoms. A follow-up multicenter trial from Australia using the same regimen in 53 patients reported a lower response rate at 33% and a median survival of 11.2 months.¹⁸² These studies, and other multicenter phase 2 studies using gemcitabine/cisplatin¹⁸³ or gemcitabine/carboplatin,¹⁸⁴ ultimately led to its widespread use for a period of time.

A 1998 report from the United Kingdom also encouraged the use of chemotherapy for MPM by showing that an overall improvement in symptoms occurred in 62% of patients treated with a regimen of three agents: mitomycin C, vinblastine, and cisplatin (MVP).¹⁸⁵ Steele et al.¹⁸⁶ reported a similar rate of clinical benefit with the single agent vinorelbine. Based on these data, the Medical Research Council and British Thoracic Society conducted the first, and only, trial to evaluate whether chemotherapy improved survival over supportive care.¹⁸⁷ Patients with MPM were randomized to either (1) active supportive care (ASC) alone, (2) ASC + MVP, or (3) ASC + vinorelbine. ASC was defined as regular follow-up in a specialist clinic, and treatment could include steroids, analgesics, bronchodilators, and palliative radiation. The trial was originally intended to enroll 840 patients, but due to slow accrual, the statistical design was modified such that only 409 patients were enrolled and the results of the two chemotherapy arms were combined. A small, nonsignificant survival benefit was seen for ASC + CT (hazard ratio [HR] = 0.89; 95% confidence interval [CI] = 0.72 to 1.1; $p = .029$). The median survival for the ASC arm was 7.6 months, and it was 8.5 months for the ASC + CT arm.

In an exploratory analysis, treatment with vinorelbine trended toward providing a survival advantage over ASC (HR = 0.80 [0.63 to 1.02]; $p = 0.08$), but this was not observed for MVP. No difference in four predefined quality-of-life measures (physical functioning, pain, dyspnea, and global health status) was observed between the groups in the first 6 months.

The development of antifolates ultimately had the greatest impact on establishing the standard of care chemotherapy regimen for MPM. Pemetrexed inhibits dihydrofolate reductase, thymidylate synthase, and glycinamide ribonucleotide formyltransferase, enzymes involved in purine and pyrimidine synthesis.¹⁸⁸ Pemetrexed enters the cell primarily through the reduced folate carrier and undergoes extensive intracellular polyglutamation by folypoly-gamma-glutammate synthetase. The polyglutamated forms, retained for long periods within the cell, have >100 -fold greater affinity for thymidylate synthase and glycinamide ribonucleotide formyltransferase than the parent drug, pemetrexed monoglutamate. Moreover, malignant mesothelioma cells overexpress the α -folate receptor, and high levels of expression of this receptor may make malignant mesothelioma more susceptible to antifolate drugs.¹⁸⁹

The potential activity of pemetrexed and cisplatin in MPM was first noted serendipitously in a phase 1 trial of the combination,¹⁹⁰ and it was this observation that led to the randomized phase 3 trial comparing that combination to treatment with cisplatin alone in patients with advanced MPM. Vogelzang et al.⁹⁴ randomized a total of 456 patients with malignant mesothelioma; 226 received a combination of pemetrexed with cisplatin and 222 received cisplatin alone. They were treated with pemetrexed 500 mg/m² intravenously followed by cisplatin 75 mg/m² on day 1 of a 21-day cycle, or with a normal saline infusion (to maintain single blinding) followed by the same dose of cisplatin alone. Median survival time in the pemetrexed/cisplatin arm was 12.1 months versus 9.3 months in the control arm ($p = 0.020$). The HR for death of patients in the pemetrexed/cisplatin arm versus those in the control arm was 0.77. Median time to progression was significantly longer in the pemetrexed/cisplatin arm: 5.7 months versus 3.9 months ($p = 0.001$), and response rates were 41.3% in the pemetrexed/cisplatin arm versus 16.7% in the control arm ($p < 0.0001$). Analysis of various pemetrexed trials conducted up to that time suggested that supplementation with folic acid and vitamin B₁₂ could lessen toxicity from pemetrexed, and this, in fact, was noted in the subset of patients who received supplementation once that was implemented midway through the trial. Interestingly, the cisplatin-alone arm also derived some benefit, possibly enabling patients to receive more cycles of chemotherapy. This pivotal trial led to the establishment of pemetrexed and cisplatin as the standard first-line chemotherapy regimen for MPM, and its regulatory approval for that indication.

Another trial with an identical design confirmed the benefits of adding an antifolate to platinum for the treatment of MPM. That study, run by EORTC, utilized raltitrexed, a more specific thymidylate synthase inhibitor.¹⁹¹ A total of 250 patients with MPM were randomized to raltitrexed in the presence or absence of cisplatin. The combination of raltitrexed with cisplatin improved response rate (23.6% versus 13.6%; $p = 0.056$), median survival (11.4 months versus 8.8 months; 95% CI = 7.8 to 10.8), and 1-year survival (46% versus 40%; $p = 0.048$).

For patients who are unable to tolerate cisplatin due to gastrointestinal, renal, neurologic, or ototoxicities, substitution with carboplatin is a reasonable alternative. In large, single-arm phase 2 trials,^{192,193} and also in the Expanded Access Program that provided patients with access to pemetrexed before its commercial availability,¹⁹⁴ pemetrexed and carboplatin was shown to have comparable response and survival rates. For patients who cannot tolerate any platinum or who have a poor performance status, pemetrexed alone can be considered, though the single-agent response rates are clearly lower.^{195,196} If pemetrexed is not available, or results in toxicity, the use of cisplatin or carboplatin together with gemcitabine can be considered as another option.

Second-Line Therapy

No standard of care regimen for patients with previously treated malignant mesothelioma exists, and there are no clear data confirming that second-line therapy increases overall survival. Best supportive care, local RT, and pain medications should be given to patients when required, and chemotherapy may also be considered. Only one phase 3 trial has been conducted in this setting, but it included patients who did not receive a pemetrexed-based regimen as first-line therapy.^{195,197} In this study, 243 patients were treated with single-agent pemetrexed and supportive care, or supportive care alone. Treatment with pemetrexed increased the response rate (18.7% versus 1.7%; $p < .0001$) and disease control rate (59.3% versus 19.2%; $p < 0.0001$), though overall survival was not improved because a significant number of patients in the supportive care arm ended up receiving chemotherapy. Treatment with pemetrexed or pemetrexed plus cisplatin also yielded high disease control rates in previously treated patients in the Expanded Access Trial.^{195,198} However, the current widespread use of pemetrexed/cisplatin as first-line therapy makes these findings mostly irrelevant.

Patients who receive pemetrexed combinations as first-line therapy may derive further benefit from being retreated with pemetrexed, particularly if there is a long interval before progression. In a retrospective analysis of second-line therapy, 42 patients who had been pretreated with pemetrexed were rechallenged, and this resulted in a higher disease control rate, longer progression-free survival, and longer overall survival as compared to treatment with a different agent.¹⁹⁹

The data supporting the use of other second-line therapies is similarly lacking. A multiple regression analysis that adjusted for baseline prognostic factors found that patients enrolled in the phase 3 trial comparing pemetrexed/cisplatin to cisplatin alone had a longer survival if they received poststudy chemotherapy which primarily consisted of either gemcitabine or vinorelbine.²⁰⁰ As treatment with single-agent vinorelbine trended toward improving survival in the Medical Research Council phase 3 three-arm trial, it seems a reasonable option for second-line therapy. Stebbing et al.²⁰¹ conducted a phase 2 trial with vinorelbine given at a dose of 30mg/m² weekly and found a 16% response rate and overall survival of 9.6 months. Only a fraction of the patients in that trial were previously treated with pemetrexed and cisplatin, however. In a retrospective analysis including 56 evaluable patients who had mostly received pemetrexed-based first-line therapy and were treated with vinorelbine or gemcitabine as second- or third-line therapy, there was 1 partial response (with gemcitabine) giving a response rate of 2% (95% CI = 0% to 5%). Forty-six percent of patients had stable disease. Median progression free survival was 1.4 months for both vinorelbine and gemcitabine, while overall median survival was 5.4 months and 4.7 months, respectively. Given the unclear benefit of further chemotherapy, these patients should ideally be enrolled in a clinical trial if available.

NOVEL THERAPEUTIC APPROACHES

Angiogenesis Inhibition

Several lines of evidence support angiogenesis inhibition as a potential therapeutic strategy in mesothelioma. VEGF induces proliferation of mesothelial cells in culture, and the addition of VEGF-neutralizing antibodies inhibits this effect.^{52,202} Mesothelioma tumor specimens express VEGF and its receptors.^{203,204} High levels of VEGF have also been detected in the serum and pleural effusions of patients with mesothelioma and correlate with poorer survival.^{203,205}

The VEGF monoclonal antibody bevacizumab has been extensively studied in mesothelioma. In a randomized phase 2 trial, 106 patients received six cycles of gemcitabine and cisplatin

combined with bevacizumab or placebo followed by maintenance therapy with bevacizumab or placebo.²⁰⁶ No improvement in response rate, progression-free survival, or overall survival was seen with the addition of bevacizumab. A subgroup analysis noted that higher baseline plasma VEGF levels were correlated with a shorter progression-free and overall survival, and that patients with VEGF levels less than the median had longer progression-free and overall survival when treated with bevacizumab. Other studies have explored bevacizumab in combination with pemetrexed and cisplatin. In a single-arm, phase 2 trial with this regimen, 53 patients enrolled at four US centers achieved a progression-free survival of 6.9 months, a disease control rate of 75%, and a median overall survival of 14.8 months; these results compare favorably with historical controls.²⁰⁷ A French Intergroup study is currently testing pemetrexed/cisplatin plus bevacizumab versus placebo in a definitive randomized phase 2/3 design.

Thalidomide, a drug with a checkered past due to its teratogenic effects, but effective and approved for use in multiple myeloma, has a putative mechanism of action of antiangiogenesis. A phase 1/2 study of thalidomide identified a suitable dose of 200 mg daily and demonstrated 28% disease stabilization for >6 months.²⁰⁸ However, a phase 3 trial conducted in the Netherlands that randomized 222 patients to maintenance thalidomide versus observation after completion of platinum-based chemotherapy did not demonstrate any benefit in progression-free survival (3.6 months versus 3.5 months; HR = 0.95).²⁰⁹

A number of VEGF receptor multikinase inhibitors have been tested in mesothelioma, and they demonstrate a consistent low level of activity (Table 114.7). Most of these drugs also inhibit other growth signaling pathways including PDGF receptors and c-KIT which are also relevant in MPM.^{210,211} The first agent in this class to be tested was SU5416, which yielded responses in 11% of patients, but clinical development for this drug was subsequently halted.²¹² A CALGB study with sorafenib highlights the issues of patient selection when studying novel agents in mesothelioma.²¹³ In this trial, patients could receive sorafenib as first- or second-line therapy. Patients who had received previous chemotherapy survived for a median of 13.2 months, compared with 5 months for chemo-naïve patients, though this large difference was not statistically significant ($p = 0.3$). One-year survival was also greater in the previously treated patients compared with those who were chemo-naïve (57% versus 30%). This suggests that the patients treated as first-line may have been poor candidates for standard chemotherapy, while the patients treated as second-line had maintained a good performance status after chemotherapy. Sunitinib malate was tested in two phase 2 trials. In the Australian study,²¹⁴ 53 patients received sunitinib as second-line therapy at a dose of 50 mg on an intermittent schedule of 28 out of every 42 days. The confirmed response rate was 12%, but 65% had stable disease including many patients with some degree of tumor shrinkage. That response rate could not be confirmed, however, in a Canadian trial,²¹⁵ which noted only one response in an untreated patient and none in the cohort of previously treated patients. Survival rates were generally poor in both studies. The sum of these trials suggests that these agents may have limited activity, but perhaps should optimally be combined with chemotherapy. This concept is being tested in a Southwest Oncology Group randomized phase 2 trial of pemetrexed/cisplatin with or without cedrerinib.

Histone Deacetylase Inhibitors

In addition to directly regulating transcription through changes in chromatin structure, histone deacetylase inhibitors modulate the acetylation of transcription factors and other nonhistone proteins. This leads to a range of biologic effects that have shown relevance to MPM in preclinical studies.²¹⁶ Vorinostat is an oral agent that binds to the catalytic site of histone deacetylase subtypes 1, 2, 3, and 6 thereby inhibiting their activity.²¹⁷ In a phase 1 trial of

TABLE 114.7

NR, not reported.

vorinostat, two unconfirmed partial responses were observed in the 13 patients with mesothelioma, and several others had prolonged disease stabilization.²¹⁸ These data led to the largest phase 3 trial in mesothelioma in which 661 patients previously treated with one or two prior chemotherapy regimens were randomized 1:1 to vorinostat or placebo. However, vorinostat did not impact overall survival; the median overall survival for vorinostat versus placebo was 30.7 weeks versus 27.1 weeks with a HR of 0.98.²¹⁹

Mammalian Target of Rapamycin Inhibitors

The neurofibromatosis-2 (NF2) gene is mutated in 50% to 60% of MM resulting in loss of the protein Merlin. Merlin mediates contact-dependent inhibition of cell proliferation in normal cells, primarily through inhibition of mammalian target of rapamycin (mTOR).²²⁰ In knockout models of Merlin, mTOR activity becomes unregulated, and this leads to increased cell proliferation that can be abrogated by mTOR inhibition. In mesothelioma cell lines, Merlin loss activates mTORC1 signaling, and cells with NF2 mutations are selectively sensitive to drugs targeting mTORC1.²²¹ These data provide the rationale for studying the mTOR inhibitors in patients with mesothelioma. However, a Southwest Oncology Group phase 2 study with everolimus in previously treated patients failed to reach its predefined 4-month progression-free survival end point.²²² Agents that also block phosphoinositide-3-kinase along with mTOR appear to have greater efficacy in early trials, though. In an expansion cohort of a phase 1 trial with GDC0980, four patients achieved a partial response, including one patient at 50 mg, one patient with the PIK3CA mutation R88Q at 8 mg, and two at the recommended phase 2 dose of 30 mg. Furthermore, 11 (41%) patients remained on study for >6 months, and 2 (7%) remained on study >12 months.²²³

Mesothelin-Directed Therapy

Mesothelin is an immunogenic cell surface antigen^{224,225} involved in cell proliferation, cell signaling, adhesion, and metastases.²²⁶⁻²²⁸ In normal tissues, it is expressed only in the pleura, pericardium, and peritoneum at low levels,^{225,229} and it is expressed in essentially all MPM tumors.^{98,224,230-232} Several therapeutic approaches targeting mesothelin have shown promise. Amatuximab (MORAb-009) is a chimeric IgG1 antibody tested in a single-arm phase 2 trial in combination with standard chemotherapy for patients with advanced MPM. Although progression-free survival did not differ from historical control and thus the trial did not meet its predefined primary end point, 90% of patients had a radiographic response or stable disease, and overall survival was significantly greater than

anticipated with a number of patients remaining on maintenance antibody treatment for an extended time. A follow-up randomized trial with that agent is planned. A mesothelin immunoconjugate, SS1P, consisting of antimethelin Fv fused to *Pseudomonas* exotoxin A, demonstrated minor activity in phase 1 trials; however, efficacy was hampered by the development of neutralizing antibodies.^{229,233} However, when SS1P was administered along with immunosuppressive agents pentostatin and cyclophosphamide, dramatic tumor regressions were observed in 3 out of 10 patients, and 2 other patients had major responses to chemotherapy following that therapy.²³⁴ The group at the University of Pennsylvania has begun treating patients with genetically engineered T cells targeting mesothelin and have reported on one patient having a minor response after recovery from a severe infusion reaction.

RADIOTHERAPY FOR MESOTHELIOMA

Curative Radiation Therapy as a Single Modality

The limitation of potentially “curative” RT for treatment of MPM is the inability to treat a large volume of disease in the chest with a curative radiation dose (>60 Gy) because of the risks of severe damage to normal tissue. Previous studies from the 1980s administered approximately 50 Gy to the pleural space with most studies demonstrating a median overall survival ranging from 3 to 10 months. Patients who received treatment had an improved outcome than those who did not receive treatment, although this is likely the result of a selection bias, with those fit enough to undergo a full course of radiation likely to have a greater survival regardless of treatment given.^{123,235-239} RT as a sole therapy should be used rarely and only in the setting of patients who are unable to tolerate any form of systemic chemotherapy.

Combined Chemotherapy and Definitive Radiotherapy

The poor results reported for definitive RT alone have led to studies evaluating the combination of chemotherapy and radiation. Both Ruffie et al.²³⁶ and Linden et al.²⁴⁰ have reported that the median survival is increased in patients treated with combined modality therapy compared with RT alone. Some investigators have evaluated the addition of radiation sensitizers to definitive RT. Herscher et al.²⁴¹ from the National Cancer Institute studied the use of a 5-day continuous infusion of paclitaxel with radical RT in

patients with mesothelioma and non-small-cell lung cancer. In patients with mesothelioma, the hemithoracic radiation was delivered before the chemotherapy. Chen et al.²⁴² reported a 12% complete response rate and an 88% partial response rate when pulsed paclitaxel was delivered during RT in a phase 1 trial. Although these combination approaches are interesting, it is not likely that the addition of radiation sensitizers to radical RT will be curative, and as such, definitive chemoradiotherapy should be considered experimental for patients with mesothelioma.

Combined Surgical Resection and Definitive Radiotherapy

RT can be used as an adjuvant treatment after EPP or P/D. After an EPP, radical RT can be administered without concern for damage to the underlying ipsilateral lung because it has been removed surgically. However, radical RT after a P/D continues to place the intact ipsilateral lung at risk for substantial loss of function and toxicity.

Rusch et al.^{140,243} at Memorial Sloan Kettering Cancer Center completed a phase 2 trial of EPP followed by postoperative radiation in patients with pleural mesothelioma. Eighty-eight patients with biopsy-confirmed mesothelioma were treated. Twenty-one patients were unresectable and taken off the study. The majority of patients ($n = 62$) underwent an EPP followed by 54 Gy delivered through anterior and posterior fields in 30 fractions of 1.8 Gy. Five patients were treated with a pleurectomy (PL), which was followed by intraoperative RT to a dose of 15 Gy using a high-dose iridium applicator. This was followed by 54 Gy to the hemithorax via anterior and posterior fields in the same fractionation schedule as those who underwent EPP. There were seven postoperative deaths, all primarily related to pulmonary complications in patients who had undergone an EPP. A total of 33 patients had some complications, with the most common being atrial arrhythmias (17 patients), respiratory failure (6 patients), pneumonia (5 patients), and empyema (5 patients). Only the patients who underwent EPP were considered for survival analysis. The median survival was 17 months, with an overall survival of 27% at 3 years. Only 13% had locoregional recurrence, with the majority of patients failing to respond and having distant metastases. The authors concluded that their approach of aggressive surgery with EPP followed by high-dose radiation to the entire hemithorax provided a favorable outcome for those patients who were able to complete the therapy when compared to historical data.

Intensity-modulated RT (IMRT) offers the potential for administering higher doses of RT with better target coverage to the hemithorax while minimizing normal tissue toxicities. IMRT is a highly conformal radiation technique that allows more effective sparing of normal tissues, providing an opportunity for safer, less toxic treatments and increased efficacy by enabling higher radiation doses to the tumor. It comes with a much higher level of dosimetric control and certainty leading to better target coverage than conventional techniques.²⁴⁴ Areas of dose inhomogeneity are readily recognizable and can be corrected. Rice et al.²⁴⁵ and Forster et al.²⁴⁶ at the MD Anderson Cancer Center treated patients with MPM with IMRT after EPP. Recent data in 100 patients who underwent EPP, 63 of whom were treated with IMRT, reveal a median survival of 14.2 months and 3-year survival of 20% for patients with IMRT. Recurrences in the irradiated field occurred in only three patients, and distant disease observed in 54% of patients was the major pattern of failure. Liver injury has been documented after hemithoracic IMRT.²⁴⁷ However, pulmonary toxicity appears to be the most significant late toxicity observed in patients with MPM after IMRT.^{248–250} Allen et al.²⁴⁸ reported fatal pulmonary complications in 6 of 13 patients with MPM treated with IMRT to a dose of 54 Gy to the clinical target volume. The median time from completion of IMRT to the onset of radiation pneumonitis was 30 days (range, 5 to 57 days). Recent data from Kristensen et

al.²⁵⁰ showed fatal pulmonary toxicity in 4 of 26 (15%) of patients with MPM treated with induction chemotherapy, EPP, and postoperative IMRT to a pleural surface dose of 50 Gy. These reports of pulmonary toxicity emphasize that care should be taken when planning and delivering IMRT to the hemithorax. An alternative technique using electrons and IMRT has been reported as an alternative to IMRT alone. However, it appears that better coverage of the target volume is achieved with IMRT.^{251,252} If the use of IMRT after EPP is planned, doses of 45 to 50 Gy in 1.8 to 2.0 Gy fractions are typically recommended. In addition to other standard normal tissue constraints, a mean lung dose of ≤ 9 Gy and a V5 (volume of lung receiving ≥ 5 Gy) of $\leq 65\%$ should be used during the planning process.

Gomez et al.²⁵³ retrospectively analyzed 86 patients who underwent hemithoracic IMRT after EPP at MD Anderson Cancer Center. Grade 3 or worse pulmonary toxicity occurred in 11.6% of patients. There were five fatal cases of pulmonary toxicity: three from radiation pneumonitis and two from bronchopleural fistula. At 2 years, the rates of overall survival, local control, and distant control were 32%, 55%, and 40% respectively. Fourteen patients (16%) experienced local failure and only two of these patients had local failure alone. Fifty-one patients (59%) had distant metastases, which included failures in the contralateral hemithorax and the abdomen.

A retrospective review from the University of North Carolina examined 30 patients who received IMRT following EPP.²⁵⁴ The median dose to the ipsilateral hemithorax was 45 Gy with an 8 to 25 Gy boost in nine patients. Two-year local control, disease-free survival, and overall survival rates were 47%, 34%, and 50%, respectively. Four patients (13%) developed radiation pneumonitis, including one fatality (3%).

Radiation after Lung Sparing

In a retrospective review of patients having P/D at Memorial Sloan Kettering Cancer Center from 1974 to 2003, 123 patients received external-beam RT (median dose, 42.5 Gy; range, 7.2 to 67.8 Gy) to the ipsilateral hemithorax postoperatively. The median and 2-year overall survival for all patients was 13.5 months (range, 1 to 199 months) and 23%, respectively. Multivariate analysis for overall survival revealed a radiation dose < 40 Gy ($p = 0.001$), nonepithelioid histology ($p = 0.002$), left-sided disease ($p = 0.01$), and the use of an implant ($p = 0.02$) to be unfavorable. These data reinforce the concept that residual disease cannot be eradicated with external RT with or without brachytherapy and that a more extensive surgery followed by external RT might be required to improve local control and overall survival.²⁵⁵ Moreover, intraoperative RT for mesothelioma is associated with toxicity and failure to prolong survival.²⁵⁶

An experience with pleural IMRT in 36 patients with two intact lungs has recently been reported.²⁵⁷ All patients were planned with a PET/CT scan to aid target delineation. With a median dose of 46.8 Gy, 1- and 2-year survival was 75% and 53%, respectively, with a median survival of 26 months in patients who underwent P/D. Seven (20%) patients experienced grade 3 or 4 pneumonitis. A typical treatment plan is presented in Figure 114.10.

A prospective study from Aviano, Italy, reported on 28 patients who were treated with helical tomotherapy after P/D or biopsy alone.²⁵⁸ All patients had FDG-PET scans after surgery for staging and were treated to an intended dose of 50 to 60 Gy. Five patients (18%) had respiratory toxicity, but only two were grade 3 (7%); none were grade 5. The contralateral lung dose was strongly correlated with the risk of pneumonitis.

Prevention of Scar Recurrences

Malignant seeding in approximately 20% to 50% of patients with mesothelioma along thoracentesis tracts, biopsy tracts, chest

Figure 114.10 Radiation therapy after pleurectomy decortication. Isodense beam distribution showing example of typical isodose distribution using eight angles equally spaced over the 200-degree to 240-degree sector encompassing the ipsilateral lung. Area within green lines depicts target volume. (Color version of figure is available online at <http://www.semthorcardiovascsurg.com>). (Reprinted from Rosenzweig KE, Zauderer MG, Laser B, et al. Pleural intensity-modulated radiotherapy for malignant pleural mesothelioma. *Int J Radiat Oncol Biol Phys* 2012;83:1278–1283, Copyright (2012), with permission from Elsevier.)

tube sites, and surgical incisions is a common complication of procedures in these patients.^{119,259} Boutin et al.¹¹⁹ randomized 40 patients after an invasive diagnostic procedure to either RT (7 Gy × three fractions) or no treatment. No patient in the radiation treatment group developed subcutaneous nodules. Alternatively, 8 of 20 patients in the untreated group developed

metastases. Two additional small randomized trials have suggested that the use of short-course RT does not reduce the frequency of cutaneous seeding after invasive procedures.^{121,260} These data are inconclusive, and reviews of contemporary practice patterns suggest that radiation is commonly used to prevent scar recurrences.^{261,262}

Palliation Using Radiation Therapy

RT is commonly used to palliate pain in patients with advanced mesothelioma,¹⁵⁷ and investigators from the Netherlands have reported using palliative RT to treat painful chest wall metastases in patients with mesothelioma. Ball and Cruickshank²³⁷ reported a 72% rate of symptom improvement using palliative courses of RT. Ruffie et al.²⁶³ and Davis et al.²⁶⁴ reported the results of palliative RT in patients with mesothelioma. When doses >45 Gy were used, pain relief was attained in >50% of the cases.

More recently, some centers have investigated the use of IMRT for unresectable patients. Treatment techniques prior to the advent of IMRT would have necessitated significant dose inhomogeneity in the setting of intact lung. Palliative RT to the entire hemithorax should only be considered when first-line and second-line chemotherapeutic options have been exhausted.

Proton Beam Radiation

The widespread interest in proton RT has begun to carry over to MPM. To date, two theoretical planning studies have been published that suggest that proton therapy allows better sparing of normal organs at risk while providing better target coverage in patients after EPP.^{265,266} However, many uncertainties regarding the feasibility of proton therapy in thoracic RT remain, given the significant impact of respiratory motion and stark tissue density variation in the thorax on accurate proton dosimetry. Clinical validation of proton therapy for MPM remains to be shown.

115 Peritoneal Metastases and Peritoneal Mesothelioma

Marcello Deraco, Dominique M. Elias, Olivier Glehen, C. William Helm, Paul H. Sugarbaker, and Vic J. Verwaal

INTRODUCTION

Peritoneal carcinomatosis, mesothelioma, and sarcomatosis are included in the group of diseases collectively referred to, in this chapter, as peritoneal metastases. Over the past three decades, there has emerged an increasing optimism concerning an individualized management plan for cancer dissemination within the abdomen and pelvis. The clinical problem was originally defined by several important clinical studies that established the natural history of peritoneal surface malignancy.¹⁻³

Concomitant with these manuscripts that identified the dismal prognosis of patients with peritoneal metastases, isolated reports appeared concerning an emerging technology that described a new approach to management. This alternative treatment plan had two essential components. First, cytoreductive surgery (CRS) was used in an attempt to resect all visible implants within the abdomen and pelvis. Peritonectomy along with visceral resections was developed to surgically eradicate cancer on peritoneal surfaces.⁴ The second component was local-regional chemotherapy (intraperitoneal chemotherapy) used in the operating room or within the early postoperative period before adhesions develop. Chemotherapy used in the operating room with moderate heat has been referred to as hyperthermic intraperitoneal chemotherapy (HIPEC)⁵; chemotherapy used within the early postoperative period has been referred to as early postoperative intraperitoneal chemotherapy (EPIC).⁶ The chemotherapy is used in an attempt to eradicate free cancer cells and minute attached nodules that remain following surgery.⁷

The unique aspect of this new combination of treatments was the perioperative timing of the chemotherapy. Currently, the perioperative chemotherapy may be both intravenous and intraperitoneal, and may be administered in the operating room or in the early postoperative period. HIPEC now abbreviates the term hyperthermic perioperative chemotherapy and includes all perioperative chemotherapy regimens. It is not adjuvant chemotherapy and it is not neoadjuvant chemotherapy; it is chemotherapy used simultaneously with a major cytoreductive surgical procedure. Of course, all efforts to maintain benefits from systemic chemotherapy in patients with peritoneal metastases or mesothelioma must continue. Patients with peritoneal surface malignancy are required to be a focus of the multidisciplinary team (MDT).

NATURAL HISTORY STUDIES DOCUMENT THE IMPORTANCE OF LOCAL-REGIONAL PROGRESSION

A strong rationale for the emergence of CRS and HIPEC as a valid treatment option comes from natural history studies. In a proportion of patients, recurrence of the primary cancer isolated to the surfaces of the abdomen and pelvis is a reality. Primary or recurrent disease at the resection site and on peritoneal surfaces in the

absence of hepatic metastases or systemic metastases does occur; these patients are appropriate for treatment by CRS and HIPEC. Isolated peritoneal surface progression of abdominal or pelvic malignancy is not unusual.⁸⁻¹²

To fully understand the importance of cancer cells that gain access to the peritoneal space prior to or at the time of a cancer resection, one must appreciate the pathophysiology of disease. Figure 115.1 illustrates the mechanism of local-regional progression. Cancer cells at low density result in peritoneal metastases at a distance from the primary cancer resection. Cancer cells at higher density become trapped within raw tissue surfaces at the resection site. A fusiform layer of cancer that conforms to the anatomic structures within the bed of the primary resection site results from high-density seeding.¹³ The progression of cancer implants within the resection site and on peritoneal surfaces in the absence of liver metastases or systemic disease presents a major rationale for comprehensive local-regional treatments.¹⁴

PATIENT SELECTION USING QUANTITATIVE PROGNOSTIC INDICATORS

A second factor strongly recommending CRS and HIPEC as a valid treatment option comes from well-established selection factors applied to this patient population. With some variations between diseases, the same group of quantitative prognostic indicators operates for all patients with peritoneal surface malignancy. Now, prognostic indicators are used to refine the selection of patients to those most likely to benefit and to exclude those who are unlikely to benefit.^{15,16} Histopathology, the peritoneal cancer index (PCI), the completeness of cytoreduction score (CC), radiologic imaging by computed tomography (CT), and TNM (tumor, node, metastasis) stage with peritoneal cytology play a central role in patient selection.

Biologic Aggressiveness as Measured by Histopathology for Epithelial Appendiceal Neoplasms and Peritoneal Mesothelioma

Mucinous appendiceal neoplasms have a broad spectrum of aggressiveness, and the histologic type of the appendiceal neoplasm has a profound effect on survival following treatment by CRS and HIPEC.¹⁷ Patients with adenomucinosis obtain maximal survival benefit, while those with mucinous carcinoma show survivals similar to that for peritoneal metastases of colorectal origin.¹⁸

Seven different histologic patterns of peritoneal mesothelioma contribute to three distinct histologic groups that have a very different prognosis following treatment with CRS and HIPEC: poor prognosis for sarcomatoid, deciduoid, or biphasic types; intermediate prognosis for papillary and epithelial types; and excellent prognosis for low-grade or multicystic types.^{19,20}

Intraoperative dissemination of gastric cancer

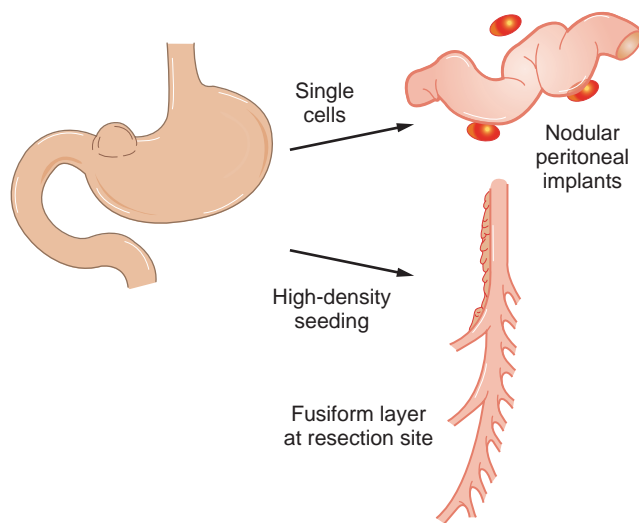

Figure 115.1 Intraoperative dissemination of gastric cancer cells. If cancer cells gain access to the peritoneal space either prior to or at the time of gastrectomy, two patterns of dissemination are observed. Low density of cancer cells into the free peritoneal space results in nodules as peritoneal implants. A high density of cancer cells dropped into the cancer resection site results in a layering of cancer.

Extent of Disease as Measured by the Peritoneal Cancer Index

The PCI is an assessment combining lesion size (0 to 3) with tumor distribution (abdominopelvic regions 0 to 12) to estimate the extent of disease within the abdomen and pelvis as a numerical score (Fig. 115.2).²¹ It is calculated from observations obtained at the time of surgical exploration of the abdomen and pelvis, and should be recorded by the surgeon before leaving the operating room. The higher the PCI, the less likely CRS and HIPEC will result in long-term survival for all the peritoneal surface malignancies discussed in this chapter.

The Completeness of Cytoreduction Score Performed after the Resection

The size of residual tumor nodules visually determined after CRS has been completed has a profound effect on outcome. The new definition of complete cytoreduction is no visible evidence of cancer or only minute nodules reliably penetrated by HIPEC, a completeness of cytoreduction score of 0 (CC-0) or CC-1, respectively. With few exceptions, a CC-0 or CC-1 score is necessary for long-term benefit with CRS and HIPEC.²¹

Preoperative Radiologic Imaging by Computed Tomography

CT of the chest, abdomen, and pelvis is an essential tool in the selection of patients for CRS with HIPEC. Systemic metastases and spread to pleural surfaces can be identified. The location and quantity of mucinous carcinoma within the peritoneal cavity can be accurately determined.^{22,23} Unfortunately, nonmucinous peritoneal metastases may be greatly underestimated by CT.²⁴ If the small bowel and its mesentery are layered by tumor or a large mass of cancer occupies the epigastric region, the likelihood of achieving complete cytoreduction is small. The CT should be performed with maximal intravenous and oral contrast in order to identify patients who have small bowel compartmentalization versus diffuse involvement of the small bowel and its mesentery.

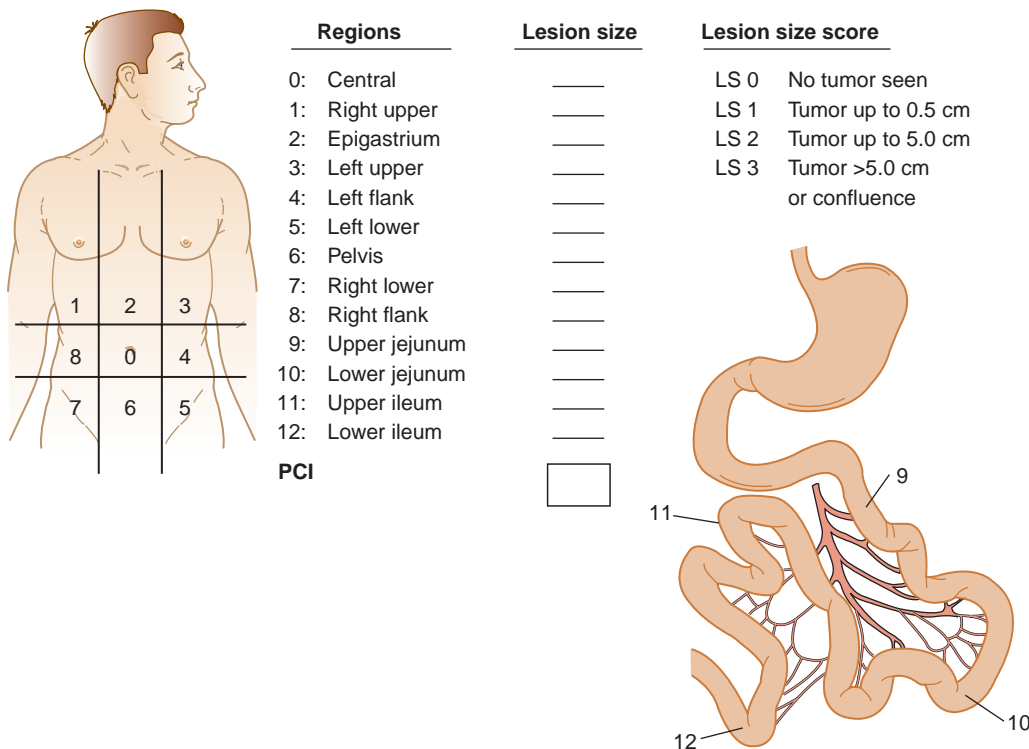

Figure 115.2 The peritoneal cancer index (PCI). This index combines a size and a distribution parameter to achieve a numerical score. The lesion size (LS) is used to quantitate the size of peritoneal nodules. The distribution of tumor is determined within the 13 abdominopelvic regions.

Tumor, Node, Metastasis Stage, Peritoneal Cytology, and Clinical Features of the Primary Cancer

A careful survey of the peritoneal surfaces at the time of primary gastrointestinal cancer resection combined with a knowledgeable and timely gross and histopathologic assessment of the resected specimen can accurately predict the incidence of peritoneal metastases that will occur in follow-up. Also, in advanced gastrointestinal cancers, peritoneal cytology provides important prognostic information. This information should be used by the MDT to consider proactive treatment with CRS and HIPEC. It is possible to prevent peritoneal metastases in high-risk groups or treat peritoneal metastases by second-look surgery in patients with documented disease.^{25–30} The fast pace at which peritoneal metastases progress and the profound effect of extent of disease (PCI) on outcome indicate this approach. Table 115.1 presents the clinical features that should alert the MDT to a high risk for peritoneal metastases.^{31,32}

Pharmacokinetic Advantage of Perioperative Chemotherapy

Another argument in favor of CRS and HIPEC as a treatment option for peritoneal surface malignancy is a well-studied

TABLE 115.1

Tumor, Node, Metastasis Stage, Peritoneal Cytology, and Clinical Features of the Primary Cancer as an Estimate of the Incidence of Subsequent Peritoneal Metastases to Guide Proactive Treatment Strategies

Clinical Feature	Incidence of Peritoneal Metastases Observed in Follow-up (%)	
	Colorectal Cancer	Gastric Cancer
Peritoneal nodules detected with primary cancer resection	70 ^a	100
Ovarian metastases	60 ^a	100
Perforation through the primary cancer	50 ^a	75 ^b
Positive margin of resection (R-1 resection)	70	70
Positive peritoneal cytology before or after resection	40 ^a	80
Adjacent organ or structure invasion	20 ^a	40
T3	20	60
T4	20	75

^a Data from Honore C, Goere D, Souadka A, et al. Definition of patients presenting a high risk of developing peritoneal carcinomatosis after curative surgery for colorectal cancer: a systematic review. *Ann Surg Oncol* 2013;20:183–192.

^b Data from Tsujimoto H, Hiraki S, Sakamoto N, et al. Outcome after emergency surgery in patients with a free perforation caused by gastric cancer. *Exp Ther Med* 2010;1:199–203.

pharmacologic rationale. As determined by physical properties, some chemotherapy agents are especially appropriate for hyperthermic use in the peritoneal cavity after CRS has been completed. Other cell cycle-specific chemotherapy agents are more appropriate for EPIC. As experience with different perioperative chemotherapy regimens has accumulated, the use of multiple-agent chemotherapy given both intravenously and intraperitoneally has evolved and promises to be increasingly effective. Heat targeting of both intravenous and intraperitoneal chemotherapy to the peritoneal surface cancer nodule is a goal of treatment.

Combined Use of Cytoreductive Surgery and Perioperative Chemotherapy as a Standard of Care in Selected Patients

A final argument for use of CRS and HIPEC as a treatment option for peritoneal surface malignancy concerns the well-defined management parameters that are currently in practice at experienced treatment centers. A standardized cytoreductive surgical procedure involves visceral resections and peritonectomy procedures in an attempt to leave the abdomen visibly free of cancer. After the CRS is complete, tubes and drains are positioned to facilitate inflow and outflow of the chemotherapy solution. The chemotherapy solution circulates through roller pumps and a heat exchanger to maintain moderate hyperthermia (42°C/109°F) within the abdomen and pelvis. The skin edges are elevated on a self-retaining retractor (open method) or the skin closed (closed method) in order to create a reservoir for the hyperthermic chemotherapy solution.

The sequence of cancer resection, intraoperative chemotherapy washing, and then intestinal reconstruction may be important to optimize the destruction of small volumes of cancer cells and prevent tumor cell entrapment in adhesions, suture lines, and the abdominal incision. During the peritonectomy and visceral resections, large volumes of cancer are removed; however, residual cancer cells remain and must be eradicated.

A review of the important recent contributions to the literature that critically assesses the benefits of CRS and HIPEC in different disease states constitutes the remainder of this chapter.

APPENDICEAL MALIGNANCY

Natural History

Although similarities exist, there are unique features of appendiceal malignancies as compared to colorectal adenocarcinoma. The first and probably the most obvious difference between the colon and the appendix malignancies is the diameter of the bowel lumen involved. A colon tumor grows as an intraluminal mass in the bowel and will invade through the wall. The intraluminal growth pattern causes the primary cancer to reach the serosa in a late stage. In contrast, the appendix is a small organ, up to 1 cm in diameter, with a thin wall. A tumor may obliterate the appendix lumen in an early stage. This may cause a rupture of the wall of the appendix, allowing a spreading of tumor cells into the abdominal and pelvic cavity. Early in the natural history of the disease, these neoplastic cells implant with a high efficiency throughout the peritoneal cavity and progress as peritoneal metastases.^{33,34}

Histologic Classification

The biology of appendiceal malignancies varies from simple mucinous adenoma to solid intestinal type adenocarcinoma. The histology of the peritoneal metastases from the primary tumor itself has a major influence on the outcome of the treatment by CRS and HIPEC. Ronnett et al.³⁵ and Bruin et al.³⁶ described three different types in their analyses of appendiceal malignancies. Metastases

Figure 115.3 Survival of 269 patients with peritoneal metastases of an appendiceal neoplasm by histologic classification. DPAM, disseminated peritoneal adenomucinosis; PMCA, peritoneal mucinous carcinoma; PCA, peritoneal carcinoma. (From Bruin S, Verwaal VJ, Vincent A, et al. A clinicopathologic analysis of peritoneal metastases from colorectal and appendiceal origin. *Ann Surg Oncol* 2010;17:2330–2340.)

with >90% mucus, flat epithelial cells, no atypia, and no mitoses had a good prognosis despite a high PCI. At the other end of the spectrum, peritoneal metastases with much atypia, abundant mitoses, and <50% mucus has a prognosis similar to colorectal carcinomatosis and is referred to as peritoneal carcinoma.

Outcome of Treatment of Peritoneal Dissemination by Cytoreductive Surgery Followed by Hyperthermic Perioperative Chemotherapy

The survival outcome with peritoneal dissemination of appendiceal origin neoplasms is shown in Figure 115.3. The overall survival is shown according to the histologic classification. For the least aggressive form (disseminated peritoneal adenomucinosis), the median survival is not reached within 5 years.³⁶ Those patients who were affected by peritoneal carcinoma had a much poorer prognosis. The median survival was only 14 months in these patients. These survival data compare with the median survival of peritoneal metastases of colorectal origin treated with cytoreduction followed by HIPEC. Accepting the fact that complete resection is always the goal of CRS, these data document that survival with peritoneal metastases from appendiceal malignancies is highly dependent upon the histopathologic characteristics of the tumor.

Success in the treatment of recurrence after primary treatment with CRS followed by HIPEC is a unique feature of appendiceal peritoneal metastases. Benefit depends largely on the number and location of tumor masses. With a limited number of locations, the first choice is resection; if more diffuse disease is present and CRS is complete, a second HIPEC can be performed.^{37,38} In patients in whom the pathology is more aggressive, definitive treatment with systemic chemotherapy, with all its limitations, should be considered by the MDT.

Surgical Learning Curve

Cytoreduction followed by HIPEC is a complex treatment that demonstrates a surgical learning curve.^{39,40} The peak of the learning curve in the study of Smeenk et al.³¹ was reached after approximately 130 procedures. Surgical skill is undoubtedly the main component of this learning process, but modified treatment strategies for an individual patient and experience in handling complications by the entire medical team has contributed to a decreased morbidity and mortality.^{41,42}

COLORECTAL PERITONEAL METASTASES: CURATIVE TREATMENT AND PREVENTION

Stage IV colorectal cancer is a very morbid disease, with a 5-year survival rate of 10% and a median survival of 14.4 months. The prognosis is significantly worse when peritoneal metastases are present, with a median survival of 6.7 months versus 18.1 months without peritoneal metastases ($p < 0.01$).⁴³ When colorectal peritoneal metastases are diagnosed, the crucial question for the MDT is whether curative (complete CRS with HIPEC) or palliative therapy (systemic chemotherapy) should be the goal of treatment.

Incidence of the Disease and Incidence of Peritoneal Metastases

At the initial diagnosis of colon cancer, the peritoneal surface is involved with tumor in 10% to 15% of patients.^{11,44} Besides the liver, the peritoneal surfaces are the most common sites of cancer recurrence after “curative” colorectal cancer resections. Unfortunately, cancer progression occurs in as many as 50% of patients who have an R0 resection. In 10% to 35% of patients with recurrent disease, the anatomic site of treatment failure is confined to the peritoneal surface.^{11,44} With recurrent disease, when peritoneal metastases

are of limited extent (low PCI), potentially curative treatment options should be considered.

Useful Prognostic Indicators for the Disease

Contraindications for this combined treatment are the presence of metastases at another site (although, up to three easily resectable liver metastases is not an absolute contraindication),⁴⁵ a poor general status (the combined treatment is rather aggressive), and extensive peritoneal metastases (PCI >20). Extensive disease is likely to be unresectable in its entirety. Also, even when a complete cytoreduction is possible, the prognosis is poor. Most of the series using complete CRS with HIPEC report a poor survival rate when the PCI is higher than 20.^{46,47}

Results of Treatment

Figure 115.4 reports the survival rates according to the completeness of surgery in the 523 patients collected by the Association Française de Chirurgie.⁴⁷ Five years after surgery, no patient was alive if the size of the residual tumor nodules exceeded 2.5 mm after surgery, whereas 30% of the patients were alive if complete CRS was possible ($p < 0.0001$). These data are confirmed in the Dutch HIPEC study, which included 960 patients.⁴⁸

A crucial role for hyperthermia for HIPEC is currently unknown for humans. In a randomized trial in rats, those treated with HIPEC survived longer than those treated with intraperitoneal chemotherapy alone or with intraperitoneal hyperthermia alone.⁴⁹ A recent retrospective study compared similar patients (all of whom underwent a laparotomy) with resectable peritoneal metastases treated with complete CRS and HIPEC to patients who received standard systemic chemotherapy. Median survival was 63 months in the complete CRS with HIPEC group versus 24 months in the systemic chemotherapy group.⁵⁰

Summary of Important Results from Other Institutions

This combined treatment (complete CRS and HIPEC) is effective. Benefits were definitively demonstrated by the randomized study of the Amsterdam group: 105 patients who presented with colorectal peritoneal metastases were randomized between surgery with HIPEC and systemic chemotherapy versus systemic chemotherapy alone.⁵¹ In this study, close to 50% of the patients in

Figure 115.4 Overall survival according to the completeness of cytoreduction after cytoreductive surgery and hyperthermic perioperative chemotherapy for peritoneal metastases. (Elias D, Gilly F, Boutitie F, et al. Peritoneal colorectal carcinomatosis treated with surgery and perioperative intraperitoneal chemotherapy: retrospective analysis of 523 patients from a multicentric French study. *J Clin Oncol* 2010;28:63–68.)

the experimental arm were at presentation not good candidates for HIPEC because their peritoneal metastases could not be completely resected. Despite this bias, the reported median survival was 22 months in the experimental arm versus 13 months in the control group ($p = 0.032$). At eight years the benefit persisted.⁵²

The results obtained with complete CRS with HIPEC in the Association Française de Chirurgie study showed a 5-year overall survival of 30%.⁴⁷ This result accepts clinical data over an 18-year interval and includes the learning curves of 28 different centers. It is the least favorable data ever to be reported by the authors' group. The results of experienced centers concerning patients who underwent complete CRS and HIPEC show 5-year overall survival rates close to 40%. It was 32% for the 70 patients in the study by da Silva et al.,⁴⁶ 43% for the 59 patients in the Verwaal et al.⁵¹ study, and 48% for the 30 patients treated by Elias et al.⁵³ Such a survival rate has never been published before for colorectal peritoneal metastases, even if the report includes only selected patients.

Furthermore, these results in the treatment of peritoneal metastases are similar to those obtained with hepatectomy for liver metastases. Selected patients with peritoneal metastases should be treated with this combined therapy just as selected patients with liver metastases should be treated with hepatectomy given that similar results are achieved in terms of survival.⁵⁴

Prevention of Peritoneal Metastases in Patients at High Risk for Progression

Unfortunately, early diagnosis of peritoneal metastases is not possible with radiologic imaging, but only with a laparotomy. This is why the authors proposed second-look surgery plus HIPEC in asymptomatic patients who presented with a primary exhibiting a high risk of developing peritoneal metastases.^{28,55} High-risk patients were those who presented with a few (resected) peritoneal implants, ovarian metastases, or perforated tumors. Second-look surgery was performed 6 months after the end of the classic 6 months of systemic adjuvant chemotherapy. Among 47 patients, macroscopic peritoneal metastases was found and treated in 50% of them. In the remaining patients with no macroscopic peritoneal metastases, peritoneal recurrence occurred frequently in those who did not receive HIPEC, but rarely in those who did receive HIPEC ($p = 0.02$). Finally, only 17% of the patients treated at the time of second-look surgery with HIPEC developed a peritoneal recurrence.²⁸

Reports of complete CRS and HIPEC being used to simultaneously treat the primary colorectal cancer and the peritoneal metastases have appeared.^{25–27} Also, patients without established peritoneal disease but at high risk for subsequent peritoneal progression are being treated with HIPEC during the same procedure used to resect the primary tumor.²⁶ The rationale for this proactive approach is three-fold: First, after the primary cancer resection and complete CRS, the PCI was maximally low. Second, reliable radiologic tests to detect the progression of a low volume of peritoneal metastases do not exist. And third, this proactive approach does not require a second-look surgery. With rectal cancer, a second-look approach with CRS and HIPEC may rarely, if ever, be curative.^{46,56}

DIFFUSE MALIGNANT PERITONEAL MESOTHELIOMA

Clinical Presentation and Diagnosis

Diffuse malignant peritoneal mesothelioma (DMPM) is characterized by progressive peritoneal seeding, eventually leading to the patient's death due to tumor layering on peritoneal surfaces, bowel obstruction, and intractable malignant ascites. Patients are usually diagnosed with presenting signs and symptoms of advanced disease. In a recently published series of 81 patients with DMPM reported

by an Italian group, ascites, abdominal pain, and asthenia were the most frequent symptoms present on 77%, 69%, and 43% of patients, respectively. CT scan shows ascites, peritoneal thickening, abdominal mass, and mesenteric thickening, respectively, on 80%, 63%, 32%, and 29% of cases.⁵⁷ CT scan is used as an accurate prognostic radiologic test for patient selection for comprehensive treatment.²³

Cytologic diagnosis of ascitic fluid is often inconclusive, as cells frequently resemble elements with mesothelial hyperplasia. In the series of the Washington Cancer Institute, diagnosis was made by fluid sampling in 0 of 68 patients. Laparotomy was required in 44% of patients, laparoscopy in 52%, and ultrasound/CT-guided biopsy in 4%.⁵⁸ Recently, refined cytological and ultrastructural methods have enhanced the diagnostic accuracy of cytologic assessment.⁵⁶

Treatment and Results with Systemic Chemotherapy

Numerous single-drug and combination regimens have been tested over the past decades with modest results. Preliminary data also suggest a possible survival advantage for a combination of cisplatin and pemetrexed as compared to cisplatin alone. Other cytotoxic agents that have shown to be active in this setting include vinorelbine and gemcitabine, either alone or combined with platinum compounds. In historical case series, standard therapy with palliative surgery and systemic or intraperitoneal chemotherapy is associated with a median survival of about 1 year, ranging from 9 to 15 months.^{59,60}

The combined approach consisting of CRS and HIPEC modified the natural history of DMPM with a dramatic improvement in outcomes in multiple single institution studies and in a multi-institutional registry series.^{9,19,61-64} Median survival grew from 12 months with a systemic chemotherapy treatment to 53 months with CRS with HIPEC, with 50% 5-year overall survival.⁶⁵

GASTRIC CANCER

Treatment and Prevention of Peritoneal Metastases

Peritoneal dissemination is the most frequent pattern of metastasis and recurrence with gastric cancer. Also, it occurs in 5% to 20% of patients being explored for potentially curative resection.⁶⁶ In the past, gastric cancer peritoneal metastases was regarded as a terminal disease, only to be palliated. Over the past two decades, novel therapeutic approaches have emerged, combining gastrectomy and peritonectomy procedures with perioperative chemotherapy.⁶⁷ Because of the aggressive nature of gastric cancer, the question regarding the efficiency of this combined procedure remains controversial.

Natural History and Palliative Treatment

The studies that prospectively evaluated patients with peritoneal dissemination of gastric cancer indicated median survival of not more than 6 months.² Despite improvements in systemic chemotherapy with encouraging tumor response rates, there has been no improvement in survival.⁶⁸ Positive effects of palliative gastric cancer resection have been recently reported in patients with peritoneal metastases but without any long-term survivors.⁶⁶

Curative Treatment: Cytoreductive Surgery and Hyperthermic Perioperative Chemotherapy

The experience of a few single institution phase 2 studies showed encouraging survival results following treatment of peritoneal metastases along with primary gastric cancer.⁶⁹⁻⁷⁴ Recently, a collaborative effort of French institutions collected data from 159 patients and represents the largest experience with treatment of peritoneal metastases of gastric origin.⁷² With a median follow-up of 20.4 months, the overall median survival was only 9.2 months but the 5-year survival rate was 13%, with some long-term survivors. These survival results are less encouraging than those obtained for other peritoneal surface malignancies, reflecting a more aggressive disease process, less response to this combined treatment modality, and the need for more strict patient selection. But the combination of CRS with HIPEC was the only therapeutic strategy that reported survivors at 5 years. In the recent French study, a 5-year survival of 23% and a median survival of 15 months were obtained in patients treated with complete macroscopic resection (Fig. 115.5).⁷²

Primary gastric cancer with localized and small peritoneal nodules seems to be the best indication for this combined procedure. In the French study, in patients who had undergone complete CRS, the extent of peritoneal metastases measured by PCI represented the only strong prognostic factor.⁷² When the PCI was >12, despite a complete CRS, no patient was alive at 3 years. The institution in which the procedure was performed played an important role in the postoperative course and in survival, suggesting the importance of a learning curve.^{41,42,75,76} The high rates of morbidity and mortality reported may reach 60% and 6.5%, respectively.⁷² These high rates of morbidity and mortality emphasize the necessity for patient selection using strict criteria regarding physiologic age and general status.

Important data regarding the treatment of peritoneal metastases from gastric cancer was provided by Yang and colleagues.⁷⁷ In a randomized trial, patients were treated by cytoreductive surgery with (34 patients) or without (34 patients) HIPEC. The median survival was 11.9 months with HIPEC but only 6.5 months with CRS alone ($p = 0.046$). Morbidity and mortality was the same in

Figure 115.5 Overall survival of 159 patients with peritoneal metastases from gastric cancer treated by cytoreductive surgery and hyperthermic intraperitoneal chemotherapy according to completeness of cytoreduction. (From Glehen O, Gilly FN, Arvieux C, et al. Peritoneal carcinomatosis from gastric cancer: a multi-institutional study of 159 patients treated by cytoreductive surgery combined with perioperative intraperitoneal chemotherapy. *Ann Surg Oncol* 2010;17:2370-2377.)

both groups. Limited but real benefits for HIPEC were demonstrated. Currently, Rau and colleagues in Germany are conducting a similar phase 3 trial, the GASTRIPEC study.⁷⁸

Prevention of Gastric Cancer Peritoneal Metastases

For many Korean and Japanese researchers, HIPEC has been performed in an adjuvant setting in phase 3 trials. Most of them demonstrated the benefit of HIPEC, especially for T3, T4, and lymph node-positive gastric tumors.^{79–82} In Western countries, some small experiences also suggested the benefit of using HIPEC as adjuvant treatment for primary gastric cancer presenting with peritoneal metastases.^{83,84} Yan and coworkers in a meta-analysis showed that HIPEC with or without EPIC after resection of advanced gastric primary cancer is associated with improved overall survival. However, increased risk of intra-abdominal abscess and neutropenia were also demonstrated.⁸⁵ Xu et al., in their meta-analysis, reported similar results.⁸⁶ Currently, a prospective randomized trial is being performed in France to test adjuvant HIPEC in gastric cancer.⁸⁷

PERITONEAL METASTASES IN OVARIAN CANCER

Cytoreductive Surgery and Hyperthermic Perioperative Chemotherapy in Epithelial Ovarian Cancer

There is emerging data helping to define the potential role of HIPEC for epithelial ovarian cancer. A registry for patients with ovarian cancer was initiated to collect data from many centers in a format that allowed analysis for factors such as prognostic indicators, variations in technique, and outcomes.⁸⁸ Patient eligibility included epithelial ovarian, fallopian tube, or primary peritoneal carcinoma treated with HIPEC at some point in the natural history of the disease. Each participating institution used its own HIPEC technology regarding chemotherapy solutions, duration of perfusion, temperature, and technique of open or closed peritoneal lavage. In the initial report, 141 women were analyzed who had been treated with either frontline ($n = 26$), at interval debulking ($n = 19$), for consolidation ($n = 12$), or for recurrence ($n = 83$). The median overall survival was 30.3 months. In multivariable analysis, the factors significant for increased survival were sensitivity to platinum response ($p = 0.048$), completeness of cytoreduction score of 1 or 0 ($p = 0.025$), carboplatin alone or combination ($p = 0.011$), and duration of hospital stays of ≤ 10 days ($p = 0.021$).

Ceelen and coworkers reported on 42 women treated for recurrent heavily pretreated ovarian cancer with extensive CRS and HIPEC.⁸⁹ In multivariate analysis, overall survival was influenced by completeness of cytoreduction, type of chemoperfusion drug, nodal status, and tumor grade. In a Cox regression model, only completeness of cytoreduction (hazard ratio = 0.06 to 0.8; $p = 0.022$) and tumor grade (hazard ratio = 1.23 to 12.6; $p = 0.021$) were independent predictors of overall survival.

Bakrin et al.⁹⁰ reported a French multicenter prospective study of 246 women with recurrent or persistent ovarian cancer treated by CRS and HIPEC. The effects of PCI, CC score, and platinum sensitivity versus resistance are shown in Figure 115.6. They conclude that salvage therapy combining optimal CRS and HIPEC is feasible and may achieve long-term survival in highly selected patients with recurrent ovarian carcinoma, including those with platinum-resistant disease, with acceptable morbidity. Into their updated experience on 566 patients, they underlined the role of PCI in patient selection because of its major and independent prognostic impact for advanced and recurrent ovarian cancer.⁹¹

Figure 115.6 Overall survival of 246 patients with recurrent or persistent ovarian cancer by (top) peritoneal cancer index (PCI), (middle) completeness of cytoreduction (CCS), (bottom) platinum-resistant/persistent group versus platinum-sensitive group. HR, hazard ratio. (From Bakrin N, Cotte E, Golfier F, et al. Cytoreductive surgery and hyperthermic intraperitoneal chemotherapy (HIPEC) for persistent and recurrent advanced ovarian carcinoma: A multicenter, prospective study of 246 patients. *Ann Surg Oncol* 2012;19:4052–4058.)

In a case-control study, Fagotti et al.⁹² reported significantly better 5-year survival of 68.4% versus 42.7% ($p = 0.017$) for 30 cases of platinum-sensitive recurrent ovarian cancer undergoing CRS and HIPEC versus 37 control patients who underwent either

CRS without HIPEC and/or systemic chemotherapy only. Deraco et al.⁹³ reported 60.7% 5-year survival with CRS and HIPEC used as frontline treatments.

The results of five ongoing randomized controlled trials of HIPEC in the setting of frontline surgery, interval debulking after neoadjuvant chemotherapy and for recurrent disease are awaited (NCT01539785, NCT00426257, NCT01091636, NCT01628380, NCT01767675: available at <http://clinicaltrials.gov/>. Accessed November 27, 2013).

SARCOMATOSIS

Soft tissue tumors of the viscera or retroperitoneum are associated with high rates of local-regional relapse. An attempt to achieve

adequate margins of excision may be impossible because of anatomic constraints. Cancer cell seeding into the peritoneal cavity either prior to or at the time of sarcoma resection combined with positive or narrow margins of excision result in this high likelihood of local-regional recurrence.⁹⁴ In patients with local-regional disease progression or sarcomatosis, the survival is limited to approximately 2 years.

If CRS is performed in this group of patients and combined with HIPEC, the median survival is extended past 2 years. In four of the five studies referenced, an overall 5-year survival was >30%.⁹⁵⁻⁹⁹ Unusually large benefits with CRS and HIPEC in patients with uterine sarcomatosis have been reported.¹⁰⁰ The mechanical removal of sarcoma peritoneal metastases that occurs with HIPEC may be as important or even more important than the cytotoxic effects. A consensus statement has been published.¹⁰¹

116 Intraocular Melanoma

Paul T. Finger

INTRODUCTION

Metastatic choroidal melanoma patients rarely present with the classic “distended abdomen and a glass eye.” Though metastases occur in up to 50% of cases, most do not cause symptoms having been discovered by periodic hepatic screening.^{1,2} The rationale for early detection is that it allows for palliative treatment, enrollment in clinical trials, and end-of-life planning.³

Prosthetic eyes are less commonly required after uveal melanoma treatment. This is because fewer patients with uveal melanoma are being treated by removal of the eye (enucleation). For example, at The New York Eye Cancer Center, <10% of patients with uveal melanoma typically require enucleation. This trend toward eye preservation can be related to early detection, referral of smaller more treatable uveal melanoma, and the widespread belief that radiation is equivalent to enucleation for the prevention of metastases.⁴ Confronted with the choice between enucleation and eye-sparing radiation therapy, patients prefer to keep their eye.

Vision-sparing radiation therapy techniques are widely used around the world. For example, 47 eye cancer specialists from 10 countries participated in a committee to create the American Brachytherapy Society Ophthalmic Oncology Task Force guidelines for plaque radiation therapy.⁵ In these guidelines, enucleation was recommended in cases of American Joint Committee on Cancer (AJCC) stage T4e uveal melanomas, tumors with basal dimensions that exceed the limits of irradiation; blind painful eyes and those with no light perception vision. Thus multi-center, international consensus allows for eye and vision-sparing plaque brachytherapy for almost all patients.⁵ This shift toward eye preservation has been augmented by the advent of post-radiation, eye- and vision-preserving laser photocoagulation as well as anti-vascular endothelial growth factor (anti-VEGF) treatment. In 2007, radiation maculopathy and radiation optic neuropathy were first suppressed by periodic intraocular injections of bevacizumab (Avastin, Genentech, South San Francisco, CA).⁶⁻⁸ Since that time, centers around the world have used anti-VEGF treatment to preserve vision, eyes, and quality of life for most patients.

In the modern era, patients with metastatic uveal melanoma are likely to present with a normal abdominal examination, their natural globe, and binocular vision.

INCIDENCE AND ETIOLOGY

Uveal melanomas are the most common primary intraocular malignancy in adults and account for 5% of all melanomas.⁹ As compared to Caucasians, uveal melanoma is progressively less likely to occur in Hispanics, Asians, and Africans.¹⁰ The incidence of ocular melanomas for whites in the United States (Surveillance, Epidemiology, and End Results program) was 0.69 per 100,000 person-years for males and 0.54 for females.^{11,12} The Collaborative Ocular Melanoma Study (COMS) found the mean age of enrolled patients was 60.¹³ Patients with dysplastic nevus syndrome, ocular

melanosis, and the nevus of Ota have been found to be at greater risk to develop uveal melanoma.¹⁴

Environmental causes are less clear.^{9,15} While a 2011 multi-center, international study of biopsy-proven iris melanomas found that most occurred on the lower, more sun-exposed iris, others have suggested no correlation to ultraviolet light.^{9,16} Though specific genetic defects have been found within choroidal melanoma cells, there is no clear mode of inheritance.^{17,18}

ANATOMY AND PATHOLOGY

The uvea is the primary vascular matrix of the eye. It is continuous within the iris, ciliary body, and choroid. Melanocytes within any of these structures can transform. However, intraocular melanoma location affects tumor size at diagnosis, prognosis for vision, and risk for metastasis.

Iris melanomas are the most easily visible. They tend to be the smallest at diagnosis, spindle cell type, and least likely to metastasize.¹⁶ In contrast, ciliary body melanomas are the least visible as they are hidden behind the iris, typically discovered as larger, and more likely to have metastasized.¹⁹

Choroidal melanomas are located posterior to the ciliary body. Often asymptomatic, they are commonly found during routine periodic ophthalmic examination. Thus, choroidal melanomas are typically small to medium-sized tumors. When symptomatic, choroidal melanomas can induce early changes in vision and/or symptoms of “flashing lights” due to tumor-induced exudative retinal detachment. A subset termed “subfoveal choroidal melanomas” are located beneath the center of vision and are recognized earlier due to visual symptoms and are thus smaller and less likely to have metastasized.²⁰

Therefore, unless a melanoma is large enough to be visible, extend into the visual axis, tilt the natural lens, induce a symptomatic exudative retinal detachment, or displace the fovea, they are discovered during routine eye examination.

Histology

In 1931, Callender recognized distinct types of melanocytes within uveal melanomas.²¹⁻²³ His subsequent cytology-based tumor staging system “The Callender Classification” divided uveal melanoma into three categories:

1. Spindle cell melanomas (spindle A, spindle B, or both)
2. Mixed-cell melanomas, when less than half of the cells are composed of epithelioid cells
3. Epithelioid cell melanomas, greater than half are composed of epithelioid cells

While there is general agreement that epithelioid cell melanomas are more aggressive, there exists great variation among pathologists’ diagnosis of cell types, the number of sections required for review, and the quantity of epithelioid cells required to make the diagnosis of an “epithelioid cell melanoma.”²⁴

Figure 116.1 Left, iris melanoma (arrow) in inferior quadrant demonstrates corectopia, ectropion uveae, and intrinsic vascularity (at pupillary margin). Middle, a pigmented ciliary body melanoma (arrow) causing anterior iris displacement and a sector cataract of the adjacent lens. Right, a posterior choroidal melanoma demonstrating MOST (Melanoma = Orange pigment, Subretinal fluid and Thickness ≥ 2 mm).

Intraocular Tumor Growth Patterns

Uveal melanomas either grow from a preexisting nevus or de novo. However, there are uveal-location specific patterns of tumor growth:

Iris Melanoma

Iris melanomas typically originate in the iris stroma. While growing, they can displace, erode, or consume the underlying iris pigment epithelium.²⁵ Along its posterior margin, it may invade the trabecular meshwork gaining egress to the episcleral aqueous veins and or grow into the adjacent ciliary body. When discohesive, tumor-cell dispersion can induce secondary glaucoma.²⁶ Other signs that suggest malignancy include iris dysfunction such as corectopia (irregular pupil) or dysmorphism such as ectropion uveae and tumor neovascularization (Fig. 116.1, left). Additional tumor-associated vasculopathies include dilated iris feeder vessels and adjacent episcleral hypervascularity.

Ciliary Body Melanoma

Ciliary body melanomas arise immediately posterior to the iris and are more likely to indent the adjacent lens and cause lenticular astigmatism and cataract (Fig. 116.1, middle). They can infiltrate along ciliary vessels and nerves to form nodules of epibulbar extrascleral extension (Fig. 116.2, left). The sclera above the tumor may exhibit recruited “sentinel” blood vessels. As ciliary body melanomas enlarge, they may find resistance at the iris root, leading to a circumferential growth pattern as to form an intraocular “ring” melanoma. Alternatively, they can erode through and displace the iris root into the anterior chamber.

Choroidal Melanoma

Choroidal melanomas arise posterior to the ciliary body (Fig. 116.1, right). As a choroidal melanoma grows, it typically displaces the overlying retina inwards toward the vitreous humor to form a dome shape.²⁷ High interstitial tumor pressure, leakage, and tumor invasion combine to obliterate, erode, and weaken the overlying tissues. In 25% of cases, the choroidal melanoma breaks through its overlying Bruch’s membrane and mushrooms beneath the retina.²⁷ A rare, alternative growth pattern is “diffuse melanoma.” This tumor is low-lying, more superficial spreading, and causes less uveal thickening.

Extrascleral Extension

Extrascleral tumor extension can occur with any size uveal melanoma (Fig. 116.2). However, it is more common with tumors located in the ciliary body, larger choroidal melanomas, or after sclera weakening by laser thermotherapy. Less common paths of extraocular and orbital extension include through the emissary vortex veins and into the optic nerve.

OPHTHALMIC DIAGNOSIS

Finger’s “MOST” Mnemonic

There is consensus that, when seen together, the most common characteristics of choroidal melanoma are diagnostic. As a choroidal melanoma invades and destroys the overlying retinal pigment

Figure 116.2 Left, minimal extrascleral extension as seen before plaque radiation therapy. Middle, a nodule of moderate extrascleral melanoma seen after enucleation. Right, in this case, massive orbital recurrence is seen 16 months after enucleation surgery. (Reprinted from Finger PT, Tena LB, Semenova E, et al. Extrascleral extension of choroidal melanoma: post-enucleation high-dose-rate interstitial brachytherapy of the orbit. *Brachytherapy*. 2014;13:275–280, with permission from Elsevier.)

epithelium, accumulations of orange pigment (lipofuscin and melanolipofuscin) can be visualized on the surface of a choroidal melanoma (Fig. 116.3, top left). Choroidal melanoma–associated incontinent tumor blood vessels leak serum beneath the retina, seen as overlying retinal pigment epithelial detachments or subretinal fluid. Lastly, choroidal melanomas are typically ≥ 2 mm thick. Therefore, Dr. Finger created the mnemonic MOST where Melanoma = Orange pigment + Subretinal fluid + Thickness of ≥ 2 mm. That said, not all choroidal melanomas will exhibit all three findings. However, MOST is diagnostic when all three are present.

Ophthalmic Examination

The clinical diagnosis of iris, ciliary body, and choroidal melanomas has reached a high degree of accuracy.²² In the modern era, multimodality tumor imaging can be used to clinically diagnose almost all uveal melanomas. Office-based imaging techniques range from photography, intraocular angiography, fundus autofluorescent imaging, optical coherence tomography, transillumination, and ultrasound imaging. Select cases may require orbital radiographic imaging (magnetic resonance imaging [MRI], computed tomography [CT], or positron emission tomography [PET]/CT). Biopsy is rarely required for diagnosis.²²

Ophthalmic Photography and Angiography

Photographic techniques include slit-lamp, gonioscopy for iris and ciliary body tumors, as well as fundus photography for choroidal melanoma. Photography documents the current state of the affected eye, facilitates observations of tumor characteristics, and plays an important role in the diagnosis of tumor growth, posttreatment tumor response, and normal tissue side effects.

Fundus Autofluorescent Imaging

Light (500 to 750 nm, peak 630) is used to induce hyperautofluorescence from orange pigment lipofuscin.²⁸ Thus, fundus autofluorescence can be used to detect and document one of the most important diagnostic characteristics of choroidal melanoma (Fig. 116.3, top right).

Intraocular Angiography

Angiographic photography is used to evaluate tumor microcirculation. Though some choroidal melanomas may demonstrate a pathognomonic choroidal “double circulation” pattern and/or late diffuse microaneurysms, many merely show diffuse or focal hyper-

Figure 116.3 Top left, fundus photograph demonstrates orange pigment lipofuscin deposition (arrows) on the surface of the choroidal melanoma, subretinal fluid extending into the macula, and thickness ≥ 2 mm seen on ultrasound imaging. Top right, fundus autofluorescence imaging reveals orange pigment lipofuscin hyperautofluorescence (arrows). Bottom left, optical coherence tomography reveals exudative subretinal fluid (arrow) from the melanoma. Bottom right, 20 MHz B-scan ultrasound imaging reveals a typical dome-shaped, medium-reflective choroidal melanoma with a secondary exudative retinal detachment (arrow).

fluorescence. However, these findings can be used to distinguish between the hypofluorescence of choroidal hemorrhage, the coarse vascular pattern of choroidal hemangioma, or the plethora of subretinal hyperfluorescent microaneurysms seen with angiography of choroidal metastasis.

Optical Coherence Tomography

Optical coherence tomography is a laser light-based computerized imaging system used to create tomographic slices and three-dimensional volumes of the retina, choroid, and sclera. Tumor associated subretinal and intraretinal fluid are best seen with optical coherence tomography (Fig. 116.3, bottom left).

Ophthalmic Ultrasound Imaging

Ultrasound imaging offers 0.1 mm resolution of intraocular tissues. Ultrasound imaging of choroidal melanoma typically reveals low to moderate internal tumor reflectivity, a dome shape, and/or secondary exudative retinal detachment (Fig. 116.3, bottom right).²⁷ Less common ultrasound-imaged tumor characteristics include a mushroom shape, choroidal excavation, and extrascleral extension, as well as internal vascularity on dynamic examination. Alternative tumor-specific ultrasonographic diagnostic findings of choroidal hemangioma, osteoma, hemorrhage, or metastasis help differentiate these tumors.

High-frequency (20 to 50 MHz) ultrasonography also called ultrasound biomicroscopy (UBM) has allowed almost histopathology quality imaging of iris melanoma capable of viewing extension into the underlying pigment epithelium or adjacent ciliary body.²⁹ Smaller ciliary body melanomas have been detected by ultrasound biomicroscopy, saving both vision and life.

Ultrasound imaging is commonly used to measure the height and basal dimensions of all uveal melanomas.^{27,29} Tumor measurements have been used to detect tumor growth, facilitate radiation therapy (plaque brachytherapy and proton beam), and to monitor posttreatment tumor regression.

Intraocular Tumor Biopsy

Unlike cutaneous melanoma, biopsy of uveal melanoma is controversial. With the exception of transcorneal biopsy of iris melanomas, transvitreal and transscleral biopsy requires a conjunctival and scleral incision. Discohesive tumor cells are liberated within the eye and exit through the sclerostomy into the orbit. Though no one has proved a metastatic risk associated with choroidal melanoma biopsy, known risks include vitreous hemorrhage, retinal tear, retinal detachment, infection, and cataract. Consensus indications for uveal tumor biopsy include atypical tumors, metastatic tumors, when patients require a pathology diagnosis, and for genetic/molecular analysis.³⁰

The recent advent of genetic/molecular analysis of choroidal melanoma, its resultant prognostic information, and evolving systemic treatment protocols have prompted eye cancer specialists to recommend biopsy.³¹ However, the risks of biopsy must be weighed against the accuracy of clinical diagnosis and the lack of an effective treatment for metastatic disease.

UNIVERSAL STAGING AND UVEAL MELANOMA

The American Joint Committee on Cancer–International Union for Cancer Control Ophthalmic Oncology Task Force

The AJCC and The Eye Cancer Foundation sponsored The AJCC Ophthalmic Oncology Task Force with a directive to include

members of the International Union for Cancer Control (UICC).³² Thus the seventh edition AJCC eye cancer staging system was created by 46 eye cancer specialists from 11 countries (France, England, Sweden, Finland, the United States of America, Canada, India, Japan, The Netherlands, Hungary, and Germany).³² These included experienced specialists in medical oncology, pediatric oncology, radiation oncology, medical physics, radiology, ocular plastic surgery, orbit, pathology, and ophthalmic oncology.

As a result, the seventh edition AJCC-UICC staging for uveal melanoma has become widely accepted.^{5,33–35} Most ophthalmic journals now either require or suggest authors use the seventh edition AJCC staging system in manuscript preparation. Adopted by the UICC, world cancer agencies use AJCC staging for uveal melanoma (Table 116.1). Universal staging has allowed us to better categorize and understand medical information.^{34,36,37} The AJCC staging system for uveal melanoma has been validated by a large single-center study and is currently being evaluated within a second large multicenter, retrospective database study (<http://www.eyecancer.com/research/bioinformatics-grid-big>).^{34,38}

MANAGEMENT OF THE PRIMARY UVEAL MELANOMA

The Case for Observation of Small T1 Uveal Melanomas

Eye cancer specialists may observe small choroidal melanomas for evidence of tumor growth prior to treatment. This is because current belief is that “small choroidal melanomas” carry a low risk ($\approx 11\%$) for metastases and that most current treatments risk severe vision loss. In addition, observation of small choroidal melanomas has been justified by the concept that “tumor growth demonstrates malignancy.” In practice, documented tumor growth both reassures the doctor that the tumor is malignant and reassures the patient that treatment is indicated. Specifically, the risk of treatment-related loss of vision is more than offset by a reduction in the probability of metastasis and tumor-induced vision loss.

This is particularly true for patients with small choroidal melanomas close to the fovea, monocular patients, or systemically ill patients. In these cases, serial observation may allow for years of useful vision prior to treatment. For all patients, the case for observation of small melanoma growth has been governed by the potential benefit of vision preservation (in the affected eye).

The Case Against Observation of Small T1 Uveal Melanomas

Once the eye cancer specialist is convinced that a tumor is a malignant (albeit small) choroidal melanoma, treatment becomes the most reasonable choice. In support of this approach, one can cite multiple studies that show increased tumor size (specifically largest tumor diameter) is associated with an increased risk of metastatic death.^{4,38,39} Therefore, it is reasonable to assume that such observations of malignant melanoma growth increase (albeit marginally) a patient’s risk for metastatic disease.

Currently, small choroidal melanoma can be offered effective eye- and vision-sparing treatments.⁴⁰ They typically require particularly small radiation treatment volumes that can be associated with less vision loss. Should radiation retinopathy and optic neuropathy occur, they are treatable with intravitreal anti-VEGF medications.^{6–8,41}

In 2013, researchers at The New York Eye Cancer Center analyzed the results of 72 small melanomas treated with palladium-103 plaque brachytherapy and followed for a mean 54 months.⁴⁰ The authors noted that almost half of the eyes developed radiation maculopathy and almost 20% developed radiation optic neuropathy.

However, since the advent of intravitreal anti-VEGF therapy for radiation retinopathy and optic neuropathy, only 19% or 4 of 21 affected patients lost more than two lines on the visual acuity chart. Clearly, the clinical decision “to treat or not to treat a small choroidal melanoma” is both complex and controversial (<http://www.eyecancer.com/research/article/12>).

Overview: Treatment of Uveal Melanoma

Fewer patients must lose their eye due to choroidal melanoma. This shift has been partly related to the COMS finding that (in treatment of select medium-sized melanomas) plaque radiation therapy was equivalent to enucleation for survival.⁴ This resulted in a shift toward the use of eye and vision-sparing treatments within subspecialty eye cancer centers.⁵

Radiation therapy is presently the most widely used eye-sparing treatment. Methods include brachytherapy plaque techniques and external beam radiation using photons, charged particles, stereotactic radiosurgery, or multisource cobalt units.^{5,35} The techniques with the most widely reported clinical experience are plaque brachytherapy and proton beam. A comparison of clinical outcomes is given in Table 116.2.^{4,37,42–49}

Episcleral Plaque Radiation Therapy

Low energy plaques (iodine-125 [¹²⁵I] or palladium-103 [¹⁰³Pd]) are bowl-shaped devices constructed to house rice-sized radioactive sources (or seeds).³⁵ Ruthenium-106 (¹⁰⁶Ru) plaques are solid disc-shaped electron-emitting sources where the beta-radionuclide is covered by a 0.1 mm thick layer of silver at its episcleral aperture.³⁵

Used with permission of the journal, *Ophthalmology*. The original source for this material is Finger PT, Chin KJ, Duball G, et al. Palladium-103 ophthalmic plaque radiation therapy for choroidal melanoma: 400 treated patients. *Ophthalmology* 2009;116:790–796.

Low-energy plaque construction and dosimetry requires a multi-specialty team that integrates information about each tumor size and location from data derived from clinical examination, photography, and ultrasound imaging.^{35,50} The plaque is temporarily sutured to the sclera overlying the tumor, left in place for 5 to 7 days, and then surgically removed.⁵

Recent research suggests that dose to the fovea and lens can be correlated to the incidence of radiation maculopathy and cataract, respectively.^{51,52} However, each type of plaque has characteristic patterns of dose distribution within the eye. For example, ¹⁰⁶Ru plaques emit electrons with limited intraocular penetration and less side-scatter penumbra (compared to ¹⁰³Pd or ¹²⁵I). Conversely, ¹⁰³Pd and ¹²⁵I offer greater intraocular penetration and more side scatter. All these characteristics must be taken into account when choosing a radionuclide source and plaque size.^{35,50} Lastly, it is important to consider dose to normal ocular structures, because side effects may be predicted based on these measurements.^{20,51–53}

The 2014 American Brachytherapy Society (ABS) guidelines for ophthalmic plaque radiation therapy include potential methods to decrease ocular morbidity and patient mortality.⁵ Specifically, that ophthalmic radiation therapy should be performed in subspecialty eye cancer referral centers, that radiation oncologists and medical physicists follow the American Association of Physicists in Medicine–ABS guidelines for plaque construction, dosimetry, and quality assurance, that preoperative comparative dosimetry of available radiation sources be considered prior to treatment and that centers use the seventh edition AJCC staging system to periodically report clinical outcomes.^{5,33,35,50}

Proton Beam

Proton beam for uveal melanoma is available at 13 institutions around the world. Pioneered at Harvard University, typical treatment involves surgical placement of metallic markers on the episclera around the tumor's base.⁴⁹ Then protons are administered over 4 consecutive days and thus four high-dose-rate treatment fractions to a prescription dose of 60 Gy. Proton therapy has been effective for local tumor control, preservation of the globe, and functional vision (see Table 116.2).

However, in contrast to low-energy plaque therapy, proton beam typically requires an anterior entrance dose resulting in more commonly reported lash loss, dry eye, neovascular glaucoma, and cataract.⁵⁴ Also unlike plaques, proton treatment can be confounded by eye movement leading to a mobile target volume.⁵⁴

Two clinical studies compared plaque versus proton.^{55,56} Both reported that charged particles offered local tumor control and reasonable vision retention compared to plaque brachytherapy. However, anterior segment complications, particularly iris neovascularization, glaucoma, and secondary enucleation, were higher after proton beam therapy.⁵⁷

TREATMENT FOR SPECIAL CASES

Iris and Iridociliary Melanoma

The overall 5-year risk for iris melanoma metastasis is 10.7%.¹⁶ However, small iris melanomas are often observed for growth prior

to treatment. Surgical iridectomy or iridocyclectomy used to be the most common treatment. However, there has been a transition to relatively safe, tissue-sparing radiation therapy techniques.⁵⁸⁻⁶⁰ For example, plaque brachytherapy avoids the uncommon risks of intraocular surgery: infection, hemorrhage, acute cataract, and retinal detachment. Radiation treatment offers iris retention, retained iris function, and relatively large treatment margins. With long-term follow-up, epicorneal ¹⁰⁵Pd plaque brachytherapy has been associated with excellent local control, a high-risk of radiation cataract formation, and almost no risk for radiation-related keratopathy, retinopathy, or optic neuropathy.⁵³

Choroidal Melanomas that Touch or Surround the Optic Disc

Standard plaque placement covers the tumor plus a 2- to 3-mm surrounding margin.^{5,35} However, obtaining standard plaque placement becomes difficult when choroidal melanoma margins are near, touch, or surround the optic disc. Ophthalmoscopy typically reveals a 1.75-mm optic disc diameter, with its edge located 3.4 mm nasal to the fovea. However, just behind the eye, the optic nerve is enveloped by a 5-mm diameter optic nerve sheath.⁶¹ Therefore, with a plaque placed against the retrobulbar optic nerve sheath, it cannot advance closer than 1.5 mm from the intraocular optic disc. When a choroidal melanoma touches or surrounds the optic disc, standard plaque positioning is impossible.

In 2005, 8-mm wide, variable depth slots were cut into standard COMS-type plaques.⁶² This allowed the optic nerve sheath to enter the plaque, thus overcome the optic nerve sheath obstruction. This normalized the plaque's position and thus the treatment volume. The slot, however, presents additional medical physics challenges. The radioactive seeds must be affixed in nonstandard patterns around the slot, to fill in the treatment volume, and provide improved local control.⁶³

Large T3 and T4 Choroidal Melanomas

Large tumor size is not necessarily a contraindication for eye sparing radiation therapy (see Table 116.1). For example, the 2014 ABS Ophthalmic Oncology Task Force Guidelines suggest that contraindications for plaque therapy be related to extraocular extension, basal diameters that exceed the limits of brachytherapy, blind painful eyes, and those with no light perception vision.⁵ With these parameters, enucleation is generally reserved for those rare melanomas >20 mm in diameter, >16 mm thick, suspected optic nerve invasion, with multifocal recurrence, and at the patient's request.^{5,40}

Extrascleral Tumor Extension

Extrascleral extension has been functionally defined as minimal (microscopic or encapsulated), moderate (localized unencapsulated nodule), or massive that fills most or part of the orbit (see Fig. 116.2).⁶⁴ In clinical practice, minimal extension may be included within the irradiated zone; moderate and select massive extrascleral extension can be removed by enucleation with local orbital resection to a point where there is no residual visible tumor. Subsequent external beam radiation therapy (50 Gy) would be employed to treat the presumed residua of subclinical orbital melanoma.⁶⁴

Otherwise unresectable, massive extrascleral extension typically requires orbital exenteration with postoperative radiation therapy. Though postresection radiation typically involves 6 MV photons from a linear accelerator, this treatment is associated with significant loss of hair (eyelash and brow), dry sunken sockets, and poor cosmetic results. High-dose-rate interstitial brachytherapy has been recently reported to improve cosmesis without sacrificing local control.⁶⁴

The Collaborative Ocular Melanoma Study

The COMS was the largest multicenter, prospective randomized clinical trial on treatment of choroidal melanoma. The COMS medium-sized choroidal melanoma trial compared the efficacy of enucleation versus ¹²⁵I plaque radiotherapy for the prevention of metastasis. It consisted of 1,317 patients from 43 centers in the United States and Canada randomly assigned to enucleation or ¹²⁵I plaque brachytherapy. At 12 years, 471 of 1,317 patients had died. The 12-year all-cause mortality rate was 43% in the ¹²⁵I brachytherapy arm and 41% among those enucleated. Thus, the COMS found no statistically significant difference in survival.⁴

The COMS large-sized choroidal melanoma trial enrolled tumors that were ≥ 16 mm in basal dimension or >10 mm in height. In order to determine if enucleation induced metastases, these tumors were randomized to receive 20 Gy (4 Gy in five daily fractions) versus no radiation prior to enucleation. At 12-years follow-up, the COMS found no survival advantage attributable to pre-enucleation radiation, effectively ending this practice.¹³

QUALITY OF LIFE

The COMS group interviewed 209 patients from the medium-sized tumor study.⁶⁵ They found those who had brachytherapy initially noted significantly better visual function than those treated with enucleation. Select parameters included ability to drive and peripheral vision, for up to 2 years following treatment. However, after 3 to 5 years after treatment, those differences diminished along with visual function. In addition, patients treated with plaque brachytherapy experienced more symptoms of anxiety than patients treated by enucleation.⁶⁵

In consideration of the advent and evolution of vision sparing anti-VEGF medication therapy for radiation maculopathy and optic neuropathy, it may be reasonable to assume that current patients are benefiting from more long-lasting functional vision and improved quality of life.^{41,66}

DIAGNOSIS OF UVEAL MELANOMA METASTASIS

History and Physical

Not all eye cancer specialists are located in subspecialty centers. Therefore, each eye cancer specialist (often without medical oncology guidance) typically determines how patients will be initially staged and subsequently screened for metastatic disease. Worldwide patterns are largely dependent on social and economic conditions as well as the availability of radiographic imaging.

That said, when medical oncologists are referred patients with a history of uveal melanoma, the initial TNM (tumor, node, metastasis) staging (seventh edition, AJCC) should be used to help determine their metastatic risk (see Table 116.1).³³ A history of weight loss, subcutaneous nodularity, or abdominal pain should raise suspicion. Signs or symptoms of radicular or focal bone pain suggest possible osseous disease. The choroidal melanoma specific physical examination should focus on subcutaneous nodularity (subcutaneous nodules can be normal or have a dark blue color), focal back pain, hepatomegaly, or ascites.³⁹

Systemic Surveys

Before Treatment

Liver enzymes assays have proved very specific but not sensitive for hepatic metastases.² Thus, the COMS surveillance protocol led

to late discovery of patients with advanced metastatic disease. In contrast, periodic hepatic radiographic imaging typically provides early detection of asymptomatic liver metastases.

At The New York Eye Cancer Center, initial uveal melanoma systemic screening is performed utilizing a physical examination, a hematologic survey, and a total body PET/CT. These PET/CT surveys have revealed that when patients were discovered with metastasis, 100% had hepatic and 75% had multiorgan disease (mostly subcutaneous and osseous).⁶⁷⁻⁶⁹ Almost all had larger T3- or T4-sized tumors. An additional non-tumor-size-dependent finding was that 3.3% had second nonocular primary cancers.^{68,70,71} Further, in evaluation of the primary intraocular melanoma, PET/CT specific uptake values (>4) were associated with metastasis. After treatment, specific uptake value has been used to evaluate uveal melanoma viability.^{72,73}

After Treatment

In consideration of the incidence of metastasis after local treatment, I currently recommend that follow-up staging include abdominal imaging every 6 months for 4 years and then annually for at least 6 additional years (Fig. 116.4).^{2,34,37,74-78} In consideration of both preference and efficacy, abdominal MRI and CT are preferred over ultrasound imaging.

In sum, PET/CT allows for whole body scanning and staging with remarkably high positive predictive values. In addition to staging, PET/CT is used to clarify the nature of suspicious MRI, CT, or ultrasonographic findings. Also consider that, whole body imaging offers patients piece of mind, particularly those at high risk for metastatic disease.

The Incidence of Metastasis

Multiple large and several statistically significant studies have found that largest tumor diameter can be used to predict risk for metastasis.^{4,13,39} In addition, a relatively recent European based multicenter, international study found intraocular melanoma size was predictive for metastatic disease. This study was used as a framework component of the 7th edition AJCC uveal melanoma staging system (see Table 116.1).^{19,33,38} Additional risk factors for metastasis were ciliary body and extrascleral extension.

Management of Patients with Metastatic Disease

Though the liver is the most commonly discovered site of metastatic uveal melanoma spread, most are found to have multifocal hepatic or multiorgan disease. Therefore, when hepatic metastases are suspected or confirmed systemic staging is warranted.³

In cases where metastases are limited to the liver, or when the liver must be treated, local control or palliation of liver metastases can be achieved with a wide range of procedures. The literature contains reports of hepatic artery chemoembolization, hepatic perfusion, or radiofrequency ablation.^{79,80} In these cases, procedure selection is made in consideration of the extent of hepatic disease, the location of the tumors, the patient's performance status, and the institution's interventional capability. Relatively rare cases of solitary, slow-growing hepatic or extrahepatic metastasis, typically found 5 or more years after treatment of their primary uveal melanoma, have been treated by local metastasectomy.⁸⁰⁻⁸²

Figure 116.4 Metastatic death from uveal melanoma. COMS, Diener-West et al.²; Damato, Damato³⁴; Pe'er, Kaiserman et al.⁷⁵; Seregard, Bergman et al.⁷⁶; Kivela, Kujala et al.⁷⁷; Saakyan, Saakyan et al.⁷⁸; Finger, Finger, et al.³⁷; Shields, Shields et al.³⁴ Table courtesy of Ekaterina Semenova, MD. The data used to make these graphs was culled from the published literature.

In that there is no accepted treatment, patients with metastatic uveal melanoma should be treated within clinical trials (<http://www.cancer.gov/clinicaltrials/search/results?protocolsearchid=7978738&vers=1>). In addition, registration of ongoing studies offers the best chance to avoid duplication of nonfunctional studies.³

Clinical Trials for Systemic Metastases

Systemic chemotherapy, cytokine therapy with interleukin-2 and interferon- γ has been ineffective. However, new insights regarding biomarkers, genetic targets expressed by tumor cells, as well as antiangiogenic drugs are leading innovative treatment strategies.⁸³

Genetic tumor typing offers the potential to identify high-risk patients for treatment of presumed subclinical metastatic disease. Conversely, lower-risk patients may not need as rigorous periodic surveillance. Should a functional genetic pathway be identified and a pharmaceutical blockade initiated, metastatic uveal melanoma may become manageable.

BIOMARKERS: PROGNOSTIC AND PREDICTIVE FACTORS

Clinical Prognostic Factors

Tumor Size and Location

Uveal melanoma size or largest tumor dimension has been the most reproducible biomarker for choroidal melanoma metastasis. It is also useful, because tumor measurements are typically available at the time of diagnosis. Utilizing the COMS data, Diener-West et al.³⁹ performed a meta-analysis of 5-year mortality among enucleated patients, providing weighted estimates of 5-year mortality after enucleation: 16% for small tumors, 32% for medium-sized tumors, and 53% for large tumors. This analysis also found older patient age was a significant risk factor for metastasis.³⁹

Iris melanomas tend to be smaller and carry a four to five times lower (10.7%, 5-year) mortality rate than other uveal melanomas. Risk factors for iris melanoma metastasis include tumors >5 mm in largest diameter and/or those were confluent with the ciliary body. In contrast, ciliary body melanomas are typically hidden behind the iris and can develop large "ring melanoma" configurations with a 5-year mortality of 53%. Extrascleral extension (orbital invasion) is also a risk factor for metastasis.⁶⁴

Diffuse Growth Pattern

Choroidal melanomas are typically dome or mushroom shaped, but 5% grow in a diffuse pattern.⁸⁴ These diffuse melanomas are low-lying tumors often with indistinct or irregular margins that are more difficult to treat. Iris melanomas can also occur as the diffuse variant, starting as a solitary tumor then evolving to multifocal lesions after treatment.⁸⁵

Histopathologic, Physiologic, Genetic, and Molecular Prognostic Factors

Tumor-Infiltrating Lymphocytes and Macrophages

Uveal melanomas have been noted to contain lymphocytes, thought to represent an important component of the host's immune response to the tumor. In several studies, both T- and B-lymphocyte infiltration were associated with higher mortality. In addition,

tumor-infiltrating macrophages (CD68+ cells) are an independent prognostic factor with regard to survival.⁸⁶

Genetics and Molecular Biology

Of the cytogenetic and molecular genetic changes within uveal melanoma, it is the partial or complete loss of one chromosome 3 that is most widely described.^{43,87-90} It has not only been associated with aggressive features such as greater tumor size, ciliary body involvement, the presence of epithelioid cells, and closed loop vasculogenic mimicry, but is also considered a biomarker for metastasis.

Gene expression profiling involves the simultaneous measurement of mRNA expression of multiple genes in order to obtain a real-time view of tumor biology. Three gene expression profiling subgroups have been identified and related to risk for metastatic disease.⁹¹

Earlier studies of molecular deregulation provided interesting insights into the molecular pathogenesis of uveal melanoma. For example, Rb protein is expressed in virtually all melanomas, indicating a lack of *Rb* gene mutation.⁹² A combination of microarray gene expression profiling and comparative genomic hybridization showed that gain of chromosome 8q correlates strongly with expression of *DDEF1*, a gene located at 8q24.⁹³ Therefore, *DDEF1* overexpression might be a pathogenetically relevant consequence of chromosome 8q amplification associated with aggression of uveal melanoma.⁹³

Individual gene mutations have improved our understanding of the etiology of uveal melanoma. Mutation of the G-protein α subunits *GNAQ* and *GNA11* are mutually exclusive and represent early or initiating events that constitutively activate the mitogen-activated protein kinase pathway in around 85%. Mutations in *BRCA1*-associated protein-1 (*BAP1*), splicing factor 3B subunit 1 (*SF3B1*), and *EIF1AX* appear to be largely mutually exclusive and appear to occur later in tumor progression. Of interest, while *BAP1* mutations have been strongly associated with metastasis, *SF3B1* and *EIF1AX* mutations are associated with a more favorable outcome. In addition, a study by Lake et al.⁹⁴ suggests that amplification of the *CNKSR3* gene (chromosome 6q) in monosomy 3 uveal melanoma correlates with longer patient survival.⁹¹

BAP1 mutations can arise in the germline, leading to a newly described *BAP1* familial cancer disposition syndrome that includes uveal melanoma and mesothelioma. However, only a small number of familial uveal melanoma cases have been described. These discoveries have led to new clinical trials to assess several classes of compounds, including MEK, protein kinase C, and histone deacetylase inhibitors, based on known signaling pathway changes within uveal melanomas.¹⁷

SUMMARY

Improvements in the understanding of the environmental, clinical, physiologic, cytopathologic, histopathologic, immunopathologic, as well as more recent genetic and molecular characteristics of uveal melanoma lead us to marvel at its complexity. This chapter reviews the demographic, physiologic, treatment-associated, genetic, and molecular factors that allow uveal melanomas to grow and metastasize. It compares and contrasts available methods of diagnosis and treatment. It shows how the community of eye cancer specialists are working together to better define our nomenclature, medical physics, and treatment guidelines. This chapter clearly shows how multidisciplinary eye cancer care is needed to achieve the best possible clinical results for our patients with intraocular melanoma.

117 HIV-Associated Malignancies

Robert Yarchoan, Thomas S. Uldrick, Mark N. Polizzotto, and Richard F. Little

INTRODUCTION

In 1981, the US Centers for Disease Control and Prevention (CDC) reported the first cases of Kaposi sarcoma (KS) and *Pneumocystis jiroveci* pneumonia (PCP) that heralded a pandemic now known as AIDS. AIDS was subsequently found to be caused by a novel retrovirus, HIV. During the initial decade of the epidemic, patients often manifested KS or aggressive B-cell non-Hodgkin lymphoma (NHL). Before effective HIV therapy was developed, these patients had a high mortality. Since 1993, three tumors have been considered AIDS-defining in the context of HIV: KS, certain NHL (Table 117.1), and invasive cervical cancer.¹

With the development first of nucleoside reverse transcriptase inhibitors starting in the mid-1980s² and subsequently of protease inhibitors and nonnucleoside reverse transcriptase inhibitors, combination antiretroviral therapy (cART) involving three or more drugs became broadly available in 1996.³ There are now 30+ antiretroviral agents approved that target one of several stages of the HIV lifecycle.⁴ HIV suppression with cART leads to increases in CD4 lymphocyte counts, improved immune function, decreased immune activation, decreased infectious complications, decreased mortality, and decreased infectivity,⁵⁻¹⁰ transforming HIV infection into a manageable chronic disease.

The availability of cART has also transformed cancer epidemiology in people with HIV. Although AIDS-defining tumors remain the most common cancers, the incidence of KS and NHL decreased after cART became widely available in the United States and other developed countries.¹¹ Additionally, over the past 15+ years, therapy for major AIDS-associated cancers has also improved.¹² At the same time, the number of persons with HIV in the United States has increased by >50% due to an estimated 40,000 to 50,000 new HIV infections each year,^{11,13} and a decrease in infectious deaths. Worldwide, >30 million people are infected with HIV. With HIV-infected individuals living longer, the population at risk for malignant complications has increased and is aging.¹⁴ In addition to AIDS-defining malignancies, patients infected with HIV are at increased risk of certain other cancers, including classical Hodgkin lymphoma (cHL), lung, anal, head and neck, liver, and nonmelanoma skin cancer.¹⁵ Other common cancers such as breast or colon cancer are not more frequent in patients infected with HIV; even so, the burden of these cancers is increasing as the HIV-infected population ages. As such, the cumulative risk of developing *non-AIDS defining malignancies* (NADM) (Table 117.2) is an increasing public health concern.^{7,16-19} Until there are improved HIV prevention strategies^{10,20} or a broadly available HIV cure,²¹ cancer burden will likely continue to increase substantially. Given these epidemiologic trends, oncologists will be called on to manage more cancer in people with HIV.

CANCER AND HIV: INCIDENCE AND ETIOLOGY

Epidemiologic studies have led to important discoveries regarding pathogenesis of HIV-associated tumors. KS in AIDS had a different natural history than the form in elderly men described by Moritz Kaposi in 1872²² and occurred in a specific subpopulation of patients with AIDS: young men who had sex with other men (MSM).^{23,24} MSM without HIV also occasionally developed KS. This suggested that KS had an infectious cause other than HIV itself, and ultimately a novel gamma-herpesvirus, *KS-associated herpes virus* (KSHV) or *human herpes virus* (HHV)-8, was discovered in 1994.²⁵ KSHV is an essential causative agent for all epidemiologic forms of KS. Seroprevalence of KSHV parallels geographic incidence of KS.²⁶ In the United States, KSHV seroprevalence is high in MSM but is <10% in the general population.²⁷

KS epidemiology has evolved with the changing AIDS epidemic. In the United States prior to 1985, KS was the initial manifestation of AIDS in approximately 30% of cases.²⁸ However, after peaking in the early 1990s, its incidence declined in developed countries with the introduction of nucleoside antiretrovirals and then cART. In the United States, the incidence of AIDS-associated KS decreased by 84% in the period 1996 to 2002 compared with 1990 to 1995.²⁹ Further declines since 2002 have been more modest, with incidence relatively stable at about 62 cases per 100,000 person years in recent years.¹¹ It remains the second most common tumor in people with HIV/AIDS in the United States,^{11,18} in regions such as sub-Saharan Africa, where KSHV and HIV infection are each highly prevalent, KS is a substantial public health burden.^{30,31} In parts of sub-Saharan Africa, KS has been reported to be the most common tumor in men, representing almost half of all cancers, and also the second most frequent tumor in women.³¹⁻³³ Increasing access to cART via programs such as the Joint United Nations Programme on HIV/AIDS and the US President's Emergency Plan for AIDS Relief appears to be decreasing KS incidence in parts of sub-Saharan Africa,³⁴ but the extent of this change remains to be defined.

Excess cases of NHL were also noted early in the AIDS epidemic, and certain NHLs were included in the 1985 AIDS case definition.³⁵ In the CDC 1993 definition of AIDS, three NHLs were considered AIDS-defining: Burkitt (or equivalent), immunoblastic (or equivalent), or primary brain.¹ This terminology is now dated; however, several lymphomas remain strongly associated with HIV. In this chapter, we use the term AIDS-related lymphoma (ARL) when referring to epidemiologic data that does not segregate the various lymphoid tumors (see Table 117.1).³⁶ However, ARL is no longer a clinically useful term, and lymphomas should be classified using current World Health Organization criteria.³⁶ For AIDS-defining lymphomas, risk in patients infected with HIV in the pre-cART era was more than 250-fold greater than the general population. Most lymphomas that occur in patients

TABLE 117.1

HIV-Associated Lymphomas^a

Lymphomas also occurring in immunocompetent patients
Burkitt lymphoma
Diffuse large B-cell lymphoma
Germinal center subtype
Activated B-cell subtype
Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue type (rare, mainly in pediatric patients)
Classic Hodgkin lymphoma (commonly mixed cellularity or lymphocyte depleted forms) ^b
Lymphomas occurring more specifically in HIV-positive patients
Primary effusion lymphoma
Large B-cell lymphoma arising in human herpes virus-8 associated multicentric Castleman disease
Plasmablastic lymphoma
Primary diffuse large B-cell lymphoma of the central nervous system (in patients with AIDS, >95% Epstein-Barr virus associated)
Lymphomas also occurring in other immunodeficiency states
Polymorphic B-cell lymphoma (post-transplant lymphoproliferative disorder-like)

^a Adapted from the most current lymphoma nomenclature from (The 2008 World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues³⁶).

The Centers for Disease Control and Prevention definition of AIDS-defining lymphoma in 1993 as Burkitt (or equivalent term), immunoblastic (or equivalent term), and primary brain lymphoma is based on older terminology.

^b In this chapter, as in general usage, Hodgkin lymphoma will be considered as a separate entity and will not be encompassed in the term *AIDS-related lymphoma*.

infected with HIV are high-grade mature B-cell lymphomas,³⁷ including diffuse large B-cell lymphoma (DLBCL) with either centroblastic (germinal center [GC]) or immunoblastic (activated B-cell [ABC]) phenotypes,³⁸ Burkitt lymphoma (BL), plasmablastic lymphoma (PBL), primary diffuse large B-cell lymphoma of the central nervous system (PCNSL), and primary effusion lymphoma (PEL). By contrast, these histologies make up 25% of NHL in the general population.³⁹ ARL risk increases with the degree and duration of immunosuppression, and is inversely related to CD4 count.⁴⁰ Inflammation⁴¹⁻⁴⁴ and uncontrolled HIV viremia⁴⁵⁻⁴⁸ also contribute to lymphoma risk. Since the advent of cART, NHL incidence has decreased by 50%.⁴⁹ Overall, populations on cART have improved immune status and CD4 counts at levels where lymphoma standardized risk ratio is lower. Still, within any CD4 cell strata, the standardized risk ratio for lymphoma remains elevated in individuals infected with HIV and comparable between pre-cART and early cART eras.⁴⁹ Indeed, changes in NHL incidence partially reflect changes in the proportion living with a certain CD4+ cell level. Despite a decrease in incidence, with an estimated incidence of 97 per 100,000 person-years in the cART era, NHL is the commonest malignancy in individuals infected with HIV in the United States.¹⁸ ARL is an increasing public health problem in areas of sub-Saharan African with high HIV prevalence.^{50,51}

With cART, epidemiologic and clinical patterns of ARL have changed. In the United States, ARL survival has increased since introduction of cART by nearly two-fold,^{12,29,52} due in part to the effect of cART on AIDS and its infectious complications, as well as a shift away from poor-prognosis histologies that tend occur with advanced AIDS.⁵³ This is most remarkable for PCNSL, which generally occurs in patients with <50 CD4 cells/mm³, and whose incidence has fallen 80%.²⁹ For systemic ARL, immunoblastic subtypes predominated in the pre-cART era, but the predominant subtypes emerging in areas where cART is widely available are those with the GC phenotype of DLBCL and BL,^{49,54-56} which are

TABLE 117.2

Risks of Various Malignant Conditions in Patients with AIDS^a

Tumor	Standard Incidence Ratio		
	Pre-cART (1980–1989)	cART (1996–2002)	
AIDS-Defining	Kaposi sarcoma	52,900	3,640
	Non-Hodgkin lymphoma	79.8	49.5
	Burkitt lymphoma	57.4	49.5
	DLBCL	98.1	29.6
	Immunoblastic	140.5	59.5
	Primary diffuse large B-cell lymphoma of the CNS	5,000	1,020
	Cervix	7.7	5.3
Non-AIDS-Defining	Hodgkin lymphoma	7.0	13.6
	Oral cavity and pharynx	1.2 (NS)	2.1
	Anus	18.3	19.6
	Lung	2.5	2.6
	Vagina and vulva	0 (NS)	4.4 (NS)
	Seminoma	2.6	0.8 (NS)
	Penis	0 (NS)	8.0
	Renal cell carcinoma	0.8 (NS)	1.9
	Liver	2.4 (NS)	3.3
	Myeloma	2.7 (NS)	2.2
	Breast	0	0.8 (NS)
	Colon	0.9 (NS)	1.0 (NS)
	Prostate	0.9 (NS)	0.5

cART, combination antiretroviral therapy; DLBCL, diffuse large B-cell lymphoma; CNS, central nervous system; NS, not significant.

^a Identification of cancers in people with AIDS based on matches to the cancer registries in patients grouped according to AIDS onset as either prior to development of combination antiretroviral therapy (1980–1989) or following cART (1996–2002). Cancer risk was described using the standardized incidence ratio, which compares incidence to that in the general population. All standardized incidence ratios in table are significant ($p < 0.05$) unless noted.

From Engels EA, Pfeiffer RM, Goedert JJ, et al. Trends in cancer risk among people with AIDS in the United States 1980–2002. *AIDS* 2006;20:1645–1654, with permission.

associated with longer survival.⁵⁷ Lymphoma therapeutic advances also contribute to improved survival. With current regimens, prognosis for the most common HIV-associated lymphomas approach that of the general population. This is particularly apparent for the GC phenotype of DLBCL⁵⁵ and BL.⁵² Outcomes in PCNSL remain poor,^{53,58} in part due to difficulty in diagnosis, neurologic comorbidities, lack of standardized therapy, and delayed or inadequate treatment of lymphoma.⁵⁹

While the incidence of ARL and KS has decreased, the incidence of certain NADMs has increased. Where cART is widely available, NADMs now occur as frequently as AIDS-defining malignancies.^{19,60} Furthermore, cancer has emerged as the leading cause of death in people with HIV,^{7,58,60–62} with about half of cancer-associated deaths caused by AIDS-defining malignancies and half by NADM.^{7,63} Excess risk of certain NADMs is partly attributable to patients infected with HIV having increased infection with, and in some cases, poor immunologic control of oncogenic pathogens, such as *human papillomavirus* (HPV), *Epstein-Barr virus* (EBV), *hepatitis B virus* (HBV), and *hepatitis C virus*. It is possible that additional infectious agents will be discovered and

found responsible for some of these tumors. For example, a novel virus, *Merkel cell polyomavirus*, was recently identified as the etiologic agent for Merkel cell carcinoma,⁶⁴ a rare skin cancer that occurs with increased frequency in immunosuppressed individuals, including those with HIV.⁶⁵ Other risk factors for certain of these tumors are more common in patients with HIV, including cigarette smoking and alcohol use. For many of these tumors, there is evidence that HIV also plays a pathogenic role, although the mechanisms may be complex or indirect. For example, a nearly five-fold excessive lung cancer risk in HIV appears related to age and cART use, but not CD4 cell count, and the risk remains approximately two-fold greater than that of the general population even when adjusted for smoking.^{66,67} A contributing factor increasing the risk of lung cancer in people with HIV may be recurrent lung infections.^{67,68}

KAPOSI SARCOMA

Pathophysiology

KS is a multifocal angioproliferative tumor caused by KSHV. Its characteristic purplish lesions are found histologically to have proliferating spindle cells with markers of lymphatic endothelial cells, leaky vascular slits, and an inflammatory infiltrate.^{69–71} KS spindle cells are generally considered polyclonal or oligoclonal, although advanced lesions may have elements of monoclonality.^{72,73} The lesions are most commonly cutaneous, but may involve internal organs including the lungs, lymphatic system, and gastrointestinal tract (Fig. 117.1).

KSHV is a necessary cause of KS. In the absence of cofactors such as HIV or iatrogenic immunosuppression, the risk of KS among individuals infected with KSHV is relatively low. KS was initially categorized based on epidemiologic characteristics. As first described by Moritz Kaposi in 1872,²² KS was an indolent tumor usually seen in elderly Mediterranean men (now called *classical* KS). KS also exists in parts of Africa, where KSHV seroprevalence is 40% to 80% (*endemic* KS, seen in men, women, and occasionally young patients), in immunosuppressed populations (i.e., transplant recipients [*iatrogenic* KS]), and persons with HIV (*epidemic* KS). Clinical behavior varies between epidemiologic subtypes and

may be related to etiology of underlying immunodeficiency and presence of other KSHV-associated diseases.

Hyperproliferation of KSHV-infected spindle cells is the hallmark of KS.^{74–76} KSHV modifies host cellular pathways by multiple mechanisms, in part through expression of KSHV-encoded mimics of human genes, viral microRNA, and activation of cellular genes.⁷⁷ Through these mechanisms, KSHV activates prosurvival and proangiogenic pathways. In particular, a KSHV-encoded G-protein-coupled receptor (vGPCR, also known as ORF74) induces production of vascular endothelial growth factor (VEGF) and other angiogenic factors.^{75,78–80} Other important viral proteins include homologues of a macrophage inhibitory protein with angiogenic activity^{74,81} and a viral interleukin (IL)-6 (vIL-6) with inflammatory and prosurvival effects. KSHV also induces c-Kit and endothelial-to-mesenchymal transformation.^{82,83} These and overproduction of human cytokines and growth factors such as VEGF and platelet derived growth factor by KSHV-infected cells contribute to spindle cell proliferation and angiogenesis.

The marked elevation in KS in immunosuppressed individuals suggests an important role for defective immune surveillance of KSHV in risk of KS pathogenesis.^{84,85} Decreasing CD4 cell count is associated with increasing risk of KS in both AIDS-associated and classic KS.^{86,87} In patients with controlled HIV, KS is associated with a T-cell immunosenescence phenotype marked by increased CD57+ and decreased CD28+ T cells.⁸⁸ Patients with KS have decreased KSHV-specific CD4 responses compared to HIV/KSHV co-infected individuals without KS.⁸⁵ KS response to immune modulation is associated with increases in absolute CD4 count and/or KSHV-specific T-cell responses in patients infected with HIV on cART and organ transplant recipients after reduction in immunosuppression.^{89–91} HIV may promote KS by other mechanisms as well. For example, the Tat protein of HIV can enhance infection of target cells by KSHV.⁹²

Staging and Prognosis

KS is a multifocal tumor without evidence of clonal expansion and dissemination. KS can arise simultaneously at multiple sites (see Fig. 117.1) but should not be described as metastatic. Standard oncologic staging and response criteria are not applicable. The most widely used staging system for KS is the AIDS Clinical Trials

Figure 117.1 (A–B) Mucocutaneous manifestations of AIDS-Kaposi sarcoma observed in the era of combination antiretroviral therapy.

TABLE 117.3

Revised and Proposed AIDS Clinical Trials Group Staging Classification for Kaposi Sarcoma^a

Stage	Good Risk (0) (All of the Following)	Poor Risk (1) (Any of the Following)
Tumor (T)	Confined to skin and/or lymph nodes and/or nonnodular oral disease confined to the palate	Tumor-associated edema or ulceration Extensive oral KS Gastrointestinal KS KS in other nonnodal viscera
Immune system (I) (not included if HIV-sensitive to cART ⁴⁹)	CD4 cells <150/mm ³	CD4 cells <150/mm ³
Systemic illness (S)	No history of opportunistic infection or thrush No B symptoms (unexplained fever, night sweats, >10% involuntary weight loss, or diarrhea) persisting more than 2 weeks Other HIV-related illness (e.g., neurologic disease, lymphoma)	History of opportunistic infections and/or thrush; "B" symptoms present Performance status <70 Performance status <70 (Karnofsky)

KS, Kaposi sarcoma; cART, combination antiretroviral therapy.

^aBased on Krown et al.⁹³ and Nasti et al.⁹⁴ The revised CD4 cutoff of 150 cells/mm³⁹³ is lower than the original proposal of 200 cells/mm³. However, in the cART era, CD4 cells do not appear to confer prognostic information. Example of staging: in the pre-cART era, a patient with KS restricted to the skin, CD4 count of 10 cells/mm³, and a history of *Pneumocystis jirovecii* pneumonia would be T₀I₁S₁, and would be considered poor risk.³⁰ Suggested revision since cART would be staged as T₀S₁, and would be considered good risk.⁹⁴

Group Oncology Committee TIS staging system^{93,94} (Table 117.3). Risk stratification is based on tumor burden (T_{0 or 1}), immune status (I_{0 or 1}), and presence of any systemic illness (S_{0 or 1}). For each category, poor risk (subscript 1) is defined respectively by the presence or extensive cutaneous or oral disease, tumor-associated edema, ulceration, or visceral disease (T₁); CD4 <150 cells/mm³ (I₁); and the presence of other opportunistic infections, constitutional symptoms, or poor performance status (S₁). Before cART, poor risk in one or more categories was considered poor risk. In the cART era, a baseline CD4 cutoff of 150 cells/mm³ is not as important prognostically,⁹⁵ and two main risk categories have been defined: good risk (T₀S₀, T₁S₀, or T₀S₁) and poor risk (T₁S₁). Notably, pulmonary involvement carries a particularly elevated risk of death.⁹⁶ Also, women who develop HIV-associated KS have a worse prognosis independent of other TIS risk factors.^{95,97,98}

In assessing KS response to therapy, most clinical trials use some modification of criteria established by the AIDS Clinical Trials Group Oncology Committee.⁹⁹ Criteria for a partial response include 50% decrease in the total number of prespecified indicator lesions, 50% decrease in the area of measured cutaneous lesions, or flattening of 50% of nodular indicator lesions in the absence of progressive disease. Complete response requires resolution of all measurable disease, although residual skin hyperpigmentation is common. Outside of the research setting, KS is commonly treated to a symptomatic endpoint or response plateau.

Treatment

Treatment with cART is fundamental to therapy of HIV-associated KS, and generally should be the first therapeutic maneuver. Drugs associated with iatrogenic KS, such as steroids, cyclosporine, and rituximab, should be avoided or minimized.^{100,101} KS-specific therapy is reserved for select cases, in particular patients with advanced (T₁) KS who generally will not have adequate and timely responses to cART alone or patients who have some other need for a rapid response. In patients with pulmonary KS, chemotherapy may be required urgently. Also, specific KS therapy is used in patients with KS unrelated to HIV that requires therapy, or transplant patients that do not respond to changes in the immunosuppressive regimen.

Regression of KS with cART alone has been documented in up to 80% of cART-naïve patients with early disease (T₀).^{95,102,103} Control of HIV viremia and immune reconstitution are key

determinants of the anti-KS effect of cART. Some laboratory studies have suggested that HIV protease inhibitors may have specific KS activity,¹⁰⁴ but clinical trials have generally not shown any such benefit of protease inhibitor-based cART in preventing or treating KS.^{103,105,106} The time to partial response or better with cART alone is commonly 6 to 12 months, and many responses are incomplete. In a randomized trial in South Africa of cART versus cART with early chemotherapy in treatment-naïve patients with largely T₁ disease, the group randomized to chemotherapy showed a significantly higher KS response at 12 months (39% versus 66%), supporting a role for KS-specific therapy in patients with KS-associated morbidity. Overall, however, survival was similar in both arms.⁹⁵ Patients infected with HIV occasionally demonstrate new KS or KS progression soon after cART initiation. It has been suggested that an immune reconstitution inflammatory syndrome may be contributing to the KS progression.^{107,108} However, the pathogenesis of worsening or initial development of KS in the setting of initiation of cART remains unclear. Such patients should be considered for additional anti-KS therapy.

Localized therapies are generally of limited utility in KS and can be associated with troublesome toxicity. However, for patients with symptomatic disease in a highly restricted area, a number of approaches have activity. While a biopsy is needed to confirm the diagnosis of KS, surgical resection is otherwise rarely indicated. Also, clear surgical margins do not suggest cure and KS can even develop in the site of a surgical scar.¹⁰⁹ Topical 9-*cis*-retinoic acid (Panretin gel; Eisai Inc., Woodcliff Lake, NJ) is approved by the US Food and Drug Administration (FDA) for use in KS. While response in up to 45% of treated lesions are reported, local inflammation is common and the cosmetic result may also be inadequate.¹¹⁰⁻¹¹² Intralesional injection or iontophoresis of low-dose vinblastine (0.1 mL of 0.1 mg/mL) or 3% sodium tetradecyl sulfate injection (0.1 to 0.3 mL), as well as laser therapy and cryotherapy¹¹³ have also been described. Again, these local therapies can be painful, cosmetic results may be unsatisfactory, and disease progression outside of treatment site is common. Radiation therapy is effective, though progression outside the treated area is common. Local toxicities can include radiation dermatitis or ulceration. Over the longer term, induration and fibrosis may develop. For these reasons, it is generally reserved for disease that is quite limited, yet causing severe pain or distress. Dosing is individualized, ranging from an 8 Gy single dose to fractionated therapy to a total of 16 to 30 Gy.

Indications for systemic therapy in HIV-associated KS are imprecise and should be individualized. Strong indications include KS that is life threatening, symptomatic visceral or substantial pulmonary disease, and cutaneous disease that is extensive, ulcerating, or associated with edema or pain. In such cases, it should be initiated as soon as possible. Systemic therapy is also justified in more limited disease where response to cART alone is unlikely to be sufficient or timely from a symptomatic perspective, or where worsening KS would not be tolerated. It may also be justified when KS impairs quality of life due to social withdrawal or psychological distress. Although complete and long-lasting resolution of evident disease can be realized, this outcome does not imply cure. Treatment is aimed at decreasing tumor burden and symptom palliation, which may require chronic intermittent administration.

Several cytotoxic agents have activity in KS. The most commonly used agents are liposomal doxorubicin and paclitaxel. Liposomal doxorubicin is approved by the FDA for KS and has become the standard-of-care first-line chemotherapy, generally at the dose of 20 mg/m² every 3 weeks.¹⁰² In the cART era, response rates of 45% to 80% may be anticipated.^{114,115} Liposomal daunorubicin is also approved for advanced KS, though less commonly used. An important consideration with anthracyclines is the risk of cumulative cardiotoxicity; the FDA warns against cumulative lifetime doses exceeding 550 mg/m². While the risk appears to be lower with liposomal formulations than with bolus nonliposomal anthracyclines, this dose should not be exceeded without cardiac monitoring and individualized risk-benefit analysis. Paclitaxel is approved by the FDA as second-line therapy for KS, with responses ranging from 59% to 71% demonstrated in phase 2 trials conducted prior to the use of cART.^{116,117} A randomized trial comparing liposomal doxorubicin 20 mg/m² every 3 weeks with paclitaxel 100 mg/m² every 2 weeks in subjects with advanced KS showed comparable efficacy, but increased hematologic and neurologic toxicity in the paclitaxel arm.¹¹⁵ Symptomatic progression after ceasing therapy was common, and overall progression-free survival at 12 months was approximately 70%.¹¹⁵

Other agents with demonstrated KS activity include vincristine, vinblastine, doxorubicin, etoposide, and bleomycin. Oral etoposide 50 mg/day on days 1 through 7 of a 14-day cycle is active, with an overall response rate of 36% in previously treated patients, the majority of whom were not receiving cART.¹¹⁸ This approach may be useful in resource-limited settings, although the risk of secondary myeloid leukemia raises concerns with long-term administration. Early in the AIDS epidemic, high response rates were obtained with combination regimens of doxorubicin, bleomycin, and vinblastine or vincristine, although toxicity was often substantial.¹¹⁹ This regimen has been largely replaced by liposomal doxorubicin, which was shown in a randomized trial to be more effective and less toxic.¹²⁰

A further systemic option is interferon (IFN)- α , a cytokine with immune modulatory and antiangiogenic activity. In HIV-associated KS, it is most active in patients with limited disease and preserved CD4 counts.^{121,122} Unfortunately, systemic side effects limit tolerability for many patients. Constitutional symptoms, cytopenias, mood disturbances including major depression, and hypothyroidism are common and may be severe. Most practitioners begin with IFN- α 1 to 5 \times 10⁶ units subcutaneous injection daily and gradually increase the dose as tolerated. IFN- α should be used in combination with cART in HIV-associated KS.¹²³

A general strategy is to treat patients with KS until a response plateau or remission is attained. The number of cycles of chemotherapy required is variable. Patients with good immune reconstitution on cART are more likely to be able to stop chemotherapy after an early response, with maintained or even improved KS response with cART continuation. However, some patients require ongoing or periodic antitumor therapy in addition to cART. In cases of advanced immune suppression or uncontrolled HIV, KS may progress shortly after discontinuing therapy, and close observation is required. Growth of KS after therapy with a given chemotherapy

does not necessarily imply tumor resistance, and a previously effective agent can often be used again.

There is a substantial unmet clinical need for novel, less toxic agents for KS. Established therapies have important limitations. In particular, there are few effective oral agents, and the most useful cytotoxic agents often are associated with neutropenia. The risk of cumulative anthracycline cardiotoxicity can limit use of liposomal anthracyclines, making them less favorable in heavily pretreated patients and patients with coexisting cardiovascular disease. Also, delivery of the most effective agents within existing health infrastructure is impracticable and/or unaffordable in resource-limited settings. Development of effective oral anti-KS agents could assist in addressing this significant global health problem.^{30,124}

Oral agents that interfere with KSHV replication have been shown to prevent KS in patients with AIDS; a randomized clinical trial of ganciclovir for *cytomegalovirus* infections showed systemic administration was associated with a lower rate of KS development.¹²⁵ However, the risk/benefit ratio of antihertic agents in preventing KS has not been evaluated and may be unfavorable. Furthermore, targeting KSHV replication with antiviral drugs has shown little utility in treating established KS. Ganciclovir and cidofovir have been evaluated in small studies, but not found to have meaningful activity in either classic or HIV-associated KS.^{126,127}

Given the angiogenic nature of KS and its sensitivity to changes in immune status, both immune-modulating and antiangiogenic therapies have been explored in clinical trials. The cytokine IL-12 showed promising results alone and in combination with chemotherapy.^{128,129} Thalidomide, an oral agent with immune modulatory and antiangiogenic effects, has shown activity in two phase 2 studies, though its use is limited by toxicity.^{130,131} Studies are under way of thalidomide analogs. Targeted inhibition of angiogenesis with the monoclonal antibody to VEGF, bevacizumab,¹³² and imatinib,¹³³ an inhibitor of c-kit and the platelet-derived growth factor receptor, have shown activity in phase 2 studies. Interestingly, in renal transplant-associated KS, modification of immunosuppression from cyclosporine to the mammalian target of rapamycin inhibitor sirolimus leads to tumor regression.¹³⁴ However, in a study of sirolimus in HIV-associated KS, responses were limited and drug interactions with the antiretroviral drug ritonavir complicated dosing.¹³⁵ Ongoing clinical studies will help define the role of additional novel agents in KS.

Kaposi Sarcoma Herpes Virus–Associated Multicentric Castlemann Disease

The term Castlemann disease is used to describe a group of related lymphoproliferative disorders. There are several forms of idiopathic Castlemann disease that can be classified either anatomically (unicentric or multicentric) or by morphology (hyaline-vascular, plasma cell, or mixed histology). With the discovery of KSHV, it was recognized that this virus causes a plasmablastic variant of multicentric Castlemann disease (MCD).¹³⁶ Nearly all Castlemann disease arising in the setting of HIV infection is KSHV-associated MCD (KSHV-MCD). This polyclonal¹³⁷ hyperproliferative B-cell disorder is considered rare, although its incidence is not well defined. Unlike KS, KSHV-MCD may be more common since the advent of cART.¹³⁸

KSHV-MCD is characterized by intermittent flares of inflammatory symptoms, including fevers, fatigue, cachexia, and edema, together with lymphadenopathy and splenomegaly. Gastrointestinal and respiratory symptoms are common, and rheumatologic, neurologic, and dermatologic manifestations may also be present. Laboratory abnormalities include anemia, thrombocytopenia, hypoalbuminemia, hyponatremia, and elevated C-reactive protein.^{139,140} The clinical course may wax and wane, but untreated, it is frequently fatal, with patients succumbing to inflammatory manifestations or progressing to large cell lymphoma.¹⁴¹

The symptoms of KSHV-MCD, while potentially severe, are nonspecific. KSHV-MCD should be considered in the differential diagnosis of patients with HIV and unexplained lymphadenopathy, splenomegaly, and/or inflammatory symptoms or autoimmune phenomena, particularly anemia or thrombocytopenia. Diagnosis generally requires excisional lymph node biopsy and demonstration of KSHV-infected plasmablasts. There is no validated staging or prognostic system, although definitions of symptomatic disease¹⁴² and National Cancer Institute (NCI) response criteria have been defined for clinical studies.¹³⁹ These criteria rely on evaluation of clinical signs and common laboratory abnormalities. Symptomatic KSHV-MCD is associated with an elevated circulating KSHV viral load and associated cytokine dysregulation. In particular, viral IL-6 production and induction of human IL-6 and IL-10 are implicated as pathogenic factors.^{92,140,141} KSHV viral load decreases with effective therapy.^{139,140}

There is no standard therapy for KSHV-MCD. However, based on an appreciation of the viral etiology and pathogenic mechanisms of KSHV-MCD, new therapeutic modalities are being developed that can control disease activity,^{101,139,142} improve overall survival,¹⁴³ and may reduce the risk of KSHV-associated lymphoma.¹⁴⁴ Best studied is the anti-CD20 monoclonal antibody rituximab.^{101,142} Most patients respond initially to rituximab-containing regimens. However, rituximab monotherapy may be insufficient in advanced disease, and it has been associated with exacerbation of concurrent KS. Approximately 30% of patients will relapse within 1 year.^{101,142} Rituximab combined with liposomal doxorubicin (in part to control KS) appears promising in preliminary reports.¹⁴⁵ Zidovudine and ganciclovir are activated to toxic moieties by KSHV-encoded enzymes; based on this observation, high-dose zidovudine combined with ganciclovir has been tested and found to be active, although not as effective as rituximab in patients with severe inflammatory symptoms.¹³⁹ Historically, chemotherapy regimens used in NHL¹⁴¹ and/or splenectomy^{141,146} have sometimes been used; however, recent studies suggest these can often be replaced by targeted approaches, sparing patients unnecessary toxicities and long-term infectious risks associated with splenectomy.¹⁴⁷ Patients infected with HIV should receive cART, although intolerance to a number of drugs, including antiretrovirals, may occur until MCD is controlled. Given the many uncertainties in managing patients with KSHV-MCD, including length of treatment, role of maintenance therapy, and evaluation and management of concurrent malignancies, consideration should be given to referral to a clinical trial.

Inflammatory symptoms similar to those in KSHV-MCD have been described in patients infected with KSHV without pathologic evidence of KSHV-MCD.¹⁴⁸ These patients presented with a constellation of fevers, cachexia, and laboratory abnormalities including cytopenias, hypoalbuminemia, and elevated C-reactive protein. Patients had elevated KSHV viral loads and disturbances of vIL-6 and human IL-6 and IL-10 similar to those seen in KSHV-MCD. However, splenomegaly, and lymphadenopathy were not prominent, and pathologic evidence of KSHV-MCD was not demonstrable. This syndrome has been provisionally named KSHV inflammatory cytokine syndrome, and a working case definition has been proposed.¹⁴⁹ KSHV inflammatory cytokine syndrome may accompany KSHV-associated tumors (KS or PEL) or occur in their absence. Its pathophysiology, clinical outcomes, and relationship to KSHV-MCD are being evaluated.

LYMPHOID TUMORS IN PATIENTS WITH HIV

Overview

Lymphoid tumors (see Table 117.1) in individuals infected with HIV represent a range of histologies and include lymphomas seen in immunocompetent patients as well as lymphomas more

specifically associated with HIV infection. Risk for individual tumors vary based on the underlying HIV disease status, while outcomes are largely defined by the natural history of a specific tumor as well as choice of an appropriate therapeutic approach for a given tumor. The most common tumors, DLBCL, BL, and cHL, generally occur among patients infected with HIV with relatively preserved immune function. Treatment options for these tumors are informed by clinical studies, and they are highly curable, highlighting the importance of accurate diagnosis of HIV disease status. Less common tumors include PCNSL, systemic DLBCL with immunoblastic phenotype, plasmablastic lymphoma, PEL, and KSHV-MCD (previously discussed with KS). These tumors continue to represent a clinical challenge due to lack of prospective clinical studies, but should also generally be approached with curative intent.

Prior to the cART era, prognosis for patients with HIV with lymphoid tumors was determined primarily by CD4 cell count.¹⁵⁰ Systemic ARLs were often treated as a single disease entity, often with reduced dose chemotherapy regimens, and outcomes were generally poor. However, clinical trials performed in the cART era demonstrate that standard-dose chemotherapy regimens can be administered and improve survival. While baseline CD4 cell count remains important prognostically, lymphoma-specific features^{49,52,55,151} and treatment related factors are now critical, especially in patients with CD4 cell counts $>100/\text{mm}^3$.

Clinical decision making must be based both on lymphoma classification and assessment of the immune status and possible AIDS-related comorbidities. The clinical status of patients with HIV infection ranges from healthy with preserved immunity to immunosuppressed with multiple comorbidities. An individualized clinical approach must take this potential spectrum into account. For healthier patients, treatment is similar to the HIV-unrelated counterpart. However, patients with advanced AIDS may not tolerate therapy as well, and close coordination of chemotherapy with HIV management and supportive care is critical. Importantly, poor performance status is often due to the underlying malignancy or treatable opportunistic infections, and even patients with poor performance status should be considered for full-dose curative therapies in most instances. With a shift in demographics of HIV infection to communities with less access to medical care, patients continue to present with lymphoma as the initial manifestation of HIV. These cART-naïve patients usually have HIV that can be rapidly suppressed, and with effective lymphoma treatment and access to cART, they generally have favorable long-term survival. Effective cancer therapy in these patients is therefore essential.

Pathophysiology

HIV-related lymphomagenesis depends on numerous factors, including the degree of immune suppression (discussed with each specific tumor type) and cumulative time with uncontrolled HIV viremia.⁴⁷ The pathogenesis is related to B-cell immune activation. Elevated serum cytokines including IL-6, IL-10,^{42,152} and tumor necrosis factor- β , as well as the activation marker, soluble CD30,¹⁵³ are detectable prior to ARL diagnosis. Several genetic polymorphisms related to B-cell activation are also associated with ARL risk, including the 3'A variant of stromal cell-derived factor 1¹⁵⁴ and -592C/C IL-10 promoter.⁴² The HIV coreceptor CCR5 deletion variant CCR5- $\Delta 32$ also confers protection against NHL, independent of its HIV protective effect.¹⁵⁵ In the setting of HIV, B-cell activation in EBV-infected cells may be increased in part due to expression of a virally encoded CD40-like latent membrane protein.¹⁵⁶ Activation also occurs also in EBV-uninfected B-cells through other inflammatory stimuli^{44,48} and perhaps direct interactions with HIV itself.^{157,158}

Regardless of the nature of immune activation, translocations and aberrant somatic hypermutation are common features of many ARL,¹⁵⁹ including DLBCL and BL. For most ARL, B-cell

activation leads to upregulation of activation-induced cytidine deaminase,¹⁶⁰ an enzyme required for GC class switch recombination and somatic hypermutation. However, activation-induced cytidine deaminase also can induce mutations and pathogenic translocations,¹⁶¹ which is a critical step in lymphomagenesis. Translocation of *c-myc/Ig* are seen in not only in BL, but are also present in DLBCL in patients infected with HIV at a higher frequency than observed in HIV-uninfected cases,¹⁶² and a majority of EBV+ plasmablastic lymphomas.¹⁶³

Clinical Presentation, Staging, and Approach to Treatment

Lymphoid malignancy can be the initial presenting illness in HIV,^{164,165} and HIV testing should be performed in patients with aggressive B-cell lymphomas or cHL. ARL frequently presents with either a rapidly growing mass or “B” symptoms (fever, night sweats, or weight loss in excess of 10% of the normal body weight). Extranodal involvement of bone marrow, gastrointestinal tract, and central nervous system (CNS) is common.³⁷ Staging should include computed tomography of neck, chest, abdomen, and pelvis; fluorodeoxyglucose (¹⁸FDG)-positron emission tomography (PET); lactate dehydrogenase; complete blood count with differential; bone marrow biopsy; and lumbar puncture with evaluation of cerebral spinal fluid (CSF) by cytology and flow cytometry. Evaluation of cardiac function is recommended. CNS imaging, generally with magnetic resonance imaging (MRI) with gadolinium, should be performed to evaluate for CNS involvement in patients with NHL, particularly BL. CNS imaging is not standard for cHL or KSHV-MCD, although in rare cases, cHL in patients with HIV can involve the CNS. Baseline HIV viral load, CD4 count, HBV core antibody and surface antigen, and hepatitis C virus serology should be evaluated. Patients with detectable HBV core antibody or surface antigen should be screened for quantitative HBV viral load.

A high percentage (12% to 57%) of patients with ARL, especially BL, have CNS involvement at presentation.^{37,54,55} Routine CNS prophylaxis is generally used, although some favor stratifying patients based on extranodal disease. Prophylaxis has varied between studies, but generally includes intrathecal methotrexate (12 mg) and/or cytosine arabinoside (50 mg) for a total of four to eight doses. CNS involvement by DLBCL confers a poor prognosis. Several intensive intraventricular and intrathecal methotrexate schedules have shown activity. Most commonly, therapy is administered using an Ommaya reservoir twice weekly until 2 weeks after negative CSF flow cytometry is documented (for a minimum of eight doses), and then continued weekly for 6 to 8 weeks, then monthly for 6 months.^{55,56}

Supportive care and use of cART during lymphoma therapy deserves special consideration. While effective cART has reduced the incidence of HIV-associated lymphoid tumors and has improved survival, no randomized trial exists to clarify the utility of cART during chemotherapy. On one hand, earlier control of HIV viremia and immune reconstitution may improve long-term infectious outcomes, especially in patients with low CD4 counts. However, there are important potential pharmacokinetic and toxicity interactions between cART and chemotherapeutic agents. As a class, protease inhibitors (especially ritonavir) inhibit CYP3A4 and have potential interactions with other drugs, such as cyclophosphamide.^{166–168} Additionally, zidovudine should generally be avoided because of additive hematotoxicity, and renal function should be monitored in patients on tenofovir. Nonetheless, substantial data from phase 2 studies that have included cART suggest that chemotherapy and cART can be concomitantly administered,¹⁶⁹ usually with growth factor support. However, use of cART during chemotherapy for DLBCL and BL is not essential, and phase 2 studies of dose-adjusted etoposide, doxorubicin, and vincristine with oral prednisone and bolus cyclophosphamide (DA-EPOCH; both with

and without rituximab) demonstrated excellent results while withholding cART during lymphoma treatment.^{54,55} More recently, pooled data from 19 trials with varied approaches to cART suggests that after correction for CD4 count and other prognostic and treatment-related factors, concurrent cART may be associated with improved response rates and a trend toward improved overall survival.¹⁷⁰ While these studies suggest an advantage for concurrent cART, it is important that in the face of toxicity-limiting ability to administer curative-intent therapy, suspension of nonessential drugs, including cART, is a reasonable first maneuver, especially in patients with CD4 counts >100 cells/mm³. When cART is discontinued, it should be resumed promptly after completion of therapy. Often, physicians who treat patients infected with HIV who have lymphoid tumors, continue cART, preferably with a protease inhibitor-sparing regimen. Additionally, newer antiretroviral drugs to avoid during chemotherapy are class-combination formulations that contain potent pharmacologic boosters such as cobicistat, which may have substantial effects on the chemotherapy. It is also reasonable to defer cART initiation in patients not on therapy until after initiating chemotherapy.

Given risk of infections both during and after completion of chemotherapy, especially in patients with CD4 counts <100 cells/mm³, attention to supportive care is critically important. All patients infected with HIV being treated for lymphoma, regardless of baseline CD4 count, should receive prophylaxis against PCP, preferably with trimethoprim-sulfamethoxazole. Patients with a CD4 count <50 to 100 cells/mm³ also require azithromycin 1,200 mg weekly as prophylaxis against atypical mycobacterial infections. Prophylaxis against herpes simplex virus reactivation using valacyclovir should be strongly considered. Patients with detectable hepatitis B viremia require antiviral therapy for HBV. Care is required to ensure that therapy of intercurrent HBV avoids compromising HIV control, as single-agent therapy for HBV will increase the likelihood of a specific HIV mutation, M184V, which renders patients resistant to several important antiretroviral agents. Patients with mucosal *Candida* infections should not receive azoles concurrently with chemotherapy.

Diffuse Large B-Cell Lymphoma

The majority of NHL occurring in patients with HIV are large B-cell lymphomas or BL. With more sophisticated molecular categorization, DLBCL itself is increasingly recognized as a constellation of genetically unique diseases. In the setting of HIV, various large B-cell lymphoma subtypes are associated with the degree of immune suppression and in some cases dysregulated control of oncogenic herpesviruses.

Immunohistochemical (IHC) markers are helpful in categorizing DLBCL subtypes (Table 117.4) and may provide important diagnostic and prognostic information.^{57,171–173} However, DLBCL seen in HIV is often categorized as DLBCL, not otherwise specified, because it does not meet the criteria of the other more highly specified DLBCL types. Although many cases are DLBCL, not otherwise specified, phenotypic characterization as centroblastic (associated with higher CD4 cells and with GC phenotype) and the immunoblastic variant (associated with lower CD4 cells and the ABC phenotype) remains useful.⁵⁵ Gene expression profiling (GEP) is the gold standard for distinguishing GC from ABC DLBCL in patients not infected with HIV. However, gene expression profiling and associated IHC algorithms were not developed or validated in the setting of HIV-associated DLBCL. Identification of DLBCL subtypes by ICH does not consistently segregate the biologic entities into the GEP-defined prognostic groups, regardless of HIV status.¹⁷⁴ However, assessment of GEP in HIV DLBCL is needed to insure that there are no major differences in ABC and GBC DLBCL subtypes based on HIV status. A combination of IHC for B-cell lineage markers and the KSHV protein, latency-associated nuclear antigen, in situ hybridization for

TABLE 117.4

Comparison of HIV-Associated Lymphomas

Histogenetic Origin	Histology	Viral Associations (%)		Histogenetic Markers (%)			Pathobiologic Markers (%)			CD4 Cells	Prospects for Chemosenstivity	Prognosis in cART Era

EBV, Epstein-Barr virus; KSHV, Kaposi sarcoma-associated herpes virus; MUM1, multiple myeloma-1; cART, combination antiretroviral therapy; DLBCL, diffuse large B-cell lymphoma; GC, germinal center subtype; ABC, activated B-cell subtype; PCNSL, primary diffuse large B-cell lymphoma of the central nervous system.

EBV-encoded small RNAs, and evaluation for *c-myc/Ig* translocations is warranted, and is generally necessary to categorize the rarer large B-cell lymphoma subtypes such as PBL and PEL. Determination of B-cell clonality by polymerase chain reaction (PCR) evaluation of immunoglobulin genes is sometime helpful, and additional molecular diagnostic biomarkers are likely to become increasingly important. Given development of novel agents such as lenalidomide and ibrutinib in HIV-unrelated DLBCL, it will become increasingly important to determine DLBCL subtypes in the setting of HIV, as these agents appear particularly active in ABC DLBCL. In anticipation of these advances, the NCI-sponsored AIDS-Malignancy Consortium (AMC) is conducting trials to determine safety and dosing considerations of novel agents in conjunction with the various classes of cART.

Therapy with curative intent is indicated for nearly all patients with HIV and lymphoid malignancies. This is particularly true for the commonest and best-studied tumor, DLBCL. DA-EPOCH-R (rituximab, 96-hour continuous infusion etoposide, doxorubicin, and vincristine with oral prednisone and bolus cyclophosphamide, followed by filgrastim, dose-adjusted for tolerance), short-course DA-EPOCH with dose-dense rituximab (SC-EPOCH-RR), R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone), and R-CDE (rituximab, 96-hour continuous infusion cyclophosphamide, doxorubicin, and etoposide, followed by filgrastim) have all been evaluated prospectively (Table 117.5). Studies have enrolled populations with varying HIV-related and other characteristics, as well as differing disease subtypes, including in some cases BL and unclassifiable NHL, as well as a varying

or unknown proportion of GC and immunoblastic phenotypes of DLBCL. They have also used different approaches to cART and varying numbers of chemotherapy cycles. Given the impact of these factors, comparison of studies is difficult. Nonetheless, recent studies have clarified the role of rituximab, provided evidence that patients can tolerate full-dose regimens, and demonstrated that patients with GC DLBCL and BL generally have excellent outcomes when treated with SC-EPOCH-RR.^{55,170,175,176} Recently, pooled data from 1,546 patients in 19 ARL prospective trials was analyzed for treatment factors affecting outcomes. It demonstrated that after correcting for established prognostic factors and intensity of chemotherapy, compared to CHOP, infusional chemotherapy resulted in decreased treatment-related mortality and progressive disease, as well as improved overall survival for patients with DLBCL.¹⁷⁰ This should be viewed as the strongest level of evidence data supporting infusional chemotherapy over standard bolus R-CHOP in HIV-related DLBCL.

The majority of ARLs express CD20, and consensus exists that rituximab, an anti-CD20 monoclonal antibody, should be used in CD20-expressing lymphomas in the setting of HIV. The pooled ARL prospective trial data¹⁷⁰ showed rituximab conferred a remarkable overall survival benefit with a hazard ratio of 0.51 ($p < 0.0001$) after correcting for established prognostic factors and intensity of chemotherapy. Some of the major studies included in this pooled analysis are discussed in the following, and this pooled data should be viewed as the strongest evidence level to support use of rituximab in patients with HIV and CD20+ lymphoma. These results are important, because early in the cART era, a randomized phase 3

No exclusion of high-risk patients	80/86	158	69	55		Ribera et al. ¹⁶⁸

CDE, cyclophosphamide, doxorubicin, and etoposide; cART, combination antiretroviral therapy; R-CDE, rituximab with CDE; EPOCH, etoposide, doxorubicin, and vincristine with oral prednisone and bolus cyclophosphamide; R-DA-EPOCH, rituximab (R) with dose-adjusted (DA) EPOCH; R-CHOP, rituximab with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP).

Patients enrolled in the short-course DA-EPOCH-RR study received cyclophosphamide 750 mg/m² compared to lower doses adjusted to CD4 counts in the other DA-EPOCH studies, as well as additional rituximab 375 mg/m² on day 6 of therapy. Only the studies in Dunleavy et al.⁵⁵ and Ribera et al.¹⁶⁸ were limited to diffuse large B-cell lymphoma.

trial comparing CHOP with R-CHOP found insufficient evidence of a rituximab benefit. The study showed evidence of rituximab activity; complete response rate was 22% higher in the R-CHOP arm, and only 8% of the group receiving R-CHOP had disease progression, compared with 21.6% of those receiving CHOP alone, consistent with expectations of rituximab benefit in the non-HIV setting.¹⁷⁷ However, the trial was not powered to be statistically significant at this level of difference. Additionally, 14% of patients receiving rituximab died of treatment-related infections, annulling any survival advantage.¹⁷⁸ Importantly, the majority of deaths were attributed to infections in patients with <50 CD4 cells/mm³ at entry. Two subsequent phase 2 trials of R-CHOP in ARL have demonstrated a complete response rate of 69% to 75%.^{167,168} In one trial that excluded high-risk patients with CD4 <100 cells/mm³, prior AIDS-defining illnesses, or Eastern Cooperative Oncology Group performance status <2 , no excess in infectious deaths were observed.¹⁶⁷ These findings emphasize the importance of detailed attention to management of AIDS, including antibiotic prophylaxis and surveillance for infections, in patients with <50 CD4+ cells/mm³ undergoing immunochemotherapy.

Rituximab has also been evaluated in combination with infusion regimens in HIV-associated lymphomas. An early phase 2 trial of DA-EPOCH with suspension of cART reported a complete response rate of 74% and a disease-free and overall survival of 92% and 60%, respectively, at a median follow-up of 53 months.⁵⁴ Two follow-up studies evaluated rituximab combined with DA-EPOCH. The first was an AMC-sponsored multicenter randomized phase 2 study of DA-EPOCH with concurrent versus sequential rituximab. Cyclophosphamide dosing was based on CD4 count, and cART was continued in 71% of patients. Therapeutic benefit of rituximab was suggested, with a 73% complete response rate in the concurrent rituximab arm compared with 55% in the sequential rituximab arm.¹⁷⁶ In a study performed by the NCI intramural program, SC-EPOCH-RR with suspension of cART during therapy and no decrease in cyclophosphamide dosing based on CD4 count was evaluated in patients with DLBCL.⁵⁵ The number of cycles administered was adapted to response, with patients receiving one cycle beyond stable radiographic and negative ¹⁸F-DG-PET scans. Patients received a median of three cycles (range, three to five cycles). Complete response rate was 91%, and with 5-year median follow-up, progression-free and overall survival were 85% and 68%, respectively. Tumor histogenesis was important prognostically: 95% of patients with GC phenotype were progression-free, compared with $<40\%$ with ABC phenotype. Additional studies to evaluate the generalizability of interim ¹⁸F-DG-PET in determining the number of cycles are required. The third rituximab-based regimen is R-CDE. In a pooled analysis from three phase 2 studies of R-CDE every 4 weeks for six cycles, and with 76% of patients receiving concurrent cART, the complete response rate was 70% and both disease-free and overall survival were 55% at a median follow-up of 23 months.¹⁷⁹ There was a 3% infection-related death rate during treatment, and additional deaths due to opportunistic infections following treatment.

Primary Diffuse Large B-Cell Lymphoma of the Central Nervous System

AIDS-related PCNSL almost always occurs in patients with a CD4 count of <50 cells/mm³. Contrast computed tomography or MRI usually demonstrates single or multiple contrast-enhancing masses that are not reliably distinguishable from toxoplasmosis or other CNS processes. Definitive diagnosis requires stereotactic biopsy. In the pre-cART era, patients with AIDS and PCNSL rarely survived more than 6 months, regardless of treatment.^{180,181} Despite cART, outcomes in AR-PCNSL remain poor.^{53,58} Factors associated with improved survival include receiving lymphoma-directed therapy, availability of cART, and lack of a diagnosis of CNS infection prior to PCNSL diagnosis.⁵⁹ For patients with AIDS and

ring-enhancing brain masses, optimal outcome is predicated on initiation of cART and timely institution of appropriate therapy for the brain lesions. Treatment delays increase the likelihood of permanent residual neurologic disability. Historically, this patient population was treated with empiric antibiotics for possible toxoplasmosis with a 2-week watch-and-wait period; however, this approach is no longer justified. Neurologic impairment with a brain mass should be viewed as a medical urgency requiring appropriate diagnostic evaluations and prompt treatment.

A major advance in diagnosis of CNS masses in patients with AIDS was the incorporation of relatively noninvasive diagnostic methods.^{182,183} Essentially, all AIDS-PCNSL is EBV-related,¹⁸³ and detection of EBV DNA by PCR in the CSF combined with positive brain ²⁰¹Tl single-photon emission computed tomography (²⁰¹Tl-SPECT) has been shown to reliably predict the presence of PCNSL.¹⁸⁴ Increased ²⁰¹Tl-SPECT uptake combined with positive EBV-DNA had 100% sensitivity and 100% positive predictive value for PCNSL, whereas if both tests have negative results, negative predictive value is 100%. ¹⁸F-DG-PET is also highly specific for malignancy and can also be used in combination with evaluation of CSF for EBV in patients with <50 CD4 cells/mm³.^{185,186} These diagnostic modalities should be incorporated in upfront evaluation of patients with AIDS and CNS masses. However, it should be noted that CSF evaluation of EBV-PCR is not specific for PCNSL.^{187,188} Also, brain ¹⁸F-DG-PET can detect other malignancies, and evaluation must take into account the possibility of CNS involvement of systemic NHL or metastatic NADM. Ideally, PCNSL requires tissue diagnosis. Nonetheless, in the context of CD4 count <50 cells/mm³, the combination of a high EBV viral load in the CSF, a ring-enhancing brain mass on MRI, and a positive ²⁰¹Tl-SPECT or ¹⁸F-DG-PET may be considered highly suggestive of AIDS-PCNSL, and if a tissue diagnosis cannot be obtained, it can be used as a basis to institute therapy for presumptive AIDS-related PCNSL.

There is no standard therapy for AIDS-related PCNSL, and patients should be considered for referral to a clinical trial. Treatment should include initiation of cART, which has been shown in retrospective studies to improve overall survival.^{181,189} AIDS-PCNSL is highly responsive to whole-brain irradiation, and most patients can be expected to have initial clinical improvement. Early in the cART era, the 1-year overall survival with whole-brain irradiation and cART was only 20%.¹⁸¹ In a subsequent Japanese report, the estimated 3-year overall survival in patients receiving >30 Gy whole-brain irradiation (57% received focal boost) combined with cART was 64%.¹⁹⁰ However, given improved survival of patients with AIDS with the availability of cART and the risk of devastating late neurotoxicity from radiation therapy to the CNS, especially when combined with chemotherapy,^{54,191} radiation-sparing approaches may be preferable. The best therapeutic approach in such patients may be shown to be institution of cART to achieve rapid immune reconstitution and control the EBV-related lymphoproliferative process, along with immunochemotherapy for the lymphoma. Intriguingly, reports of sustained complete responses in select patients with posttransplant primary CNS EBV-associated lymphoproliferative disorder treated with rituximab alone have been reported.¹⁹² Ongoing clinical trials are investigating the incorporation of rituximab into chemotherapy-based PCNSL treatments, and preliminary data suggest this to be useful.^{193,194}

Lymphomas Found More Specifically in HIV: Plasmablastic Lymphoma and Primary Effusion Lymphoma

A number of rare lymphomas can develop in patients infected with HIV. Two recently recognized large B-cell lymphomas are of special interest given their strong association with both HIV and gamma-herpes viruses. PBL is an EBV-associated B-cell NHL proposed as a new entity in 1997.¹⁴⁰ Although most common in the

setting of HIV, PBL also occurs in organ transplantation patients and elderly individuals.¹⁹⁵⁻¹⁹⁷ It often presents in the oral cavity, but may occur at other extranodal or nodal sites. A retrospective review of 112 published cases summarized the spectrum of clinical presentations.¹⁹⁸ HIV-associated PBL was found to usually present as either stage I or stage IV disease and to have a 7:1 male:female predominance. The median CD4 count at diagnosis was 178 cells/mm³. Ann Arbor staging did not appear prognostic, and patients with stage I disease should be treated the same as those with systemic disease. PBL is characterized by a high proliferative index and aggressive clinical course, perhaps due to *c-myc/Ig* translocations that are seen in 74% of EBV-associated plasmablastic lymphomas.¹⁶³ Historically, prognosis has been poor, with median survival <2 years. Outcomes are poor with CHOP.¹⁹⁹ However, retrospective data suggest outcomes for PBL in patients infected with HIV may be improved in the cART era.²⁰⁰ In 17 patients infected with HIV with PBL, 1-year overall survival was 67% with a number of patients alive at several years. As a rare disease, additional studies are required to better define optimal therapy. Currently, treatment with regimens effective in tumors with high proliferative rates, such as DA-EPOCH, is recommended, preferably within the setting of a clinical trial.

PEL is a rare KSHV-associated aggressive mature B-cell lymphoma that usually presents as a lymphomatous effusion; patients are at risk for other KSHV-associated malignancies. Patients often present with inflammatory syndromes, hypoalbuminemia, thrombocytopenia, anemia, and associated elevated IL-6 and circulating KSHV viral load.²⁰¹ Pleural, peritoneal, pericardial, and leptomeningeal presentations can be seen. Extracavitary PEL has phenotypic and molecular similarities to PEL²⁰² and may present in a variety of locations, including lymph nodes, the gastrointestinal tract, or cutaneous tissues. Diagnosis of PEL depends on the demonstration of KSHV infection of tumor cells. In >70% of cases, tumor cells are co-infected with EBV. Common B-cell surface markers (CD19, CD20, CD79a) are absent, while activation markers (CD30, CD38, CD71, CD138) are often present; immunoglobulin gene rearrangements confirm B-cell monoclonality. Evaluation of the extent of disease should be performed following the guidelines for NHL staging. There are few data to guide therapy in PEL, and the outcome is generally poor, with a median survival of <6 months in most case series.²⁰³ However, there are a few case reports of patients having long-term remissions. Patients should ideally be treated within clinical studies if possible.

Burkitt Lymphoma

BL often occurs in patients with relatively preserved immune status and makes up 17% of HIV-associated lymphomas in the cART era.⁵³ Until recently, clinical trials of ARL generally included both DLBCL and BL. It is now appreciated that just as in the HIV-unrelated setting, BL requires specialized curative intent therapy. CHOP-based therapy results in poor outcomes in HIV-associated BL,⁵² and increasing evidence supports short course intense therapy or short course low-intensity therapy with EPOCH-R. Studies of BL in the adult setting are mainly comprised of relatively small phase 2 studies, and randomized data does not exist to inform standard treatment, therefore the phase 2 data presented is the best evidence available. Additionally, the pooled data analysis from 19 ARL studies had an insufficient number of BL cases to form firm conclusions.

Importantly, excellent 90% long-term overall survival was recently reported for BL in 11 patients infected with HIV treated with SC-EPOCH-R with cART deferred until after treatment.⁵⁶ This study treated 30 patients overall, and the HIV-positive and HIV-unrelated patients all did equally well. A prospective NCI sponsored study with participation by the US Cooperative Groups is under way to further evaluate DA-EPOCH-R in BL. An important advantage to EPOCH-R in this setting is its favorable toxicity profile. Most cycles can often be given as an outpatient.

The more conventional short course high-intensity BL regimens have also been studied in HIV and are feasible to administer. However, they are toxic regimens requiring hospitalization in most cases and have some treatment-related mortality. CODOX-M/IVAC (cyclophosphamide, vincristine, doxorubicin, methotrexate plus ifosfamide, etoposide, and cytarabine)²⁰⁴ is one such regimen.^{205,206} A 70% complete response rate was seen in retrospective studies in HIV-associated BL; however, treatment-related mortality was 30%.²⁰⁶ Evaluation of a prospective AMC-sponsored phase 2 study of 34 patients treated with modified CODOX-M/IVAC combined with rituximab is ongoing. Preliminary results demonstrated 1-year overall survival of 83% and 9% treatment-related mortality.²⁰⁷ HyperCVAD (cyclophosphamide, vincristine, doxorubicin, dexamethasone, cytarabine, mesb, methotrexate, leucovorin) has also been reported in 13 patients with a 2-year overall survival of 48%.²⁰⁸ Inclusion of rituximab in whatever regimen is used is recommended. DA-EPOCH-R with full-dose cyclophosphamide and intrathecal methotrexate should be strongly considered for patients with AIDS-BL, preferably within the ongoing NCI-sponsored national clinical trial.

Hodgkin Lymphoma

cHL²⁰⁹ occurs with a markedly increased frequency in people infected with HIV; it is categorized as an NADM. EBV-associated mixed cellularity histology is most common, while nodular sclerosis histology is most common in patients who are HIV-negative.^{210,212} The association between cHL and CD4 cell count is complex. In general, cHL occurs when the CD4 cells are relatively intact. Often, the diagnosis is made shortly after the diagnosis of HIV and median CD4 count is at diagnosis is >200 cells/mm³.^{210,212} Declining CD4 counts are sometimes noted before diagnosis and later attributed to cHL itself.²¹³ There is uncertainty as to why there is excess risk of cHL in the first year of cART therapy, but it has been speculated that disease manifestations may be related to an immune reconstitution phenomena. Interestingly, a precipitous drop in CD4 cells in the year before cHL diagnosis may be a heralding event.^{165,213} Patients with HIV-associated Hodgkin lymphoma are generally older and present with higher-stage disease. They present less frequently with mediastinal involvement as noted in the nodular sclerosing subtype, and more frequent involvement of extranodal sites of disease, and more frequent "B" symptoms compared to patients with cHL and without HIV. Bone marrow involvement is common, and 20% of cases of hemophagocytic syndrome in patients with HIV may be attributed to cHL.²¹⁴

In the cART era, treatment outcome for cHL in patients infected with HIV is comparable to the HIV-unrelated counterpart.²¹⁵ Conventional chemotherapy regimens such as ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine)²¹⁶ or risk-adapted combined-modality therapy are often used.²¹² In a prospective German multicenter study, 108 patients with HIV-associated cHL were treated with risk and stage-adapted therapy. Patients with early stage disease were treated with two to four cycles of ABVD and involved-field radiation, while those with unfavorable disease were treated with six to eight cycles of BEACOPP (bleomycin, etoposide, cyclophosphamide, vincristine, procarbazine and prednisone), unless they had advanced HIV infection, in which case they were treated with ABVD. Patients received concurrent cART. The 2-year progression-free survival was 95% to 100% for early stage disease and 89% for advanced-stage disease. Two-year overall survival in the entire cohort was 90.7%. Although toxicities were manageable in this study, severe hematotoxicity and neurotoxicity due to drug-drug interactions between vinblastine and protease inhibitors have been observed, and as with ARL, protease inhibitor-based regimens should generally be avoided.²¹⁷ A clinical trial sponsored by the AMC is currently evaluating the anti-CD30-immunotoxin brentuximab in combination with doxorubicin, vincristine, and dacarbazine in HIV-associated cHL.

Relapsed and Refractory Lymphoma in Patients Infected with HIV

Outside the setting of HIV infection, high-dose chemotherapy with autologous peripheral stem cell transplant (HDT-PBSCT) is sometimes used for patients with relapsed DLBCL or cHL. HDT-PBSCT is feasible in patients infected with HIV.^{218–221} Across several conditioning regimens, treatment-related mortality is 3% to 5%, and outcomes are generally comparable to HIV-negative patients.^{218–221} There is the risk of secondary myelodysplastic syndrome.²²¹ In a retrospective series across AMC sites, 88 patients with refractory lymphoma were treated with curative intent second-line therapy with regimens such as DA-EPOCH; ifosfamide, carboplatin, etoposide; and etoposide, methylprednisolone, cytarabine, and cisplatin. A total of 32 patients (36%) had a response to second-line therapy (21 complete responses), and 10 went on to HDT-PBSCT. However, there was no difference in survival amongst those who went on to transplant compared to those who did not, with estimated 1-year survival in responding patients of approximately 70%.²²² These results suggest that HDT-PBSCT transplant outcomes in DLBCL and HL are comparable with results in HIV-negative patients, but that durable responses may be achievable with second-line therapy alone in some cases.

Allogeneic transplant has also been explored in a limited number of patients with ARL. In one case where a patient infected with HIV with refractory leukemia received a matched unrelated donor transplant, the use of a donor with a $\Delta 32$ CCR5 mutation that makes the cells resistant to infection with CCR5 strains of HIV appears to have resulted in the eradication of HIV infection.²²³ However, two other cases of allogeneic transplantation in which the donor did not have the $\Delta 32$ mutation failed to achieve such eradication, even though cART was continued throughout therapy. Future studies will be needed to clarify the role of allogeneic transplantation in the treatment of refractory lymphoma as well as its potential role in eradicating HIV.

HUMAN PAPILLOMAVIRUS-ASSOCIATED CANCER IN HIV INFECTION

Patients infected with HIV have an increased incidence of several cancers caused by HPV, including cancer of the cervix, anus, penis, vulva, oral pharynx, and tonsil.^{224,225} Of these, only cancer of the cervix is considered AIDS-defining.¹ Women infected with HIV have about a five-fold increased incidence of cervical cancer as compared with women not infected with HIV.²²⁵ The increase in all these cancers is related both to an increased exposure to oncogenic strains of HPV and an impaired ability to clear these strains attributed to HIV-associated immunodeficiency. Women infected with HIV also have an increased risk of premalignant cervical,²²⁶ vulvovaginal, and anal intraepithelial neoplasia.²²⁷ Compared to women not on cART, women on cART have a decreased incidence of precancerous cervical lesions, increased regression of existing precancerous lesions, and increased clearance of oncogenic HPV.^{228–230} Although not AIDS-defining, people with HIV, especially women and MSM, have a markedly increased risk of anal cancer. The annual incidence of anal cancer in patients with HIV in the United States, estimated at 80 per 100,000 individuals, is much higher than that of the general population, and is increasing.²²⁵ Smoking and lower CD4 nadir are associated with increased risk of development of anal cancer.^{231,232} Other HPV-associated cancers, especially cancers of the oral pharynx and tonsil, have also increased in the past decade in individuals infected with HIV.

Cervical Cancer

Prevention of cervical cancer is an important part of care for women with HIV. In the United States, cervical cancer

screening guidelines are based largely on regular periodic cervical Papanicolaou (Pap) testing.²³³ The CDC and the US Preventive Services Task Force recommend cytologic screening as part of the initial evaluation when HIV is diagnosed.²³⁴ Pap smears showing severe inflammation with reactive squamous cellular changes should be repeated within 3 months. If the initial Pap smear is normal, additional evaluation should be repeated within 6 months. Subsequent monitoring guidelines vary. Additional evaluation of HPV DNA, with a subsequent screening frequency of 6 months in women with detectable high-risk subtypes of HPV and yearly in those without high-risk HPV has been proposed.²³⁵ High-risk women with normal PAP smears should be re-evaluated at least annually, whereas approaches used in women not infected with HIV have been advocated for women on effective cART, relatively preserved CD4 counts, no evidence of oncogenic HPV, and negative Pap smears.

If a Pap smear shows squamous intraepithelial lesions or atypical squamous cells of undetermined significance, cervical colposcopic examination with directed biopsies of mucosal abnormalities is indicated. Management of premalignant cervical lesions in woman with HIV, especially those with low CD4 counts, is more complicated than that in women not infected with HIV because of higher rates of positive margins and recurrent cervical intraepithelial neoplasia (CIN).^{236,237} Low-grade lesions (CIN1) are generally observed, and higher-grade lesions (CIN2-3) are generally treated. Initiation of cART and associated immune reconstitution has been associated with regression of lesions over time and may decrease the risk of recurrence.²²⁸ Treatment options for CIN include ablative therapy, loop excision of the transformation zone, or conization procedures, and should be individualized based on lesion size and location. In resource-limited settings, cervical cancer is a leading cause of cancer-related mortality in women. In this setting, development of cervical cancer screening programs that are less technologically intensive and do not depend on cytopathology are underway. Programs based on cervical visual inspection with acetic acid and immediate cryotherapy (a “screen and treat” approach) as well as rapid HPV testing and treating are being scaled-up and evaluated.^{238–241}

Invasive cervical cancer should largely be approached using principles of oncologic management that guide treatment in HIV-negative patients. The International Federation of Gynecology and Obstetrics staging system, used for patients not infected with HIV, is used in this population as well. More recently, ¹⁸F-DG-PET has been incorporated in the initial assessment of women with cervical cancer to evaluate para-aortic lymph nodes. However, in women with HIV and cervical cancer, results should be interpreted with the understanding that uncontrolled HIV viremia is associated with generalized lymph node ¹⁸F-DG avidity.²⁴² Treatment is based on clinical stage. There are no clinical trials specific to women infected with HIV with cervical cancer, and HIV-positive women with cervical cancer should be treated in the same manner as those without HIV infection, with cART integrated into the overall treatment plan.

Anal Cancer

Given biologic similarities to cervical cancer and the effectiveness of cervical cancer screening, some experts have suggested that routine periodic cytologic examination of the anal mucosa should also be considered in high-risk individuals.²⁴³ Programs to screen men and women infected with HIV for anal intraepithelial neoplasia and to treat high-grade lesions have been developed. This approach has the potential to prevent anal cancer by detecting and treating premalignant lesions.²⁴⁴ The primary tool to screen for anal cancer is cytology of the anal epithelium. Most practitioners recommend that abnormal cytology should be followed up with high-resolution anoscopy. Treatment decisions are based on the grade of the lesion. Current options for

high-grade anal intraepithelial neoplasia include local treatment with topical immune modulators (e.g., imiquimod)^{245,246} or antiviral agents (e.g., cidofovir),²⁴⁷ electrocautery, laser or infrared coagulation,^{248,249} and surgery. It should be noted, however, that while plausible, treatment of anal dysplasia has not been shown to prevent anal cancer. Also, a major difference between anal and cervical cancer prevention is the greater difficulty and morbidity in surgical resection of precancerous lesions of the anus and a high rate of recurrence. An NCI-funded prospective study is planned to determine the effect of treatment of precancerous lesions on subsequent development of anal cancer.

The standard of care for stages I–III anal cancer is concurrent chemoradiation, and patients with HIV should receive standard regimens. In the pre-cART era, patients with CD4 counts <200 cells/mm³ were more likely to suffer treatment-related toxicity including cytopenias, intractable diarrhea, moist desquamation requiring hospitalization, or a colostomy either for a therapy-related complication or for salvage, whereas patients with ≥200 CD4 cells/mm³ appeared to have better disease control with acceptable morbidity.²⁵⁰ However, with the availability of cART, as well as increasing use of intensity-modulated radiation therapy in the treatment of anal cancer over the past decade, toxicities associated with concurrent chemoradiation in this patient population may have decreased. Outcomes in patients with HIV receiving concurrent chemoradiation, including mitomycin-C–based therapy, appear comparable to that of the general population.²⁵¹ Surgical abdominoperineal resection is an option for patients with poor performance status and those who do not wish to undergo concurrent chemoradiation. Patients are left with a permanent colostomy, and therefore surgery is generally employed only for the management of locoregional recurrence.

FUTURE DIRECTIONS

Many HIV-associated cancers are associated with oncogenic viruses. In this regard, HIV can play a varied role. HIV-induced immunosuppression can lead to an environment where oncogenic viral infection and opportunistic neoplasia can develop relatively unchecked. HIV can also stimulate immune system cytokine production that promotes cellular proliferation and oligoclonal

expansions of premalignant cells. There are thus opportunities to reduce the risk of various HIV-associated cancers by preventing or treating either HIV or the specific oncogenic virus. The HBV and HPV vaccines, for example, hold the potential to dramatically reduce the incidence of hepatocellular, anogenital, and oropharyngeal cancers. Also, studies of the biology of the oncogenic viruses may lead to more targeted treatment or prevention strategies.

In the cART era, NADMs are an increasingly important cause of morbidity and mortality.^{19,61} For some NADM, there are biologic differences between those that arise in patients infected with HIV compared to patients not infected with HIV. In cHL, for example, patients infected with HIV are more likely than the general population to develop mixed cellularity and lymphocyte-depleted subtypes. However, in other cancers, such biologic differences have not been established. There is an NCI initiative to encourage enrollment of patients infected with HIV on NCI-funded cancer trials whenever possible. In the absence of evidence for specialized cancer treatment regimens in patients with HIV, standard therapeutic approaches should be strongly considered, especially in patients with good performance status and who are free of other HIV infectious comorbidities.

With the availability of cART, many patients infected with HIV are now able to tolerate standard cancer therapy, including allogeneic stem cell transplantation.²⁵² Special considerations in treating patients with HIV and cancer include whether to modify the standard treatment for the cancer, whether to continue or start cART, and whether prophylaxis is required for herpes simplex virus, PCP, or *Mycobacterium avium*-intracellulare. Special attention should be paid to potential drug-drug interactions between antiretroviral agents and chemotherapeutic agents. Furthermore, protease inhibitors, especially nelfinavir, may have radiosensitizing effects. Pharmacokinetic studies evaluating the effect of commonly used antiretroviral agents on chemotherapeutic agents are warranted.^{253,254}

Although increased knowledge about treatment outcomes for patients with HIV and cancer are required, it appears that with the better-studied tumors, treatment outcomes for HIV-related malignancies that are equivalent to those obtained in HIV-seronegative patients may be attainable.^{55,251} In order to promote the oncologic care of patients with HIV/AIDS, it will be important for clinical trials to increasingly include or focus on this population.²⁵⁵

118 Transplantation-Related Malignancies

Smita Bhatia and Ravi Bhatia

INTRODUCTION

An important and potentially devastating complication of hematopoietic cell transplantation (HCT) is the occurrence of subsequent malignant neoplasms (SMN).¹⁻¹¹ The magnitude of risk of SMNs after HCT ranges from 8-fold to 11-fold that of the general population (Table 118.1).

Several host and clinical factors are associated with an increased risk of SMNs after HCT. These include age at HCT, exposure to chemotherapy and radiation prior to HCT, use of total-body irradiation (TBI) and high-dose chemotherapy for myeloablation, infection with viruses such as Epstein-Barr virus (EBV) and hepatitis B and C viruses, type of transplantation (autologous versus allogeneic), and immunodeficiency after HCT aggravated by the use of immunosuppressive drugs for prophylaxis and treatment of graft-versus-host disease (GVHD).¹

The heterogeneous nature of SMNs, with differing clinicopathologic characteristics, precludes assessment of risk factors in aggregate. It has become conventional practice to classify SMNs into three distinct groups¹²: (1) myelodysplasia (MDS) and acute myeloid leukemia (AML), (2) lymphoma, including lymphoproliferative disorders, and (3) solid tumors. Although secondary leukemia and lymphoma develop early in the posttransplantation period, secondary solid tumors have a longer latency. In this chapter, the three broad categories of SMNs seen among patients undergoing HCT are discussed, with emphasis on clinical presentation, magnitude of risk and associated risk factors, current insights into pathogenesis, and treatment options and outcome of patients with these malignancies. We will conclude the chapter with a brief summary regarding strategies for early detection of SMNs.

MYELODYSPLASIA AND ACUTE MYELOID LEUKEMIA

Therapy-related MDS (t-MDS) and therapy-related AML have emerged as the major cause of nonrelapse mortality in patients undergoing autologous HCT for Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL).^{4,13} The risk of t-MDS/AML approaches 9% after autologous HCT for lymphoma with a median latency of 12 to 24 months after HCT (range, 4 months to 6 years).⁴

Clinicopathologic Syndromes

Two types of t-MDS/AML are recognized in the World Health Organization classification, based on the causative therapeutic exposure: alkylating agent/radiation or topoisomerase II inhibitor.¹⁴

Alkylating Agent/Radiation-Related Therapy-Related Myelodysplasia/Acute Myeloid Leukemia

In patients exposed to alkylating agents, t-MDS/AML usually appears 4 to 7 years after exposure. Approximately two-thirds of

patients present with MDS and the remainder with AML with myelodysplastic features. Patients frequently present with cytopenias. There is a high prevalence of abnormalities involving chromosomes 5 (-5/del[5q]) and 7 (-7/del[7q]).

Topoisomerase II Inhibitor-Related Acute Myeloid Leukemia

AML secondary to topoisomerase II inhibitors presents as overt leukemia, without a preceding myelodysplastic phase. The latency is brief (6 months to 5 years) and is associated with balanced translocations involving chromosome bands 11q23 or 21q22. Other translocations include inv(18)(p13q22) or t(17,19)(q22;q12).¹⁵

Clinical Diagnosis

The common occurrence of cytopenias after autologous HCT and their nonspecific nature necessitated the need for specific criteria for diagnosing t-MDS/AML developing after HCT. These criteria include (1) significant marrow dysplasia in at least two cell lines, (2) peripheral cytopenias without alternative explanations, and (3) blasts in the marrow defined by French-American-British classification.¹⁶ In patients without blasts, presence of a clonal cytogenetic abnormality in addition to morphologic evidence of dysplasia may aid in making this diagnosis.

Risk Factors for Therapy-Related Myelodysplasia/Acute Myeloid Leukemia After Hematopoietic Cell Transplantation

An increased risk of t-MDS/AML is associated with older age at HCT¹; pretransplantation exposure to alkylating agents, topoisomerase II inhibitors, or radiation⁴; use of peripheral blood stem cells (PBSC; compared to bone marrow); stem cell mobilization with etoposide; conditioning with TBI; low number of CD34+ cells infused; and multiple transplants (see Table 118.1).^{1,4,17}

The impact of pre-HCT chemotherapy and radiation on the risk of t-MDS/AML after HCT points toward an origin of events prior to HCT. A role for pretransplantation exposures is further supported by the observation that specific cytogenetic abnormalities observed posttransplantation have also been observed in the pretransplant marrow or peripheral blood graft among patients who develop t-MDS/AML after HCT, supporting a role for injury induced by prior cytotoxic chemotherapy in the etiology of t-MDS/AML.

TBI at 12 Gy does not increase the risk, whereas an increased risk is observed with TBI at 13.2 Gy.¹⁸ An association with TBI indicates that the disease may arise from residual stem cells that persist in the patient despite myeloablative treatment, rather than from re-infused stem cells, although TBI-induced alteration in the hematopoietic microenvironment may contribute to the development of t-MDS/AML.

TABLE 118.1

Magnitude of Risk and Populations at Increased Risk of Subsequent Malignant Neoplasms After Hematopoietic Cell Transplantation

Study	Study Design	Sample Size/ Number of SMNs	Primary Diagnoses; Type of HCT	Magnitude of Risk and Risk Factors
All Second Malignancies				
Bhatia et al. ¹	Retrospective cohort study	2,150/53 leukemia, lymphoma, solid malignancies	All hematologic malignancies, inborn diseases of immune system Autologous and allogeneic HCT	11.6-fold increased risk compared with general population Cumulative probability: 9.9% at 13 y for all SMNs; 1.6% at 4 y for PTLD; 5.6% at 13 y for solid malignancies. T-cell depletion, use of ATG, unrelated donor HCT, primary immune deficiency associated with increased risk of PTLD
Baker et al. ⁷⁵	Retrospective cohort study	3,372/147 leukemia, lymphoma, solid malignancies	All malignancies and metabolic disorders; immune deficiency; aplastic anemia Autologous and allogeneic	8.1-fold increased risk compared with general population Cumulative incidence: 6.9% at 20 y for any malignancy; 1.4% at 10 y for PTLD; 1.4% at 10 y for MDS/AML; 3.8% at 20 y for solid tumors
Therapy-Related MDS/AML				
Krishnan et al. ⁴	Retrospective cohort study Nested case-control study	612/22 MDS/AML	Hodgkin lymphoma Non-Hodgkin lymphoma Autologous HCT	Cumulative probability of MDS/AML: 8.6% at 6 y Stem cell priming with etoposide, pre-HCT radiation associated with increased risk of t-MDS/AML
PTLD				
Landgren et al. ⁵²	Retrospective cohort study	26,901/127 PTLD	Hematologic malignancies and severe aplastic anemia Allogeneic HCT	T-cell depletion, use of ATG, unrelated donor HLA-mismatched grafts. Cumulative risk increased to 8.1% with more than three risk factors
Curtis et al. ⁵³	Retrospective cohort study	18,014/78 PTLD	Hematologic malignancies Allogeneic HCT	Cumulative incidence 1% at 10 y Unrelated donor HCT, T-cell depletion, use of ATG, use of anti-CD3 monoclonal antibody
Solid Tumors				
Curtis et al. ³	Retrospective cohort	19,229/80 solid malignancies	Allogeneic HCT	2.7-fold increased risk of solid tumors compared with the general population Cumulative incidence: 6.7% at 15 y; younger age at HCT associated with increased risk of solid malignancies; chronic GVHD and male sex associated with increased risk of squamous cell carcinoma
Bhatia et al. ¹¹	Retrospective cohort study	2,129/29 solid malignancies	Hematologic malignancies Autologous and allogeneic HCT	Two-fold increased risk compared with general population Cumulative probability: 6.1% at 10 y
Shimada et al. ⁷⁶	Retrospective cohort study	809/19 solid malignancies	All malignancies Autologous and allogeneic HCT	2.8-fold increased risk Cumulative incidence: 4.2% at 10 y Extensive chronic GVHD and older age were associated with increased risk
Gallagher et al. ⁷⁷	Retrospective cohort study	926/28 solid malignancies	Hematologic malignancies Allogeneic HCT	10-y cumulative incidence: 3.1%; 1.85-fold increased risk compared with general population Older age at HCT, female donor associated with increased risk
Socie et al. ⁷⁸	Retrospective cohort	3,182/25 solid tumors; 20 PTLD	Acute leukemia in childhood	Cumulative risk of solid tumors: 11% at 15y Age <5 y at HCT; TBI were associated with increased risk of solid tumors; chronic GVHD associated with decreased risk Chronic GVHD, unrelated donor HCT, T-cell depleted graft, use of ATG associated with increased risk of PTLD

TABLE 118.1

Magnitude of Risk and Populations at Increased Risk of Subsequent Malignant Neoplasms After Hematopoietic Cell Transplantation (continued)

Study	Study Design	Sample Size/ Number of SMNs	Primary Diagnoses; Type of HCT	Magnitude of Risk and Risk Factors
Solid Tumors				
Majhail et al. ⁶⁰	Retrospective cohort	4,318/66 solid cancers	AML; CML; allogeneic HCT	Cumulative incidence: 1.2% at 10 y; 1.4-fold increased risk compared with general population Chronic GVHD associated with increased risk, in particular oral cavity
Rizzo et al. ⁶	Retrospective cohort	28,874/189 solid malignancies	All malignancies/ allogeneic HCT	2.1-fold increased risk Age at exposure to TBI <30 y associated with nine-fold increased risk of nonsquamous cell carcinoma Chronic GVHD, male sex associated with risk of squamous cell carcinoma

SMN, subsequent malignant neoplasm; HCT, hematopoietic cell transplantation; PTLD, posttransplantation lymphoproliferative disorder; ATG, antithymocyte globulin; MDS, myelodysplasia; AML, acute myeloid leukemia; t-MDS, therapy-related MDS; HLA, human leukocyte antigen; GVHD, graft-versus-host disease; TBI, total-body irradiation; CML, chronic myelogenous leukemia.

Recipients of CD34-enriched cells isolated from peripheral blood after chemotherapy priming and growth factors are at a higher risk of t-MDS/AML as compared with recipients of CD34+ cells from the bone marrow.^{1,4} Potential explanations include harvesting of hematopoietic precursor cells damaged by chemotherapy at a time before they have completed DNA repair or an overrepresentation of damaged cells in the mobilized product. Supporting this hypothesis is the study⁴ demonstrating an increased risk of t-AML with 11q23 abnormalities among patients mobilized with high doses of etoposide for collection of stem cells prior to autologous HCT.

Patients receiving a smaller number of re-infused cells have been reported to be at an increased risk of t-MDS.¹⁷ Reconstitution of bone marrow clearly may result in greater proliferative stress in the setting of low stem cell numbers, increasing susceptibility to irreversible DNA damage associated with t-MDS. These observations are supported by in vitro data suggesting an increased proliferative stress placed on committed progenitors at the expense of primitive progenitors.¹⁹

Pathogenesis of Therapy-Related Myelodysplasia/Acute Myeloid Leukemia

t-MDS/AML is a clonal disorder that results from acquired genetic or epigenetic changes induced by cytotoxic therapy in hematopoietic stem cells. Improved understanding of the molecular pathogenesis of t-MDS/AML is required to allow development of strategies to identify populations at increased risk. Additionally, t-MDS/AML offers a unique perspective on mutagen-induced carcinogenesis. The clinical and epidemiologic data suggest that t-MDS/AML after autologous HCT results from genetic damage to the stem cell from pretransplant cytotoxic treatment, which may be potentiated by the transplant process itself.

Genetic Lesions Associated with Therapy-Related Myelodysplasia/Acute Myeloid Leukemia

Loss of chromosome 5 or del(5q) and loss of chromosome 7 or del(7q) are recurring abnormalities in t-MDS/AML. This has led to a search for candidate tumor suppressor genes in these regions. The majority of patients with 5q deletions exhibit losses at the 5q31 locus, with deletions in 5q33 being seen in some patients.

Systematic evaluation of all 28 chromosome 5q31.2 genes for heterozygous nucleotide mutations or microdeletions using total exonic gene sequencing and array comparative genomic hybridization²⁰ did not reveal any somatic nucleotide changes or cytogenetically silent 5q31.2 deletions. The mRNA levels of seven genes in the commonly deleted interval were reduced by 50% in CD34+ cells from del(5q) MDS samples, but complete loss of expression was not seen. These findings suggest that deletion leads to haploinsufficiency of multiple genes, but additional deletions or point mutations in 5q31.2 genes are uncommon. The role of specific genes has been evaluated. For example, the *APC* gene located in the commonly deleted 5q region has been studied. Mice with the *Apcmin* allele that results in a loss of APC function showed no abnormality in steady-state hematopoiesis but had reduced long-term stem cell function and developed an MDS phenotype over time,²¹ supporting a potential role for *Apc* haploinsufficiency in the MDS phenotype in patients with del(5q).

Chromosomal segment 7q22 is a common site of chromosome 7 deletions. Molecular analysis of a 2.5-Mb commonly deleted segment of chromosome band 7q22 has failed to uncover a candidate tumor suppressor gene. Mice with deletion of the targeted segment showed normal hematologic parameters and did not spontaneously develop myeloid malignancies.²² The targeted deletion did not cooperate with oncogenic *Kras*, *Nfl* inactivation, or retroviral mutagenesis to accelerate leukemia development. These results fail to support the hypothesis that the 7q22 deletion contains a tumor suppressor gene. Further, 5q and 7q deletions in familial platelet disorder with leukemia are associated with mutations or deletions of a single *AML1* allele.²³ Balanced translocations involving the *AML1* gene have also been associated with t-MDS/AML in patients exposed to topoisomerase II inhibitors.²³ Transgenic expression of *AML1*-ETO leads to immortalization of murine myeloid progenitors but not overt leukemia; additional mutations are required for leukemogenesis.²³ Therefore, altered *AML1* function may have a major role in dysregulation of hematopoietic growth and genomic instability and predispose to leukemia through a multistep process.

Thus, although several candidate genes have been identified in these regions, including genes that regulate hematopoietic cell growth and differentiation, identification of a commonly deleted tumor suppressor gene has been elusive. It is possible that haploinsufficiency and reduced gene dosage for critical genes involved in hematopoiesis on 5q, including *RPS14*, *EGRI*, *APC*, *NPM1*,

and *CTNNA1*, may sufficiently alter the balance between growth and differentiation to induce dysplastic hematopoiesis.²⁴ Alternatively, epigenetic inactivation of the remaining allele or alterations in gene expression through loss of miRNA loci could play a role.

MLL rearrangements can be induced when primary human CD34+ cells are exposed to etoposide; stable genome rearrangements originating within the *MLL* translocation breakpoint hotspot were readily detected in etoposide-treated cells.²⁵ The *MLL* gene located at chromosome band 11q23 has a major role in developmental regulation. Altered *MLL* function, as with *AML1*, may dysregulate hematopoietic growth and genomic instability and predispose to leukemia through a multistep process.

A second class of mutations in genes regulating cytokine signaling pathways has been recognized in AML. The RAS signaling pathway is activated downstream of several cytokine receptors. Constitutively activating point mutations of NRAS are detected in 10% to 15% of patients with t-MDS/AML. In contrast, mutations of the *FLT3* gene (point mutations and internal tandem duplications), commonly seen in de novo AML, are not seen in t-MDS/AML.²⁶

Genetic Susceptibility

The observed interindividual variability in risk of t-MDS/AML for a given genotoxic exposure is likely related to common polymorphisms in low-penetrance genes that regulate the availability of active drug metabolite, or those responsible for DNA repair. Knight et al.²⁷ conducted a genome-wide association study in and identified three single nucleotide polymorphisms (rs1394384 [odds ratio (OR) = 0.3; 95% confidence interval (CI) = 0.2 to 0.6], rs1381392 [OR = 2.1; 95% CI = 1.3 to 3.4], and rs1199098 [OR = 0.5; 95% CI = 0.3 to 0.8]) to be associated with t-MDS/AML with chromosome 5/7 abnormalities.²⁷ rs1394384 is intronic to *ACCN1*, a gene encoding an amiloride-sensitive cation channel that is a member of the degenerin/epithelial sodium channel; rs1199098 is in LD with *IPMK*, which encodes a multikinase that positively regulates the prosurvival AKT kinase and may modulate Wnt/beta-catenin signaling; rs1381392 is not near any known genes or regulatory elements. The investigators confirmed findings in an independent replication cohort.

Mouse strains resistant or susceptible to t-AML induced by the alkylator ethyl-N-nitrosourea were analyzed to identify genes that regulate t-AML susceptibility. Thirteen quantitative trait loci were significantly associated with ethyl-N-nitrosourea-induced leukemogenesis. These quantitative trait loci contained several genes that could contribute to leukemogenesis, including p53, DNA repair, and apoptosis-regulating genes, suggesting that susceptibility to alkylator-induced leukemia may be a complex trait related to multiple genes.²⁸ The next section summarizes reports of associations between t-MDS/AML and low-penetrance genes that regulate the availability of active drug metabolite, or are responsible for DNA repair.

Drug Metabolism. Allan et al.²⁹ examined associations between polymorphisms in the glutathione S-transferase genes (*GSTM1*, *GSTT1*, and *GSTP1*) and t-MDS/AML. Individuals with at least one *GSTP1* codon 105 Val allele were significantly over-represented in t-AML cases compared with de novo AML cases (OR = 1.8; 95% CI = 1.1 to 2.9). Also, relative to de novo AML, the *GSTP1* codon 105 allele occurred more often among patients with t-MDS/AML with prior exposure to chemotherapy (OR = 2.7; 95% CI = 1.4 to 5.1), particularly among those with prior exposure to known *GSTP1* substrates (OR = 4.3; 95% CI = 1.4 to 13.2) and not among patients with t-MDS/AML with exposure to radiation alone.

DNA Repair. Individuals with altered DNA repair mechanisms are likely susceptible to the development of genetic instability that drives the process of carcinogenesis as it relates to t-MDS/AML. Ellis et al.³⁰ examined the association between patients

with t-MDS/AML and two common functional p53-pathway variants: the *MDM2* SNP309 and the TP53 codon 72 polymorphism. Neither polymorphism demonstrated a significant association. However, an interactive effect was detected such that *MDM2* TT TP53 Arg/Arg double homozygotes, and individuals carrying both a *MDM2* G allele and a TP53 Pro allele were at increased risk of chemotherapy-related t-MDS/AML.

Mismatch Repair. Defects in the mismatch repair pathway result in genetic instability or a mutator phenotype, manifested by an elevated rate of spontaneous mutations characterized as multiple replication errors in simple repetitive DNA sequences (microsatellites)—functionally identified as microsatellite instability (MSI). Approximately 50% of patients with t-MDS/AML have MSI, associated with methylation of the mismatch repair family member *MLH1*.^{31,32}

Double-Strand Breaks. Cellular pathways available to repair double-strand breaks include homologous recombination, nonhomologous end-joining, and single-strand annealing. *RAD51* is one of the central proteins in the homologous recombination pathway, functioning to bind to DNA and promote ATP-dependent homologous pairing and strand transfer reactions. *RAD51-G-135C* polymorphism is significantly overrepresented in patients with t-MDS/AML compared with controls (C allele: OR = 2.7).³³ *XRCC3* also functions in the homologous recombination double-strand break repair pathway by directly interacting with, and stabilizing *RAD51*. The variant *XRCC3-241Met* allele has been associated with a higher level of DNA adducts compared with cells with the wild-type allele, implying aberrant repair³⁴ and has also been associated with increased levels of chromosome deletions in lymphocytes after exposure to radiation.³⁵ Although *XRCC3-Thr241Met* was not associated with t-MDS/AML (OR = 1.4; 95% CI = 0.7 to 2.9), a synergistic effect resulting in an eight-fold increased risk of t-MDS/AML (OR = 8.1; 95% CI = 2.2 to 29.7) was observed in the presence of *XRCC3-241Met* and *RAD51-135C* allele in patients with t-MDS/AML compared with controls.³³

Base Excision Repair. The *XRCC1* protein plays a central role in the base excision repair pathway and also in the repair of single-strand breaks, by acting as a scaffold and recruiting other DNA repair proteins. The protein also has a BRCA1 C-terminus (BRCT) domain—a characteristic of proteins involved in DNA damage recognition and response. The presence of variant *XRCC1-399Gln* has been shown to be protective for t-MDS/AML.³⁶

Nucleotide Excision Repair. Nucleotide excision repair removes structurally unrelated bulky damage induced by radiation and chemotherapy. The nucleotide excision repair pathway is linked to transcription and components of the pathway comprise the basal transcription factor IIH complex, which is required for transcription initiation by RNA polymerase II. One of the genes involved in the nucleotide excision repair pathway (*ERCC2*) is a member of the basal transcription factor IIH complex. The polymorphic Gln variant (*ERCC2 Lys751Gln*) is associated with t-MDS/AML.³⁷

Telomeric Shortening

Telomeres are noncoding regions of DNA that provide a cap at the ends of chromosomes and prevent dicentric fusion and other chromosomal aberrations. Each somatic cell division is associated with a loss of telomere length. Cumulative telomere shortening can impose a limit on cell divisions and lead to cell senescence. Telomere shortening is also associated with genetic instability. Following HCT, the increased replicative demand on stem cells associated with hematopoietic regeneration can lead to accelerated telomere shortening. Telomere shortening could be an important issue in autologous HCT, especially when telomere length in the transplanted cells is already short because of prior chemotherapy,

older age at HCT, or increased replicative stress on the stem cells because of a small number of cells transplanted. A prospective, longitudinal study revealed accelerated telomere shortening in patients with t-MDS/AML (preceding the onset of t-MDS/AML) when compared with matched controls who did not develop t-MDS/AML. Patients with t-MDS/AML also showed reduced generation of committed progenitors, suggesting that telomere alterations were related to reduced regenerative capacity of hematopoietic stem cells.³⁸

Hematopoietic Abnormalities

Autologous HCT for NHL and HL is associated with hematopoietic abnormalities including marked and prolonged reduction in primitive progenitor long-term culture-initiating cells and committed progenitor colony-forming cell numbers, altered progenitor expansion potential, and microenvironmental defects. These abnormalities may be related in part to damage to hematopoietic cells from pretransplant chemotherapy because hematopoietic defects can also be seen in pretransplant samples.¹⁹ Although committed progenitors recover to pretransplant levels, primitive progenitor capacity is further depleted and does not show evidence of recovery for up to 2 years after HCT, consistent with extensive proliferation and differentiation of the committed progenitors and subsequent depletion of primitive progenitors during hematopoietic regeneration post-HCT.¹⁹ HCT may also be associated with defects in the marrow hematopoietic microenvironment, including reduction in stromal precursor growth and reduced capacity to support growth of myeloid progenitors and B progenitors. These microenvironmental defects may contribute to hematopoietic abnormalities posttransplantation. Extensive proliferation of stem cells bearing genotoxic damage posttransplant may have a role in establishment and amplification of an abnormal clone. Alternatively, the numerous replication cycles imposed on hematopoietic stem cells after HCT may result in excessive shortening of telomeres in descendant cells (as previously discussed). Telomeric shortening may be associated with genomic instability and chromosomal abnormalities, and could contribute to the pathogenesis of t-MDS/AML.³⁹

CD34+ cells in the graft from patients with NHL also show reduced migration compared with normal CD34+ cells. In vitro migratory capacity of CD34+ cells in the graft correlated with the speed of hematopoietic recovery after transplantation.⁴⁰ Therefore, pretransplant chemotherapy may also lead to reduced engraftment potential of primitive progenitor cells. HCT may also be associated with defects in the marrow hematopoietic microenvironment, including reduction in stromal precursor growth and reduced capacity to support growth of myeloid progenitors and B cell progenitors.^{41,42}

Microenvironmental defects may contribute to hematopoietic abnormalities after transplantation. There is evidence supporting the importance of the hematopoietic microenvironment in MDS pathogenesis. Repeated sublethal irradiation of mice was shown to result in bone marrow dysfunction with features of MDS including low white blood cell counts, macrocytic anemia, and reduced platelets and megakaryocytes. Bone marrow dysfunction was associated with increased bone marrow angiogenesis, vascular endothelial growth factor, and activation of the transcription factor NFκB. Tumor necrosis factor-α deleted mice were protected from irradiation effects,⁴³ suggesting that radiation-mediated tumor necrosis factor-α induction may contribute to bone marrow dysfunction and t-MDS/AML. Deletion of the microRNA processing factor Dicer1 in mouse osteoblast progenitors resulted in hematopoietic abnormalities leading to development of MDS and AML, associated with reduced expression of the *Sbds* gene that is mutated in the Schwachman-Bodian-Diamond syndrome, an inherited human marrow failure disorder.⁴⁴ Deletion of *Sbds* in osteoblast progenitors also induced marrow dysfunction and myelodysplasia. These results support a role for perturbation of microenvironmental cells in hematopoietic defects in t-MDS/AML.

Gene Expression Profiling

Gene expression profiling of acute lymphoblastic leukemia cells at diagnosis has been shown to be predictive of subsequent t-MDS/AML.⁴⁵ Gene expression profiling of CD34+ hematopoietic progenitor cells from patients with t-MDS/AML has identified different subtypes of t-MDS/AML with characteristic gene expression patterns.⁴⁶ Common to each subgroup were gene expression patterns characteristic of arrested differentiation in early progenitor cells. Li et al.⁴⁷ performed microarray analyses of gene expression in patients who developed t-MDS/AML after autologous HCT for HL or NHL (cases) and patients who did not develop t-MDS after autologous HCT (controls). To evaluate gene expression changes pre-HCT, PBSC samples obtained from t-MDS/AML cases and controls before HCT were studied. Patients who later developed t-MDS/AML showed significantly altered gene expression when compared with controls, related to mitochondrial function, ribosomes, DNA repair, and hematopoietic stem cell regulation. Additional alterations in cell-cycle regulatory genes were seen on progression to overt t-MDS/AML. PBSC CD34+ cells from cases that developed t-MDS/AML demonstrated altered mitochondrial function, increased reactive oxygen species (ROS), reduced ROS detoxification, and enhanced DNA damage after therapeutic exposure. These results indicate that genetic programs associated with t-MDS/AML are perturbed long before disease onset and are consistent with previous studies indicating a potential role for abnormalities in stem cell growth, DNA repair, and checkpoint response in t-MDS/AML pathogenesis.

Outcomes of Patients with Therapy-Related Myelodysplasia/Acute Myeloid Leukemia After Autologous Hematopoietic Cell Transplantation

The response of t-MDS/AML to chemotherapy is lower than that seen in de novo leukemia, with an average complete remission rate between 35% and 40%, and poor overall long-term survival. As a result, allogeneic transplantation has been evaluated as a therapeutic modality for t-MDS/AML. Armand et al.⁴⁸ applied an optimal cytogenetic grouping (developed for de novo MDS/AML) to patients with t-MDS/AML, and showed that the optimized cytogenetic classification (adverse cytogenetics: abnormal 7 or complex; favorable cytogenetics: 5q- or 20q- or Y- or normal; intermediate: all others) outperformed the established grouping schemes for outcome prediction. Using this new scheme, cytogenetics was the strongest prognostic factor for overall survival through its impact on the risk of relapse. After accounting for cytogenetics, patients with t-MDS/AML had an equivalent outcome to those with de novo disease.⁴⁸ Yakoub-Agha et al.⁴⁹ analyzed the predictors of survival, relapse, and treatment-related mortality among 70 patients with t-MDS/AML undergoing allogeneic HCT. Older age (>37 years), male sex, positive recipient cytomegalovirus serology, absence of complete remission at HCT, and intensive conditioning schedules were independently associated with poor outcome. Litzow et al.⁵⁰ analyzed the outcomes in patients with t-MDS/AML treated with allogeneic HCT between 1990 and 2004. The incidence of treatment-related mortality and relapse was 41% and 27%, at 1 year, respectively, and 48% and 31% at 5 years, respectively. In multivariable analysis, four risk factors had adverse impact on disease-free survival and overall survival: (1) age older than 35 years, (2) poor-risk cytogenetics, (3) t-AML not in remission or advanced t-MDS, and (4) donor other than a human leukocyte antigen (HLA)-identical sibling or a partially or well-matched unrelated donor. Five-year survival for subjects with none, one, two, three, or four of these risk factors was 50%, 26%, 21%, 10%, and 4%, respectively.

These data show that HCT provides potentially curative therapy for t-MDS. The major risk factors for inferior outcome appear

to be disease stage and cytogenetics, together with patient age and donor HLA match or mismatch. Treatment of t-MDS/AML should include consideration of the likelihood of success of achieving remission with chemotherapy and, depending on the availability of an appropriate donor, the likelihood of a successful outcome with an allogeneic transplant approach. It is important to follow patients at risk for development of t-MDS/AML closely to identify the early development of MDS. Prompt transplantation should be considered after diagnosis of t-MDS/AML. It is clear, however, that innovative transplant strategies are needed to reduce the high risks of relapse and nonrelapse mortality.

Prediction of Risk of Therapy-Related Myelodysplasia/Acute Myeloid Leukemia

Because of the poor prognosis associated with t-MDS/AML, attempts are under way to identify predictors or early biomarkers to decrease the morbidity associated with this disease. Several studies have attempted to correlate identification of genetically abnormal clones with subsequent risk of t-MDS/AML. Assessment of risk of t-MDS/AML after autologous HCT is complicated by the lack of a single underlying genetic abnormality; development of t-MDS/AML requires acquisition of several mutations. Moreover, t-MDS/AML is a heterogeneous disorder with multiple subtypes characterized by different genetic abnormalities. Therefore, identification of a single genetic abnormality may not necessarily have predictive value for development of t-MDS/AML. Identification of early biomarkers would allow the timely use of appropriate measures to treat the disorder, such as reduced intensity conditioning or other novel agents, rather than waiting for the t-MDS/AML to present in the clinically overt form, when the disease burden would require higher-intensity therapy, with a greater risk of resultant morbidity. In fact, identification of patients at high risk for t-MDS/AML prior to transplantation would allow treatment strategies other than autologous transplantation—such as reduced-intensity allogeneic transplantation—to be considered for such patients to avoid the risk of t-MDS/AML.

Standard Cytogenetics and Fluorescent in situ Hybridization

Abnormal clones are frequently detected after autologous HCT for lymphoma. Significant levels of clonally abnormal cells could be detected by fluorescence in situ hybridization prior to high-dose therapy in samples obtained from 20 of 20 patients who developed t-MDS/AML, but only 3 of 24 patients did not.⁵¹ However, this technique is locus-specific and requires prior selection of markers for analysis and has limited sensitivity of detection.

Polymerase Chain Reaction Assays for Point Mutations

Mutations in genes such as *MLL* or *AML1* or gene rearrangements involving the 11q23 gene may be useful markers for risk of subsequent t-MDS/AML. This method is highly sensitive, but is locus specific, and the specificity and predictive value of such assays is unknown at present.¹⁶

Gene Expression Analysis

Gene expression microarray analysis of PBSC CD34+ cells from patients who developed t-MDS/AML after autologous HCT for HL or NHL and controls that did not develop t-MDS/AML was used to derive a cross-validated t-MDS/AML gene signature.⁴⁷ This 38-gene signature when applied to an independent test set of patients who developed t-MDS/AML after autologous HCT for NHL or HL, and matched controls correctly classified 14 of 16 subjects who developed t-MDS/AML, and 19 of 20 subjects who did not. Clonal abnormalities characteristic of t-MDS/AML were

not seen on cytogenetic analysis of bone marrow samples obtained prior to autologous HCT nor were they seen in fluorescence in situ hybridization analysis of PBSC CD34+ cells, indicating that the gene expression profile of cytogenetically normal hematopoietic cells can potentially identify patients at risk for t-MDS/AML post-HCT.

Reducing Risk of Therapy-Related Myelodysplasia/Acute Myeloid Leukemia After Autologous Hematopoietic Cell Transplantation

Our understanding of the etiology and pathogenesis should help develop potential risk-reduction strategies, such as minimization of pretransplant cytotoxic exposure by bringing high-risk patients to HCT earlier in the course of disease. Standardized screening of patients in the immediate pre-HCT period with marrow pathology and cytogenetics could potentially help identify high-risk populations that would then benefit from an allogeneic rather than autologous HCT. Alteration in hematopoietic cell procurement and conditioning regimens could also be considered. If strategies to develop predictors for patients at high risk prior to HCT are realized, alternative treatment approaches such as allogeneic transplantation or nontransplant modalities may be considered for patients identified at increased risk. Finally, strategies for chemoprevention may be worth exploring in this population.

LYMPHOMAS

Posttransplantation Lymphoproliferative Disorders

Posttransplantation lymphoproliferative disorders (PTLD) are the most common SMN in the first year after allogeneic T-cell-depleted HCT and are related to a compromised immune status and EBV infection.^{52,53} Subgroups of patients at elevated risk of PTLD have been clearly defined for whom prospective monitoring of EBV activation and early therapeutic intervention may be particularly useful. The vast majority of PTLDs develop within the first year. The risk of PTLD is strongly associated with T-cell depletion of the donor marrow, antithymocyte globulin use, unrelated or HLA-mismatched grafts, presence of acute or chronic GVHD, older age at HCT, and multiple transplants. The cumulative incidence is low (0.2%) among patients with no major risk factors, but is increased to 1.1%, 3.6%, and 8.1% with one, two, and three or more major risk factors, respectively. The large majority of the PTLDs have a B-cell origin.

B-cell PTLD, a clinically and morphologically heterogeneous group of diseases, usually develops within the first 6 months after HCT, with a cumulative incidence of 1% to 2% at 10 years. Risk factors include in vitro T-cell depletion of the donor marrow, unrelated or HLA-mismatched related donor, use of antithymocyte globulin or anti-CD3 monoclonal antibody, TBI, and primary immunodeficiency (see Table 118.1).^{1,54} The risk of PTLD also depends on the method of T-cell depletion, being considerably higher when specific monoclonal antibodies are used for T-cell depletion (11% to 25%) rather than in patients in whom techniques removing both T and B lymphocytes, such as soybean agglutinin or Campath-1 (<1%), are used.⁵³

Pathogenesis of B-Cell Posttransplantation Lymphoproliferative Disorder

B-cell PTLD is commonly associated with T-cell dysfunction, occurs in the presence of EBV infection, and is thought to develop because of a combination of depressed EBV-specific cellular immunity and the inherent transforming capacities of EBV.

EBV is a ubiquitous herpesvirus that infects 95% of individuals by adulthood. The virus persists as a latent infection in B lymphocytes, where reactivation and replication occur intermittently. The latent membrane protein 1 (LMP-1) is one of the EBV-encoded proteins believed to have an important role in B-cell immortalization by inducing the expression of *bcl-2*, which inhibits programmed death of infected cells. LMP-1 is also considered to be an oncogene, and deletions near the 3' end of the *LMP-1* gene, in a region that affects the half-life of the LMP-1 protein, have been reported in some PTLDs. Infection of B cells by EBV also induces high levels of cytokines such as interleukin (IL)-1, IL-5, IL-6, IL-10, CD23, and tumor necrosis factor. Some of these factors have been shown to act as autocrine growth factors, stimulating the proliferation of EBV-transformed B cells and inhibiting their susceptibility to apoptosis.

Cytotoxic T-lymphocyte precursor frequencies are low at 3 months after allogeneic HCT, but appear to normalize at 9 to 12 months, thus correlating with the period when B-cell PTLD is most frequently observed. Moreover, the EBV-specific cytotoxic T lymphocytes home preferentially and induce selective regression of autologous EBV-induced B-cell lymphoproliferative lesions in xenografted severe combined immunodeficiency syndrome mice. These studies have formed the basis for clinical trials using adoptive transfer of EBV-specific cytotoxic T lymphocytes.⁵⁵ The studies demonstrated long-term persistence of gene-marked EBV-specific cytotoxic T lymphocytes *in vivo*, which not only restore cellular immunity against EBV but also provide a population of cytotoxic T-lymphocyte precursors that respond to *in vivo* and *ex vivo* challenges with the virus for as long as 18 months.⁵⁶ These studies have demonstrated that a combination of granulocyte-macrophage colony-stimulating factor and low-dose IL-2 therapy can prevent the immunodeficiency that leads to fatal EBV lymphoproliferative disease in xenografted SCID mice depleted of murine natural killer cells, and thus support a critical role for several human cellular subsets in mediating this protective effect.

Treatment of B-Cell Posttransplantation Lymphoproliferative Disorder

Close monitoring of patients at increased risk for PTLD allows for early institution of appropriate therapy prior to development of overt disease. Therapeutic approaches include B cell-specific monoclonal antibodies and cellular therapy. The efficacy of anti-CD20 monoclonal antibody (rituximab) in the treatment of PTLD has been reported. The drug is more efficacious in patients without mass lesions, forming the basis for recommendations to initiate treatment at an early stage, based on increasing EBV load. Because EBV-associated PTLD results from T-cell dysfunction, reconstitution of "at-risk" patients with EBV-specific cytotoxic T-lymphocyte lines reactivated and expanded *in vitro* has been shown to be efficacious in controlling PTLD, with a decrease in the EBV DNA concentrations and clinical remission.

Thus, over the past few years, the administration of *in vitro*-generated EBV-specific cytotoxic T cells or anti-B cell monoclonal antibodies has provided an effective option for the prophylaxis or treatment of PTLD. Advances in quantitative polymerase chain reaction-based assays allow both the precise measurement of EBV load in peripheral blood samples and the identification of high-risk patients for early initiation of therapy. Patients should be monitored weekly by quantitative competitive polymerase chain reaction because viral load is a significant predictor of PTLD. Prevention of EBV PTLD by preemptive therapy based on molecular monitoring of EBV load may be used to decrease the occurrence of PTLD. Preemptive therapy with a single dose of rituximab has been reported to lead to the prevention of PTLD and was first demonstrated by Van Esser et al.⁵⁷ The cutoff value of >1,000 EBV genome copies in 10⁵ peripheral blood mononuclear cells shows a sensitivity and specificity of 100% and a positive and negative predictive value of 1.00.⁵⁸

In summary, chemotherapy seems not to contribute to improved survival of patients with PTLD after HCT, and antiviral agents are not active against PTLD. On the other hand, preemptive use of rituximab and EBV-cytotoxic T lymphocytes significantly reduces the risk of death due to EBV-PTLD in HCT recipients with survival rates of ~90%. The overall success rates for established PTLD is lower than after preemptive therapy, ranging from ~60% (rituximab) to ~80% (cytotoxic T lymphocytes). A reduction of immunosuppression and/or donor lymphocyte infusion might also reduce the risk of death due to EBV PTLD; the responses range from 40% to 50%.⁵⁹

Hodgkin Lymphoma

HL has also been described after HCT.⁵ Mixed cellularity is the most commonly reported subtype, and most of the cases contain the EBV genome. These cases differ from the EBV-PTLD by the absence of risk factors commonly associated with EBV-PTLD, by a later onset (>2.5 years), and relatively good prognosis.

SOLID TUMORS

The cumulative incidence of solid tumors after allogeneic HCT ranges from 7% to 11% at 15 years posttransplantation.^{1,3,6,9,11,60} The magnitude of risk of solid tumors after HCT exceeds two-fold that of an age- and sex-matched general population.^{3,6,11} The risk increases with time from HCT and, for those who survive ≥10 years after HCT, is reported to be eight-fold that of the general population. Types of solid tumors reported in excess among HCT recipients include melanoma, basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) of the skin, and cancers of the oral cavity and salivary glands, brain, liver, uterine cervix, thyroid, breast, bone, and connective tissue.³ The risk of solid tumors is higher among those exposed to radiation at a younger age and rises with the dose of radiation (see Table 118.1). Majhail et al.⁶⁰ evaluated the risk of solid SMNs after HCT using high-dose busulfan-cyclophosphamide conditioning in 4,318 recipients of allogeneic HCT for AML or chronic myelogenous leukemia. The cumulative incidence of solid cancers at 10 years after HCT was 1.2% among AML and 2.4% after chronic myelogenous leukemia. In comparison to general population, HCT survivors were at a 1.4-fold increased risk. Significantly increased risks were observed for tumors of the oral cavity, esophagus, lung, soft tissue, and brain. Chronic GVHD was an independent risk factor for all solid cancers, and especially cancers of the oral cavity. The risk of specific solid SMNs after HCT are summarized in the following sections and detailed in Table 118.2.

Skin Cancer

The 20-year cumulative incidence of BCC and SCC after allogeneic HCT is reported to be 6.5% and 3.4%, respectively.⁷ TBI is a risk factor of BCC, particularly among patients younger than 18 years at HCT. Schwartz et al.⁸ demonstrated that the risk of BCC associated with radiation is highest for the youngest ages at exposure, with relative risks exceeding 20 for those transplanted at ages <10 years, and decreasing with increasing age at exposure until age 40 years, above which no excess risk was identified. GVHD (acute and chronic for SCC and chronic for BCC) and male sex are associated with an increased risk of skin cancer.⁷

Breast Cancer

The 25-year cumulative incidence of breast cancer is reported to be 11% after allogeneic HCT. Allogeneic HCT survivors are at a 2.2-fold increased risk of developing breast cancer, when compared

TABLE 118.2

Magnitude of Risk and Populations at Increased Risk of Specific Subsequent Malignant Neoplasms After Hematopoietic Cell Transplantation

Study	Study Design	Sample Size/ Number of SMNs	Primary Diagnoses/ Type of HCT	Magnitude of Risk and Risk Factors
Hodgkin Lymphoma				
Rowlings et al. ⁵	Retrospective cohort	18,531/8 Hodgkin lymphoma	Hematologic malignancies and severe aplastic anemia Allogeneic HCT	6.2-fold increased risk; Grade 2 to 4 acute GVHD, treatment for chronic GVHD
Skin Cancer				
Leisenring et al. ⁷	Retrospective cohort study design	4,180/237 nonmelanoma skin cancer	All malignancies and metabolic disorders Allogeneic HCT	20-y cumulative incidence: BCC: 6.5%; SCC: 3.4% TBI and younger age at irradiation, light skin color, chronic GVHD associated with BCC Acute and chronic GVHD associated with SCC
Curtis et al. ⁶⁹	Case-control	58 SCCs and 125 BCCs; 501 matched controls	Hematologic malignancies, severe aplastic anemia, hemoglobinopathies Allogeneic (matched related and unrelated) HCT	Prolonged and severe chronic GVHD and its therapy (azathioprine, corticosteroids, cyclosporine) were associated with SCCs
Schwartz et al. ⁸	Retrospective cohort	6,306/282 BCCs	Hematologic malignancies; severe aplastic anemia; Autologous, matched related and unrelated donor HCT	TBI exposure; youngest age at HCT; increasing attained age; whites; more recent birth cohorts
Breast Cancer				
Friedman et al. ⁹	Retrospective cohort	3,337 females/52 breast cancers	Hematologic malignancies Allogeneic HCT	Cumulative incidence: 11% at 25 y Longer time since HCT, use of TBI, younger age at HCT
Thyroid Cancer				
Cohen et al. ¹⁰	Retrospective cohort	78,914/32 thyroid cancer	All malignancies and severe aplastic anemia Autologous, allogeneic	3.26-fold increased risk Young age at HCT, irradiation, female sex, chronic GVHD

SMN, subsequent malignant neoplasm; HCT, hematopoietic cell transplantation; GVHD, graft-versus-host disease; BCC, basal cell carcinoma; SCC, squamous cell carcinoma; TBI, total-body irradiation.

with age- and sex-matched general population. The incidence of breast cancer is higher among those exposed to TBI (17%) than among those who did not receive TBI (3%).⁹ The median latency from HCT to diagnosis of breast cancer is 12.5 years. The risk is increased among those exposed to TBI at a younger age.

Thyroid Cancer

HCT recipients are at a 3.3-fold increased risk of thyroid cancer, when compared with age- and sex-matched general population.¹⁰ Age younger than 10 years at HCT, neck radiation, female sex, and chronic GVHD are associated with an increased risk. Thyroid cancer develops after a latency of 8.5 years and is associated with an excellent outcome.

Pathogenesis of Solid Tumors After Hematopoietic Cell Transplantation

Radiation is the single most important risk factor for the development of solid tumors. These radiogenic cancers have a long latent period, and the risk is frequently high among patients undergoing irradiation at a young age. Immunologic alterations may predispose

patients to SCC of the buccal cavity, particularly in view of the association with chronic GVHD.⁷ In immunosuppressed patients, oncogenic viruses such as human papillomavirus may contribute to SCC of the skin and buccal mucosa after transplantation.

Chronic tissue stress due to interaction of alloreactive donor cells with host epithelium may cause genomic alterations and increase the risk of SMNs. This hypothesis was tested by analyzing buccal cells from allotransplanted patients for MSI.⁶¹ MSI was observed in 52% of the allotransplant recipients, but not among healthy or autotransplanted controls. SMNs were identified in five of the MSI-positive patients (14%) and only one of the MSI-negative patients. In an in vitro model of mutation analysis, significant induction of frameshift mutations and DNA strand breaks in HaCaT keratinocytes cocultured with mixed lymphocyte cultures were observed, but not after exposure to interferon gamma, tumor necrosis factor-alpha, transforming growth factor-beta, or phytohemagglutinin-stimulated peripheral blood mononuclear cells, suggesting an ROS-mediated mechanism. These data indicate that alloactions may induce genomic alterations in epithelium.

Patients with a family history of early onset cancers have been shown to be at an increased risk for developing a SMN. The tumor types occurring in excess in close relatives were also observed as SMNs in patients (cancers of the breast, bone, joint, or soft tissue), indicating that the risk of SMN is associated with a familial

predisposition.⁶² Genetic predisposition also has a substantial impact on risk of SMNs (e.g., sarcomas in patients with hereditary retinoblastoma). This risk is further increased by radiation and increases with the total dose of radiation.⁶³

In summary, an interaction of cytotoxic therapy (radiation in particular), genetic predisposition, viral infection, and GVHD with the consequent antigenic stimulation and use of immunosuppressive therapy may play a role in the development of new solid tumors, and needs to be explored comprehensively.

Treatment of Patients with Solid Tumors After Hematopoietic Cell Transplantation

Treatment strategies for patients developing solid tumors after HCT are not well defined. Small case series indicate both ends of the spectrum: favorable outcomes and hence a recommendation for an intensive approach and aggressive tumor growth, and early relapse after standard therapy. A comprehensive study of a large number of patients with second solid tumors will help determine the nature of these tumors and their outcomes as compared to de novo tumors. Until then, patients with solid tumors should be treated with the best available therapy for that tumor, unless there is compelling evidence that they will not be able to tolerate that therapy.

Screening for Subsequent Malignant Neoplasms in Hematopoietic Cell Transplantation Survivors

Theoretically, if screening resulted in an earlier diagnosis of SMNs, then treatment would be more successful and survival rates higher. Additionally, less aggressive treatment could be instituted with less toxicity. The issue of who to screen, how to screen, and when to do it are all important but largely unanswered questions. For the pediatric survivor population, the Children's Oncology Group has developed comprehensive long-term follow-up guidelines that provide risk-adapted, yet consensus-based recommendations.⁶⁴ For HCT survivors, screening recommendations must incorporate risks associated with pre-HCT therapy, transplant conditioning therapy, and other HCT-associated conditions such as chronic GVHD. Joint recommendations for screening and preventative practices for long-term survivors after HCT from the European Group for Blood and Marrow Transplantation, the Center for International Blood and Marrow Transplant Research, and the American Society of Blood and Marrow Transplant were published in 2006.⁶⁵ This reference provides general guidance for SMN screening for HCT survivors, but recommendations are limited to annual risk awareness counseling and clinical assessments. General recommendations for colorectal, breast, and cervical cancer are provided but are for the most part based on guidelines for the general

population. Screening guidelines developed for use in the general population^{66,67} may or may not be sufficient or applicable for use in HCT survivors. For some individuals, additional risk factors, either pre-HCT (exposure to chest radiation, cranial radiation, alkylating agents, topoisomerase II inhibitors) or associated with HCT (TBI, chronic GVHD, duration of immunosuppression, T-cell depletion), may lead to elevated risks and must be considered in the screening strategies. Thus, as summarized by Socie and Rizzo,⁶⁸ the following recommendations could be made:

1. Reduce ultraviolet skin exposure through use of high-sun protective factor sunscreens or skin coverage
2. Avoid high-risk behaviors such as avoidance or cessation of tobacco use
3. Annual screening among those at highest risk—these are detailed in the Children's Oncology Group Guidelines as well as the joint ASBMT/CIBMTR guidelines

Risk-Reduction Strategies

While strategies aimed at altering therapeutic exposures (chemotherapy and radiation) will most likely result in a reduction in the risk of subsequent malignancies in some patients, it is unlikely that these exposures are the only factors that convey risk. Furthermore, it is often not feasible to alter therapeutic exposures while preserving clinical outcomes. In HCT recipients, the risk of SMNs associated with chronic GVHD⁶⁹ could benefit from efforts to prevent GVHD and to improve immune reconstitution after HCT.

There is increasing concern related to the risk of cancer and cancer death associated with obesity and a sedentary lifestyle.⁷⁰ Functional and performance limitations and lower levels of physical activity have been reported in HCT survivors, particularly in those who have chronic GVHD.^{71,72} Obesity (as determined by body mass index) is uncommon in HCT survivors⁷³; however, preliminary studies of body composition reveal that they have a high percentage of fat mass and a reduction in muscle mass. This state of sarcopenic obesity contributes to the development insulin resistance, hyperinsulinemia, and chronic inflammation—factors that have been implicated in the causal pathway of obesity-associated cancer risk.⁷⁴ Thus interventions recommended for the general population aimed at improving nutrition and maintaining a physically active lifestyle are likely of even greater significance for HCT survivors as risk-reduction strategies. Finally, as the pathogenesis of SMNs becomes more clearly elucidated, screening for known genetic susceptibility to cancer could possibly be undertaken and alternative therapeutic options presented to the vulnerable subpopulation. These strategies, as well as those encouraged for all, such as avoidance of tobacco and alcohol, use of sunscreen, and HPV vaccination, may help to reduce the risk of SMNs in HCT survivors.

119 Superior Vena Cava Syndrome

Andreas Rimner and Joachim Yahalom

INTRODUCTION

Superior vena cava syndrome (SVCS) is the clinical expression of obstruction of blood flow through the superior vena cava (SVC). Characteristic symptoms and signs may develop quickly or gradually when this thin-walled vessel is compressed, invaded, or thrombosed by processes in the superior mediastinum. Most cases reported in the past were due to syphilitic aneurysms or tuberculosis mediastinitis.¹ Nowadays, malignancy is the most common underlying process in patients with SVCS.² With the increased use of intravascular devices such as catheters and pacemakers, thrombosis of the SVC caused by these foreign bodies has been more frequently observed.³ It is estimated that SVCS develops in 15,000 people in the United States each year.²

ANATOMY AND PATHOPHYSIOLOGY

The SVC is the major low-pressure vessel for drainage of venous blood from the head, neck, upper extremities, and upper thorax. It is located in the right mediastinum and is surrounded by the sternum, trachea, right mainstem bronchus, aorta, pulmonary artery, and perihilar and paratracheal lymph nodes. The SVC extends from the junction of the right and left innominate veins to the right atrium, over a distance of 6 to 8 cm. The distal 2 cm of the SVC is within the pericardial sac, with a point of relative fixation of the vena cava at the pericardial reflection. The azygos vein, the main auxiliary vessel, enters the SVC posteriorly, just above the pericardial reflection. The physiologic width of the SVC is 1.5 to 2 cm. The SVC is thin-walled, compliant, easily compressible, and therefore vulnerable to any space-occupying process in its vicinity. The SVC is completely encircled by chains of lymph nodes that drain the right thoracic cavity. Other critical structures in the mediastinum, such as the auxiliary azygos vein, main bronchi, esophagus, and spinal cord, may be involved by the same process that leads to obstruction of the SVC.

When the SVC is fully or partially obstructed, venous collateral circulation may develop if the SVCS gradually develops over time, thus allowing time for collaterals to form. The azygos venous system is the most important alternative pathway. Other collateral systems include the internal mammary veins, lateral thoracic veins, paraspinous veins, and esophageal venous network.⁴ Engorgement of collateral subcutaneous veins in the neck and thorax is a typical physical finding in SVCS. Despite these collateral pathways, venous pressure is almost always elevated in the upper compartment if the SVC is obstructed (Fig. 119.1). Venous pressures in the upper extremities have commonly been recorded to be >300 mm saline in severe SVCS.⁵

CLINICAL PRESENTATION AND ETIOLOGY

A subjective sensation of fullness in the head or objective facial swelling and dyspnea are common presenting symptoms

(Table 119.1).^{6,7} The characteristic physical findings are venous distention of the neck (66%) and chest wall (54%), facial edema (46%), plethora (19%), and cyanosis (19%). These symptoms and signs may be aggravated by bending forward, stooping, or lying down. SVCS may be the earliest manifestation of invasive involvement of additional critical structures in the thorax such as the bronchi. Pleural effusions are common in SVCS. In one series, effusions were detected in 60% of patients, both in those with malignant etiology and in those with a nonmalignant cause.⁸ The majority are exudative and often chylous. Rarely do patients present with life-threatening symptoms like confusion, obtundation, stridor or syncope without precipitating factors, hypotension, or renal insufficiency.

Malignant disease is the most common cause of SVCS. The percentage of patients in different series with a confirmed diagnosis of malignancy varies from 60% to 86% (Table 119.2).^{7,9-12} In large series of lung cancer, SVCS was identified in 4% to 8.6% of the patients.^{13,14} Small-cell lung cancer (SCLC) and squamous cell carcinoma are the most common histologic subtypes because of their frequent central location.^{7,15,16} Lymphoma involving the mediastinum was the cause of SVCS in 2% to 21% (see Table 119.2). In a large series, most patients with lymphoma with SVCS had either diffuse large-cell lymphoma or lymphoblastic lymphoma.¹⁷ The presence of dysphagia, hoarseness, or stridor was a major adverse prognostic factor for patients with lymphoma who presented with SVCS. In a series of patients with primary mediastinal B-cell lymphoma with sclerosis, SVCS was present in 57% of patients.¹⁸ Other primary mediastinal malignancies that may cause SVCS are thymomas and germ cell tumors. SCLC, non-Hodgkin lymphoma (NHL), and germ cell tumors constitute almost half of the malignant causes of SVCS. Hodgkin lymphoma commonly involves the mediastinum, but it rarely causes SVCS. Breast cancer is the most common metastatic disease that causes SVCS in up to 11% of the cases.^{9,10} The prognosis of patients with SVCS strongly correlates with the prognosis of the underlying disease.

In recent years, nonmalignant conditions causing SVCS have been more often observed. When the data were collected from general hospitals, as many as 40% of patients had noncancerous causes of SVCS, most commonly due to thrombosis in the presence of central vein catheters or pacemakers.^{7,10,12,19} The increasing use of such catheters for the delivery of chemotherapy agents or hyperalimentation in conjunction with a common thromboembolic disposition in many patients with cancer contributes to the development of SVCS.¹⁹

Obstruction of SVC in the pediatric age group is rare and has a different etiologic spectrum, mainly iatrogenic, secondary to cardiovascular surgery for congenital heart disease, ventriculoatrial shunt for hydrocephalus, SVC catheterization for parenteral nutrition, and mediastinal fibrosis secondary to histoplasmosis.^{20,21}

DIAGNOSTIC WORKUP

The modern treatment of SVCS has become disease-specific from the outset. Therefore, a clear diagnosis prior to initiation of emergency treatment such as mediastinal irradiation should be made. Mediastinal irradiation before a biopsy may preclude proper interpretation of the specimen in almost half of the patients and should be avoided.²² The safety of modern, minimally invasive diagnostic procedures such as bronchoscopy, mediastinoscopy, computed tomography (CT)-guided biopsy or supraclavicular lymph node biopsy has markedly improved, and concerns about risks from these procedures should not preclude proper diagnostic workup. In contrast to past opinions, there is little evidence to suggest that diagnostic procedures such as venographies, thoracotomies, bronchoscopies, mediastinoscopies, and lymph node biopsies carry an excessive risk in patients with SVCS.² Therefore, patients should, if possible, undergo a complete staging workup prior to the initiation of treatment.

The most common radiographic abnormalities are superior mediastinal widening and pleural effusion apparent on chest X-ray. CT with intravenous contrast provides more detailed information about the SVC, its tributaries, and other critical structures, such as the trachea, the bronchi, the esophagus and the spinal cord.²³ The additional anatomic information is necessary to more clearly determine the involvement of these structures that requires prompt action for relief of pressure. Although not fully evaluated, fluorodeoxyglucose-positron emission tomography scanning is useful in patients with SVCS caused by lymphoma or lung cancer, as it may significantly influence the design of the radiotherapy field and treatment intent (definitive versus palliative).²

Pathologic confirmation of a thoracic malignancy can be obtained as a cytologic specimen via endobronchial fine needle aspiration, or via CT-guided needle biopsy or mediastinoscopy. Endobronchial fine needle aspirations are as accurate as tissue diagnosis and supply sufficient malignant cells for cytologic evaluation in most cases of lung cancer.²⁴ Mediastinoscopy has a very high success rate for providing a diagnosis and has a complication rate of approximately 5%.²⁵ Reports by several authors on using mediastinoscopy for patients with SVCS whose histologic diagnosis could not be established with less invasive techniques confirmed the safety and high diagnostic yield of mediastinoscopy.^{25,26} No perioperative mortality was recorded, and the diagnostic yield was excellent. Percutaneous transthoracic CT-guided fine needle biopsy is an effective and safe alternative to an open biopsy or mediastinoscopy.²⁷ In the presence of a pleural effusion, thoracentesis can establish the diagnosis of malignancy in 71% of patients with malignancy.⁸ A thoracoscopic biopsy or thoracotomy is diagnostic if all other procedures have failed.

DISEASE-SPECIFIC MANAGEMENT AND OUTCOMES

The goal of treatment of SVCS depends on the cause and—in malignancies—the stage of the disease. Malignant tumors are potentially

curable if they present at a nonmetastatic stage, even in the presence of SVCS. The treatment of SVCS should be selected according to the histologic disorder and stage of the primary process. During the diagnostic process, the patient can benefit from bed rest and oxygen administration. Some clinicians advocate the use of diuretics and/or corticosteroids if the patient is uncomfortably symptomatic. This should only be considered after pathologic confirmation of the cause of SVCS in symptomatic patients who require urgent palliation, as steroid initiation prior to pathologic confirmation can significantly hamper efforts for an accurate diagnosis, especially with lymphomas. Prophylactic anticoagulation in the absence of thrombosis is of no proven benefit and may interfere with diagnostic procedures.

When the therapeutic goal is only palliation of SVCS, or when urgent treatment of the venous obstruction is required, direct opening of the occlusion should be considered. Endovascular stenting and angioplasty with possible thrombolysis may provide prompt relief of symptoms before more cancer-specific therapy.^{3,28}

SMALL-CELL LUNG CANCER

Chemotherapy alone or in combination with thoracic irradiation therapy is the standard treatment for SCLC and is effective in rapidly improving the symptoms of SVCS.^{14–16,29} No significant difference in response rates to chemotherapy or radiation has been detected in most studies. Response rates to chemotherapy range from 73% to 93% and to radiation from 43% to 94%.^{14,29} Relief of SVCS typically occurs within 7 to 10 days after initiation of therapy. In patients with SCLC with recurrent or persistent SVCS, additional chemotherapy and/or radiotherapy is still likely to relieve symptoms.²⁹

NON-SMALL-CELL LUNG CANCER

A review of SVCS in lung cancer indicated that chemotherapy relieved SVCS in 59% of patients with non-SCLS (NSCLC); radiotherapy relieved the obstruction in 63% of patients with NSCLC.²⁸ Nevertheless, in almost 20% of the patients the obstruction recurred. Response to radiotherapy was higher in patients who had received prior therapy (94% versus 70%).²⁸

NON-HODGKIN LYMPHOMA

The primary treatment for NHL is chemotherapy, as it has both local and systemic activity. Local consolidation with radiation therapy is beneficial in patients with early stage diffuse large-cell lymphoma, particularly if the mass is bulky.

In a report of 36 patients with SVCS secondary to NHL, all patients achieved complete relief of SVCS symptoms within 2 weeks of the onset of any type of treatment, whether treated with chemotherapy alone, chemoradiation, or radiotherapy alone.¹⁷

Eighteen of twenty-two patients (81%) with large-cell lymphoma achieved complete response. However, relapse was common, and the median survival was only 21 months.

NONMALIGNANT CAUSES

Patients with nonmalignant SVCS often have longstanding symptoms before they seek medical advice, and the time to establish the diagnosis and survival are typically markedly longer.¹⁰ The average survival rate has been reported as 9 years for benign causes, compared with 5 months for lung cancer as the cause of SVCS. A total of 12 (75%) of 16 patients with benign SVCS had a mediastinal granuloma that was attributed to histoplasmosis.³⁰ Ten patients who were available for 1 to 11 years were all doing well at the time of the report. Given the good prognosis of patients with benign SVCS, a need for SVC bypass surgery may not be justified, except for patients in whom SVCS develops, progresses, or persists after 6 to 12 months of observation for possible collateral development.³⁰ Ketoconazole may prevent recurrent SVCS from active histoplasmosis.

CATHETER-INDUCED OBSTRUCTION

In catheter-induced SVCS, the mechanism of obstruction is usually thrombosis. Streptokinase, urokinase, or recombinant tissue-type plasminogen activator may achieve lysis of the thrombus early in its formation.³¹ Heparin and oral anticoagulants may reduce the extent of the thrombus and prevent its progression. Removal of the catheter should be considered, if possible, in combination with anticoagulation to avoid embolization. In patients for whom electrodes of a pacemaker must be changed, the wires should be removed to prevent the risk of developing SVCS.³² Percutaneous transluminal angioplasty, with or without thrombolytic therapy, and stent insertion have been successfully used to open catheter-induced SVC obstructions.³³

TREATMENT

Radiation Therapy

Radiotherapy is a treatment option for most patients with malignant SVCS. Radiotherapy does not only provide immediate relief of the obstruction, but will also treat the underlying cause of the obstruction, thus improving symptoms in the long-term and effectively preventing SVCS recurrence. The primary effect of palliative radiotherapy for SVCS is exerted by decreasing the extrinsic pressure on the SVC by the surrounding or invading malignant masses. However, serial venograms and autopsies suggest that the symptomatic improvement may be enhanced by the development of collaterals after the pressure in the mediastinum is eased.

In general, when radiation is given as initial treatment, CT-based simulation and fractions of 1.8 to 2 Gy are recommended for lymphomas. For lung cancers, higher daily fractions of 3 Gy may be considered. However, no data clearly support a particular fractionation scheme. The field and fractionation may be altered after administration of several fractions and achievement of symptomatic relief.² In the absence of distant metastatic disease, the radiotherapy course may be extended to a definitive treatment course, in combination with sequential or concurrent chemotherapy when feasible.

A retrospective study evaluated the efficacy of treating patients with SVCS with a regimen of three fractions of 8 Gy once a week to a total dose of 24 Gy compared to two fractions of 8 Gy within 1 week to a total dose of 16 Gy.³⁴ Transient dysphagia was the main side effect in almost half of the patients in both programs. The

24-Gy regimen resulted in a complete resolution of symptoms in 56% of patients and a partial response in another 40%. The 16-Gy regimen yielded a complete response in only 28% of patients. The mean time for SVCS recurrence and the median overall survival rate were longer in the higher-dose regimen (6 months and 9 months, respectively) compared with the low-dose regimen (3 months and 3 months, respectively). A more recent study reported the experience of using only two fractions of 6 Gy each, delivered 1 week apart, in 23 elderly patients with malignancy-related SVCS.³⁵ Overall response was 87% with mild toxicity (grade 1-2 dysphagia in six patients, fatigue in four patients, and short-lived systemic side effects consisting of chest pain, rigors, and fever in four patients).

In the definitive treatment setting, the radiation field should encompass all gross disease with appropriate margins for clinical and planning target volumes. In the palliative setting, the radiation field should encompass all gross disease responsible for the SVCS, which may include the hilar, mediastinal, and supraclavicular lymph nodes. Elective nodal irradiation is generally not recommended when treating patients with lymphoma or lung cancer as the cause of malignant SVCS.

Endovascular Stenting and Angioplasty

Percutaneous transluminal angioplasty using the balloon dilatation, insertion of expandable metal stents, or both have been successfully used to open and maintain the patency of SVC obstruction resulting from malignant and benign causes.^{3,28,33,36,37} It is an effective initial treatment for obtaining immediate relief of the obstruction if the clinical status of the patient is deteriorating. Median symptom-free survival of 6 months has been reported in a large series of 149 patients with malignant SVCS.³⁶ However, long-term experience in maintaining patency after stent therapy in patients with SVCS from benign causes who are expected to have long survival is still limited.³³ Complication rates for endovascular therapy range from 0% to 50% and include bleeding, stent migration, stent occlusion, and pulmonary embolus.³ A recent prospective study examining the outcomes of expanded polytetrafluoroethylene-covered stents found a higher patency and median survival compared to uncovered stents from a historic patient population.³⁸

Thrombolysis is often an integral part of the endovascular management of SVCS because thrombolysis is frequently a critical component of the obstruction and lysis is necessary to allow the passage of the wire. Most reports have emphasized the use of combination endovascular therapy: thrombolysis, angioplasty, and stent insertion.^{3,28} Successful experience with thrombolytic agents was also obtained in the treatment of catheter-induced SVCS.^{3,31} The higher yield of thrombolytic therapy in patients with catheters is probably related to the mechanism of obstruction, the ability to deliver the agent directly to the thrombus, and earlier recognition of SVCS in patients with malfunctioning catheters. Early intervention and use of urokinase and recombinant tissue-type plasminogen activator were associated with favorable results.³¹

Surgery

In malignancy-induced SVCS, surgical intervention should be considered only after other therapeutic maneuvers as radiotherapy, chemotherapy, and stenting have been exhausted. Most patients with SVCS of benign origin have long survivals without surgical intervention. However, if the process progresses rapidly or if there is a retrosternal goiter or aortic aneurysm, surgical intervention may be indicated to relieve the obstruction.^{39,40}

The experience with successful direct bypass graft for SVC obstruction is limited. It has been recommended that autologous grafts of almost the same size as the SVC should be used.⁴¹ Doty, Flores, and Doty⁴² used a composite spiral graft, which was

constructed from the patient's saphenous vein. They reported 23 years of experience with this procedure in 16 patients with benign obstruction of SVC; 14 patients maintained patency and 15 were relieved of symptoms of SVCS. Piccione, Faber, and Warren⁴³ used autologous pericardium to reconstruct the SVC after resection for malignant obstruction. Successful bypasses of obstructed SVCs have used Dacron (DuPont, Wilmington, DE) and polytetrafluoroethylene prostheses.⁴⁴⁻⁴⁶ The preferred bypass route is between an innominate or jugular vein on the left side and the right atrial appendage, using an end-to-end anastomosis.

The most common surgical approach is via a sternotomy or thoracotomy with extensive resection of the tumor and reconstruction of the SVC. Case series indicate an operative mortality of approximately 5% and patency rates of 80% to 90%.²

AREAS OF UNCERTAINTY

Standardized criteria to grade the severity of symptoms in the SVCS are still lacking. More recently, a grading system with an accompanying treatment algorithm has been proposed.⁴⁷ It emphasizes that in most patients (>85%) with SVCS, the symptoms are not severe (grades 0, 1, and 2) and cancer-specific treatment could follow appropriate diagnosis and staging. Grade 3 (severe) patients who present with mild or moderate cerebral edema, mild/moderate laryngeal edema, or diminished cardiac reserve may be considered for immediate stent intervention or early radiation therapy, otherwise they should receive disease-specific treatment. Only the rare (<5%) grade 4 (life-threatening) patients, who develop significant cerebral edema or laryngeal edema with stridor or have significant hemodynamic compromise, should undergo stent insertion immediately.

The benefit of either short- or long-term anticoagulation therapy for SVCS is unclear, although thrombolytic agents have been used effectively in patients with vena caval thrombosis.² Most experts recommend anticoagulation after thrombolysis (to prevent disease progression and recurrence) and aspirin after stent placement in the absence of thrombosis, but data are limited. The optimal management of recurrent obstruction of the SVC is also controversial. Placement of a stent is often considered because of

the limited benefit or the risk of excessive toxic effects from repeat chemotherapy or radiation, but data to guide decision making are limited.

RECOMMENDATIONS

The clinical course of SVCS rarely represents an absolute emergency. In patients without a clear cause of SVCS who do not have life-threatening symptoms, an efficient diagnostic effort should be attempted before any oncologic treatment is given. If all the proposed testing has failed to establish the diagnosis, the location of the suspicious lesion in the chest and the experience of the surgical team should determine whether mediastinoscopy or thoracotomy is performed.

After the cause of SVCS has been established, treatment of the primary process should promptly follow.

Combination chemotherapy with an appropriate regimen is the treatment of choice for SCLC and NHL. Radiation therapy of the lesion and adjacent nodal areas may enhance control after initial response to chemotherapy. NSCLC causing SVCS is best treated with radiation therapy. The incorporation of CT scan and fluorodeoxyglucose-positron emission tomography information into a carefully designed treatment plan may enable the administration of a more definitive total radiation dose of >50 Gy, which may provide long-term local control for some patients when appropriate. Percutaneous endovascular intervention should be considered in severe cases because it relieves symptoms rapidly without masking the diagnosis.

Most patients with nonmalignant causes for SVCS have an indolent course and a good prognosis. Percutaneous transluminal angioplasty or stent insertion should be considered an effective alternative to surgery. However, the long-term maintenance of patency with stent insertion is still unknown. Surgery is indicated only when the process is rapidly progressing or caused by a retrosternal goiter or an aortic aneurysm. If SVCS is induced by a catheter, the catheter should be removed if possible. Heparin should be administered during the removal of the catheter to prevent embolization. In catheter-induced SVCS, urokinase, streptokinase, or recombinant tissue-type plasminogen activator is of value if used early in the thrombotic process.

120 Increased Intracranial Pressure

Kevin P. Becker and Joachim M. Baehring

INTRODUCTION

An increase in intracranial pressure (ICP) is a common neurologic complication of patients with cancer involving the nervous system. Various pathomechanisms have to be considered in this patient population. Large cerebral metastases are the most common cause and can give rise to intracranial hemorrhage. Subependymal or leptomeningeal masses located at “bottlenecks” of spinal fluid pathways such as the foramen of Monro or the aqueduct of Sylvius raise pressure by obstructing spinal fluid flow. A cancer-related hypercoagulable state can lead to dural sinus thrombosis or extracranial venous outflow obstruction, and coagulopathies predispose to subdural bleeding. The patient with cancer as an immunocompromised host is at risk for infections of the nervous system such as fungal or bacterial meningitis or a bacterial abscess which can all result in increased ICP. Communicating hydrocephalus reflects decreased reabsorption of spinal fluid, which can be seen in leptomeningeal carcinomatosis or the sequela of prior infection. Dural venous sinus stenosis from dural metastases causes a syndrome resembling idiopathic intracranial hypertension.

This chapter provides an overview of the various mechanisms of increased ICP, the clinical manifestations, diagnosis, and treatment options.

PATHOPHYSIOLOGIC CONSIDERATIONS

Intracranial volume is not expandable in an adult because of its containment by the skull and the dura. The brain itself has an average volume of 1,400 ml, spinal fluid of 52 to 160 ml, and blood 150 ml.¹ An increase in the volume of one compartment occurs at the expense of the other two (Monro-Kellie hypothesis).²⁻⁴ If brain volume increases as a result of a brain tumor, the spinal fluid volume decreases as a compensatory mechanism. Up to an ICP of 200 to 250 mm cerebral spinal fluid (CSF) compartmental volume increase results in only minor increases in ICP as long as CSF flow is not obstructed, the rate between CSF production and reabsorption remains constant, and the dural venous sinuses remain open. However, intracranial compliance decreases with rising ICP (i.e., with rising pressure, increase in volume leads to a disproportionate increase in pressure). This is reflected in the occurrence of plateau waves, which are acute elevations of ICP up to 1,300 mm CSF lasting 5 to 20 minutes. These transient elevations are of pathogenic significance because they further compromise cerebral perfusion in patients with increased ICP.⁵ Plateau waves have been suspected to cause intermittent symptoms with orthostasis in patients with brain tumors.⁶

Volume changes within the brain parenchyma that lead to increased ICP in patients with cancer are caused by the direct mass effect of primary or secondary brain tumors, peritumoral edema, or indirect neurologic complications of cancer. Vasogenic edema results from increased leakage of plasma filtrate into brain tissue through leaky capillaries within a brain tumor or surrounding a brain abscess or cerebral hemorrhage. Cytotoxic edema occurs with

the breakdown of the adenosine triphosphate-dependent transmembranous ion transport system that leads to the intracellular entrapment of water. This can be seen with ischemic injury, cytotoxic chemotherapy agents, or buildup of toxic metabolites seen in liver failure. Extra-axial mass lesions can arise from neoplastic growth (dural tumors such as metastases, meningioma, or lymphoma), infection (subdural empyema), or hemorrhage (subdural hematoma in the coagulopathic or thrombocytopenic patient).

Increased ICP can also be the consequence of an imbalance between CSF production and reabsorption. Spinal fluid is produced at an average rate of 21 to 22 ml/h or approximately 500 ml/day. CSF represents a plasma filtrate passively diffusing through the choroid plexus of the lateral, third, and fourth ventricles. It is reabsorbed within the arachnoid granulations overlying the cerebral hemispheres. Mass lesions in proximity to bottlenecks of CSF flow (foramen of Monro, cerebral aqueduct, medullary foramina, basilar subarachnoid cisterns) cause obstructive or noncommunicating hydrocephalus. Carcinomatosis or meningitis directly interferes with CSF reabsorption at the arachnoid granulations. Under chronic conditions, the spinal fluid pressure reaches a new equilibrium within the high normal range, and gives rise to a condition called *normal pressure hydrocephalus* (NPH) characterized by ventricular enlargement out of proportion to age-related cortical atrophy. Increased production of CSF is a rare cause of raised ICP. Idiopathic intracranial hypertension (IIH) or pseudotumor cerebri denotes a syndrome characterized by signs of increased ICP in the absence of mass lesions or hydrocephalus. Although poorly defined from a pathophysiologic standpoint, an increasing number of patients with IIH have been found to have partial obstruction of dural venous sinuses. Iatrogenic causes of IIH include all-trans retinoic acid, tetracycline antibiotics, and sulfonamides.

Acute increases in arterial and venous pressure result in an increase in ICP. Cerebral perfusion is kept constant over a wide arterial pressure range (50 to 160 mm Hg). Once this autoregulatory mechanism fails, further increase in arterial blood pressure passively increases ICP. Venous obstruction can be reproduced with the Queckenstedt maneuver (manual compression of both internal jugular veins). Dural venous sinus pressure fluctuates with intrathoracic pressure changes. Thus, coughing, sneezing, and straining (Valsalva maneuver) are accompanied by an increase in ICP. In a patient with increased ICP and decreased intracranial compliance, gagging or coughing can lead to transient decompensation and the acute onset of symptoms (syncope in patients with colloid cyst of the third ventricle, plateau waves).

Depending on the etiology and location of an increase in cerebral parenchymal or extra-axial volume, patients may have relatively few symptoms until herniation ensues. The faster the pathologic process evolves, the more likely is the patient to have symptoms. Cingulate or transfalxian herniation denotes lateral shift of a hemisphere underneath the falx cerebri. Vascular structures (ipsilateral anterior cerebral artery, internal cerebral vein, vein of Galen) can be compromised in this process. In transtentorial herniation, the diencephalon is forced through the tentorial notch as a consequence of a supratentorial mass lesion. Infratentorial

masses can result in an upward herniation of posterior fossa structures through the tentorium or downward displacement through the foramen magnum. Uncal herniation, most often encountered in temporal lobe mass lesions, leads to compression of the midbrain at the level of the tentorial notch. When the ICP exceeds 40 to 50 mm Hg, cerebral blood flow is diminished, leading to irreversible brain damage.

EPIDEMIOLOGY AND PATHOGENESIS

Increase in Cerebral Parenchymal Pressure and Cerebral Spinal Fluid Flow Obstruction

Brain metastases are the most common cause of increased ICP in a patient with cancer. In adults, lung cancer and melanoma are particularly prone to seeding to brain.⁷ Cerebral metastasis can be further complicated by intratumoral hemorrhage. Although lung cancer is the most common primary tumor leading to hemorrhagic brain seeding, the relative incidence of hemorrhagic transformation of a cerebral metastasis is highest in melanoma, choriocarcinoma, renal cell carcinoma, and papillary thyroid cancer.⁸ In children, the brain metastases most commonly associated with intracranial hemorrhage are Ewing sarcoma, rhabdomyosarcoma, and melanoma.⁹ Primary brain tumors with a predilection for subependymal or intraventricular locations such as subependymal giant cell astrocytoma, lymphoma, subependymoma, choroid plexus papilloma, ependymoma, meningioma, central neurocytoma, choroid glioma of the third ventricle, or thalamic tumors can cause spinal fluid obstruction early in their course. Secondary cerebral volume increase in patients with cancer results from hemorrhage, ischemia, infection, or autoimmune inflammatory processes. Cerebral hemorrhage from cancer-related coagulopathies typically occurs in patients with hematologic malignancies such as acute lymphocytic or myelocytic leukemia.¹⁰ Diffuse cerebral edema and increased ICP in patients with leukemia can be the mere result of leukostasis and occurs at blast counts exceeding $4 \times 10^5/\text{mL}$. Higher counts are usually required in lymphoblastic leukemia because lymphoid cells are smaller and less adherent than myeloid blasts.¹¹ An increase in ICP can also be the consequence of diffuse cerebral hemorrhages in disseminated intravascular coagulopathy.

Herpes simplex encephalitis gives rise to extensive vasogenic edema affecting the medial temporal and inferior frontal lobe.

Depending on disease burden, patients with cerebral toxoplasmosis, aspergillosis, or candidiasis can present with signs of increased ICP as well. Brain abscess complicates neurosurgical interventions for resection of metastases, drainage of cerebral hemorrhage, or placement of ventricular catheters. Autoimmune inflammatory encephalomyelitis has been described as a rare entity in patients after stem cell transplantation.

Disorders Affecting Cerebral Spinal Fluid Production or Reabsorption

A syndrome resembling normal pressure hydrocephalus has been observed in long-term survivors of whole-brain or less commonly, partial-brain irradiation. Fibrosis of arachnoid granulations has been suspected to play a role in the pathogenesis of this entity that is also characterized by extensive white matter demyelination and frank necrosis. Selected patients seem to respond favorably to ventriculoperitoneal shunting.¹²⁻¹⁴ An acute imbalance between CSF production and reabsorption occurs in neoplastic meningitis and opportunistic meningeal infections in the immunocompromised patient with cancer. *Cryptococcus neoformans* meningitis is almost invariably associated with elevation of ICP. Patients after splenectomy are susceptible to meningitis with encapsulated bacteria. The pathogenesis of communicating hydrocephalus in patients with spinal cord tumors or nonobstructive masses of the cerebellopontine angle is not well understood. Most commonly ependymomas, but also schwannoma, meningioma, neurofibroma, and glioma, might release protein degradation products or cells into CSF that obstruct the arachnoid granulations.^{15,16} However, the protein level is rarely elevated in these patients. Others have suspected blockage of the lumbar CSF reservoir,¹⁷⁻¹⁹ arachnoiditis, or increased fibrinogen levels²⁰ as the cause of this syndrome. All-trans retinoic acid, a differentiating agent used for the treatment of promyelocytic leukemia, has been associated with episodes of communicating hydrocephalus, likely as a consequence of decreased CSF reabsorption.^{21,22} Increased ICP is rarely caused by CSF overproduction. Patients with choroid plexus papilloma, especially if they are multifocal, are at risk.²³

Venous Outflow Obstructions

A hypercoagulable state in patients with cancer can manifest itself as dural venous sinus thrombosis (Fig. 120.1A). The incidence is

Figure 120.1 (A) Increased intracranial pressure caused by venous outflow obstruction. A 48-year-old woman with idiopathic myelofibrosis complained of a severe headache. Workup revealed a left transverse sinus thrombosis (gradient echo magnetic resonance imaging, coronal section, intraluminal thrombus outlined by arrowheads). (B) Intermittent obstructive hydrocephalus caused by the “pressure-valve” effect of a colloid cyst of the foramen of Monro. This 38-year-old patient had experienced several presyncopal episodes and was suffering from positional headaches. The lateral ventricles are dilated (unenanced T1-weighted magnetic resonance image, coronal section). (C) A 78-year-old woman with gliomatosis cerebri. Hyperintense signal on this coronal fluid attenuated inversion recovery magnetic resonance imaging demarcates the extent of cerebral infiltration by neoplastic cells and vasogenic edema. There is extensive effacement of the sulcal pattern and early transtentorial herniation.

increased in patients receiving l-asparaginase therapy. Increased ICP is the only manifestation of cerebral venous thrombosis in more than one-third of patients.²⁴ Nonthrombotic causes of dural sinus stenosis or occlusion are dural mass lesions such as meningioma or diffuse meningiomatosis of the convexity, metastases from breast or prostate cancer, non-Hodgkin lymphoma, Ewing sarcoma, plasmocytoma, or neuroblastoma that either compress or invade the sinus.²⁵⁻²⁷ Venous hypertension can also arise from metastases at the base of the skull, causing obstruction of the internal jugular vein or from compression of the superior vena cava by mediastinal masses. Lesions giving rise to ITH compromise the distal superior sagittal sinus or the torcula Herophili.²⁸

CLINICAL PRESENTATION

Headache is the most common complaint of patients with increased ICP. In its classic form, the head pain is severe, resistant to common analgesics, and reaches maximum intensity on awakening in the morning.²⁹ Decreased venous drainage in the supine position likely accounts for this observation. Patients frequently report immediate relief from their headache by vomiting. However, the majority have nonspecific tension-type or migraine-like headaches. The patient with increased ICP falls easily, particularly backward. With rising pressure, nausea and vomiting ensue. The patient becomes increasingly somnolent and ultimately lapses into a coma.

Funduscopic examination reveals papilledema in about half of patients with increased ICP. Absence of venous pulsations within the center of the optic disc is an early finding, whereas papilledema with blurring of the disc margins or small hemorrhages characterizes later stages. The Foster-Kennedy syndrome—optic nerve atrophy as a result of a sphenoid wing meningioma and contralateral papilledema from increased ICP—is rarely seen in the days of improved neuroimaging methods and earlier diagnosis.

Focal neurologic deficits can help localize the mass accounting for the pressure increase. Cognitive complaints such as slowness to respond and inattentiveness reflect frontal lobe dysfunction. Gaze paresis to the side opposite the lesion indicates involvement of the frontal eye field. Posterior frontal masses cause contralateral hemiparesis. Hemianesthesia or complex neglect syndromes reflect parietal lobe pathology. Temporal and occipital lobe disease causes visual field deficits. An upward gaze paresis occurs in patients with tumors of the tectal region such as pineal neoplasms or metastases. Paresis of extraocular muscles results from stretch injury of the fourth or sixth nerve or uncinate herniation with compression of the third nerve. However, the clinician must be aware of “false” localizing signs. Temporal lobe tumors can cause compression of the cerebral peduncle at the tentorial notch on the opposite side, resulting in a hemiparesis on the same side as the mass lesion (Kernohan syndrome).³⁰

Symptoms are aggravated by vasogenic edema surrounding intraparenchymal masses and partially or completely resolve with medical management. Hyponatremia as a result of inappropriate secretion of antidiuretic hormone is observed as a metabolic complication of increased ICP. Sphincter incontinence occurs in chronically elevated ICP. Patients with acute meningitis present with classic signs of meningeal irritation, including photophobia, phonophobia, and a Kernig or Brudzinski sign. In meningeal carcinomatosis, these signs are frequently absent.

Elevated ICP in infants results in increased head circumference. Chronic hydrocephalus can be recognized on plain radiographs of the skull as focal thinning of the tabula interna of the skull (Lückenschädel). This is accompanied by personality changes and loss of previously acquired motor skills. Herniation of one cerebellar tonsil causes a head tilt, neck stiffness, and unilateral forced eye closure.³¹ Tectal masses result in upgaze inhibition, light-near dissociation of pupillary response, and convergence-retraction nystagmus (Parinaud syndrome). Pressure on the mesencephalic

tegmentum leads to pathologic lid retraction and an upward gaze palsy (setting sun sign).

Slowly progressive static ICP changes are accompanied by little or no symptoms. On the other hand, clinical deterioration is profound when dynamic pressure changes such as plateau waves occur or abnormal intracranial compartmentalization or herniation ensues.³² Signs and symptoms of increased ICP manifest earlier in patients with lesions of the posterior fossa because of the small size of this compartment. A brief bedside assessment including level of consciousness, pupillary size and reflexes, extraocular movements, blood pressure, heart rate, breathing pattern, and motor response to noxious stimuli enables the clinician to determine if herniation is present and which level of the central neuraxis is compromised. The triad of changes in breathing pattern, arterial hypertension, and bradycardia observed with rising ICP is known as the *Kocher-Cushing reflex*.³³ In uncinate herniation from temporal lobe masses or herpes encephalitis, ipsilateral compression of the third nerve and associated parasympathetic nerve fibers leads to pupillary dilatation before extraocular dysmotility. With progressive shift of brain substance, complete third nerve palsy ensues and signs of midbrain dysfunction appear. Patients develop contralateral hemiparesis from pressure on the cerebral peduncle and ultimately become stuporous. Increasing pressure from hemispheric or diencephalic mass lesions results in central (transtentorial) herniation. This leads to a progressive syndrome reflecting sequential damage to brainstem structures in a rostrocaudal fashion.³² At the early diencephalic stage, mild changes in the patient's alertness are accompanied by periodic breathing, yawning, or hiccupping. Pupils are small but remain reactive to light. With further progression of central herniation, the patient becomes obtunded or stuporous. Roving eye movements reflect diffuse cortical dysfunction and preservation of lower brainstem gaze centers. Noxious stimuli elicit flexion of upper extremities and extension of lower extremities (decorticate posturing). Midsize pupils unresponsive to light indicate midbrain dysfunction. Damage to the mesencephalic reticular activating system produces coma. A fast and regular breathing pattern evolves (central neurogenic hyperventilation). Transition to the pontine stage of central herniation is accompanied by extensor posturing of all limbs to noxious stimulation (decerebrate posturing). Absence of the oculoccephalic reflex (doll's head maneuver) and horizontal eye movements to caloric stimulation of the vestibular system indicate damage to pontine structures. Breathing becomes apneustic with pontine compression. When the cerebellar tonsils herniate through the foramen magnum, ataxic breathing is observed and the blood pressure drops.³²

The syndrome of raised ICP and cerebral herniation can evolve slowly over days to weeks or acutely over hours. Rapid progression usually indicates hemorrhage. Subdural hematomas in patients with coagulopathies can evolve so rapidly that signs of cerebral herniation are present before an imaging study can be obtained. Hemorrhage into a metastatic focus is typically characterized by the sudden onset of focal neurologic signs, including seizures. Intraparenchymal hemorrhage as a result of coagulopathy leads to slowly progressive neurologic deterioration.¹⁰

A peculiar syndrome is associated with tumors or developmental abnormalities causing a pressure valve effect, such as the colloid cyst of the foramen of Monro (Fig. 120.1B). Patients, typically in their late childhood or early adulthood, report sudden onset of severe imbalance, headache, and nausea that is brought on by positional changes (bending down) or Valsalva maneuvers. Sudden deaths have occurred, stressing the need for close observation of these patients until appropriate therapy can be provided.^{34,35}

ITH (pseudotumor cerebri) is mostly characterized by nocturnal or hypnopompic headaches aggravated by Valsalva maneuver. Non-specific visual changes, diplopia due to sixth nerve palsy, or transient visual obscuration are less frequent manifestations. Especially the latter is an ominous sign indicating the need for immediate intervention as the patient's vision is at risk. On physical examination, papilledema is the most striking abnormality.³⁶ The blind spot is enlarged.

Figure 120.2 (A) A 45-year-old patient with an anaplastic astrocytoma of the right thalamus. Computed tomography revealed obstruction at the level of the foramen of Monro (*asterisk*). (B) A 55-year-old patient with a midbrain metastasis from an adenocarcinoma of the lung. There is partial obstruction at the level of the cerebral aqueduct. The temporal horns of the lateral ventricles are dilated (T1-weighted magnetic resonance image with gadolinium). (C) A 38-year-old patient with seeding of non-small-cell lung cancer to the floor of the fourth ventricle. He presented with intractable headaches, nausea, vomiting, and severe back pain, indicative of obstructive hydrocephalus and leptomeningeal spread to the spinal canal (T1-weighted magnetic resonance image with gadolinium, sagittal view).

Another characteristic clinical syndrome is recognized in patients with chronic disturbance of spinal fluid reabsorption. These patients, or more likely their family members on their behalf, report a combination of cognitive decline, precipitate micturition, and gait apraxia.^{37,38} Dementia is usually of the subcortical type. Precipitate micturition reflects dysfunction of the cortical center for bladder control (paracentral lobule). Minimal bladder filling results in the uncontrollable urge to urinate. The gait disturbance is characterized by difficulty initiating ambulation and postural instability with retropulsion. Strength is preserved.

DIAGNOSIS

The history and clinical examination detect the presence of increased ICP. Imaging studies are helpful in determining its cause and confirming the clinical impression. The most readily available imaging study is unenhanced computed tomography. The

study is adequate to determine the presence of intraventricular and subarachnoid CSF flow obstruction (Fig. 120.2), as well as uncus, transfalcial, and transtentorial herniation (Fig. 120.3). The presence of intracranial hemorrhage or a neoplastic or infectious mass lesion can be identified and emergency treatment initiated. Transependymal edema is seen as periventricular hypodensity and indicates CSF flow obstruction.

More detailed neuroanatomic imaging and the distinction between a neoplastic, infectious, inflammatory, or ischemic process requires magnetic resonance imaging. The use of intravenous gadolinium is advised as most conditions associated with increased ICP in patients with cancer cause breakdown of the blood-brain barrier and thus can be better visualized with contrast dye. The use of diffusion-weighted imaging can help identify evolving ischemia or high cellularity suggestive of malignant tumor growth. CSF flow studies (cine magnetic resonance imaging) are helpful to evaluate the functional significance of minute structural lesions within or surrounding the cerebral aqueduct.

Figure 120.3 (A) This unenhanced computed tomographic scan of the head shows a hemorrhagic brain metastasis in a 42-year-old woman with malignant melanoma. The metastasis exerts mass effect on the right lateral ventricle. There is transfalcial herniation of the right hemisphere. (B) A 37-year-old woman with an anaplastic astrocytoma of the diencephalon. There is imminent transtentorial herniation (T1-weighted magnetic resonance image with gadolinium, sagittal view). (C) A 25-year-old woman who developed a large right temporal meningioma years after whole-brain radiation therapy for acute lymphoblastic leukemia in early childhood. The tumor compresses the cerebral peduncle and displaces the midbrain (unenhanced computed tomography).

Slit-like ventricles in the correct clinical setting are indicative of IIH. Coronal images through the orbit may reveal dilatation of the optic nerve sheaths in this condition. Ex vacuo ventricular dilatation out of proportion to cortical atrophy is characteristic for NPH. Magnetic resonance imaging of the spine should be considered in patients with unexplained communicating hydrocephalus. Obstruction or infiltration of dural venous sinuses is best visualized with magnetic resonance or computed tomographic venography.³⁹

Scintigraphic cisternography can document spinal fluid circulation abnormalities such as NPH. Early ventricular filling with tracer substance after lumbar injection and delayed or absent demarcation of subarachnoid space overlying the cerebral hemispheres is indicative of decreased reabsorption of CSF through the arachnoid granulations.

CSF pressure can be measured directly through a lumbar puncture performed in the lateral decubitus position. Puncture of the subarachnoid space below the level of spinal fluid obstruction bears the risk of initiating or aggravating cerebral herniation. The risk is considerable in mass lesions of the posterior fossa. A computed tomography scan should be obtained prior to lumbar puncture in patients with signs of increased ICP. Compartmentalization (obstructive hydrocephalus at the foramen of Monro or cerebral aqueduct, obliteration of basal cisterns as a result of transtentorial or transforaminal herniation) prohibits puncture of the subarachnoid space below the level of obstruction. When unperturbed communication between the intraventricular and subarachnoid spaces has been determined and the basal cisterns are patent, lumbar puncture should not be delayed if it is deemed necessary for accurate diagnosis.

ICP can be monitored in the intensive care unit with a variety of strain gauge, fiber optic, or pneumatic devices placed into the brain parenchyma, ventricular, subarachnoid, subdural, or epidural space. All these methods require neurosurgical intervention.⁴⁰

Transcranial Doppler sonography is helpful in the intensive care unit for monitoring cerebral perfusion and alteration in cerebrovascular resistance (e.g., in vasospasm or intra-arterial disease) in patients with increased ICP.⁴¹

TREATMENT

In the majority of cases, the onset of increased ICP in patients with cancer is protracted over days to weeks. After increased ICP is recognized and symptomatic measures have been initiated to lower pressure, a diagnostic procedure can be performed before definitive treatment is provided. Fewer patients present as an emergency but the ones that do require immediate neurosurgical intervention.

The normovolemic patient with increased ICP and suspected decreased intracranial compliance is best positioned with head and upper trunk slightly elevated (~30 degrees). As fever above 100.5°F contributes to elevated ICP, it is common practice to use antipyretics such as acetaminophen above this threshold. Serum osmolality is kept in the high normal range. Isotonic saline solutions are recommended for intravenous hydration, while hypotonic fluids are avoided because free water shifts along an osmolar gradient further exacerbate increased ICP.

Corticosteroids are effective agents for the initial management of increased ICP caused by vasogenic edema. No benefit has been convincingly shown for cytotoxic edema of an acute ischemic stroke, intracranial hemorrhage secondary to remote effects of cancer, or spinal fluid obstruction. Moderate (6 to 10 mg dexamethasone every 6 hours) to high doses (up to 100 mg/d of dexamethasone) are used. A superior therapeutic effect has not been demonstrated for high doses, and the risk of adverse reactions, in particular gastroduodenal ulceration, is considerable. Corticosteroids should be avoided if CNS lymphoma is suspected

before a tissue diagnosis has been established. Dexamethasone and related drugs induce lymphocytic apoptosis and may obscure morphologic diagnosis.

Osmotic diuresis through infusion of hyperosmolar agents such as mannitol or glycerol is an alternative or additional treatment option for the reduction of ICP. Most commonly used are intravenous infusions of 20% to 25% mannitol solutions given at an initial dose of 0.75 to 1 g/kg body weight. Repeat dosing at 0.25 to 0.5 g/kg body weight is possible every 4 to 6 hours but close monitoring of serum osmolality is required. The osmotic effect is transient, and treatment should be stopped if the target serum osmolality is exceeded (~300 to 310 mOsm/L).⁴²

Monitoring in the neurologic intensive care unit is required in patients with depressed mental status secondary to ICP elevation. Careful blood pressure adjustment is needed to avoid blood pressure peaks without decreasing cerebral perfusion.

The most rapid method to decrease ICP is intubation with mechanical hyperventilation. The pCO₂ should be decreased to 25 to 30 mm Hg. Lower pCO₂ levels are avoided because cerebral perfusion is reduced. The effect of hyperventilation is transient and thus other measures such as corticosteroid use and osmotic diuresis need to be initiated simultaneously.

Obstructive hydrocephalus constitutes a neurosurgical emergency. Rapid neurologic deterioration with signs of cerebral herniation mandates the immediate placement of an external ventriculostomy. Permanent drainage of CSF through a ventriculoperitoneal shunt or endoscopic placement of a third ventriculostomy may be necessary when the cause of spinal fluid flow obstruction cannot be definitively treated. Although filter systems are available, ventriculoperitoneal shunting is avoided in patients with leptomeningeal tumor in order to prevent peritoneal seeding.

Normal pressure hydrocephalus responds favorably to ventriculoperitoneal shunting. It is the task of the clinician to carefully select patients who may benefit from this procedure. Patients with a short history of the classic clinical triad of gait apraxia, precipitate micturition, and cognitive decline are most likely to respond. Extended lumbar drainage, large-volume spinal fluid releases, or scintigraphic cisternography have been used as objective means to predict outcome of a shunting procedure.⁴³

Disease-specific treatment of increased ICP in addition to symptomatic management with corticosteroids or osmotic diuresis is indicated in the majority of cases. Infectious complications are treated with antimicrobial therapy. Patients with a brain abscess undergo surgical drainage and a prolonged course of intravenous antibiotics. A hematoma within a metastatic focus is resected if located in a noneloquent area of the brain and in the absence of widely metastatic disease. Subdural hematoma or empyema requires immediate surgical decompression. Leukostasis in leukemic diseases responds to hydration, leukapheresis, systemic chemotherapy, and low-dose whole-brain irradiation.⁴⁴ Systemic intravenous anticoagulation with heparin or fractionated heparinoid is used in dural sinus thrombosis. When l-asparaginase therapy is involved in the pathogenesis of the prothrombotic stage, substitution with fresh-frozen plasma and antithrombin III is often administered prior to anticoagulant use. Petechial hemorrhages due to thrombocytopenia require transfusion of blood platelets. A coagulopathy can be corrected using transfusion of fresh-frozen plasma and substitution of vitamin K. Increased ICP secondary to medication requires dose reduction or discontinuation of the causative drug. All-trans retinoic acid related IIH may be alleviated with acetazolamide.⁴⁵ IIH caused by malignant dural sinus compression responds to local surgical treatment or irradiation. Leptomeningeal carcinomatosis is treated with irradiation and intrathecal chemotherapy.⁴⁶ CSF flow obstruction prohibits intraventricular injection of cytotoxic agents as it can give rise to a severe, irreversible toxic encephalopathy.

121 Spinal Cord Compression

Kevin P. Becker and Joachim M. Baehring

INTRODUCTION

Compression of the spinal cord is one of the most devastating neurologic complications, affecting 5% to 10% of patients who have cancer.¹⁻³ The majority of cases result from spine metastases with extension into the epidural space. Pain is the most common initial clinical manifestation of metastases to the axial skeleton. Within weeks, neurologic impairment ensues and is irreversible if treatment is not initiated promptly. Malignant spinal cord compression (MSCC) is a diagnostic challenge, especially in patients without a history of cancer. Back pain is one of the most common ailments in the general population and, in most cases, results from degenerative changes of the spine. Early identification of patients at risk of MSCC is essential as limitation of workup, symptomatic management, and bed rest—common practice in patients with “benign” back pain—almost invariably lead to profound neurologic morbidity.

This chapter describes the clinical syndromes, diagnosis, and treatment of epidural cancer metastases. Metastases below the conus medullaris, corresponding to the level of the first lumbar vertebra in adults and giving rise to isolated radiculopathies or a cauda equina syndrome, are included.

EPIDEMIOLOGY

An estimated 20,000 patients are diagnosed with MSCC per year in the United States.^{4,5} The lifetime incidence in cancer patients is 1% to 6%, although autopsy series have revealed higher numbers (5% to 10%).⁶⁻⁹ The majority of patients with MSCC are older than 50 years of age. However, cumulative incidence decreases with age: 4.4% in 40- to 50-year olds, 3.8% in 50- to 60-year olds, 2.9% in 60- to 70-year olds, 1.7% in 70- to 80-year olds, and 0.54% in patients older than 80 years.¹⁰ The most common types of cancer that account for spinal cord compression are breast, prostate, lung cancer, and lymphoma.^{1,6-8,11-14} The cumulative incidence of MSCC is disease specific and is highest in multiple myeloma (8%), prostate cancer (7%), nasopharyngeal cancer (6.5%), and breast cancer (5.5%).⁷ The median interval between cancer diagnosis and manifestation of MSCC ranges from 6 to 12.5 months. Late axial bone metastases that cause cord compression are more common in breast cancer (43 months).⁶ In only 1 in 500 cancer patients is spinal cord compression part of the presenting oncologic syndrome.⁷ However, 20% of MSCC cases lack a history of cancer.^{8,15} MSCC as the primary manifestation of a malignancy is more common in non-Hodgkin lymphoma, myeloma, and lung cancer, especially the small-cell variant; it is almost unheard of in breast cancer.^{16,17} Two-thirds of MSCC cases affect the thoracic spine and 20% the lumbar spine, whereas cervical and sacral spine are rarely involved (<10% for each site).^{1,12,14,18,19} Colon and prostate cancers seem to have a predilection for the lumbosacral spine, whereas lung and breast cancers are more common in the thoracic spine. Multiple epidural metastases are detected on initial presentation in up to one-third of patients in whom the whole

axial skeleton is investigated.²⁰ Local recurrence after irradiation is rare, but 1 in 10 patients develops a second metastatic deposit that causes cord compression at a different spine level within 5 months of the first event.^{1,12}

The tumor spectrum that causes cord compression in the pediatric population differs from adults and includes neuroblastoma, Ewing sarcoma, and, less commonly, primary vertebral osteosarcoma, germ cell tumors, and lymphoma. Cord compression as an initial manifestation of the tumor in children occurs more frequently than in the adult population.^{21,22}

PATHOPHYSIOLOGY

Bone, particularly the axial skeleton, is one of the most common organ systems involved by metastatic spread. Up to one-third of patients dying of cancer develop metastases to the spine at some point during their illness.²³ Release of bone-derived growth factors and cytokines, capillary structure, and peculiar blood flow phenomena may facilitate deposition and growth of metastases.^{24,25} Venous blood from intra-abdominal and intrathoracic organs is not only drained through the vena cava but also through the vertebral and epidural venous plexus (Batson plexus). This low-pressure circulation without valves and with frequent flow reversal, depending on intrathoracic and intra-abdominal pressure, would appear to be an ideal transportation system for cancer cells.

The most common mechanisms of spinal cord compression are the direct extension of tumor from a hematogenous metastasis to a vertebral body into the epidural space or the pathologic fracture of a vertebral body infiltrated by a metastatic deposit, resulting in cord injury by a bone fragment or spine instability (Fig. 121.1A). Involvement of posterior spine elements with nerve root impingement is less common.²⁶ Transforaminal progression of paravertebral tumor is encountered in lymphoma and neuroblastoma. Highly aggressive paravertebral tumors such as the Pancoast tumor of the lung apex simply grow through anatomic barriers, including bone, into the epidural space. Primary hematogenous seeding to the epidural space is rare.¹¹ Spinal cord compression can also result from intradural mass lesions (meningioma, nerve sheath tumors, large leptomeningeal metastases) (Fig. 121.2) or intraneural spread of neurogenic tumors. Nonmetastatic causes are epidural hematoma in patients with coagulopathy or abscess in an immunocompromised host.

The mechanism of cord injury is not entirely understood. The early myelopathy associated with MSCC may be due to impairment of venous drainage, leading to intramedullary vasogenic edema. When the interstitial pressure rises beyond a critical threshold, cord perfusion is compromised, resulting in necrosis. Pathologic fracture of a vertebral body and posterior displacement of bone fragments lead to mechanical cord destruction. On histopathologic examination, demyelination or necrosis of white matter is the predominant finding at the level of cord compression, whereas gray matter is relatively well preserved.¹³

Figure 121.1 (A) A 53-year-old patient with metastatic renal cell cancer. T2-weighted magnetic resonance image (MRI; sagittal view) of the lumbosacral spine shows a pathologic fracture of the T12 vertebral body, posterior dislocation of a bone fragment, and compression of the spinal cord. (B) T1-weighted MRI with gadolinium (axial view) of a 19-year-old patient with Ewing sarcoma involving the T2 vertebral body. An enhancing soft tissue lesion is seen in the paravertebral space (*arrowheads*), the intervertebral foramen (*F*) and the epidural space (*E*). The cord (*C*, *arrow*) is compressed and displaced posteriorly. The patient had noticed that his left pupil had become smaller (Horner syndrome). He then started complaining of intermittent upper back pain aggravated by coughing, difficulty walking up stairs, and initiating urination. (C) A 73-year-old man with polycythemia rubra vera complained of progressive leg weakness and back pain. An MRI of the thoracic spine (T1 without contrast dye) revealed a large hyperintense epidural mass lesion compressing the cord posteriorly. A biopsy confirmed the suspected diagnosis of extramedullary hematopoiesis.

The complex syndrome of back pain is composed of local, radicular, and referred components. Pain-sensitive structures of the spine are the vertebral periosteum, the posterior longitudinal ligament, and the synovia of the facet joints innervated by branches of segmental spinal nerves. Pain from metastatic tumor spread to the spine ensues when the cancer infiltrates the periosteum. Radicular pain results from compression or infiltration of a nerve root. Pain

can also be the consequence of irritation of long tracts of the spinal cord (funicular pain) or paravertebral muscle spasm.

Micturition is frequently impaired in patients with MSCC. A brief review of the anatomy of bladder control may help to correctly interpret patients' symptoms. Excitatory input to the detrusor muscle that promotes bladder emptying is parasympathetic and involves sacral spinal cord segments. Relaxation of the

Figure 121.2 Topical differential diagnosis of cord compression. (A) Diffuse epidural infiltration by granulocytic sarcoma in a 65-year-old woman, causing cord compression in the lower thoracic spine (*arrowheads*). The tumor originated in the uterus and likely metastasized through the epidural venous plexus (Batson plexus) into the spinal canal (T1-weighted magnetic resonance image [MRI] with gadolinium and fat suppression). (B) A 32-year-old woman with neurofibromatosis type 2 and a meningioma of the spinal canal. This T1-weighted MRI with gadolinium and fat suppression (thoracic spine, sagittal view) demonstrates an intradural, extramedullary mass lesion with cord compression. (C) Leptomeningeal metastasis with cord infiltration and compression at the level of the T10 vertebral body in a 27-year-old patient with leptomeningeal spread of a diencephalic yolk sac tumor. The tumor infiltrated the thoracic spinal cord, giving rise to a Brown-Sequard syndrome below the level of infiltration (T1-weighted MRI with gadolinium and fat suppression, lower spine, sagittal view).

internal sphincter is transmitted through the sympathetic nervous system. Preganglionic neurons originate from thoracic and upper lumbar cord segments. The external sphincter muscle is innervated by motor neurons located in the anterior horn of the sacral cord (nucleus of Onufrowicz). Voluntary bladder control requires sensory input from stretch receptors within the bladder wall. This is transmitted to the pontine micturition center that also receives descending input from the paracentral lobule of the frontal lobe. The coordinated inhibition of internal and external sphincter muscle is mediated through the pontine micturition center. Spinal cord compression above the conus results in lack of voluntary control of micturition. Reflex emptying is possible but incomplete. When the sacral spinal cord is destroyed, the patient suffers from external sphincter insufficiency, unawareness of bladder fullness, and overflow incontinence. The mechanisms for control of defecation are similar.

CLINICAL PRESENTATION

Pain is the most common presenting symptom in patients with metastases involving the axial skeleton.^{6,8,18,19} Any back pain in a patient with cancer known to frequently seed to spine or epidural space should be considered of metastatic origin until proven otherwise. Pain ensues when the richly innervated periosteum is involved. In its early stage, it may be localized to the affected spine segment. The vertebral body is tender to percussion. Pain that results from epidural mass effect is typically exacerbated by sneezing, coughing, or the Valsalva maneuver. Because it is aggravated by the recumbent position, patients experience maximum pain intensity on awakening in the morning; they may even sleep in a sitting position. Compression of a nerve root is associated with lancinating pain in the corresponding radicular distribution provoked by Valsalva maneuver. Radicular pain in the thoracic region is usually bilateral, whereas cervical and lumbar radiculopathies are unilateral.²⁷ Paravertebral muscle spasm caused by nerve root irritation from a metastasis results in straightening of the physiologic cervical or lumbar lordosis. Straight-leg raising (Lasague maneuver) or, more specifically, crossed straight-leg raising (passive elevation of the contralateral, pain-free leg), exacerbates a lumbosacral radiculopathy. Referred pain may mimic a radiculopathy. Especially with intraneural tumor spread, neuropathic features (allodynia, hyperpathia, hyperalgesia) may predominate.

Neurologic symptoms typically evolve within weeks to months of the onset of back pain.^{15,19} Hyperacute presentation with the evolution of paraplegia within hours to days is not uncommon in bronchogenic carcinoma, while a much slower course is typical for metastases from breast cancer.¹³ Motor dysfunction (weakness, spasticity) is the earliest sign and occurs before sensory disturbance. Only one-third of patients report lower extremity weakness as an initial symptom. However, at diagnosis, less than one-third of patients are ambulatory.^{6,8,18} Typical early complaints are leg "heaviness" and difficulty climbing stairs or getting up from a chair. As the majority of malignancy-related cord compressions occur at the level of the thoracic spinal cord, most patients present with a paraparesis. The rare patient with a cervical spinal cord metastasis is expected to have quadriplegia of varying degree and, if the high cervical cord is compromised, respiratory insufficiency. Epidural progression of metastases to the upper lumbar spine results in conus medullaris syndrome with distal lower extremity weakness, saddle paresthesia, and overflow leakage from bladder and bowel.

Only few patients report diminished sensation below the level of compression at initial presentation. The level of hypesthesia is usually two to three segments below the metastatic lesion. Discrepancy of up to 10 levels above or below the lesion has been described.¹⁸ Tingling paresthesias radiating down the spine into the extremities on brisk flexion of the neck (Lhermitte sign) indicates an intrinsic or extrinsic spinal cord process. Ataxia in a patient with MSCC reflects compression of spinocerebellar pathways.

Symptoms of neurogenic bladder dysfunction are less common at symptom onset but are frequently overlooked or "rationalized" by the patient. A detailed micturition history is indispensable as patients are unlikely to report their symptoms until their compensatory mechanisms fail. New onset of nocturia or pollakisuria in the correct clinical setting should alarm the physician, and a common explanation by the patient ("I've been drinking a lot") should be disregarded. Alarming symptoms of bladder dysfunction are hesitancy and urinary retention. At diagnosis, almost half of patients with MSCC are incontinent or require catheterization.⁸

Presence of a Horner syndrome (the combination of miosis, ptosis, and enophthalmos) indicates transforaminal progression of tumors located at the level of the cervicothoracic junction and infiltration of the stellate ganglion.

DIFFERENTIAL DIAGNOSIS

Infiltration of the lumbosacral plexus or peripheral nerves originating from it (femoral, sciatic nerve) has to be distinguished from malignant epidural compression of a root or the cauda equina. With unilateral involvement, bladder and bowel symptoms are absent; however, bilateral infiltration of plexus or nerve, giving rise to incontinence, has been seen in neurolymphomatosis and perineural spread from pelvic malignancies. Herpes zoster is encountered at spinal levels previously or concurrently affected by cancer.^{13,28}

The cauda equina syndrome is characterized by an asymmetric painful lumbosacral polyradiculopathy, a patchy sensory deficit corresponding to multiple lumbar and sacral nerve roots, and bladder and bowel incontinence. In a patient with cancer, this syndrome raises suspicion for leptomeningeal carcinomatosis. The presence of signs and symptoms referable to intracranial disease (headache, asymmetric cranial neuropathies) facilitates the diagnosis.

Intraparenchymal spinal cord metastases and primary cord tumors are rare but may resemble epidural disease. Metastatic cord tumors predominantly arise from small-cell lung and breast cancers.²⁹ Infectious (herpes simplex, human T-lymphotropic virus) and autoimmune myelitis are examples of not directly cancer-related myelopathies that have to be distinguished from MSCC. Predominance of transverse myelopathic features in the absence of pain is indicative of an intraparenchymal process.

Spinal cord hemisyndromes indicate intrinsic spinal cord disease. A classic Brown-Sequard syndrome characterized by leg weakness and loss of proprioception on the side of cord infiltration and loss of pain and temperature sensation on the opposite side is rarely seen but incomplete variants exist. Leptomeningeal spread of highly aggressive tumors can lead to spinal cord infiltration, causing an overlap syndrome of extrinsic and intrinsic cord disease (Fig. 121.2C).

DIAGNOSIS

The mere complaint of back pain in a patient with cancer frequently does not lead to an immediate workup for vertebral metastases. Only the occurrence of more severe symptoms such as sphincter dysfunction or paraparesis sets off a comprehensive diagnostic procedure.⁶ Despite the availability of sensitive diagnostic tests, the average time between onset of symptoms and definitive diagnosis is still 3 months (range, 37 to 205 days). Two-thirds of this time passes after the patient reports the symptoms to a health professional.¹⁸ An interesting pattern was observed in a Scottish study. The rate of cord compression diagnosis steadily increased throughout the course of the week and reached its peak on Friday.¹⁸

With the availability of magnetic resonance imaging (MRI), the diagnosis of MSCC has been simplified. The decision to use this tool depends on the clinical evaluation. New onset or change in character of preexisting back pain in a patient with cancer or

atypical back pain in the absence of a cancer history warrants measures beyond plain X-ray films and symptomatic therapy. Degenerative spine disease mostly affects the lower cervical and lower lumbar spine, the segments of largest motion. The pain waxes and wanes and responds to bed rest and symptomatic treatment with nonsteroidal anti-inflammatory agents. Pain located in the thoracic spine, progressive pain despite conservative measures, or pain aggravated by supine position should raise the suspicion for MSCC.

MRI of the entire spine is the most sensitive diagnostic test when MSCC is suspected in a patient with cancer. The study can accurately identify the level of the metastatic lesion and guide the radiation oncologist in planning the treatment field. Multiple levels of involvement present in up to one-third of patients with MSCC are recognized.^{20,30} Vertebral metastases without protrusion into the epidural space are detected before a potentially irreversible cord syndrome ensues. Metastases can be distinguished from other pathologic processes, involving the axial skeleton, epi- and intradural space, and spinal cord. Bacterial abscesses typically cause end-plate destruction and invasion of the disc space, whereas metastatic deposits leave the latter intact. Leptomeningeal carcinomatosis appears as nodular or linear tumor deposits in the medullary pia and along intradural nerve roots. Intradural extramedullary tumors such as meningioma or nerve sheath tumors can be easily diagnosed by their characteristic appearance and enhancement with contrast dye. Intramedullary metastases or primary tumors cause enlargement of the cord and thus can be distinguished from infectious or inflammatory myelitis that does not expand its transverse diameter.

Plain X-ray films of the spine lack sufficient sensitivity. Series of the pre-MRI era found signs of vertebral metastasis at the level of cord compression on plain X-ray films in only 80% of patients, and multiple levels of involvement were missed.¹⁹ The local extent of metastatic disease is frequently underestimated, and paraspinous tumors with transforaminal extension may be entirely overlooked.

Myelography after intrathecal injection of water-soluble contrast material with or without computed tomography (myelography, computed tomographic myelography) was the diagnostic procedure of choice in the pre-MRI era. Epidural lesions that result in complete block of the subarachnoid space obscure the extent of disease and require a second procedure with cervical or suboccipital injection of dye in order to characterize metastatic deposits rostral to the block. The study remains an option for patients in whom MRI is contraindicated.

Scintigraphic examination of the skeletal system is most useful as a screening procedure for bone metastases. Its resolution, specificity, and sensitivity are inadequate to evaluate a patient with signs or symptoms of epidural metastasis and predict the level of cord compromise.¹⁸ Myeloma may completely evade scintigraphic detection.

Positron emission tomography is likewise most useful as a staging procedure and cannot substitute for more detailed anatomic imaging techniques.

If cancer initially presents with MSCC, a biopsy is mandatory prior to initiation of therapy. This can be done by excisional biopsy of the mass or by computed tomography-guided needle biopsy.

A lumbar puncture is of no diagnostic value in epidural cancer. Complete obliteration of the subarachnoid space by an epidural metastasis results in compartmentation of the spinal canal with the possibility of herniation (“coning”) after pressure reduction in the compartment below the level of obstruction by a lumbar puncture. Although cord herniation is a rare event, an MRI scan of the spine is advisable whenever MSCC is suspected before a lumbar puncture is performed.

TREATMENT

Treatment with corticosteroids should be initiated immediately when MSCC is suspected. Corticosteroids not only facilitate pain management but also reduce vasogenic cord edema and may

prevent additional damage to the spinal cord from decreased perfusion. After an initial intravenous bolus, doses of up to 10 mg every 6 hours are most commonly used. Oral bioavailability is excellent and intravenous application is required only in patients who cannot swallow. Protocols using higher doses (initial bolus of 100 mg followed by 96 mg divided into four doses for 3 days and a subsequent rapid taper) may achieve better pain control, but it remains unclear if their use leads to an improvement in neurologic recovery or preservation of motor function and sphincter control.^{19,31,32} Complications of steroid use (gastrointestinal ulceration, hallucinations, euphoria, insomnia, generalized burning sensation) are more likely with use of higher doses.^{33,34}

At the time of diagnosis, two-thirds of patients are treated with radiotherapy and one in five or six patients with surgical decompression. One-quarter of patients with MSCC are provided comfort care only when there is widespread disease and poor quality of life.⁷
